Members of Council—Drs. R. Cargill, L. V. Gimson, Sir Wilson Jameson, Drs. J. H. Le Brasseur, L. C. Lyon, O. Plowright, Marion Ravell, E. B. Rayner, A. Talbot Rogers, E. P. Scott, and J. D. Wells.
Representative on Library and Editorial Committees—Dr. W. E. Chiesman.

These were unanimously elected.

Dr. ABERCROMBIE then took the chair and expressed his appreciation of the compliment. He appealed to members for papers for future meetings, preferably recording observations made in their practices. He also expressed in the name of his fellow officers and council their indebtedness to Mr. Edwards for the infinite amount of trouble he had taken in the formation of the section.

It was announced that the first scientific meeting would be held on December 20 and that the subject for discussion would be, "What is General Practice?"

A successful British Council Exhibition of nearly 200 textbooks and some 150 periodicals on medicine, engineering, and agriculture, held on the Peruvian–British Cultural Association's premises in Lima in September, resulted in more than 125 orders being placed—a satisfactory figure in view of the relatively high cost of most of the books and the fact that they were not in the buyers' native language. An article by Dr. Paz Soldan in the newspaper *La Cronica* was indicative of the professional interest aroused as well as being a tribute from the author, a leading Peruvian physician who played a major part in arranging for the visit of Dr. Douglas Guthrie, of the University of Edinburgh, some two years ago to lecture on the history of medicine.

Correspondence

Guy Fawkes Day—The Afterglow

SIR,—In previous years we have given warning in the local press of the danger of fireworks, particularly to children. We have stated that young children have no "safety sense," and consequently should not be allowed to hold fireworks, or store them in their trouser pockets. Adults should organize the display, supervise the letting off of fireworks, and see that fireworks are never thrown.

Here is the result of the neglect of these precautions from the experience of one hospital on Guy Fawkes Day, 1950. Sixty casualties were treated by us for injuries from fireworks: 35 were burns, 18 were lacerations due to explosions, and 7 were eye injuries. The circumstances of these injuries were:

29 were caused by fireworks going off in the hand.
11 were caused by fireworks exploding in the face; most of them were thrown.
4 serious burns were caused by fireworks exploding in the trouser pocket because an apparent "dud" was replaced and ignited the store.

The average age of the 49 males was 14 years, the youngest 4 and the oldest 45. There were 11 female patients, average age 13 years—the youngest a baby of 5 months, the eldest 45. We were told that the baby "cried for a firework and was given one"; it exploded, causing severe injury to her hand. Five of our patients suffered extensive full-thickness skin loss burns of the face and body and will have lifelong scars, and two will have some permanent impairment of sight.

That one hospital staff should work through Saturday night and well into the afternoon of Sunday dealing with the immediate treatment of these injuries is unimportant, yet this effort in no way represents the hospital treatment essential to this small group. We have, for example, one patient still under treatment for serious burns received on Guy Fawkes Day, 1949. What is important is the unnecessary suffering, particularly to children, and the cost of treatment to the country as a whole of casualties from this annual celebration. The Guy Fawkes Day casualty list is yet another example, if indeed another is necessary, of the meek acceptance by this generation of the inevitability of accidents. *The Times*, in a recent leader on road safety, stated that "all road users have equal obligations to share in the team-work of avoiding accidents. It is work of urgent national importance, deserving of the highest priority from every citizen." The same may be said of all types of accident. The peacetime accidents rate now stands at over one million each year, a casualty list more bloody than that of most military campaigns in our history, and "shows no signs of disappearing from the grim recurrence of official statistics."—I am, etc.,

Birmingham. WILLIAM GISSANE.

Cost of Academic Clinical Office

SIR,—In former times it was customary for aspirants to the Diplomatic Service to be asked, at their selection interview, particulars of their private means. I am surprised to find that this information is not required of candidates for academic clinical posts. Particulars of my own income and expenses will show how essential this information is to the selection committee burdened with such an appointment. I give them below without the slightest criticism of my university, which is both understanding and generous, but in this respect impotent. These figures are entirely factual and can be proved.

It might be said that some of these expenses are extravagant. I am aware that certain of my whole-time professorial colleagues do not travel by private car. I have no knowledge of their reasons for this, but in my own case I find a completely reliable car absolutely essential for the efficient performance of my work. The entertainment expenses I have included are lower on paper than in fact they are, because I have made no allowance for the domestic staff I require to enable me to entertain people in my home and to invite people

Expenses	£	£
Motor car, capital cost, spread over four years	350	
Petrol	107	
Tax, insurance, garage, repairs	250	
Societies and journals	98	
Travel (three years' average)	160	
Books	100	
Telephone	92	
Rent of bedroom in hospital	50	
Entertainment	250	1,457
Health insurance deductions		50
Superannuation		140
Income-tax deducted at source		900
Total		2,547

from abroad to stay with me. Other items, too, might be questioned, but the expenses I incur are substantially less than those of my part-time colleagues who engage in private consulting practice and are less than my own expenses were before I left private consulting practice for whole-time employment. The only real difference between expenses of part-time and whole-time consulting surgeons, apart from the question of accommodation, is that the expenses of the former are allowed by the income-tax assessor, while the expenses of the latter are not. The tax inspector affords me an overall expenses allowance of £250.

Of my gross income of £2,750 there thus remains to me a net income of £200. Expressed as a weekly wage of £3 7s. 6d., this compares not very unfavourably with the reward of the lowest-paid unskilled labour in this country. My working hours are, however, subject to no restriction other than that imposed by sleep and inanition, and they number 70 or so in the week. The hourly rate for my work is thus a trifle less than one shilling, and less even than the piece-rate of most Asiatic labourers.

This position would of course be untenable were I not, as I imagine most academic clinicians are, endowed with substantial wealth from other sources. This, however, cuts both ways, and rather painfully. Taxed as I am on my gross salary as well as on other income, I pay on that gross salary a few hundred pounds in surtax. The surtax on my salary in fact exceeds substantially my net income from it. I would be financially more comfortable if I resigned my appointment and stayed at home. I enjoy my work sufficiently, however, to regard it as a satisfying and delightful, though extravagantly expensive, hobby.

This melancholy situation could be rectified only by the proper acceptance of my expenses both by my university (which might well be sympathetic) and by the Treasury (which would not). It is comforting to recollect in this connexion the Minister's decree, promulgated some years ago and presumably after full examination of clinical university appointments throughout the country, that special awards (though not of course sessional fees) will be paid in full to university clinicians selected to receive them. This additional income, intended, one would suppose, as a reward for the clinical activities, clinical teaching, and clinical research which should occupy 95% of the academic day, will be heavily taxed, but will to some extent alleviate the present financial disorder of the academic clinician. It may also encourage men without private means to apply for academic clinical vacancies. When a clinical chair remains empty, or is filled by a part-time director (and this has already happened), those of us who have watched the slow and sometimes difficult establishment of whole-time clinical departments in universities feel great regret.

The personal details of my income which I have provided force me to ask your permission to sign myself

ACADEMICUS.

Displaced Registrars

SIR,—Your excellent summary (November 18, p. 1158) of the situation caused by the threatened dismissal of 1,100 registrars can hardly be improved upon, but I feel that no member of the medical profession should miss an opportunity of protesting against an injustice being perpetrated. Here are 1,100 doctors, many of them ex-Service men, whose professional careers have already been once disrupted, who have spent two to five years of a vital phase of their lives in hard studies with the promise of being allowed to continue training as specialists, and who now find themselves to have been "led up the garden path." There can be no argument about the rights and wrongs of the situation; there can be no argument but that justice demands a revocation of the threatened action.

I write, however, to draw attention to the concomitant impairment of medical service which must result when 1,100 partially trained doctors are discarded. In some specialties, for example psychiatry, there always has been a shortage of experienced personnel in relation to the scope of work. It is only by virtue of an influx of enthusiastic trainees that modern psychiatric needs have been met with a greater degree of adequacy. Discarding these men will undoubtedly entail a reduction of psychiatric services for the public. What makes the threatened situation more serious is that the circular R.H.B. (50) 106 does not plan practical measures for the replacement of staff that may be lost. No suggestion at all is made for the loss of middle registrars; and the idea that the already overburdened general practitioner will be able to spare the time (if he has by fortune the experience) to perform the duties of a senior registrar at cut rates does not seem proper or practical.—I am, etc.,

Basingstoke. I. ATKIN.

SIR,—Reduction in the number of senior registrars would appear to be in the best interests of the specialist aspirant. It would ensure that a man who had completed three years in this grade would be likely to get a specialist appointment. The method of introducing this change, however, is unnecessarily harsh and the scheme is too rigid. If it is applied as suggested it will throw out of employment many hundreds of senior registrars at the end of their period of office, men who deserve well since most of them have had considerable war service. We would suggest that the scheme be introduced gradually and that the term of service of these men be lengthened appropriately, so that most of them may be absorbed into the consultant ranks. Naturally the rate of production of new registrars would be slowed down for some time to allow this absorption to take place. A few years should see the whole matter adjusted at the new level. In the meantime, registrarships in excess of the new establishment would be declared supernumerary.

Consultant vacancies do not necessarily occur at regular intervals. This means that a man who has completed his term of service will often have to wait, possibly for as long as a year, and, at the end of that time, contest a vacancy, possibly unsuccessfully. During this waiting period he will have to maintain himself and his family as best he can.

The scheme takes no note of the fact that surgery is fluid and always advancing. Specialties are developing, and men have to be trained in them. In the case of urology, for instance, not enough young men are being trained in that most important procedure, per-urethral resection of the prostate. The plan fixes for all time the number of urological registrars in relation to the number of vacancies due to occur, and ignores the possibility of new appointments. The plain fact is that once again the human factor is being ignored, and an attempt is being made to squeeze a quart-sized problem into an administrative pint pot.—We are, etc.,

Birmingham. H. DONOVAN.
A. GOUREVITCH.

SIR,—The Ministry of Health circular on registrar grades contains many misconceptions, but the overriding one is the notion that the training of a specialist should be complete after five years. This may be so for some individuals in some specialties, but it is my opinion that this is far too short a period for the training of the average consultant. A general practitioner sends a patient to a consultant for an expert opinion, which he expects to be based on sound judgment, and sound judgment can be attained only by long experience. Does anyone seriously suppose that five years of training will make a consultant surgeon? Would any of the Ministry's experts who drew up this scheme submit their own bodies to the surgical judgment of a five-year specialist? I am an orthopaedic registrar and have had two years of general medicine, two years of general surgery, and three years of orthopaedics. According to the standards of the N.H.S. I should be fully trained in two years, but in my own estimation I require at least another five years before I would feel competent to give a sound judgment on any orthopaedic problem which might be presented to me. In the past specialists had to wait till they were 35 to 40 or longer before they were awarded full consultant status, and yet a specialist can now be completely trained seven years after qualifying, which means that some will complete their training for consultant posts at 30 years of age. Some may indeed be fully trained by then and be prepared to take full charge of a department, but how can any hard and fast rule be made?

Some may say that the time of training is adequate provided it is done at proper centres. This brings me to my next point. Of what should specialist training consist? From the allocation of senior registrar appointments, one gathers that the medical schools are to be the main training grounds of specialists. But it is not generally recognized that, while the teaching centres give one a good theoretical and philosophical background, it is at the far more numerous non-teaching hospitals that the most prolific practical experience is available to the young specialist. This is borne out by the fact that in the past the post of junior honorary in teaching hospitals was supplemented by posts held concurrently at non-teaching hospitals where the bulk of experience was gained. We all know how ill-suited for general practice is the academically trained newly qualified doctor. Yet it is proposed to keep this theoretical doctor in the academic aura and train him to be a theoretical specialist.

Perhaps the most surprising feature of this circular is the suggestion that suitably experienced G.P.s should take over the work of displaced registrars on a part-time basis. How does this suggestion square with the fact that specialist G.P.s who were doing this very thing before the N.H.S. have now been almost completely liquidated by the regional boards? Many G.P. specialists were expelled from hospital service, and those who were accepted for consultant status were obliged to give up their general practice. After relinquishing their practices and dissolving partnerships they are now informed that the specialist G.P. is to be reintroduced into our hospitals.

But what of the assumption that the G.P. would be willing or able to do part-time registrar work? Has the Minister any idea of the volume and scope of work done by registrars? If so, I do not think he would be so ready with suggestions for replacing them or declaring them redundant. For my own part I work a full 48-hour week, often longer, I see and treat about 70 orthopaedic and 140 fracture and accident out-patients a week, look after 30 or more orthopaedic and accident beds, and perform many minor and major operations. Owing to the shortage of house-surgeons I am almost perpetually without junior assistance. In addition it should be remembered that when consultants are on holiday or attending meetings, etc., the full work falls on the registrar, because locum consultants are non-existent. Now I do not think I work exceptionally hard and I am not complaining, but I should like to know how jobs such as mine are to be filled by a part-time G.P., unless it be by several G.P.s working in rota. Whether G.P.s with the qualifications and experience could be found I will not discuss, but what I wish to emphasize is the fact that the average registrar in my experience is doing a full-time job of work. He does not, in fact, regard himself primarily as a trainee but as a worker who is incidentally training in the school of experience. The training is continuous and forms part of his work, and there is no arbitrary time limit where his training ends and his real work begins. When the registrar thinks he is ready to shoulder the responsibilities of consultant practice let him be appointed on his merits in competition with others. If he does not succeed why should he not continue to serve as a registrar?

The idea that senior registrars should all be incubated in prescribed centres and, after a prescribed registrarship period, should all automatically be hatched out as full consultants is not in the best interests of medicine. But it also reveals a lack of appreciation of the fact that, whatever registrars may be in theory, in actual fact they are filling a very important gap. In theory they may be trainees, but in practice they are workers, as the Minister will find to his cost when he dismisses them.—I am, etc.,

Halifax, Yorks. A. W. FOWLER.

SIR,—I should like to express my congratulations on your strongly worded leading article (November 18, p. 1158) commenting on the Ministry's decision to terminate the appointments of 1,100 registrars. May I, however, draw your attention to one point of which the full implications appear to have been overlooked?

Among the measures proposed to bring about the reduction in numbers is the instruction that senior registrars' appointments should be terminated after three years as a matter of course. Now it is obvious that consultant posts will be available to a small proportion only of those senior registrars who are *at present* in their third year of appointment, and hence a goodly number of those to be—to quote your editorial—"put into the discard" will be precisely those most experienced registrars who are held to have completed their training.

In effect, a situation is being created in which youth and inexperience will be virtually the best passports to the higher ranks of the profession.—I am, etc.,

London, W.1. DAVID WEITZMAN.

Abnormalities in Developing Chickens

SIR,—Congenital abnormalities have three main groups of causes, which may act separately or in combination. The first group is genetic, which has been studied more than any other: the second group is mechanical, on which I have done a good deal of work myself: the third group is that of toxic factors, such as *x* rays, rubella, lack of vitamins, or insulin. I have been privileged to see Dr. A. K. Duraiswami's slides and specimens, and to discuss his work on this third group of factors with him (see *Journal*, October 28, p. 1002).

Dr. Duraiswami claims to have demonstrated that:

1. Certain abnormalities whose cause has so far been unknown can be produced by injections of insulin.

2. Different abnormalities can be produced according to the stage of development of the foetus when the injection is given.

3. The severity of the abnormalities is in direct proportion to the amount of insulin administered.

4. The action of the insulin can be countered and its effects aborted by administering certain substances.

Now, if these claims are correct, and they appear to me to have been most carefully checked, it is obvious that this work is of great importance, and may increase considerably both our understanding and our power of treating a very puzzling group of conditions.—I am, etc.,

London. DENIS BROWNE.

Dead Bodies in Water

SIR,—Your correspondent (November 18, p. 1172) will find this question fully discussed in Chapter 6, Book 4, of *Vulgar Errors*, by Sir Thomas Browne, which first appeared in 1646. The author notes the belief that the female body floated face downwards as being first mentioned by Pliny and in his day as "yet currant," but he himself thinks it "an assertion wherein the *hoti* or point it self is dubious: and were it true, the reason alledged for it is of no validity." He ends the matter by writing: "But hereof we cease to discourse, least we undertake to afford a reason of 'The Golden Tooth,' that is, to invent or assign a cause when we remained unsatisfied or unassured of the effect." In any case I would commend this most fascinating of bedside books to your correspondent—but perhaps he knows it already.—I am, etc.,

Halse, near Taunton. W. BALY PEACOCK.

SIR,—I read with considerable interest the letter written by Dr. Eric Gardner (November 18, p. 1172). My own experience on the Thames here is the direct opposite of that of Dr. Gardner. I have never seen a male corpse floating face upwards, either in the Thames in its tidal reaches or, during the war, in the Mediterranean or the Pacific.

In the past 18 months I have seen three male corpses, all face downwards, which are sufficiently recent to be very clear in my mind. The parts above water were the shoulders and rump, the head well bent down, arms hanging downward, and legs in similar position, giving the impression of a bather half-way off the springboard attempting a dive as close to the end of the springboard as possible.

I always understood that a woman floated face upwards owing to the flotation effect of the mammary tissues, etc., but have no personal experience in the recovery of female corpses. It is of interest that I have questioned six local watermen here in the past week, all of whom said, without any hesitation, that "males float face down, and females face up after drowning."

I note that Dr. Gardner writes from Weybridge, and it occurs to me that corpses may behave differently in fresh water as opposed to salt water. Perhaps some of your correspondents can throw further light on this very interesting matter.—I am, etc.,

Hulk "Hygeia," off Gravesend, Kent. HUGH WILLOUGHBY, Deputy M.O.H., Port of London.

Ring Round the Penis

SIR,—The treatment of cases of constricting rings and bands around the penis is usually dismissed in standard textbooks of surgery with the statement that they should be cut, although one book does state that in some cases the services of a blacksmith may have to be used. The following case is of interest because it shows the difficulty that may be experienced in removing such a constriction.

The patient, a married man aged 23, who was an electrical engineer, attended Casualty one evening, having ridden up to the hospital on a bicycle. Around the middle of the shaft of his penis was a circular ring of hardened steel. The ring had a lumen 1 in. (2.5 cm.) in diameter, and the ring was ¼ in. by ¼ in. (1.9 cm.) thick. Attached to one side was an iron rod 14½ in. (35 cm.) in length. The bar was 1½ lb. (800 g.) in weight, and the patient stated that it was a home-made poker.

There was gross oedema of the penis, which beyond the constriction measured 2½ in. (6.4 cm.) across. The difficulty was to reduce this through the lumen less than half its diameter. The patient was taken to the theatre, anaesthetized with thiopentone, gas, oxygen, and ether, and the penis was bound from the tip down to the constriction with a 1-in. bandage, and left like this for a quarter of an hour. On removal it was found that the oedema had considerably diminished, and it was possible by traction and pulsion slowly to work the ring towards the glans, keeping continual pressure on this to prevent redevelopment of the oedema. Eventually, after 45 minutes' work, the ring was removed, and apart from haematomata no serious damage appeared to have been caused. This was surprising in view of the patient's condition when he presented himself, when the problem seemed insoluble apart from amputation of the penis. If we had failed to reduce the oedema by pressure it was suggested that, after making numerous small incisions in the oedematous part, suspension in a supersaturated solution of NaCl might have reduced the oedema, though whether or not there would have been much tissue damage is not known.

The patient's penis after recovery measured in a flaccid state 7½ in. (19 cm.) in length and 1½ in. (3.8 cm.) in diameter, so it would appear to have been a not inconsiderable feat to have got it through the ring at the start.

We are indebted to Mr. R. E. Gibbins, consulting surgeon, under whose care this case was admitted, for permission to publish it.—We are, etc.,

Kidderminster. M. DRURY. K. MCKENZIE.

Transfusion and Viral Hepatitis

SIR,—Your leading article of November 11, page 1103, contains certain statements which may give a wrong impression.

Although three incidents have recently been reported from the U.S.A. in which hepatitis has followed the use of plasma or serum irradiated with ultra-violet light, it is hardly justifiable to condemn this method of sterilization out of hand, since the conditions under which the plasma or serum was irradiated are not known. The evidence presented by Oliphant,[1] Oliphant and Hollaender,[2] and by Blanchard and his colleagues[3] indicated that irradiation, under the conditions used by them, was effective, at least against a single strain of virus.

The technique of irradiation is complex; for example, slight deviations in the procedure may reduce the time or intensity of irradiation below the critical limits, thus failing to inactivate the infective agent. It is thus clear that the process must be continuously and accurately controlled and be reproducible from batch to batch of plasma before its effectiveness or lack of effectiveness can be conclusively demonstrated. Suitable methods of exercising this control are being developed. It is also clear that detailed follow-up surveys of the recipients of plasma, similar to those already made in this country, must be conducted before conclusions can be drawn regarding the relative merits of different methods of sterilization of plasma. It is to be hoped that the conditions under which the plasma or serum involved in the American cases was irradiated will be reported in the fullest detail, so that fair comparisons may be made between the effects of these and the numerous other batches of plasma which have been irradiated.

While the use of transfusion has increased since the recent war, the absolute amount of plasma used since 1946 has diminished. Simultaneously, the transfusion of whole blood, which previous surveys have shown to be associated with subsequent attacks of hepatitis in relatively far fewer cases, has grown apace, and to-day the ratio of blood to plasma used is about 10 to 1. It is perhaps worth recalling that the survey made by Lehane *et al.*[4] showed that the incidence of hepatitis after 10-bottle pool plasma (the smallest practicable pool) was only slightly greater than that following the use of whole blood (0.8%).—We are, etc.,

Haemolytic Streptococcal Gangrene Treated with Streptomycin

SIR,—After reading the article by Mr. R. Marcus (August 12, p. 394) I wish to add some remarks with reference to an article I published in *N.Z. med. J.* (August, 1949, p. 380). It so happened that I encountered three cases of the condition within a few weeks of each other. Two cases were critically ill, and the literature advocates extensive excision of the wound and zinc peroxide dressings, a drastic procedure, especially for one case with a burst abdomen. All had been on intravenous glucose–saline and had had penicillin and sulphonamides in heavy doses. All presented irregular pyrexia and pulse rate, with associated exhaustion rather than toxaemia.

I was struck by Meleney's work, and felt that, if a drug could be administered capable of destroying one of the organisms in the bacterial symbiosis of *Staph. aureus* and a micro-aerophilic streptococcus, then the disease process might be stayed. As a last effort streptomycin was tried, and the results were nothing short of miraculous. All patients were improved in 24 hours, and in 48 hours clean healthy granulations were seen. All recovered. I append brief notes of the cases.

1. An obese man, aged 57, who eight days after the removal and drainage of a gangrenous perforated appendix and appendix abscess had a burst abdomen sutured. The patient became very drowsy, and gangrene appeared in the wound. He had 6 g. streptomycin in divided doses over 72 hours, with complete recovery and healing of the wound within seven days.

2. An obese female, aged 45, developed gangrene in the area of a transverse colostomy 12 days after a Paul-Mickulicz resection of the transverse and descending colon for a recurrent volvulus of the colon. Complete recovery in 48 hours after the administration of 4 g. streptomycin in divided doses.

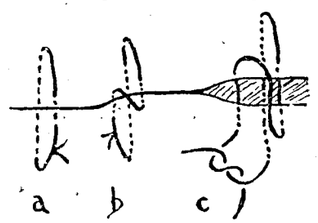
3. A female, aged 28, developed post-operative gangrene of the wound 12 days after a subtotal hysterectomy for fibroids, at which operation the appendix was removed (a common procedure in any laparotomy). Cleared in 24 hours after the administration of only 2 g. streptomycin.

All cases were given a total of 6 g. streptomycin each over a period of 72 hours (1 g. 12-hourly).—I am, etc.,

Dunedin, New Zealand. H. M. KARN.

Unabsorbable Sutures

SIR,—There have been two recent accounts (*Journal*, September 16, p. 659, and October 21, p. 949) of unabsorbable sutures being found in the uterus some years following caesarean section. It was suggested in the first that the ligatures, being silk, were therefore unabsorbable and responsible for accompanying sepsis. The use of such sutures was therefore condemned. A very similar case is described below, and again the suture material was apparently thread and was still present in the uterus when removed 13½ years later.



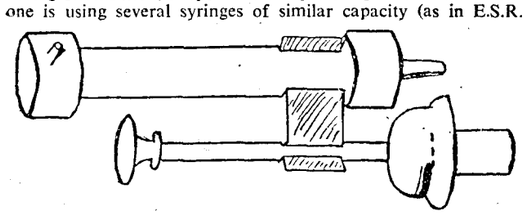
A woman aged 39 complained of vaginal discharge and pain in the left groin. The discharge was sometimes bloodstained and offensive and had been present for 13 years. She had had an upper-segment caesarean section 13½ years before, the operation being performed because of toxaemia. She was sterilized seven years ago and had had a dilatation and curettage performed four years ago. On August 3, 1949, a dilatation and curettage was performed by Mr. Mortimer Reddington, when about 4 in. (10 cm.) of thread was pulled out. The bleeding persisted and so a hysterectomy was performed and the uterus found to contain a very neat layer of sutures, except for one with a knot at the end running into the uterine cavity. There was also a small fibroid in the fundus, and the left ovary was removed at the same time.

Mr. Reddington has recalled another case which kept coming back and back with an infected wound and from which was removed finally a piece of thread about 2 ft. (61 cm.) long.—I am, etc.,

Dartford, Kent. M. NEAL RANKIN.

A Modified Skin Stitch

SIR,—The vertical mattress suture is widely used to obtain accurate coaptation of skin edges, but where thin skin overlies an excessive amount of fat, as sometimes happens, for example, in the axilla and groin, gaping of the edges tends to occur and small lobules of fat bulge through the gaps in the incision. The modification of this suture, illustrated herewith, in which the superficial portion of the stitch is reduplicated, has been found of value in holding the edges together. A small "S-bend" is produced by each stitch, but this straightens out when the silk is removed.—I am, etc.,



A.—Ordinary mattress suture. B.—Modified mattress suture. C.—Modified suture placed.

Birmingham. J. W. RIDDOCH.

A Clip for Syringes

SIR,—It is generally admitted that syringes and their pistons are not interchangeable. A badly fitting piston renders the syringe useless when required for aspirating fluids. To obviate this nuisance I have devised a simple double metal clip which, during sterilization, keeps the three parts together so that when one is using several syringes of similar capacity (as in E.S.R. estimations) it is impossible for them to become detached and subsequently fitted to their wrong units. The clip is so small that it does not need to be detached while the syringe is in use. Messrs. C. F. Thackray, Park Street, Leeds, can supply these clips.—I am, etc.,

Leeds. DAVID A. HERD.

Orf in Man

SIR,—I was most interested to see the letter from Drs. A. Lyell and J. A. R. Miles (November 11, p. 1119). My attention was first drawn to the condition by Dr. Ian Macquarrie when I came here as his assistant over 25 years ago. He recognized it as being an infection due to contact with sheep. A specimen of the lesion was sent for pathological examination, but its exact nature was not established. I must have seen upwards of 30 cases since then, the last a month ago.

The lesion is invariably single, and seems to confer immunity, as the condition has not occurred twice in the same person. With the exception of two cases all my patients have been males, and the lesions have been on the hand or forearm. The two exceptions were small girls who had pet lambs. In one case the lesion was on the upper lip, and in the other on the leg. At first sight the condition looks alarming, but, as mentioned in the letter, one is struck by the comparatively little pain and the absence of any general reaction. The temperature has been normal in all cases in which it was taken. The glands connected with the area of the lesion are often enlarged, but do not go on to abscess formation. Rarely has a definite history of trauma been obtained, but, as one patient said, "We are always getting pricks and scratches at farm work."

Treatment by slicing off the top of the blister, applying hot foments, and cauterizing the lesion daily with copper sulphate shortens the duration of incapacity. The condition, in my experience, is not so very rare, and, now that Drs. Lyell and Miles have proved it definitely to be orf, I think it should be added to the list of scheduled diseases.—I am, etc.,

Aspatria, Cumberland. A. K. RANKIN.

Mass Radiography

SIR,—Critics, mainly in London and Birmingham, have been scathing, almost vicious, in their denigration of mass radiography. Fortunately their efforts have not been crowned with success and the work advances. I do not wish here to defend mass radiography; it does not need it. Those who have been engaged in the work during recent years have no doubt concerning its value or of the high position that it holds in the armament against pulmonary tuberculosis.

The critics often say that the receipt of a satisfactory report on a miniature film is apt to engender a false sense of security. It is argued that as a result warning symptoms will tend to be overlooked during subsequent months. There is considerable weight in this argument and it applies equally to the satisfactory report on either a miniature or a full-size film. It depends for its validity on two factors. First, it is insufficiently realized that pulmonary tuberculosis may develop with great rapidity, cavitation, perhaps in both lungs, appearing within a few months. Secondly, that rapidly developing cases are frequently unaccompanied by any disturbance in general health. In many cases the symptoms of pulmonary tuberculosis are conspicuous by their virtual absence. In this country there is at present one at least out of every 500 adults who is suffering from active tuberculosis and in need of treatment, a potential menace to his Mantoux-negative contacts, whose general health and sense of well-being is so good that medical advice has not been sought. Some form of routine radiography of large numbers, whether on large films, miniature films, or fluorescent screen, offers the only hope of an early diagnosis.

But there is a large group of patients in whom the disease is usually more advanced, who are already attending their doctors, and, because of the triviality of their symptoms and absence of physical signs, are being treated as cases of upper respiratory tract infection. It is with these cases that there is room for improvement in the management of pulmonary tuberculosis, for failure to refer them for radiography condemns many such patients to the consequences of pulmonary cavitation which early diagnosis, adequate bed rest, chemotherapy, etc., would avert. Experience with mass miniature radiography, in spite of what they say about it, leads one to support most strongly those of your subscribers and correspondents who have been advocating that much greater attention should be paid to the symptomatology of tuberculosis and that greater use should be

made of the chest clinic *x*-ray apparatus. Any doctor who fails to send for a chest film a patient suffering from the symptoms of a respiratory tract infection of longer than three weeks' duration runs the grave risk of missing a case of tuberculosis. Your correspondents have on several occasions given lists of suspicious symptoms. It is not necessary to mention them again here. I have mentioned only those which are in my experience the commonest. Large film and screening sessions should be part of the weekly routine of a chest clinic, and doctors should feel free to send to it any case that arouses the slightest suspicion. I do not think it is far from the truth to say that one adult per 1,000 of city populations is being treated for respiratory tract infections when all the time pulmonary tuberculosis, perhaps remarkably far advanced, is the cause of the trouble.

If in the next five years we are to progress with the early diagnosis of pulmonary tuberculosis, then it is imperative that existing radiographic facilities be greatly improved and used more than they are to-day. At present emphasis is on treatment. In the near future, by the widespread use of routine radiography and B.C.G. we should shift the emphasis to where it rightly belongs—prevention.

In spite of the declining case mortality during the past 50 years pulmonary tuberculosis still remains supremely the major medical problem of the day. As a result of the appalling havoc it causes in the lives of so many tens of thousands of young adults, it should receive the respect that it deserves and which I feel it is still not receiving.—I am, etc.,

Buckhurst Hill, Essex. THOMAS PAXON.

Child Welfare—Past, Present, and Future

SIR,—Professor A. Moncrieff (October 7, p. 795) criticizes the pattern of child-welfare work under local authorities as being geared to vital statistics of thirty or forty years ago, while he himself uses the decline in breast-feeding as a stick to beat the service, which he summarizes as being "largely continued as part of a campaign to reduce deaths in infancy from digestive disorders."

About fifty years ago the prevalence of artificial feeding was considered to have contributed to the rise in deaths from diarrhoeal diseases (Tatham, 1904). In 1906 Newman stated that epidemic diarrhoea was the most destructive of all diseases attacking children under 5 years of age, and it was being shown (Matthew Hay, 1907–8) that the excessive mortality in bottle-fed babies was proportionately greater in the one-roomed houses. It was then easy to point the moral. During the next twenty years numerous investigations were undertaken to discover the cause, although we are still in doubt, but by the mid-1920's the proportion of infant deaths due to digestive disorders had fallen to 10% in the larger Scottish towns, although it remained a serious problem longer in the English towns. This has fallen steadily ever since, apart from a slight rise during the last war when, with exceptions (Glasgow, 1944), the outbreaks have been in hospitals and other places where children are congregated together. The improvement in general education, the increase in personal cleanliness, and the rise in the standard of living are probably the main reasons why deaths from digestive disorders are no longer a menace to the baby in its own home. The educational influences of the public health services are usually given some of the credit, although the child-welfare services as such were only in their infancy in the 1920's.

The decline in breast-feeding had a good twenty years' start on the child-welfare services, and although I am not convinced that child-welfare officers do not encourage breast-feeding whole-heartedly there is no justification for going all righteous about it. After all, the child-welfare medical officers and health visitors come on the scene after the hospitals, midwives, and general practitioners. The bigoted medical officer who is "whole-hearted," instead of helping the anxious mother who is having feeding difficulties, will make her feel a criminal if she is not breast-feeding, and will now be able to quote Professor Moncrieff that she is fulfilling her proper task in the community. America is held up as an example of a country which has reduced its infant mortality more rapidly than Great Britain. What is its record in breast-feeding?

Professor Moncrieff raises so many hares it is impossible to chase them all. He does not seem to have made up his mind whether he would rather have the medical part of the service run by general practitioners, assisted in the nursing of sick children by the health visitor, who is apparently to displace the present specially trained home nurse, or by specialist paediatricians as envisaged in circular 118/47; but, if the latter, is the paediatrician (who does not realize the value of routine medical inspections in getting to know the child and its mother, noting the progress made over a period and using the opportunity to assess the mother's care and standard of nutrition) going to interest himself in sanitation of schools, the present school curriculum, or even school meals and hygiene? The present school medical officers do these things, but then they are specialists in school medical work, not specialists in diseases of children.

The main idea is that the present maternity and child-welfare officers and school medical officers should disappear. This, as Professor Moncrieff says, is implicit in circular 118/47, which has a good deal to answer for in producing frustration in the service. Before it was suggested by obstetricians and paediatricians that maternity and child-welfare and school medical work was a boring routine and soul-destroying, and how much more interesting it would be if the participants did either (*a*) obstetrics or (*b*) paediatrics, the majority of medical officers did not find their work boring: they had chosen to do preventive work, and after several years' experience of it they found it absorbing. It is uncertain what proportion of doctors is equally interested in preventive and in curative work, but in my opinion it is only a minority, and if the present trend continues the amount of preventive work done will decrease.

After the issue of circular 118/47, and action which is being taken as a result of this circular, medical officers in the public health service find their status is falling. Having trained themselves to do one job they are now being told to go and do something else. No longer are they to have the opportunity of acquiring an insight into the whole field of maternity and child-welfare and school medical work, studying the family as a whole. They must specialize and keep themselves abreast of the times. It will be so much more interesting for them. At the same time they must not refer a child direct to a specialist, that is the privilege of the general practitioner; and, although the preventive services never dealt much in drugs, should the medical officer consider that a mother or child should benefit by medicine, the mother must now be sent on a second journey to the general practitioner. Is it surprising that there is frustration and that those already in the service are advising their younger colleagues to choose another branch of medicine?

Professor Moncrieff tells us that forward-looking authorities and progressive medical officers have already adopted the suggested changes. As far as maternity and child-welfare and assistant school medical officers are concerned they will presumably progress presently out of the public health service altogether into the ranks of the obstetricians and paediatricians.—I am, etc.,

Chelmsford. HILDA MENZIES.

Factory Doctors in the Health Team

SIR,—Various correspondents have stressed the value of school medical examinations and the need for closer teamwork between public health medical officers, general practitioners, and other health workers. No one so far has mentioned the appointed factory doctor. Since nearly a quarter of a million children enter industry each year, the importance of close liaison between the school medical service and the appointed factory doctor is clear. It must be rare for a general practitioner to know the work or conditions of employment of more than a handful of the youngsters for whose health he is responsible. They come for cure when ill, but otherwise may remain for long in subnormal health. Close team-work of the school medical officer, appointed factory doctor, and general practitioner would appear to offer great opportunities for health promotion and prevention of disease. Employers as well as parents and youngsters are often in need of advice and grateful for assistance.—I am, etc.,

Farnham Royal, Bucks. M. E. M. HERFORD.

Teething

SIR,—May I take the liberty of stating that not all paediatric teachers would agree with the opinion expressed in "Any Questions?" (October 28, p. 1013) that many ailments of an infant are connected with teething? Professor Von Pirquet and Professor Schick, of the Vienna University medical school, who were my teachers, would invariably emphasize in their lectures that there was no proof at all that any ailment could be traced to teething. They used to state that infants would get all the illnesses mentioned in the quoted reply from birth on, whether teething or not. For the general practitioner it may be a purely theoretical problem, since he will treat the little patient for the symptoms he notices. The danger lies with the mother, who will too easily consider her baby's illness as a "teething trouble" and neglect to ask for her doctor's advice in good time.

Besides that, the problem seems to be a very interesting one, deserving a thorough investigation. May I add a few abstracts from translated quotations?

"Teething is a physiological process without any disturbance." (H. Finkelstein, *Lehrbuch der Säuglingskrankheiten*, 2nd edition, Berlin, 1921, p. 646.)

"If one takes the trouble to watch the teething of healthy infants one would never be able to state with any authority that anything abnormal was related to teething." (Rudolf Fischl, *Diseases of the Mouth in Childhood*, in *Handbuch der Kinderheilkunde*, edited by M. Von Pfaundler and A. Schlossmann, 3, p. 35, 3rd edition, Leipzig, 1924.)—I am, etc.,

Plymouth. H. M. TIETZE.

Wrong Use of Fenestration Operation

SIR,—A good deal has been written and spoken lately about the surgery of otosclerosis. I greatly fear that this operation is being performed in this country on cases that are not otosclerosis. No case should be diagnosed as such in which a radiograph of the labyrinth has not been taken and the characteristic condition of the bone seen. I have quite recently been consulted about a case which was not otosclerosis, and in which both sides had been operated on without any good result.—I am, etc.,

Bath. H. NORMAN-BARNETT.

R.M.B.F.

SIR,—As Christmas Day is near at hand I would like to remind your readers of our Christmas Gifts Fund in the hope that those who have not sent their contributions will now do so quickly. We must not fail in bringing happiness and extra comforts to our beneficiaries.

Contributions should be sent to Royal Medical Benevolent Fund, 1, Balliol House, Manor Fields, Putney, S.W.15, marked "Christmas Gifts," and will be gratefully acknowledged.—I am, etc.,

C. LUTHER BATTESON,
Honorary Treasurer,
Royal Medical Benevolent Fund.

POINTS FROM LETTERS

Employment of Epileptics

Dr. H. A. JOHNSON (Cheltenham) writes: The sorry plight of epileptics needs investigation and most sympathetic help. . . . They need training and work in specialized factories, living either in their own homes or in hostels, with facilities for transport. They also need financial assistance when unable to work. Epileptics are the unwanted in our midst, living wretchedly unhappy lives. Medicine has failed to cure, but there is no denying the presence of hundreds of inarticulate sufferers and outcasts.

Exercises in the Bath

Dr. S. SHUBSACHS (Manchester) writes: Sir Leonard Hill (November 18, p. 1153) does not mention the temperature of the water. I take this to be an accidental oversight, as Sir Leonard must be more aware than most people of the effect of temperature on oxygen consumption and carbon dioxide output, which is what he has estimated.

Obituary

J. A. MURRAY, M.D., F.R.S.

Dr. J. A. Murray, one of the pioneers of experimental cancer research, died in Hove on November 20, aged 76 years. For 32 years he worked in the laboratories of the Imperial Cancer Research Fund, and for the last 20 of those years he was its director.

James Alexander Murray was born at Cramond, Midlothian, in 1873. He received his early education at the George Heriot College, and subsequently entered Edinburgh University as a science student. After graduating B.Sc. in natural science, he won a scholarship which enabled him to go to Germany and engage in zoological research work. During the summer sessions of 1895–7 he worked with Professor Theodor Boveri in the Zoological Institute of the University of Würzburg. His main problem was to study in molluscan spermatocytes the cytoplasmic structure then known as the Nebenkern and later as the Golgi apparatus. He also spent some time in Professor R. Wiedersheim's laboratory at Freiburg im Breisgau, working on the morphology of the amphibian vertebral column. On his return to Edinburgh he was appointed assistant to Professor J. Cossar Ewart in the department of zoology. At the same time he studied in the medical school of the university, and in 1899 took the degrees of M.B., Ch.B. During the next four years he had experience of general practice, and was for a period medical officer of a mental hospital. But the decisive decision of his career was made in 1903 when he accepted the invitation of Dr. E. F. Bashford to join him in the work of organizing the experimental investigation of malignant disease, a task with which the latter had been entrusted by the then recently constituted Imperial Cancer Research Fund. Here Murray found his real bent. In addition to his medical training, he brought to this work a profound interest in cellular biology, which had been stimulated by his association with Theodor Boveri, and a wide knowledge of zoology and comparative anatomy gleaned from his early student days. Murray proceeded M.D.(Edinburgh) in 1907, with the award of a gold medal. In 1915 he was appointed director of the Fund, and 10 years later he was elected a Fellow of the Royal Society. In 1936, the year after his retirement, he was awarded the Honorary Medal of the Royal College of Surgeons.

Walter Stoneman, London.

We are indebted to Dr. R. J. Ludford for the following appreciation: The initial work of the Imperial Cancer Research Fund, which was published in detail in its scientific reports, laid the foundations of experimental cancer research. It demonstrated that cancer was widely distributed among the various races of mankind and occurred also in vertebrate animals, in which it presented the same essential features. The various aspects of tumour transplantation, which had been opened up by the work of Jensen, were explored with meticulous care, and it was conclusively established that the successful transplantation of tumours in laboratory animals was dependent upon the

survival and growth of the malignant cells of the grafted tissues. Cancer was thus shown to be essentially a cellular problem. One of the most significant of Murray's contributions to cancer research, in view of later developments, was his discovery that in female mice with an immediate cancerous ancestry breast cancer was more than twice as frequent as in mice without such an ancestry. His observations extended over only three generations, but it is of interest to recall that in a paper communicated to the Royal Society in 1911 he stated, "It should be possible by continued selective mating to breed two strains of mice with a still greater difference in their liability to cancer." He lived to see this prediction amply confirmed.

Apart from his cancer investigations Murray attained distinction in other fields of scientific research. During the first world war he undertook the duties of honorary pathologist to the Zoological Society, and was elected a life Fellow of that society in appreciation of his valuable work. At the Annual Meeting of the British Medical Association in Newcastle-upon-Tyne in 1921, he was vice-president of the Section of Pathology and Bacteriology. He was an enthusiastic microscopist, and took a very active part in the affairs of the Royal Microscopical Society, being its president during the periods 1928–9 and 1946–7. Only last year he was elected to its honorary Fellowship in recognition of his distinguished services to the society and to microscopical science. As a tribute to him, the *Journal of the Royal Microscopical Society* published an issue in June this year containing seven papers by former colleagues on the staff of the Imperial Cancer Research Fund. Murray zealously maintained the highest traditions of scientific research in the academic spirit of freedom and toleration. He welcomed clear and decisive expressions of opinion, believing it was better to be proved wrong than misunderstood. He detested ambiguity, and was implacable in his opposition to anybody or anything that he considered in any way dishonest. A loyal and generous friend, he was always ready to share his scientific knowledge and experience with anyone willing to learn from him.

He married in 1927 Ethel Emily, daughter of the late L. Beere, Esq., and to her is extended the deepest sympathy of his many friends and former colleagues.

ALEXANDER LOW, M.D., LL.D.

Dr. Alexander Low, emeritus professor of anatomy in the University of Aberdeen, died in Aberdeen on November 15, aged 82 years.

Alexander Low was born of good farming stock on the estate of Grandhome on the banks of the River Don, within sight of the farms that saw the birth of Sir David Ferrier and Sir Arthur Keith. At Aberdeen University, which he entered in 1886, he first studied arts, and, after taking his M.A., he turned to medicine and graduated M.B., C.M. in 1894. He proceeded M.D. with highest honours in 1912. He became a member of the staff of the anatomy department of the University in the same year that he graduated, and was appointed professor in 1925. Although he retired in 1938 he maintained his connexion with the university and its students by serving on various committees until the last. He was a past president of the Anatomical Society of Great Britain and Ireland, of the Aberdeen Medico-Chirurgical Society, a director of the Aberdeen Royal Infirmary, a governor of the Royal Mental Hospital, and a member of the Scottish Universities Board. He had an international reputation for his research upon the development of the lower jaw. His histological technique was most accomplished, and his preparations were exquisite. Thanks to his enthusiasm the Anthropological Museum of Aberdeen University probably possesses the finest collection of the skeletal remains of the Short Stone Cist or Beaker People. For many years he made careful measurements of the growth of people born and bred in the north-east of Scotland. Certain twins and triplets he measured annually from infancy to 20 years of age.

When he retired from the chair in 1938 his former students presented him with a portrait etching, and on this occasion many touching tributes were sent by his pupils from the four corners of the world. During his office as dean of the medical faculty in Aberdeen he was responsible for welding the union of clinical professorships with ward appointments. Professor Low took an active part at several Annual Meetings of the B.M.A. At Belfast in 1909 he was secretary of the Section of Anatomy and Physiology; at Birmingham in 1911 vice-president of the Section of Anatomy and Physiology; and at Aberdeen in 1939 he was president of the Section of Anatomy and Anthropology. In the same year Aberdeen University conferred on him the honorary degree of LL.D.

We are indebted to Professor R. D. Lockhart for the following appreciation: Alexander Low had qualities that endeared him to generations of students: serious grey eyes with a pleasant twinkle set in handsome and distinguished features; an earnest purpose; attention to detail in all his work; a gentle unassuming personality; a word that could be depended upon to stand the test of time; courtesy to all people, and a kindness to his pupils in sickness or difficulty that invariably took practical form. He would find time to visit students in hospital, and, always unobtrusively left, there would be a parcel of food and sweets and cigarettes. If a man were hard up some bursary fund would be found to help, and a fine new overcoat might appear—from a "fairy godmother" for all the student knew. Many graduates will remember him as an examiner and how he would soften the blow with his characteristic, "Well, maybe, perhaps, but one usually finds . . ." No wonder he was so affectionately known as "Daddy" Low. Certainly our university will not dip her pennant in salutation to a more loyal and devoted son, and at the news of his passing the eyes of many of her graduates will be filled with wistful and happy memories.

With the passing of Dr. WILLIAM HUGH STEELE on November 1 at the age of 79 South Devon has lost a well-known figure and a remarkable personality. He was a native of Torquay and studied medicine at Edinburgh University. After graduating M.B., C.M. in 1895, he became a pioneer in radiography, and took the first *x*-ray apparatus to the relief of Ladysmith in the Boer War. After returning to this country he settled in general practice in Torquay and remained there until the outbreak of the 1914–18 war, when he again joined up and returned to radiography, serving in France and later at Plymouth. For health reasons he did not return to general practice after demobilization but took up the study of radiology and obtained the D.M.R.E. (Camb.) in 1927. He was appointed radiologist to Newton Abbot Hospital, and it is in this post that he will be best remembered by the people of South Devon and by the medical men in the district, who were always welcome and received every assistance in any problem submitted to him. His skill and kindness were outstanding qualities which testified his greatness and cannot be forgotten by a host of grateful patients and colleagues. He took a full part in all medical activities, and was a member of the British Institute of Radiology, a past chairman of the Torquay Division of the B.M.A.; and a past president of the Torquay and District Medical Society. Although he did not approve of the N.H.S. Act, he served on the house committee of Newton Abbot Hospital until his death. All his life he was a sportsman, and as a raconteur of his experiences in all

spheres he was inimitable. As a youth he played rugby football for a Torquay side, but his real loves were horses and hunting, and in the summer he delighted in trout fishing. All these pursuits he took up with an infectious enthusiasm. He married Miss Potts-Chatto, who survives him and to whom our sympathy is extended.—D. C.

Dr. JAMES KILIAN PATRICK CLARKE died at Nottingham after a long illness on November 1, aged 64. Born in Bray, Ireland, he graduated M.B., B.Ch. at the Royal University of Ireland in 1908. He settled in England in 1909 and obtained the D.P.H. in 1910. Between 1910 and 1914 he worked in mental hospitals, first at the Bethlem Hospital, Lambeth, and later at Hill End Asylum in Hertfordshire. During the 1914–18 war he served with the R.A.M.C. in Egypt, and it was in this period that he first became interested in bacteriology. After the war he was appointed lecturer in pathology at the Egyptian Government Medical School, holding also the post of bacteriologist to the Citadel Military Hospital in Cairo. In 1921 he obtained the D.T.M.&H. (Cambridge). On returning to this country in 1923 he took up research into the aetiology of dental caries, working at St. Mary's Hospital for the Medical Research Council. He published the results of this work in 1924 in a paper entitled "The Bacterial Factor in the Aetiology of Dental Caries." In 1925 he was appointed the first pathologist to the Ransom Memorial Laboratory of the General Hospital, Nottingham, a post which he held for 24 years until his retirement due to ill-health in 1949. His main interest, however, remained in the field of bacteriology, and he helped very considerably in the development of vaccine therapy while this was in vogue. At his desk or bench Clarke had a rare power of concentration upon the problem in hand. Outside the laboratory he relaxed into the most natural and friendly of men, eager to give a helping hand to anybody. One of his activities was to give pleasure to others as a topographical lecturer—a recreation in which his Irish relish for a well-turned anecdote found free play. He was a keen freemason and a member of Lodges in Nottingham, London, and Egypt. He leaves a widow, two sons, and a daughter. The elder son is a member of the medical profession.

Dr. CHRISTOPHER ROLLESTON, formerly county medical officer of health for the county of Rutland and the Soke of Peterborough, died at his home at Ketton, Rutland, on November 19, aged 73 years. Rolleston came of a distinguished medical family. His father, George Rolleston, was Regius Professor of Anatomy at Oxford University; his eldest brother was the late Sir Humphry Rolleston, and another brother was the late Dr. J. D. Rolleston, well known as a specialist in infectious diseases and as the author of many books and papers on medical subjects. Christopher Rolleston was a student at New College, Oxford, to which he won a science exhibition, and Charing Cross Hospital, where he was a university scholar. He graduated M.B., B.Chir. in 1903, proceeded M.D. in 1907, took the D.P.H. in 1909, and became a Member of the Royal College of Physicians in 1910. For a time he worked as assistant county medical officer for Berkshire, but in 1910 he was appointed county medical officer and school medical officer for Rutland. Two years later the appointment of county medical officer for the Soke of Peterborough was combined with the Rutland post. He partially retired in 1948, but he continued to act as school medical officer for the rural schools in Peterborough until December 1, 1949, his last report on school health being but recently published. Rolleston was a keen clinician, being particularly interested in tuberculosis. He was one of the earliest to undertake artificial pneumothorax treatment regularly, and was probably the first tuberculosis officer in the country to induce such treatment in the homes of his patients. The first article he published on this subject appeared in 1918, and he described the results of treating 50 cases in a paper which appeared in *Tubercle* in 1924. He was also in charge of the local V.D. clinic. He wrote on many medical subjects in this and other journals, and his annual reports usually contained some original observations about the health and social conditions of the people in his area. He was never afraid of saying what he thought—a characteristic which was not always appreciated. He was a member of the B.M.A., being chairman of the Soke of Peterborough Division in 1935–6. Apart from his work, his main interest was in literature, especially history. He was a member of the Peterborough Historical Society, before which he read a number of papers. Rolleston was twice married; he left no children.

Mr. Richard Battle writes: HUGH POMFRET KILNER, the son of Thomas Pomfret Kilner and the late Olive Mary Kilner, died suddenly in the R.A.F. Hospital, Fayid, Egypt, on November 5, aged 26 years. He was educated at Oundle School and Clare College, Cambridge. He came down to St. Thomas's Hospital in October, 1945, and graduated M.B., B.Chir. in 1949. After completing a house appointment at his hospital, he was accepted by the R.A.F. for the period of compulsory service and to his delight was posted overseas only a month or two ago. Hugh Kilner, or "Pomf" as he was known to all, was a fellow with a delightful personality. He never achieved high academic distinction, but was by contrast a really good doctor and, like his father, was intensely interested in the patients under his care and in the human side of medical practice. He took a very special interest in children, and had he been allowed to return from his Service would probably have become a paediatrician. He inherited from his mother a great talent for music, and was an accomplished pianist and a leading light in the students' Christmas show at St. Thomas's. Nobody who met "Pomf" would fail to like him, and we at St. Thomas's are much the poorer for his loss.

Medico-Legal

DEATH FROM TETANUS

A verdict of accidental death was recorded by the coroner of St. Pancras, Mr. W. Bentley Purchase, on September 22 at the inquest on Mrs. Sarah Fels, aged 50, who died in the Elizabeth Garrett Anderson Hospital, London, on August 17 from tetanus.[1]

At the inquest Mr. Bernard Fels said that in February his wife was operated upon for cancer by Mr. Vincent Nesfield. She had made a good recovery and subsequently was treated by weekly injections, usually given by a nurse. On July 19, according to Mr. Fels, Mr. Nesfield himself gave the injection at his consulting-room in Harley Street.

Some time later a swelling had developed, and on August 11 Mrs. Fels was admitted to hospital, where she died six days later from tetanus. Pus from an abscess in her leg contained *Cl. tetani*, and the same organism was recovered from the bottle from which the injections had been given.

Mr. Vincent Nesfield, who gave his qualifications as M.R.C.S.Eng., L.R.C.P.Lond., admitted to the coroner that his name was not on the *Medical Register*. He said that, after removal of Mrs. Fels's breast for cancer, he prepared an emulsion from part of the growth for injections to prevent a recurrence of the cancer. He denied that he had himself given any of the injections. On July 19 Mrs. Fels brought him the bottle of emulsion and said that it had been spilt and asked what she was to do. He saw that there was a deposit at the bottom of the bottle, so he added bi-creosol and returned the bottle to Mrs. Fels.

In recording his verdict, the coroner said that he was satisfied beyond doubt that death had been due to an injection from the bottle and that the injection had been made on July 19 by Mr. Nesfield.

Mr. Nesfield was struck off the *Medical Register* in 1932 after a charge of advertising and of being interested in the commercialization of a secret remedy had been found proved by the General Medical Council.[2]

Medical Notes in Parliament

Fate of Registrars

On the motion for the adjournment on November 22, Dr. CHARLES HILL raised the matter of the proposed cut in registrars employed in the Health Services. In England and Wales there were 5,200 specialists, and 150 deaths or retirements from their ranks each year. There had been the hope of building a comprehensive specialist service in all parts of the country, and it seemed to him tragic that the annual increase in the number of specialists was calculated at 30 specialists a year. There were 2,800 practitioners training to be specialists, and to fit in with this policy of a tiny annual increase in the specialist establishments 1,100 of these trained or semi-trained men were to be swept out of the registrar ranks. In the only region whose case he had examined, this meant that three-quarters of the senior registrars would have to go as soon as possible after January 1, and two-thirds of the other registrars. He urged that the whole position should be re-examined, first, on the basis that if the implied undertaking that there should be a consultant service everywhere was to be carried out an increase of establishment of 30 consultants a year was insignificant; and, second, that the revised establishment of registrars was too drastic, and to take away these registrars from the hospitals would lower the quality of the hospital service for some time to come. The Ministry had calculated that the country needed 7,500 whole-time specialists. Yet it had only 5,200, most of whom were part-time, and its progress was to be at the rate of 30 specialists a year. That timid attitude would damage the hospitals from the early part of next year.

Mrs. JEAN MANN said she was glad Dr. Hill had raised this subject. The Minister's circular had come as a shock to all hospital services in the country. When she had read that circular in the *Supplement* to the *British Medical Journal* she had been shocked by its ruthless treatment of the registrars. These were blandly told there would be no promotion for them although they had served an apprenticeship, much of which had been financed by the Government. Many had taken diplomas in specialized branches, and a great deal of the expense of taking those diplomas had been borne by the Government. These registrars had been encouraged to go on by the statements of the Minister and of many Members on the Government side of the House that the Service was expanding, that everyone would be entitled to a specialist's attention, and that the country would not have nearly enough consultants and specialists to conduct the new services. Where would the Ministry get general practitioners with the expert knowledge which the senior registrars possessed? She believed that this memorandum had not been sent to the Scottish registrars. She hoped they would set the heather on fire when they received it.

Mr. NIALL MACPHERSON hoped that the Under-Secretary of State for Scotland would be able to tell the House whether the memorandum applied to Scotland. He had heard that it would apply if not from January at least in the course of next year. He added that the memorandum suggested in a callous way that surgeons and embryo surgeons, who in many cases had served long in the Forces, should go back to the Forces at a lower rate of pay than they would have received if they had stayed in the Services. They were also invited to go into the Colonial Service, which was not remunerated on the same scale.

Mr. WALTER ELLIOT said the House was entitled to know if the circular applied to Scotland, and, if not, whether the general conditions published in the circular applied in Scotland as in England.

Mrs. E. M. BRADDOCK said a lot of the difficulties of the Health Service were created when Dr. Hill was in an important position in the British Medical Association. The difficulties were due to the fact that his organization had laid down emphatically that no full-time medical service should be provided by the Bill.

The House then rose, without any reply being made for the Government.

The Tuberculosis Position

New cases of tuberculosis in England and Wales notified in 1049 were 52,041. Mr. ANEURIN BEVAN said on November 16 that he thought there had been an increase compared with 1948 but that the increase was due to the use of mass radiography. Although the increase in the notifications of respiratory tuberculosis was 5½%, there had been a decrease in the number of deaths over the last five years of 12½%. Treatment was resulting in a reduction in the number of fatalities. The general overall position was improving. Since the issue of a circular asking hospital authorities to make beds available for tuberculosis cases in general hospitals there had already been a large increase in the number of beds. He would be able before long to give a report on the progress made in making beds available.

Miss MARGARET HERBISON stated on November 14 that a visit by two officials of the Scottish Office to Switzerland for the purpose of inquiring into the treatment of tuberculosis was sufficiently encouraging to justify a further visit by clinical experts, arrangements for which were being put in hand.

Answering Mr. Walter Elliot, Mr. BEVAN said on November 16 that he was prepared to consider making use of the beds available in Switzerland, but that currency difficulties were involved.

Reducing the Doctor's List

On November 13 Mr. EDWARD HEATH raised the question of the reduction of doctors' lists of patients. He said that in the Borough of Bexley one doctor had been told that his list had to be reduced and 800 patients had to find another doctor. This was also happening all over the country. He hoped that his raising the matter would result in the welfare of the patient receiving full consideration in the administration of the regulation, which was not happening at present. As the result of this doctor declining to alter his list or to take a partner the county executive council had the job of cutting the list. It drew an ellipse round the area which included both his surgery and branch surgery so that it would take in the maximum of 4,200 patients. After that it sent a notice to every patient who lived outside the area, saying, "You are struck off Dr. Green's list seven days from to-day. You are given notice that in seven days you must find another doctor by going to the Post Office and there looking at the list of doctors in the borough." Mr. Heath said that meant that patients with a long relationship with that doctor were suddenly told that this relationship was ended. One constituent who with his family had for 26 years been attended by this doctor was told that he must find another. So was an old lady of 73 who had had this doctor for 15 years. Mr. Heath asked whether it was necessary suddenly to reduce this doctor's list of 5,000 to 4,200. He understood that the general turnover of a doctor's list varied between 300 and 600 patients, so he asked if the list could not be closed and left to reduce itself in about a year and a half to about 4,200. If the Minister insisted on suddenly reducing the list Mr. Heath suggested that those who had joined the list last should be the first to go. Members of families of long-standing patients should not be struck off: The doctor could provide the information required, and an attempt should be made to get it. In striking the patients off the list at seven days' notice the local executive council had been callous. It was wrong that administrative convenience should be placed before the welfare of a patient.

Mr. N. N. DODDS said the way this matter had been handled was an example of soulless bureaucracy and was bringing the Health Service into disrepute.

Mr. A. BLENKINSOP said he did not think the wording of the circular sent out by the executive council was the best that could have been desired. Had the doctor concerned tried to help the executive council, as most doctors had tried to help in carrying out the general decision on limitation, the Ministry would have been able to avoid a great deal of difficulty which had arisen. A doctor mentioned by Mr. Maudling, the Member for Barnet, had co-operated to the extent of suggesting those names which came latest on the lists. Not having the assistance of the doctor, the executive council in the Bexley case had taken what was on the whole a reasonable decision, to rule out those patients who appeared to be farthest away from the doctor's main centre of practice. He thought that executive councils should give the patients another list of doctors in the area. This had been left in the past to the discretion of the executive council, and the practice varied from one area to another. It would be desirable if this method were more generally used. He thought that one or two points might well be looked at further, but had the doctor in the case offered his assistance more, as other doctors had elsewhere, this problem would not have arisen.

Doctors for New Estates*

Miss P. HORNSBY-SMITH raised on November 16 the method of appointing doctors to the London County Council estate area known as St. Paul's Cray, which comprised over 3,000 houses to which a large population was being moved, with scope for more medical practitioners. She wished to bring to the notice of the House the manner in which these medical appointments were made. She had found that Dr. J. D. Paulett had been granted by the county council a house compulsorily acquired from a private owner, and that having got these premises he had applied to the medical practices committee, saying he had been granted the doctor's house on the estate and asking the committee to permit him to practise. Other doctors had submitted their names to the L.C.C. as wishing to practise on the estate, but only the name of Dr. Paulett appeared to have gone forward, and the medical practices committee had no option but to appoint him. Its position was obviously prejudiced when only one name was submitted and when the applicant claimed that he had the premises. It virtually had to accept the nomination of the L.C.C. The L.C.C., by deciding what doctors should be allocated a house from which they could practise, were choosing the doctors on the estate instead of the medical practices committee.

Mr. A. BLENKINSOP said that any doctor might apply to go on the list in any area, and could be refused only if the area was over-doctored. Vacancies were advertised only when a sitting doctor withdrew or when the area was classified as being under-doctored. A doctor had full liberty to apply to go in an area, and the medical practices committee could not refuse him unless it was over-doctored. Applications went to the medical practices committee through the local executive council, but applications for houses went to the L.C.C., and provisional permission to practise was granted contingent on accommodation being granted also.

Dr. CHARLES HILL said that the St. Paul's Cray case was a particular instance of a general difficulty. When a vacancy arose through the death or retirement of a doctor and the full procedure of advertisement and selection was followed, and if a doctor obtained by purchase or otherwise the use of the professional premises from which the practice was conducted, or of the only appropriate professional premises in the area, it was difficult to make effective choice of any other applicant. That way of short-circuiting a proper form of selection was a difficulty which the medical practices committee was trying to tackle. The L.C.C. should have followed another method, informed the official machinery of the vacancy, and asked for an advertisement to be published so that selection could be made through the proper channel; and, having done that, it could have allotted to the selected doctor the house it had built as the doctor's house on the estate. He asked Mr. Blenkinsop to look into the matter to protect local authorities from the invidious task of picking a doctor. The same system of selection should apply, whether the house had been built by the local authority or not.

Mr. BLENKINSOP said the matter was under consideration between the Ministry and the British Medical Association, to find some way of dealing with the difficulty.

Admitting Foreign Dentists

On November 16 Mr. S. S. AWBERY asked Mr. Bevan, in view of the shortage of dentists, to introduce legislation to enable qualified dental surgeons from European countries, who had a practice in their own countries before becoming domiciled here but were not qualified for registration, to practise here.

Mr. ANEURIN BEVAN replied that for the protection of the public the Ministry must ensure that foreign-trained dentists admitted to practise here were no less well qualified than British-trained dentists. Subject to this principle, he was about to discuss with the bodies concerned the question whether existing arrangements could be improved.

Merit Awards

Colonel M. STODDART-SCOTT inquired on November 23 whether the Medical Merit Awards Committee was permanent; how far the chairmanship was intended to be permanent; what sum it was proposed to pay the chairman; and how many awards the committee had made.

Mr. ANEURIN BEVAN replied that so far as he was aware this was a continuing body. The remuneration of the chairman was to be reviewed at the end of the third year, and at present he received 2,000 guineas. The committee had so far recommended 1,504 consultants for awards. It was not intended to publish a list of them.

Nurses for Sanatoria

Mr. R. J. MELLISH on November 23 raised the question of the shortage of nurses in tuberculosis sanatoria. A Ministry of Health spokesman had said that out of a total of 27,763 T.B. sanatorium hospital beds in England and Wales 4,409 were unstaffed on June 30 last. This spokesman went on to say that a waiting-list of approximately 11,000 people in England and Wales had tuberculosis and awaited entry into hospital. Mr. Mellish said he was a member of the South-eastern Hospital Board, and throughout the whole of his region there was an enormous waiting-list. Men had to wait on the average five months before they could hope to go to hospital, and women had to wait 10 to 12 months. The Minister had asked the regional boards to open wards in general hospitals for tuberculosis cases, but they could not get the staff. It ought to be obligatory on the General Nursing Council to insist that all student nurses should do three months in a T.B. sanatorium as part of their general training. The pay of these nurses ought to be increased more than that of nurses in general hospitals.

Mr. J. ENOCH POWELL said that the task was to restore T.B. nursing to the parity of esteem which it had lost. A nurse who had done a year in children's, fever, or mental nursing could offset that year against the length of her general training. That did not apply to work in a sanatorium. This definitely deterred a nurse from training in a T.B. sanatorium. He suggested that a T.B. nursing bonus of £30 should be available pro rata so that a nurse who did 11 months did not lose the bonus entirely. Prejudice against T.B. nursing existed in the senior ranks of the nursing profession, and there was a great deal to be done inside the profession itself in educating people about the value and interest of T.B. nursing.

Mr. ANTHONY GREENWOOD said there was need for adequate housing, especially for male nurses. The fear of infection was deep-seated among the girls, and to an even greater extent among their parents. Sputum mugs should be abolished and replaced by destructible cartons. Nurses should be freed from the duty of counting dirty bed linen and the soiled clothing of patients. There should be facilities for the cleaning of the clothing of patients who were able to walk about and work among the other patients. There should be facilities in all wards for boiling crockery and cutlery. That was of particular importance where tuberculous patients were treated in general hospitals. Lastly, there should be electrical appliances for cleaning wards. He suggested that the Ministry of Health should set up a T.B. Nursing Corps, and if possible secure Royal Patronage for it.

Mr. A. BLENKINSOP, replying for the Government, said the number of nurses still required for the T.B. service was about 2,900. B.C.G. vaccine was being made generally available for sanatoria and general hospital staffs, as well as in the domiciliary fields. This was especially important in connexion with possible contact. Special allowances for nurses undertaking T.B. work were a matter for the Whitley Council, which had agreed upon improved scales of general pay which would, he

*See correspondence, *Supplement*, p. 232.

hoped, make this nursing more attractive. Perhaps the most important question was the secondment of nurses from teaching and other hospitals to work in sanatoria. This was a matter for the General Nursing Council and not for the Ministry. It would be hardly practicable to make secondment compulsory, but the Ministry was undertaking consultations with the teaching hospitals to work out detailed plans for secondment from those hospitals. The Ministry was anxious to secure the greatest accommodation in general hospitals, provided that adequate and proper precautions could be taken against contacts, and so on. That required either separate blocks, or at least separate ward accommodation. Reports were being made to let the Ministry know what progress could be made in this way. The Ministry hoped that there would result a valuable increase in the number of immediate beds and a steady reduction in the waiting-list. For patients at home there was the question of the recruitment of nursing staff for domiciliary nursing and the proper information to all those who had the care of patients. Local health authorities were anxious to co-operate with hospital authorities in a joint attack upon this problem.

Other Steps for the Tuberculous

Mr. GERALD WILLIAMS took up the discussion again on November 24. People were dying without treatment, and others were left so late that there was little hope of their recovery. He had two or three minor suggestions, such as that for night hostels, which would probably require no trained nurses. Plenty of beds were available abroad in Switzerland, France, and Scandinavia. The cost over there, apart from the fare, would be little more than in Britain. Despite difficulty in obtaining exchange, the Government could be a little more lenient in allowing money for such a cause. The beds were there and it was wicked not to use them.

Mr. IAIN MACLEOD said the L.C.C. had been forbidden by the Ministry of Health, on grounds of expense, to build certain night sanatoria and certain hospitals for this disease, of which St. Peter's, Stepney, was an example. This could be justified only if the House was satisfied that the £400m. spent on the Health Service was being spent on more worthy objects.

Mr. A. BLENKINSOP replied. He said that facilities in Switzerland were under review, but all the information which the Ministry of Health had from that country suggested that the contribution it could make would be much smaller than Mr. Williams had mentioned. Close co-ordination was necessary of the local health authority, of the general-practitioner service through the executive councils, and of the hospitals to solve the tuberculosis problem. The Ministry had under consideration the administrative organization of the Health Service, both in respect of tuberculosis and other special fields.

School Dental Service.—At the beginning of June the number of dentists employed was equivalent to 734 full-time officers. For a complete service of dental inspection and treatment, in which every child was seen annually and all children who required treatment accepted and received it, a ratio of about one dentist to 3,000 children would probably be required. An additional 1,150 dentists would have been needed last June to give such a ratio. The immediate aim is to get the service back to its 1948 level, for which purpose some 200 additional school dentists are needed in England and Wales.

The Penicillin (Merchant Ships) Bill.—This will enable penicillin and certain other substances to be sold or supplied to and administered on board merchant ships which carry no doctor; it was introduced by the Government in the House of Lords on November 14.

Part-time Nurses.—The present total is 25,000, and was about 17,000 when the National Health Service began. The policy is to encourage their employment wherever there are serious staff shortages.

Aureomycin.—Imports from the U.S.A. during the nine months period ended September 30 totalled 140,075 grammes, apart from small quantities for sample and trial purposes.

Supply of Spectacles.—The Parliamentary Secretary to the Ministry of Health said on November 14 that there was now a reasonable delivery date for simple types of lenses, while delivery dates were steadily improving for bi-focals and other special types. There was sufficient capacity in the country to deal with demands for both the simple and the more complex types of lenses.

Universities and Colleges

UNIVERSITY OF OXFORD

In a Congregation held on October 28 the degree of B.M. was conferred, in absence, on Patience Proby.

UNIVERSITY OF CAMBRIDGE

Members of the committee for the appointment of the director of the Molteno Institute have been appointed for two years from January 1, 1951, as follows: *By the General Board*, Professor E. D. Adrian, O.M., F.R.S., and J. T. Saunders, M.A.; *By the Council of the School of the Biological Sciences*, Professor H. R. Dean, Dr. V. B. Wigglesworth, Professor G. E. Briggs, M.A., and Mr. K. M. Smith, Ph.D.

The Faculty Board of Biology "B" has elected Professor Adrian as a manager of the Arnold Gerstenberg Studentship until December 31, 1955.

The Raymond Horton-Smith Prize for 1949–50 has been awarded to Anthony Guy Everson Pearse, M.D., for his essay on "Cytochemistry and Secretory Cytology of the Anterior Hypophysis"; *proxime accessit*, Basil Gerald Parsons-Smith, M.D., whose subject was "The Value of Electroencephalographic Study in Cases of Cerebral Tumour."

UNIVERSITY OF LONDON

The Sanderson-Wells Lecture on "Food and Folly" will be delivered by Sir Stanton Hicks, professor of human physiology and pharmacology in the University of Adelaide, in the Senate House, University of London, Bloomsbury, W.C., on Thursday, December 14, at 5.30 p.m. The lecture is addressed to students of the University and to others interested in the subject. Admission is free, without ticket.

UNIVERSITY OF WALES

The following candidates for the degrees of M.B., B.Ch. at the Welsh National School of Medicine have satisfied the examiners at the examination indicated:

PATHOLOGY AND BACTERIOLOGY.—L. V. Chubb, Patricia M. Coldrick, C. W. J. Hunt, A. P. Jones, Olive C. Jones, Margaret E. Lloyd, G. K. Penn, T. B. N. Richards, Eve Wiltshaw, Isobel M. Young.

UNIVERSITY OF BIRMINGHAM

Professor C. F. V. Smout has been reappointed Sub-Dean and Tutor of the Faculty of Medicine for five years from October 1.

Professor Hilda N. Lloyd, President of the Royal College of Obstetricians and Gynaecologists, has resigned from the Chair of Obstetrics and Gynaecology in the University, as from December 31.

The title of Reader in Medicine has been conferred on Kenneth William Donald, M.D., M.R.C.P., who has been appointed Lecturer in Medicine in the Faculty of Medicine from October 1.

The title of Reader in Surgery has been conferred on Bryan Nicholas Brooke, M.Chir., F.R.C.S., Lecturer and First Assistant in the Faculty of Medicine.

Professor Edward D. Churchill, M.D., Chief of the General Surgical Services, Massachusetts General Hospital, Boston, U.S.A., has accepted an invitation to participate in the surgical work of the teaching hospitals during the Spring Term, 1951.

Mr. John A. Stallworthy, F.R.C.S., M.R.C.O.G., will deliver the Ingleby Lectures for 1951.

The following appointments are announced: *Lecturer in Bacteriology*, M. B. Conran, M.B., B.S. *University Lecturer in Minor Operative Surgery*, Alexander Innes, M.B., F.R.C.S. *University Clinical Lecturers.—Obstetrics*, Jean L. Hallum, M.D., M.R.C.O.G., D.C.H., G. S. Lester, M.B., F.R.C.S.Ed., M.R.C.O.G., L. M. Park, M.B., F.R.C.S., F.R.C.S.Ed.; *Radiology*, J. C. Bishop, M.B., Ch.B., D.M.R.D., W. H. Bond, M.B., F.R.C.S., O. E. Smith, M.B., Ch.B., D.M.R.D.; *Dental Surgery*, R. F. Pusey, M.R.C.S., L.R.C.P., B.D.S.

Isobel T. Hinde, M.B., B.Chir., and John Hardwicke, M.B., B.S., Research Fellows of the Medical Research Council, have been given the title of Honorary Research Fellow in Experimental Pathology in the Department of Pathology of the University.

UNIVERSITY OF BRISTOL

The following candidates have been approved at the examination indicated:

DIPLOMA IN MEDICAL RADIODIAGNOSIS.—*Part II:* J. B. Fox, Z. Lachowicz.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a meeting of the Council of the College held on November 9, with Sir Cecil Wakeley, *President*, in the chair, Mr. W. Kelsey Fry was admitted as a co-opted Member of the Council.

Professor G. Grey Turner has been elected a Hunterian Trustee; Dr. Howard K. Gray, of the Mayo Clinic, a Moynihan Lecturer; and Professor Francis E. Stock, of Hong Kong, a Hunterian Professor. The re-election of Mr. F. Masina as Prophit Student was reported.

The Council received from Dr. G. M. Vevers a gift of a cast of the Cheselden Medal.

Diplomas in Child Health were awarded, jointly with the Royal College of Physicians of London, to S. Binder, F. S. W. Brimblecombe, and P. West. A Diploma in Medical Radio-Diagnosis was awarded, jointly with the Royal College of Physicians of London, to P. F. J. New.

The following hospitals were recognized under paragraph 23 of the Fellowship regulations: Waikato Hospital, Hamilton, New Zealand; Birmingham and Midland Ear and Throat Hospital (junior registrar); Royal Victoria Hospital, Bournemouth (four house-surgeons, orthopaedic house-surgeon, all for six months); Archway Group, London (registrar, two junior registrars, three house-surgeons, one orthopaedic house-surgeon, ear, nose, and throat registrar); Hackney Hospital, London (registrar, two house-surgeons, for six months).

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

At a quarterly meeting of the College held on November 7, with the President, Sir David K. Henderson, in the chair, the following were elected Fellows of the College: I. C. Macdonald, R. B. McMillan.

The following were elected Members of the College: B. W. Anderson, A. A. H. Gailey, S. A. Mannan, M. Mousiquddin, P. R. Mohan, A. W. Lees, W. L. H. Jackson, S. A-K. Karagulla, E. D. Levittan, J. F. McHarg, A. B. Da Costa, D. L. Murti Rao, R. F. Brooks, A. A. A. El Sherif, S. E. Large, R. J. C. Southern, R. D. Young, J. B. Clark, N. K. Smith, M. F. G. Buchanan, J. A. McConachie, R. L. Richards, I. S. Collins, T. L. Henderson, N. H. Dalal.

The Hill-Pattison Struthers Bursary was awarded to Alan Fennell Bushby.

A presentation was made to Mr. T. H. Graham on his retirement after 40 years' service as librarian of the College.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

At the annual meeting of the Royal Faculty of Physicians and Surgeons of Glasgow, held on November 6, the following officers were elected for the ensuing year: *President*, Mr. Walter W. Galbraith; *Visitor*, Mr. Andrew Allison; *Honorary Treasurer*, Mr. Matthew White; *Honorary Librarian*, Dr. Archibald L. Goodall; *Representative on General Medical Council*, Mr. Andrew Allison.

SOCIETY OF APOTHECARIES OF LONDON

At a meeting of the Court of Assistants held recently with Dr. Frank Howitt, Master, in the chair, Mr. R. Ogier Ward resigned his seat on the Court. Dr. J. P. Hedley was re-elected as the Society's representative on the General Medical Council for a further year.

The annual Master's Day Service was held at the Church of St. James, Garlickhithe, Garlick Hill, London, E.C., on October 31, by permission of the Rector, the Rev. M. F. Foxell, Chaplain to the Master.

It was reported that the Strickland Goodall Triennial Memorial Lecture is due to be delivered in 1951.

In connexion with the Festival of Britain it was decided that the Hall should be open to visitors on certain days to be arranged and that the Society should lend some of its ancient silver to an exhibition at Goldsmiths' Hall.

The following candidates were granted the diploma of L.M.S.S.A. upon examination: C. S. Paul, H. Davidson, P. S. McClure, D. J. Müller.

CONJOINT BOARD IN SCOTLAND

The following candidates, having passed the final examinations, have been granted the diploma of L.R.C.P.Ed., L.R.C.S.Ed., L.R.F.P.&S.Glasg.: W. St. C. Bauld, T. L. Bowden, W. Brabbin, L. Brinberg, J. P. Capel, S. Caplan, J. T. Davidson, J. W. Davison, D. Duck, Ruth M. Eaton, R. Y. Forbes, Isabel M. Forster, M. Frieze, K. M. Graham, J. G. Green, A. I. Hutchinson, J. L. W. Johnson, Anna M. M. Lepper, Veronica R. E. Lethbridge, T. J. McCabe, R. H. G. McKay, I. T. McLachlan, A. M. Muir, D. Murray, P. A. O'Brien, A. Pollok, Anne McK. Rodger, B. Schulberg, H. B. Singh, P. I. Sless, B. D'A. Smith, L. Steen, I. S. Trotter, E. G. C. Valerio.

No. 45

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended November 11.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each Infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1950 (a)	(b)	(c)	(d)	(e)	1949 (Corresponding Week) (a)	(b)	(c)	(d)	(e)

Rate per 1,000 total births (including stillborn)			29					30		

* Measles is not notifiable in Scotland, and the returns are therefore an approximation only.

† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

‖ Includes puerperal fever for England and Wales and Eire.

¶ Primary pneumonia no longer notifiable in Eire.

EPIDEMIOLOGICAL NOTES

Poliomyelitis

Notifications of poliomyelitis in the week ending November 18 were: paralytic, 110 (161); non-paralytic, 39 (64); total, 149 (225). The figures for the previous week, compared with which there was a total decrease of 76, are in parentheses. Uncorrected notifications for the corresponding week in 1947 and 1949 totalled 201 and 229 respectively. Total uncorrected notifications for 1950 to and including the week under review are 8,121. The corresponding figures for 1947, 1948, and 1949 are 8,676, 2,165, and 6,134 respectively. The marked downward trend in the week under review is very satisfactory.

Discussion of Table

In *England and Wales* infectious diseases were more prevalent during the week, and the increases in the number of notifications included measles 1,042, whooping-cough 638, dysentery 151, scarlet fever 98, acute pneumonia 32, and acute poliomyelitis 21.

The incidence of measles during the autumn has been high, and the present level has been exceeded only in 1940 and 1942 since this disease was made notifiable in 1939. The largest rises in measles during the week were Lancashire 333, Lincolnshire 163, Warwickshire 111, Glamorganshire 108, Nottinghamshire 105, Yorkshire West Riding 105, while the largest falls were Derbyshire 87, Surrey 74, Yorkshire East Riding 59, and Herefordshire 43. The incidence of whooping-cough during the past weeks has been at the highest level for this period of the year since notification was started in 1939. The largest rises in whooping-cough during the week reviewed were Lancashire 131, Essex 69, and Middlesex 46. The chief features of the returns for diphtheria were a decrease of 4 in London and a rise of 9 in Warwickshire (11 of the 12 cases in this county were notified in Birmingham C.B.). The chief variations in the trends of scarlet fever were increases in Yorkshire West Riding 37 and Durham 23.

The chief centres of dysentery were Lancashire 69 (Liverpool C.B. 13, Manchester C.B. 10, Oldham C.B. 8, Southport C.B. 8), Leicestershire 62 (Leicester C.B. 58), London 61 (Lambeth 36), Northumberland 36 (Rothbury R.D. 29), Essex 28 (Romford M.B. 15, Leyton U.D. 10), Yorkshire West Riding 19 (Huddersfield C.B. 7), Kent 17 (Chatham M.B. 7, Orpington U.D. 7), Glamorganshire 13 (Cardiff C.B. 13), Anglesey 10 (Valley R.D. 8), Staffordshire 10.

The largest of the local increases in acute poliomyelitis was a rise of from 2 to 12 in Dorsetshire. The largest returns were Lancashire 14 (Liverpool C.B. 8), Cheshire 13 (Birkenhead C.B. 4), Dorsetshire 12, Yorkshire West Riding 12, Surrey 12 (Croydon C.B. 4), Gloucestershire 11 (Bristol C.B. 7), London 11, Devonshire 10, Cornwall 10, Warwickshire 10 (Birmingham C.B. 5), Durham 10.

In *Scotland* increases were recorded in the number of notifications of measles 64, whooping-cough 45, and dysentery 22. The notifications of acute poliomyelitis were 4 more than in the preceding week, and the largest returns were Glasgow 6 and Fife county 3. The largest centres of dysentery were Glasgow 57, Lanark county 40, Edinburgh 13, and Stirling county 10.

In *Eire* increases were recorded in the number of notifications of scarlet fever 34, whooping-cough 29, diarrhoea and enteritis 17, and a decrease of 19 in the notifications of measles. These trends were due to small variations in incidence throughout the country.

In *Northern Ireland* an increase of 49 in the number of notifications of measles was the only large fluctuation in the totals for infectious diseases. A rise in the incidence of measles occurred throughout the country; the largest was 16 in Armagh county. Only 4 cases of poliomyelitis, 5 fewer than in the preceding week, were notified. In Belfast C.B. the notifications of diarrhoea and enteritis increased by 9, but a fall of 7 was reported in the remainder of the country.

Week Ending November 18

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,386, whooping-cough 4,130, diphtheria 76, measles 10,132, acute pneumonia 558, acute poliomyelitis 149, dysentery 474, paratyphoid fever 1, typhoid fever 5.

Medical News

Annual Dinner of the Society of M.O.H.s

The Society of Medical Officers of Health held their annual dinner at the Piccadilly Hotel on November 23. The toast to the society was proposed by Dr. E. A. Gregg, Chairman of Council of the B.M.A., who referred to the strengthening of the link between the society and the Association. He marvelled at the moderation and patience of the Society, whose members steadfastly discharged their duties under conditions which it was unfair to expect them to accept. Dr. Gregg concluded with a tribute to Dr. Metcalfe Brown, chairman of the Public Health Committee of the B.M.A., and to other medical officers of health who had worked hard for the Association and the society. Dr. J. M. Gibson, president of the society, responded. He said that members of the society had been disturbed in recent years by the lack of recognition which was the due of the public health service. Above all, the N.H.S. Act had dulled their spirits, and they had been cheered by the support given by the B.M.A. He thought the pendulum was now swinging back and things were not so bad as they once seemed. Dr. Hugh Paul, proposing the health of the guests, delighted his hearers with a series of rapid-fire witticisms. He paid particular tribute to Sir George Elliston, who had done so much for public health, and to Dr. A. V. Kelynack for helping the members of the society to get what they wanted. Dr. Paul referred to the fact that their chief guest, Sir John Charles, now Chief Medical Officer at the Ministry, had once been a medical officer of health. In his reply Sir John said he saw no final definition of nor steady pattern in the work of an M.O.H. Legislation took away and added functions, but in general the tasks of a medical officer of health well befitted a man and constituted a man's work. Sir Cecil Wakeley also replied for the guests.

Dinner for Bart's Men

The Bart's men in South Africa have arranged a dinner to be held at the time of the B.M.A. Congress next year. It will take place on the evening of July 19, 1951, at the Rand Club, Johannesburg. Any Bart's men who may be visiting South Africa at that time, whether to attend the Congress or not, should communicate with Dr. J. Gluckman, P.O. Box 455, Johannesburg.

X-ray Photographs by Radio

X-ray photographs can be telegraphed overseas by means of the Post Office Cable and Wireless phototelegraphy service. This can be of the utmost importance when a doctor wishes to have an urgent consultation with a colleague in another country. The charge depends on the size of the photograph to be transmitted and also upon the country of destination. It ranges from £1 10s. for a small picture to Belgium or France up to £15 for a large one to the United States. A reply can be paid for in advance and express delivery can be arranged at a small additional fee. Full particulars can be obtained at any Cable and Wireless office and the large post offices, or by telephone to London: Temple Bar 1222, extension 282; Monarch 8060, extension 305.

Princess Tsahai Memorial Hospital, Ethiopia

Five members of the hospital staff, including the medical superintendent and the matron, have now been appointed, and a gynaecologist and nursing staff are being sought. Medical equipment has already been shipped out. Donations for the work of the hospital may still be made to the honorary treasurers, Lord Horder and Lord Amulree, care of Messrs. Gould and Prideaux, 88, Bishopsgate, E.C.2.

International Centre for Chemical Microbiology in Rome

The World Health Organization, with the consent of the Italian Government, has recognized the Istituto Superiore di Sanità in Rome as an International Research Centre for Chemical Microbiology. It is an active centre of research, the largest in Italy, and, mainly thanks to the initiative and outstanding organizing capability of its director-general, Professor Domenico Marotta, its laboratories are among the most modern and best equipped in Europe. The research departments include physics, therapeutic chemistry, biochemistry, malariology, and bacteriology. The Istituto Superiore di Sanità is also the main Food and Drug Control Centre of the Italian Government. Recent extensions of the Institute contain a fermentation pilot plant, with fermenters up to 18,000 litres capacity and all the processing equipment required for the isolation on an industrial scale of biologically important substances, such as antibiotics, enzymes, growth factors, etc. The International Centre for Chemical Microbiology will be under the scientific direction of Professor E. B. Chain, F.R.S., formerly of Oxford University, joint winner of the Nobel Prize for 1945 for his chemical work on penicillin, and recently elected first chairman of the newly formed Expert Committee on Antibiotics of the World Health Organization. The entire idea of the project was born as the result of a lecture tour which Dr. Chain undertook in Italy for the British Council in 1947.

New Antibiotic against Amoebiasis

At the first Medical Symposium on Tropical Diseases of the Middle East, held in Beirut under W.H.O. auspices on November 18 and 19, Dr. Hamilton H. Anderson, dean of the medical faculty of the American University, who had just returned from the United States, announced that a new antibiotic, called fumigillin and still in the experimental stage, had shown great potential value for the treatment of amoebic dysentery.

Science in Africa

According to *The Times*, the Scientific Council for Africa South of the Sahara, which has just concluded its first session at Nairobi under the presidency of Dr. P. J. Du Toit, is to investigate the preparation of regional maps dealing with climatology, vector-borne disease, geology, etc., and the sponsoring of development in field hydrology and water conservation. The council has delegates from South Africa, Madagascar, Portugal, Britain, British East Africa, French West Africa, British West Africa, Southern Rhodesia, Belgian Congo, and French Equatorial Africa, and is trying to co-ordinate and promote scientific work throughout the greater part of the continent. The first African Malaria Conference opened on November 27 at Kampala, Uganda, under W.H.O. auspices.

Aureomycin Made in Britain

At Hirwaun, near Merthyr Tydfil, in South Wales, a factory owned by the Lederle Laboratories division of Cyanamid Products Ltd. will shortly begin to produce enough aureomycin for home consumption and some export. By arrangement with the Ministry of Health, only the purification and packaging of the crude antibiotic imported from the U.S.A. will be carried out here, but the erection of a complete fermentation plant by Lederle, who hold the patents, is under consideration.

Lasker Awards

The American Public Health Association has announced that its 1950 Lasker awards have been given to three American doctors and to the International Health Division of the Rockefeller Foundation. These awards are made for work on diseases which are the main causes of death and disability, and for distinguished service in public health administration. The International Health Division receives the award for its outstanding achievements in the control of hookworm, yellow fever, malaria, and other infectious diseases. Individuals to whom the award has been made include Dr. G. W. Beadle, professor of biology at California Institute of Technology, for work on the control of transmission of hereditary factors in disease; Dr. G. Papanicolaou, of Cornell University, for outstanding contributions to the early diagnosis of cancer; and Dr. E. L. Bishop, of the Tennessee Valley Authority, for original work in public health administration, particularly in the reduction of endemic malaria.

Wills

Mr. Warwick Deeping, the novelist and medical man, left £33,675. Professor A. B. Appleton, emeritus professor of anatomy at St. Thomas's Hospital, left £6,879. Dr. Harman Taylor, of Liverpool, left £8,236; Dr. C. R. Harvey, of Bristol, £61,883; Dr. A. W. Young, of Boxmoor, £31,192. Mr. Eldred Moss Corner, consulting surgeon to St. Thomas's Hospital and to Great Ormond Street Hospital for Sick Children, left £15,680. Dr. Gerald D. Channell, who lost his life in a fire following an explosion at Brompton Hospital, left £3,281. Dr. A. de W. Snowden, formerly of Linford, Ringwood, left £22,683.

COMING EVENTS

FitzPatrick Lectures

Dr. William Brockbank will deliver the FitzPatrick Lectures on "The History of Some Therapeutic Procedures" before the Royal College of Physicians of London (Pall Mall East, S.W.), on Tuesday and Thursday, December 5 and 7, at 5 p.m. In the first lecture Dr. Brockbank will discuss the enema, and in the second cupping and leeching.

Third Legg Memorial Lecture

Sir Thomas Fairbank will give the third Legg Memorial Lecture at King's College Hospital Medical School, Denmark Hill, London, S.E.5, on Friday, December 8, at 4.30 p.m., and his subject will be "The Spine."

Suprarenal Cortex in Disorders of Childhood

Sir Stanton Hicks, professor of human physiology and pharmacology in the University of Adelaide, will deliver a lecture on "The Role of Suprarenal Cortical Function in Disorders of Childhood" at the Ciba Foundation, 41, Portland Place, London, W., on Tuesday, December 12, at 5 p.m., with Lord Horder in the chair. Admission is by ticket obtainable from the secretary of the Foundation at the above address.

Aberdeen University Club, London

The club is holding a dinner and dance on Thursday, December 14, at the Hyde Park Hotel, Knightsbridge, London, S.W., at 7 p.m. for 7.30 p.m., with dancing till 11.45 p.m. Tickets may be had from the secretary, Aberdeen University Club, Southern Hospital, Dartford, Kent, on or before Monday, December 11, at 25s. each.

Florence Tong Lecture

The first Florence Tong Lecture of the Association of British Neurologists will be delivered by Dr. E. C. Lumsden in the lecture theatre, National Hospital, Queen Square, London, W.C., on Saturday, December 16, at 10 a.m. His subject is "Basic Problems in the Pathology of Disseminated Sclerosis and Demyelinating Disease." Admission to the lecture is free.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Friday

WHIPPS CROSS HOSPITAL MEDICAL SCHOOL, Leytonstone, E.—December 1, 8.30 p.m., *"Vitamins and Human Beings,"* by Professor J. R. Marrack.

Monday

●HUNTERIAN SOCIETY.—At Talbot Restaurant, 64, London Wall, London, E.C., December 4, 7 for 7.30 p.m., dinner meeting. *"Bad Habits in Children,"* discussion to be opened by Dr. Felix Brown and Dr. Wilfrid Sheldon.

●INSTITUTE OF NEUROLOGY, National Hospital, Queen Square, London, W.C.—December 4, 5 p.m., *"Infantile Hemiplegia,"* by Dr. W. G. Wyllie.

INSTITUTE OF OPHTHALMOLOGY, Judd Street, London, W.C.—December 4, 5.30 p.m., *"Spontaneous Hyphema,"* by Mr. J. H. Doggart.

INSTITUTE OF PSYCHIATRY, Maudsley Hospital, Denmark Hill, London, S.E.—December 4, 5.30 p.m., lecture-demonstration for postgraduates by Dr. K. Cameron.

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN, 17, Bloomsbury Square, London, W.C.—December 4, 7.30 p.m., *"Veterinary Therapeutics,"* by J. Carmichael, D.Sc.

●ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.—December 4, 3.45 p.m., *"Human Pharmacology, with Special Reference to Antihistaminics,"* by Professor W A. Bain.

●ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—December 4, 5.30 p.m., *"Anatomy of the Eye and Orbit,"* by Professor T. Nicol.

●SOCIETY OF APOTHECARIES OF LONDON, Black Friars Lane, Queen Victoria Street, E.C.—December 4, 3.30 p.m., *"The Theoretical Aspects of Isotopes in Relation to Medicine,"* by Professor A W. Wormall; 5 p.m., *"Practical Aspects of Isotopes in Relation to Medicine,"* by Professor J. S. Mitchell.

UNIVERSITY COLLEGE, Gower Street, London, W.C.—December 4, 4.45 p.m., *"Aspects of Protein Structure,"* by Dr. A. Elliott and Dr. W. E. Hanby.

Tuesday

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C., December 5, 5.30 p.m., *"High Blood Pressure and Renal Disease,"* by Professor Clifford Wilson.

●INSTITUTE OF DERMATOLOGY, Lisle Street, Leicester Square, London, W.C.—December 5, 5 p.m., *"Pigmentary Conditions of the Skin,"* by Dr. I. Muende.

INSTITUTE OF UROLOGY (UNIVERSITY OF LONDON).—(1) At St. Paul's Hospital, Henrietta Street, London, W.C., December 5, 3 p.m., ward round by Mr. J. D. Fergusson; (2) At St. Peter's Hospital, Henrietta Street, London, W.C., December 5, 10.30 a.m., ward round by Mr. H. K. Vernon; (3) At St. Peter's Hospital, Henrietta Street, London, W.C., December 5, 5 p.m., *"New Growths of the Bladder,"* by Mr. J. G. Sandrey.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East, S.W.—December 5, 5 p.m., *"The History of Some Therapeutic Procedures: The Enema,"* FitzPatrick Lecture by Dr. William Brockbank.

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—December 5, 5 p.m., *"Science and Art of Refraction,"* by Dr. T. H. Whittington.

●SOCIETY OF APOTHECARIES OF LONDON, Black Friars Lane, Queen Victoria Street, E.C.—December 5, 3.30 p.m., *"Biochemical Considerations of the Suprarenal Gland and its Relationship to Medical Therapy, with Special Reference to Rheumatoid Arthritis,"* by Professor E. C. Dodds, F.R.S.; 5 p.m., *"The Use of Steroid Hormones in Rheumatoid Arthritis,"* by Dr. W. S. C Copeman.

Wednesday

●INSTITUTE OF DERMATOLOGY, Lisle Street, Leicester Square, London, W.C.—December 6, 5 p.m., *"X-ray Technique,"* by Dr. C. W. McKenny.

INSTITUTE OF UROLOGY (UNIVERSITY OF LONDON).—At St. Peter's Hospital, Henrietta Street, London, W.C., December 6, (1) 3.30 p.m., museum specimens by Dr. Cuthbert Dukes; (2) 5 p.m., *"New Growths of the Bladder,"* by Mr. J. G. Sandrey.

LONDON UNIVERSITY.—At University College (Anatomy Theatre), Gower Street, London, W.C., December 6, 5.30 p.m., *"The Cyto-architectonic Organization of the Spinal Cord,"* by Professor Bror Rexed (Stockholm).

●NATIONAL INSTITUTE OF INDUSTRIAL PSYCHOLOGY.—At London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, W.C., December 6, 6 p.m., *"The Institute's Inquiry into Joint Consultation,"* by Mrs. Winifred Raphael.

●ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.—December 6, 3.45 p.m., *"Principles of Immunity in Relation to Surgical Practice,"* by Lord Stamp.

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—December 6, 4 p.m., *"Clinical Ophthalmology"* (Revision), by Mr. R. A. Burn and Mr. R. P. Crick; 5.30 p.m., *"Proptosis,"* by Mr. L. H. Savin.

●SOCIETY OF APOTHECARIES OF LONDON, Black Friars Lane, Queen Victoria Street, E.C.—December 6, 3.30 p.m., *"The Theoretical Aspects of the Investigation of Renal Diseases,"* by Professor E. J. King; 5 p.m., *"Some Aspects of Treatment in Renal Disease,"* by Professor Max Rosenheim.

Thursday

BRITISH MEDICAL STUDENTS' ASSOCIATION.—At Bearsted Theatre, The London Hospital, Whitechapel, E., December 7, 5.30 p.m., *"Travels and Experience in Australia,"* by Dr. A. Peacock.

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C., December 7, 5.30 p.m., *"Dynamics of Heart Failure,"* by Professor J. McMichael.

FACULTY OF HOMOEOPATHY.—At Royal London Homoeopathic Hospital, Great Ormond Street, London, W.C., December 7, 5 p.m., film: *"Varicose Ulceration: Its Treatment. Method of Bandaging Curative of Varicose Ulceration,"* to be presented by Dr Stuart McAusland. Discussion to be opened by Mr. Harold Dodd.

HONYMAN GILLESPIE LECTURE.—At University New Buildings (Anatomy Theatre), Teviot Place, Edinburgh, December 7, 5 p.m., *"Osteoarthritis of the Hip,"* by Professor Walter Mercer.

●INSTITUTE OF DERMATOLOGY, Lisle Street, Leicester Square, London, W.C.—December 7, 5 p.m., *"Hirsutism,"* by Dr. A. D. Porter.

INSTITUTE OF OPHTHALMOLOGY, Judd Street, London, W.C.—December 7, 5.30 p.m., *"Non-inflammatory Lacrimal Obstruction,"* by Mr. G. G. Penman.

INSTITUTE OF PSYCHIATRY, Maudsley Hospital, Denmark Hill, London, S.E.—December 7, 3 p.m., *"Neural Control of Pituitary Gland,"* by Dr. G. W. Harris.

INSTITUTE OF UROLOGY (UNIVERSITY OF LONDON).—At St. Paul's Hospital, Henrietta Street, London, W.C., December 7, 5 p.m., *"Neoplasms of the Urethra, Penis, and Scrotum,"* by Mr. D. I. Williams.

LONDON COUNTY MEDICAL SOCIETY.—At New End Hospital, Hampstead, London, N.W., December 7, 3 p.m., clinical meeting.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East, S.W.—December 7, 5 p.m., *"The History of Some Therapeutic Procedures: Cupping and Leeching,"* FitzPatrick Lecture by Dr. William Brockbank.

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—December 7, 5 p.m., *"Artificial Eyes,"* by Mr. G. C. Pritchard.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, Hyde Park Corner, London, S.W.—December 7, 4.30 p.m., lecture-demonstration on psychiatry by Sir Paul Mallinson.

●SOCIETY OF APOTHECARIES OF LONDON, Black Friars Lane, Queen Victoria Street, E.C.—December 7, 3.30 p.m., *"The Medical Aspects of Peripheral Vascular Disease,"* by Sir Horace Evans; 5 p.m., *"The Surgery of Peripheral Arterial Disease,"* by Sir James Paterson Ross.

WINGFIELD-MORRIS ORTHOPAEDIC HOSPITAL: NUFFIELD ORTHOPAEDIC CENTRE, Oxford.—December 7, 8.30 p.m., *"The Treatment of 'Intractable' Spasticity,"* by Dr. L. Guttmann.

WREXHAM AND DISTRICT CLINICAL SOCIETY.—At Wynnstay Arms Hotel, Wrexham, December 7, 7.30 p.m., *"Epidemiological Aspects of Tuberculosis,"* by Dr. C. O. Stallybrass.

Friday

INSTITUTE OF OPHTHALMOLOGY, Judd Street, London, W.C.—December 8, 5.30 p.m., *"Structure and Function of the Cornea,"* by Dr. H. Davson.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, Denmark Hill, London, S.E.—December 8, *"The Spine,"* Legg Memorial Lecture by Sir Thomas Fairbank.

●MAIDA VALE HOSPITAL MEDICAL SCHOOL, London, W.—December 8, 5 p.m., clinical neurological demonstration by Dr. Anthony Feiling.

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—December 8, 4.15 p.m., *"Pathology,"* by Miss M. Savory.

●ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—December 8, 5.30 p.m., *"Physiology of the Eye."*

ROYAL MEDICAL SOCIETY, 7, Melbourne Place, Edinburgh.—December 8, 8 p.m., Hat Night.

ROYAL SANITARY INSTITUTE.—At Newe Hall, Pilgrim Street, Newcastle-upon-Tyne, December 8, 10 a.m., papers: *"A Home of One's Own,"* by Dr. J. V. Walker; *"Drains and Sewers—The Legal Aspect,"* by Mr. L. Mair. Afternoon: visits.

●SOCIETY OF APOTHECARIES OF LONDON, Black Friars Lane, Queen Victoria Street, E.C.—December 8, 3.30 p.m. and 5 p.m., *"Thyroid and Parathyroid Diseases,"* by Sir Henry Cohen.

Saturday

KENT PAEDIATRIC SOCIETY.—At Star Hotel, Maidstone, December 9, 2.30 p.m., *"The Value of Intelligence Testing,"* by Mr. M. B. Shapiro.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Elias.—On November 13, 1950, to Dr. Mary Elias (formerly Wiggins), wife of Major T J G. Elias, of 29, Firs Drive, Cranford, Middlesex, a son—David Robin Cliveden.

Finlay.—On November 24, 1950, at the Royal Hospital for Women, Sydney, Australia, to Francesca Maxwell (formerly Best), wife of Donald M. L. Finlay, M.B., a daughter.

Hargrove.—On November 16, 1950, at the Hill Nursing Home, Reading, to Elizabeth (formerly Corbett-Lowe), wife of Dr. Peter Hargrove, a daughter—Carole Susan

Mackay.—On November 16, 1950, to Viola (formerly Shafto), wife of Dr. Hugh Mackay, Gladwynne, Birtley, Co. Durham, a daughter.

MARRIAGES

Griffiths—Poulton.—On November 11, 1950, at Cheltenham, Eric Probert Griffiths M.R.C.S., L.R.C.P., D.C.H., D.R.C.O.G., to Elizabeth Ann Poulton

Shepherd—Graham.—On November 18, 1950, at Broughty Ferry, William Shepherd M.B., Ch.B., to Shirley Anne, eldest daughter of H. A. Graham, M.D., F.R.C.S.Ed.

DEATHS

Broadley.—On November 23, 1950, at 2, Beech Hill Road, Sheffield, John Broadley, M.B., F.R.C.S.Ed.

Brophy.—On November 16, 1950, at 94, Wimbledon Hill Road, London, S.W., Cyril Mary Brophy, M.C., F.R.C.S.

Clark.—On November 15, 1950, in Glasgow, John Sawers Clark, M.C., M.B., Ch.B., D.P.H., of Carnock, Willow Avenue, Lenzie, Dunbartonshire, late of Sittingbourne, West Wickham, and Newmilns, Ayrshire.

Douglas.—On November 20, 1950, at Royal Infirmary, Edinburgh, Andrew Douglas, M.B., Ch.B.

Murray.—On November 20, 1950, in a nursing-home, Brixton, James Alexander Murray, M.D., F.R.S., aged 76.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Athletes and "Heart Strain"

Q.—*In athletic circles laymen often speak of sustaining a "strained heart" following some violent effort. Does this condition exist? If so, how does one recognize it, and what is the exact pathology?*

A.—It is not possible for a healthy young adult to strain his heart in the performance of heavy exercises. The effect of heavy exercise, such as rowing in the Boat Race, is often to cause the individual to become collapsed. In such cases, if there is any cardiac dilatation, which is questionable, this is quite transitory. The collapse is partly vasomotor and partly psychological in origin. There is also a transitory oxygen debt in the body.

If an individual is of the nervous type predisposed to effort syndrome, there is no doubt that physical overstrain may bring out the symptoms of this condition. This again causes no physical change in the heart but is an abnormality of the nervous system in which nervous stimuli to the heart cause undue tachycardia and nervous stimuli from the heart cause undue sensations arising from the heart beat.

Tropical Gastro-enteritis in Children

Q.—*We are losing a number of infants, about 6 months old, from gastro-enteritis in this area (Tel-el-Kebir). What treatment is recommended? At present we use intravenous saline and large doses of penicillin. Castor oil followed by sedation has not been tried recently. "Chloromycetin" was tried once, but it had no beneficial effect. Is "aureomycin" of any value in these cases, or is there any other effective antibiotic?*

A.—In hot climates where infection spreads through poor sanitation and defective food storage, gastro-enteritis continues to be a serious and fatal disease, and the younger the child the more serious it is. There is no specific cure for this disease. Castor oil followed by sedation does more harm than good. Chloromycetin and aureomycin may help in individual cases when the pathogenic organism is known, but their results are disappointing. The chief danger in the disease is in the chemical injury which comes from dehydration and electrolyte loss. The first step in treatment is to correct the dehydration by parenteral administrations of fluid, using saline, Hartmann's solution, or Darrow's solution, whichever may be indicated. If these are given intravenously great technical skill and constant supervision by both doctor and nurse are required; in the absence of adequate supervision it is better to give the fluid subcutaneously. When the pathogenic organism is not known sulphonamides can be given empirically (after the urine flow has been re-established)—or chloromycetin or aureomycin may be tried in the same way—but these are merely adjuvants. The correction of dehydration, and good nursing, are the first requirements.

Treatment of Dwarfism

Q.—*What is the treatment of dwarfism? After what age can any improvement cease to be expected?*

A.—The treatment of dwarfism is unsatisfactory. Retarded growth may be due (*a*) to deficiency of growth hormone, as in hypopituitarism, (*b*) to arrest of growth of bone and premature union of the epiphyses, as may be caused by chronic cachectic diseases in the past, and (*c*) to an inherent unresponsiveness of the growing ends of the bones to the normal growth stimulus, which may possibly be the cause of genetic or hereditary dwarfism. In the last two types there is no treatment which will be effective. In pituitary dwarfism the administration of growth hormone is the logical procedure, but the results obtained with the commercial preparations at present available are not impressive, probably on account of their low potency and inadequate dosage. Attempts may be made with doses of the order of 5 ml. of anterior pituitary growth hormone extract injected intramuscularly three to five times a week, but it is unlikely that any satisfactory therapeutic response will be obtained until pure growth hormone is available. When hypothyroidism is present this should be treated in the usual way. No improvement can ever be expected once the epiphyses have united.

Palatable Prescriptions of Iron

Q.—*What is the most palatable and yet effective prescription for iron for use in secondary anaemias? Are haemoglobin preparations any good?*

A.—It is difficult to state categorically which is the best and most palatable iron preparation. It is definitely established that soluble ferrous salts are the most active form of iron, but they are also the most astringent and most likely to cause nausea. Flavoured preparations of ferrous salts include syrup of ferrous iodide and syrup of ferrous phosphate, *B.P.C.*, 1949, and ferrous sulphate syrup, *U.S.P.*, XIV. Ferrous carbonate pills are slightly less liable to cause unpleasant side reactions than the sulphate, and absorption of iron from them is reasonably satisfactory.

Metallic iron, colloidal ferric preparations, and the scale preparations in which the iron is in a complex form and not readily ionized, all require to be given in large doses to produce effects. Solution of dialysed iron, *B.P.C.*, is a colloidal solution of ferric hydroxide and contains the equivalent of 3 to 4% of iron. This is non-irritant and non-astringent and is sometimes prescribed with two parts of glycerin.

For those patients who cannot tolerate any form of oral iron preparation or who do not appear to absorb iron from the digestive tract, the intravenous preparations "ferrivenin" and "iviron" are available.

Haemoglobin, after oral administration, is converted into haematin in the stomach and then passes through the bowel, very little, if any, being absorbed. An elixir of haemoglobin was included in the 1934 *B.P.C.*, but was so much inferior to the iron salts that it was deleted from the 1949 edition.

Vaginal Examination in Virgins

Q.—*What are the objections to examining a virgin without an anaesthetic?*

A.—The possibility of arousing erotic sensations under such circumstances is so remote that it can be dismissed. Indeed, such would be more likely to occur in a woman with sex experience. The reason for hesitating to make a pelvic examination in a virgin, even an inspection of the vulva, is that in most cases a young girl finds it acutely embarrassing, if not repulsive. Even if she is not hurt it is conceivable that she may suffer psychological trauma which may remain to cause aversion to coitus, vaginismus, and other marital difficulties in later life. Women in older age groups tend to tolerate pelvic examination better, and nowadays even in the younger age groups false modesty is less common. There can be no general rule, and the decision in each case must be based on clinical assessment of the likely reaction of a given patient. Whenever a tentative approach makes it clear that the patient is strongly averse to the examination, and that she is unlikely to co-operate, there should be no attempt at persuasion. If rectal examination does not then supply all the necessary information, vaginal examination under anaesthesia is indicated.

Ringworm of the Nails

Q.—*What is the best method of treating ringworm of the nails without surgical removal of the nails?*

A.—Nails infected with ringworm may be painted twice daily with tinct. iodi mitis, or they may be softened by soaking in a

solution of potassium permanganate (1 in 4,000) with subsequent scraping with the edge of a glass slide and the application of iodine, dithranol, or other fungicide. Fractional doses of *x* rays may be tried, either alone or with these measures, but no treatment is very successful, and treatment even after surgical removal fails in a considerable proportion of cases. Some fungi penetrate more deeply into the nail substance than others and are in consequence less easily cured.

Worn Incisors

Q.—*Can anything be done to improve the appearance when the upper incisors begin to wear down in middle age?*

A.—The remedy is the construction of porcelain or acrylic jacket crowns. The discoloured enamel is removed from the teeth and replaced by a shell of porcelain or acrylic resin. With this method of crowning the nerve of the tooth is left intact.

Allergic Rhinitis

Q.—*What investigations should be carried out to establish a diagnosis of allergic rhinitis? What is the treatment? Is there any known association between allergic rhinitis and glucose tolerance or gastric acidity?*

A.—The patient should be asked about the mode of onset and any seasonal incidence of the symptoms, and about his occupation and environment, with special reference to any food, dust, or other specific factor which might be a cause of the symptoms. Any substances suspected can be tested by appropriate cutaneous tests to ascertain if the patient is sensitive to it. If such sensitivity is established, treatment consists in avoiding the allergen where possible, a carefully graduated course of injections to desensitize the patient, or, if multiple sensitivity is present, a combination of these.

Many allergic patients have some degree of achlorhydria, and children who suffer from asthma have low blood sugars in over 60% of cases.

"Chloromycetin" and Hoarseness

Q.—*Can chloromycetin ever produce hoarseness or aphonia?*

A.—The most serious "toxic" effect of chloromycetin is the production of mucous membrane lesions. These commonly affect the tongue, mouth, and throat and give rise to infection, oedema, and pain. "Black tongue" has been described. The lesions are probably due to yeast infection, and it has been suggested that induced riboflavin deficiency may be a factor in causing these changes. Hoarseness and aphonia might well result, but the writer has not seen it reported. Less commonly, proctitis, vaginitis, and perineal irritation may occur and may persist for a considerable time after treatment is stopped. Nausea, anorexia, and diarrhoea are common symptoms during chloromycetin administration.

NOTES AND COMMENTS

Punch-drunkenness.—Dr. ERNST JOKL (Pretoria) writes: May I refer to your note in "Any Questions?" (September 30, p. 793). The point I wish to make is that punch-drunkenness is not a single syndrome. In our first communication on the subject in 1933 the late Eric Guttmann and I[1] made a distinction between two kinds of chronic impairment encountered in boxers—viz., behaviour anomalies indicative of psychopathic traits, and neurological or psychiatric conditions resulting from head injuries. As regards the former there are on record cases of "viciousness when drunk," "murder committed from jealousy," "boisterousness," "subnormal intelligence," "*malingering*," "vagrancy," "simple dementia," and "euphoria and delinquency." Instances are quoted in my book,[2] and Macdonald Critchley has recently contributed further evidence.[3] Sometimes there are neurological symptoms. Sometimes there are none. The question of the relation of the abnormal behaviour and boxing is often difficult to answer.[4] Conditions assumedly caused by head injuries in the ring include parkinsonism, cerebellar signs, dysarthria, epilepsy, paroxysmal headache, and hemiplegia.[5] Post-mortem studies in boxers have shown subdural haematoma (many cases), early delayed subarachnoid haemorrhage, multiple layers of coagulated blood (pachymeningitis haemorrhagica interna), haemorrhage into the pons, petechial haemorrhages into the cerebellum, petechial haemorrhages into the mid-brain, oedema of the entire brain, oedema of the medulla oblongata, bi-polar parenchymatous contrecoup lesions, laceration of the brain, and septic meningitis. *Ex definitione*, punch-drunkenness is a state of gradual deterioration. But, disregarding for the moment the psychopathic group, the cerebral lesions underlying the condition under discussion are assumed to be similar to those responsible for acute injuries. In fact, virtually every variety of symptom described in Rowbotham's textbook on head injuries[6] has been observed in boxers. The multiplicity of anomalies encountered renders unacceptable the assumption of a single syndrome of punch-drunkenness.

Prickly Heat.—Dr. MARY E. EGERTON (Freetown, Sierra Leone) writes: I feel it is a pity that the readers of "Any Questions?" should not be reminded of the wartime discoveries with regard to the prevention of prickly heat (October 7, p. 847). By the issue of salt tablets the armies in tropical areas succeeded in reducing the incidence of all disabilities due to heat, including heat stroke and prickly heat. My own work on this subject hardly deserves mention, being infinitesimal by comparison, but I have again and again proved the efficacy of saline drinks to prevent prickly heat in the European newborn baby. All European babies born at the Princess Christian Hospital, Freetown, are at once put on to slightly hypertonic saline drinks instead of the usual boiled water, and by this means we have prevented the distressing prickly heat to which their sensitive skins are subject. Babies born elsewhere are frequently brought to us smothered in the rash, and I have found that saline by mouth is in every case an effective remedy, reducing the inflammation in the course of a day, and preventing further increase as long as it is continued. For adults extra salt (about three teaspoonfuls daily added to drinks) is also a remarkably effective remedy for heat lassitude.

Dr. C. J. WILSON (Kenya Colony) writes: In the *Journal* of October 7, "Any Questions?" (p. 847), occurs the statement: "There is no truly specific treatment for prickly heat." Can the author of this statement deny that the application of a mercurial lotion is invariably successful in curing prickly heat, and therefore can claim to be specific treatment (see *Journal*, 1948, **1**, 76, 228, 317, 525, 573, and 811)? When prickly heat is at last generally recognized for what it is—namely, a fungus infection at once curable by a mercurial application of requisite strength (my preference is for an aqueous solution of corrosive sublimate, 1 : 500)—perhaps we shall no longer be advised to smear the body with grease and avoid soap in an attempt to alleviate a condition so easily curable.

Dr. P. A. WITH (Trinidad) writes: I have just received the *Journal* for October 7, in which the statement is made that there is no specific treatment for prickly heat ("Any Questions?" p. 847). I notice that 1 : 1,500 solution of mercury perchloride is suggested. The specific treatment is: R Liquor hydrarg. perchlor. 1 : 1,000; strong HCl 1 min. to each ounce of the liquor. When very young and serving in the Mesopotamia campaign in World War I, this prescription was given to me by a planter doctor who had come out on service. I saw some very severe cases, the body being swollen and accompanied with high fever. This lotion, swabbed all over the body several times a day and allowed to dry, was almost magical in 24 hours. . . .

Correction.—Reporting a meeting of the General Medical Services Committee (*Supplement*, November 18, p. 206) we erroneously said that acute primary (including influenzal) pneumonia is not notifiable. It is in fact notifiable.

LESSONS FOR FUTURE TREATMENT FROM 472 FATALITIES IN DIABETIC CHILDREN*

BY

ELLIOTT P. JOSLIN, M.D., AND JAMES L. WILSON, M.D.

Boston

Our diabetic children are living a great deal longer than formerly, yet they still die prematurely and as a rule unnecessarily. We were much encouraged to learn that the average duration of diabetes in the 135 children who succumbed in 1944–9 exceeded the average duration in those dying in the previous six-year period, 1937–43, by approximately eight years, and that they were eight years older when they died. However, we were much discouraged to learn that tuberculosis and coma played a far more important part in mortality than among all our cases, young and old. In fact, these two preventable complications caused 21.5% of the deaths. Furthermore, an analysis of the cardiorenal-vascular group, which accounts for 56.3% (revised 59.3%) of the deaths, showed 37% (revised 51.9%) age, up to the end of 1949, 472 were dead, 2,381 living, and only 20 untraced at January 18, 1950. This table is compiled in conformity with all our previous records. It is based upon causes of death reported by the family physician or recorded on death certificates. Table II, discussed in detail later, gives what we consider a more accurate classification of causes of death, because this is derived from a detailed reinvestigation of the last illness and the utilization of ante-mortem records. These figures appear in the text as revised percentages. The changes in diagnosis relate almost exclusively to the cardiorenal-vascular group. Justification for such changes and a few others is mentioned below but cannot be explained in each instance because of lack of space.

TABLE I.—*Causes of Death of Child Diabetics. Number and percentage of Deaths from Selected Causes by Eras of Treatment. Experience of E. P. Joslin, 1898 to Date**

Causes of Death	Pre-insulin Era 1898–6/8/22		Insulin Era

* Deaths reported up to January 18, 1950.

to be renal. The future holds even greater promise for diabetic children, because we believe not only that the number succumbing to tuberculosis and coma can be reduced but that progress can be made towards decreasing the large number of deaths now resulting from complications in the kidney. A similar optimistic view has come from Boulin's clinic.

In Table I the causes of death of 472 children are recorded in successive periods from 1898 to 1949. Of the 2,873 diabetic children seen, with onset before 15 years of

*Aided by a grant from the Life Insurance Medical Research Fund. Statistical analyses prepared by Statistical Department, Metropolitan Life Insurance Company.

It is true that the incidence of deaths due to diabetic coma has steadily dropped from 86% in the pre-insulin era to 9.6% since 1944, while the frequency of cardiorenal-vascular disease has steadily risen from 0.6% to 56.3%.

Inspection of the cardiorenal-vascular group discloses that only two cases of renal disease were recorded prior to 1937, but recently the figure has risen to 37%. Angina pectoris or coronary disease, likewise, did not appear until 1937, but since that time has risen from 2.5% to 10.4%. Apoplexy was observed only once among these children before 1944 and in only three cases since that time. As for gangrene, only two deaths were noted among the total number.

Fatal infections rose from an incidence of 6.4% before insulin to a peak of 24.7% in 1937–43, but since the introduction of specific chemotherapeutic agents and antibiotics they have fallen to 7.4%.

The children lived for so short a time prior to the discovery of insulin that none was recognized as dying from tuberculosis until the period 1922–36; and, indeed, until this present detailed follow-up of all our cases was made we really did not appreciate that since the use of insulin the deaths from this cause were as high as 8.1% from 1922 to 1936, 9.9% from 1937 to 1943, and 11.9% from 1944 to 1950.

Deaths before 1944 are really "water over the dam," but there is plenty to discuss about the most recent deaths.

Causes of Death of Juvenile Diabetics, 1944–9

A comprehensive review of the ante-mortem clinical records of the 135 patients whose deaths occurred in 1944–9 has just been completed (Table II). This detailed study was very revealing, and was particularly informative in those 76 cases (Table I) in which death was attributed primarily to cardiorenal-vascular causes, of which only 50 were recorded as renal. There were 13 such deaths assigned to cardiac disease because of statements on death certificates. However, we have definite evidence that severe renal diseases had existed for many years before the patients' sudden exitus. Most probably this was quite unknown to the physician signing the death certificate, for he may never have seen the patient before the terminal incident or not even until after death.

TABLE II.—*Revised Table of Causes of Death of Juvenile Diabetics, 1944–9, Based on Ante-mortem Clinical Records*

Causes of Death	No. of Cases	%
Diabetic coma, primary	12	8·8
Cardiorenal-vascular:		
Cardiac	8	5·9
Nephritis	70 } 80	51·9 } 59·3
Apoplexy	2	1·5
Infections	8	5·9
Tuberculosis	15	11·2
Cancer	1	0·7
Accidents:		
Suicide	1	0·7
Others	6 } 7	4·5 } 5·2
Miscellaneous	5	3·7
Unknown	7	5·2
Total	135	100

Two of the deaths reported on the certificate as due to previous gangrene were really due to advanced renal disease. Likewise, two of the cases classified under deaths due to infections were actually severe infections of the kidney superimposed upon a chronically diseased renal apparatus. Three other cases—reported as suicide (based upon suspicion), coma, and apoplexy—were in fact renal deaths. Other changes in our revised classification included one case which we deducted from the tuberculosis group because the osteopath who signed the death certificate told one of us he had included tuberculosis on the certificate on hearsay evidence only. Four others were similarly erroneously reported, but the errors were perpetuated statistically. Our final revisions appear in Table II.

The information disclosed by this critical analysis of the fundamental disease of the patient, as contrasted with the reported terminal event assigned on the death certificate, we believe to be of great significance. Among the diabetic children the true complication which we must combat is renal rather than cardiac. The early signs and symptoms for which we must be ever alert, and for which prophylaxis and newer therapeutic aids may be helpful, are those of complications in the kidney. These observations are in conformity with those published by Fanconi, but they lead us to hope that Boulin, with his group of cases of, as yet, shorter duration, may be justified in his more optimistic attitude.

Tuberculosis

Of the 135 fatal cases among children in 1944–9, there were 15 (11.2%) whose lives ended in tuberculosis. In all of our patients, young and old, tuberculosis never has caused more than 4.9% mortality in any period, and since 1944 it has been 2.5%. With children the previous highest rate was 9.9%, none of the deaths up to 1922 having been caused by it, presumably because before insulin the life-span of a diabetic child was so short. We are uncertain of how many of our living children have tuberculosis.

Six of these 15 deceased children were seen but once, either at a single visit to our office or upon their first and only stay in hospital. Two of them already had advanced tuberculosis. Most of these 15 cases should have been discovered earlier. One had tracheo-bronchial adenitis and another had calcified bronchial glands at their first visit, and two others had findings suggestive of old healed tuberculosis. Having known formerly that one in five of our patients who recovered from diabetic coma developed tuberculosis within five years, we should have supervised more closely the six cases with a history of coma. The diagnosis in six cases was first made by us. In nine cases *x*-ray examination was not carried out at the first visit or during the first stay in the hospital. In fact, six of the cases saw us within six months of the detection of the tuberculosis, and we have no comforting assurance of a negative radiograph in our files.

A special, and warning, lesson is to be learned from the three cases which were at an excellent charitable tuberculosis preventorium long before the tuberculosis was recognized. Certainly they were studied for tuberculosis while there, but after leaving the institution they were not sufficiently followed up. We cannot help wondering what will be the fate of the boys and girls who outgrow the sheltering care of any diabetic children's home. Only two of the fifteen children were ever treated in a diabetic summer camp. All the cases save one came from especially underprivileged families. Four of these patients married; three of them did so before the onset of tuberculosis. One patient married two years after the onset of her tuberculosis and later had one child. In one case pregnancy was interrupted at seven months because of tuberculosis, and another had a nephrectomy for a tuberculous kidney.

Yet there is a hopeful aspect to the picture of these 15 deaths due to tuberculosis in that the average duration of diabetes at death was 13.2 years, though the duration of diabetes since the appearance of tuberculosis was much less. If diabetic children can live 13 years *with* tuberculosis, how much longer should they live *without* it!

Diabetic Coma

Twelve (8.8%) of the 135 deaths in this group of juvenile diabetics were directly attributable to diabetic coma. Five males and seven females, three of whom were married, comprised the group. Six of these patients were known to have relatives who were also diabetic. The average age at onset of diabetes in these 12 patients was 7.9 years and the average duration of the disease before the fatal attack of coma was 10.0 years. Thus the fatal complication occurred in the group at an average age of 17.9 years.

No attacks of coma had occurred during the interval between diagnosis of diabetes and the fatal episode in seven of these cases. One patient had been grossly neglectful and was repeatedly treated for coma before his final attack. Information was inadequate in another case. One patient had suffered two attacks, and two other patients had each been in coma on one occasion between the onset of their disease and their fatal attack of coma.

It was impossible to determine definite precipitating factors in seven of these cases of fatal coma. One patient, having previously been in coma, omitted her insulin for three days because of an upper-respiratory infection; coma in one of the cases was reported to have been precipitated by complications of pregnancy. Dietary excesses alone or associated with the omission of insulin were responsible for the onset of coma in two other cases. Advanced bilateral pneumonia, unsuspected clinically, was first found at necropsy in one case treated at another hospital. This patient received much glucose intravenously during the course of treatment of her coma and was found to have a post-mortem blood sugar of 700 mg. Two of the children were severe behaviour problems, one of whom had associated epilepsy and died at a State mental hospital. Four of the children attended the diabetic camps during one or more summer sessions, but six of the group saw us only once. Not one of these 12 patients was treated at the New England Deaconess Hospital or seen by any one of our staff during their terminal illness. Only three patients were seen within twelve months of their final coma, and only two others had been seen within three years of their fatal illness. Nine of the deaths occurred during the second decade of life, two between the ages of 20 and 30, and one past the age of 30.

The usual variety of associated conditions was seen in these patients: thus one case each of epilepsy, necrobiosis lipoidica diabeticorum, retarded growth, nocturnal diarrhoea, retinitis with generalized arteriosclerosis, xanthomatosis, and insulin lipodystrophy were seen.

Arteriosclerosis

In general, arteriosclerosis when present in one part of the body will manifest itself in the vascular system throughout. As a result of this and its major incidence after 50 years of age the tendency in the past has been to group together all patients showing degenerative vascular disease under the general heading of deaths due to arteriosclerosis. However, a discriminating review of the clinical records of the 135 fatal cases in this series has revealed the presence of ante-mortem renal damage of considerable degree in at least 70 cases, or 51.9% of the entire number. There were 15 post-mortem examinations in the group of 70 fatal cases. The clinical data accumulated on the other 55 patients before their deaths clearly indicate that, despite various other death-certificate classifications, death was in reality due primarily and chiefly to renal disease. The majority of these 55 cases showed all three of the most frequently seen ante-mortem clinical manifestations of vascular nephritis—namely, proteinuria, oedema, and hypertension. Twenty-six of these 55 had shown frank uraemia. Records available indicated that retinitis was an associated manifestation in at least 60% of this group.

It was noted consistently in those cases having adequate follow-up examinations that the proteinuria invariably preceded the elevation of blood pressure, thus strongly supporting the thesis that the condition was primarily renal in origin rather than attributable to the onset of essential hypertension.

Most post-mortem examinations of children dying with diabetes mellitus reveal a mixture of several types of renal pathology, including pyelonephritis, intercapillary glomerulosclerosis, and arteriolosclerotic and arteriosclerotic disease. This was strikingly true in the 15 necropsies in this group. An exception to this general finding was, however, a case in which careful microscopical analysis failed to show evidence of any kidney lesions other than those of chronic glomerulonephritis, despite the fact that before her death the patient showed the classical symptoms of vascular nephritis and was in clinical uraemia terminally. In this case no arteriosclerotic renal changes were evident, although atheromatous changes were described in the aorta and coronary arteries.

Distribution of the cases according to sex seemed irrelevant, since 37 males and 33 females comprised the group. It was anticipated that there would be a considerable preponderance of females in this renal group because of the increased incidence of urinary-tract infections in these young girls. Infection, although playing some part in the pathogenesis of these renal complications, was far from being the entire explanation, though many of these cases revealed a history of previous severe urinary-tract or kidney infections, but without adequate follow-up studies.

Cardiac and Cerebral

Arteriosclerosis, as stated above, is seldom if ever confined to one organ, but in the 10 cases in which the changes were predominantly localized the heart was involved in eight and the brain in two. To say that the heart was not affected in the 70 cases of death due primarily to renal disease would be untrue, but the functional cardiac impairment was apparently of far less importance. Three of these cardiac patients showed also severe hypertension and proteinuria, and two of them had clinical nephritis before death. In one case at necropsy intercapillary glomerulosclerosis was present. These eight patients (five males and three females) died primarily of cardiac disease complicating their diabetes, which had been present for an average of 22 years. The two cerebral deaths were due to emboli, in one case after 26.3 years of diabetes and in the other case after 16.5 years of the disease.

Complications were numerous in the cardiac group. Pulmonary tuberculosis was suspected but never proved in two cases. Five cases had retinitis proliferans, and there was one instance of necrobiosis lipoidica diabeticorum. Severe diarrhoea, presumably on the basis of diabetic neuropathy, had occurred in two patients. None of these patients died in a Boston hospital, and a necropsy was performed in only one case, thus emphasizing our ignorance of the exact nature of the final illness. Very little information was available for review regarding the terminal events in these 10 patients whose death resulted from occlusive cardiovascular phenomena. One was known to have been markedly hypoglycaemic for a considerable period before his terminal coronary occlusion. The youngest patient to have a fatal coronary attack was 21.9 years old, and this same girl was also the only patient having been seen within two years of her death. In all the other cases the patients were last seen at the office or hospital from 3 to 25 years before the final outcome.

Miscellaneous Deaths

As shown in Table II, 27 (20%) of the cases were the result of accidents, infections, and miscellaneous or unknown causes. In seven cases it was impossible to trace the cause of death.

The seven accidental fatalities included a fractured skull in an industrial accident, flame burn in a circus fire, a car accident, a deer-hunting accident, suffocation in bed during

an epileptic seizure, one drowning, and one suicidal death from gunshot wounds. One death resulted from carcinoma of the bladder.

Infections were responsible for eight deaths: pneumonia accounted for four, and systemic infections for the remaining four.

Conclusions

Above all else, these 135 deaths of diabetic children within the last six years—11.2% from tuberculosis, 8.8% from diabetic coma, and 51.9% from renal disease—show that the diabetic with onset of disease in childhood should be followed more closely. Only in this way can needless deaths be avoided. Continuity of treatment is essential. Roentgenograms of the chest should be taken yearly. A constant awareness for evidences or incipient signs of renal disease must be maintained. Research should be concentrated on the kidney in the young diabetic. The importance of post-mortem examinations cannot be too strongly emphasized.

To preserve in comfort and prolong the lives of diabetic children the need is paramount for inexpensive and attractive opportunities, in children's and adolescents' camps, and especially in hospitals, of reviewing their physical condition and promoting morale and zeal for the continuing control of their diabetes.

ERYTHROCYTE SEDIMENTATION IN ANAEMIA

BY

RICHARD TERRY, M.D., M.R.C.P.

Senior Registrar, St. Bartholomew's Hospital

In 1921 Robin Fahraeus introduced his method of measuring the erythrocyte sedimentation rate (E.S.R.) and, after describing the various disorders in which it was increased, discussed the factors involved. Most of his findings are still widely accepted, especially the view that anaemia had an accelerating effect on blood sedimentation. Others studied this problem and also became convinced that anaemia, *per se*, increased the E.S.R. (De Courcy, 1925; Meeker, 1925; Rubin, 1926; Hubbard and Geiger, 1928; Cherry, 1934). It was soon suggested that the E.S.R. was so dependent on the red cell count that it was wholly unreliable in anaemia (Hunt, 1929) and that small increases in the E.S.R. should be discounted in the presence of anaemia (Bannick *et al.*, 1937). With few exceptions further studies have been in agreement on the effect of anaemia and on the need for correction of the increased rate, differing only over the best method of making this correction.

The object of this paper is to give certain theoretical, clinical, and experimental reasons for believing that the E.S.R. is not increased by anaemia, and therefore that the observed E.S.R. has the same significance in anaemia as in normal blood states.

Existing Correction Methods

Some recommend estimation of the E.S.R. in anaemia only after the packed cell volume (P.C.V.) has been adjusted to normal by manipulation of the blood sample (Hubbard and Geiger, 1928; Chung, 1935; Gibson, 1938), others after removal of enough plasma to raise the red cell count to 5 millions per c.mm. (Walton, 1933; Schuster, 1938). Charts have been devised to correct for various haemoglobin levels (Gram, 1929) or haematocrit readings (Ernsterne and Rourke, 1930). The latter method was adopted by Wintrobe and Landsberg (1935), who constructed a chart based on numerous readings on normal blood samples made "anaemic" by dilution with their own plasma. Certain impossible situations in this chart were pointed out by Hynes and Whitby (1938), whose modification is based on the same data. Other methods include simple subtraction based on the haemoglobin level (Gregg, 1939) and a proportional correction depending on the P.C.V. (Della Vida, 1947).

Contrary views have been expressed, but they have been weakened by inadequate evidence (Bouton, 1938; Vogt, 1941) or change of opinion (Gregg, 1937, 1939). Britton (1936) concluded that an increased E.S.R. in anaemia indicated a search for some accompanying disorder, but not only did he allow an upper limit of 15 mm. an hour (Westergren) for women, accounting for this high figure by their lower average red cell count, but he also lent support to a correction chart (Whitby and Britton, 1946). A number of cases of anaemia with normal E.S.R.s were reported by Sugarman (1939), but he gave few details and made no comment on correction. Without referring to clinical results, and believing that the red cells played an entirely passive part in sedimentation, Cutler *et al.* (1938) opposed correction.

This opposition has been too indecisive, and the field is now firmly held by the supporters of correction. The present position remains as described in the exhaustive review of blood sedimentation by Ham and Curtis (1938), who concluded: "It has been clearly established that decrease in erythrocyte concentration causes acceleration of the sedimentation rate."

Fallacies of Correction

Anaemia is not a simple entity. Alterations occur in the red cells affecting their number, mass, size, shape, uniformity, and haemoglobin content, and these alterations vary with the cause of the anaemia, as do changes in the plasma proteins. It follows that a single correction factor will not be suitable for all forms of anaemia, and that consideration of one aspect of the anaemia will lead to other aspects being ignored or distorted. Thus adjustment of the haemoglobin to 100% in an anaemic sample may well increase the red cell count to 10 millions per c.mm. and the P.C.V. to 60%, while manipulating the red cell count of the same specimen to 5 millions per c.mm. may leave the haemoglobin at 40% and the P.C.V. at 30%; similarly, adjusting the P.C.V. to normal will not produce normality in other respects.

These methods of "correcting" the blood sample before estimating the E.S.R. also ignore other changes in the red cells. Cutler *et al.* (1938) maintained that the red cells played an entirely passive part in sedimentation. It seems certain that this view is incorrect. Ham and Curtis (1938), by suspending washed red cells of varying size in the same plasma, showed that large cells sediment faster than small cells. The experiments of Bunting (1939) with cases of sickle-cell anaemia are convincing. He found that their E.S.R. was greatly increased after reducing the sickling by bubbling oxygen through the blood, whereas when about 50% sickling was produced by using carbon dioxide, rouleaux formation and sedimentation were almost abolished.

Plasma protein changes affecting the absolute and relative amounts of albumin/globulin fractions and fibrinogen vary with the cause of the anaemia, but they are not considered in any correction method.

That anaemia is not a simple entity therefore casts doubt on the whole system of correction.

Further doubt arises when one examines the construction of the most widely used correction chart, that of Wintrobe and Landsberg (1935). They diluted specimens of normal blood to produce various degrees of "anaemia." The E.S.R. of each "anaemic" sample was then estimated and the chart constructed from the results. Their argument was simply that if a blood sample of normal P.C.V. with an E.S.R. of 8 mm. an hour was diluted to a P.C.V. of 25% and the E.S.R. thereby increased to 42 mm. an hour, then an E.S.R. of 42 mm. an hour in an anaemic patient whose blood had a P.C.V. of 25% could be regarded as normal. It is apparent that the "anaemic" blood samples on which the chart was based consisted in fact of normal plasma and cells unaltered in any way except concentration. It is therefore difficult to see how this chart is applicable to anaemia.

Thus there seem to be reasonable grounds for doubting the validity of existing correction methods and also for believing that, even if correction were necessary, the complexity of the anaemias would make it impossible. The necessity for correction must now be examined.

Correction methods rest on the assumption that anaemia increases sedimentation. The grounds for this assumption appear to be flimsy. Fahraeus (1921) introduced the concept of anaemia increasing the E.S.R. at the same time that he published his method of measuring sedimentation, and it seems that the great value of the test and the excellence of his report have conferred immunity on his views on the effect of anaemia. He had been impressed by the frequent association of anaemia and increased sedimentation and, not perceiving that both had a common origin, concluded that the increase was due to the anaemia. The absence of sedimentation in polycythaemia seemed to confirm this view. When he found that he could increase the E.S.R. of normal blood by diluting the sample with its own plasma, he regarded the accelerating effect of anaemia as proved. Thus was pseudo-anaemia originated, and others, repeating the same error, have perpetuated the belief that anaemia increases sedimentation.

Evidence against any accelerating effect of anaemia will now be described. Unless otherwise stated, all E.S.R.s mentioned will have been estimated by the Westergren technique, using 0.4 ml. of 3.8% sodium citrate to 1.6 ml. of blood in a 200-mm. tube. The advantages of the Wintrobe technique are appreciated, but the Westergren method is still the most widely used. For similar reasons haemoglobin levels are given as % Haldane.

Range of Normal E.S.R.

There is considerable variation in the figures given for the normal E.S.R., but an upper limit of 10 mm. an hour agrees with most accepted figures. Fig. 1 shows the percentage distribution of E.S.R.s of 10 mm. per hour or less among 367 healthy women and 228 healthy men encountered during the present investigation, both groups having haemoglobin values above 86%.

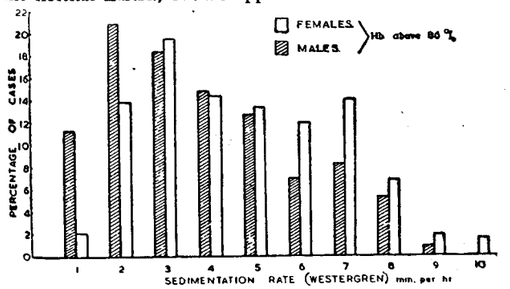

FIG. 1.—Percentage distribution of normal E.S.R.s in non-anaemic men and women.

The mean E.S.R. for the women is 4.72 mm. an hour (twice standard error = ± 0.22), with a modal E.S.R. of 3 mm. an hour; while for the men the mean E.S.R. is 3.82 mm. an hour (twice standard error = ±0.26) with a modal E.S.R. of 2 mm. an hour. Thus there is a highly significant difference.

Range of E.S.R. in Simple Hypochromic Anaemia

The percentage distribution of E.S.R.s between 1 and 10 mm. an hour found in 367 women with Hb values above 86% and in 160 women with Hb levels of 86% and less is shown in Fig 2

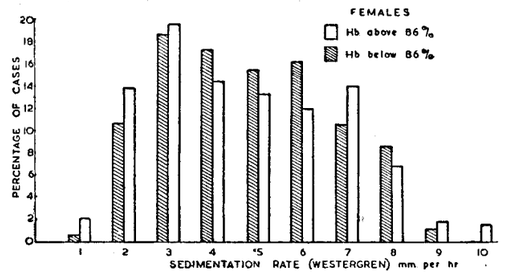

FIG. 2.—Percentage distribution of normal E.S.R.s in anaemic and non-anaemic women.

Of the 160 cases, the Hb levels were between 86% and 77% inclusive in 86, between 76% and 67% inclusive in 27, and 66% or less in 47. The anaemia was of a benign origin in every instance. The mean E.S.R. of the non-anaemic group is 4.72 mm. an hour (twice standard error = ±0.22) and of the anaemic group 4.79 mm. an hour (twice standard error = ±0.30). The modal E.S.R. is 3 mm. an hour in both groups.

The absence of any significant difference is considered to be evidence against anaemia having any accelerating effect on the E.S.R

A further conclusion suggested by these two distribution charts is that the higher E.S.R. of women is due to factors other than their lower average red cell count.

A similar comparison between anaemic and non-anaemic groups of males is not presented, simply because insufficient cases are available, anaemia of benign origin being so much less common in men.

Normal Sedimentation in Anaemia

Whatever theoretical grounds exist for thinking that anaemia has no accelerating effect on sedimentation, it is essential to determine whether normal E.S.R.s do in fact occur in significant anaemia. During this study 60 instances have been encountered and are detailed in Tables I and II. Table I shows the full blood counts of 30 patients with haemoglobin levels below 60% and E.S.R.s of 9 mm. an hour or less. Table II shows a similar group in which the indices were not estimated. All the cases were women except Nos. 58, 59, and 60. Without exception the anaemias were secondary to simple blood loss, usually menstrual and never neoplastic.

Clearly hypochromic anaemia does not inevitably increase sedimentation.

Slightly Increased Sedimentation in Anaemia

If these arguments are correct, slight increases in the E.S.R. should be significant even when there is marked anaemia. Table III is presented in support of this view.

TABLE III.—*Slightly Abnormal E.S.R.s in Anaemia*

Case No.	E.S.R.	Hb%	R.B.C. (millis.)	P.C.V. (%)	M.C.H.C. (%)	M.C.V. (μ^3)	Diagnosis

80	15	64	4·5	—	—	—	Advanced phthisis

In each case an abnormality usually associated with an increased E.S.R. was present, though the cause was sometimes obscure. It is emphasized that during this investigation no case of hypochromic anaemia with raised E.S.R. has been seen in which there was not good cause for that increase.

Grossly Increased Sedimentation in Anaemia

When there is gross acceleration of the E.S.R., anaemia with its reduced P.C.V. will delay the packing phase of sedimentation and so permit a greater fall over a period of time than if the P.C.V. were normal. The longer the packing phase is delayed the more accurate the reading with the Westergren and Wintrobe methods of estimating the fall in a specific time. But when the E.S.R. is assessed by the time required for a fall of specific length (Linzenmeier, 1920), or by the rate during the phase of constant sedimentation (Cutler, 1932), the effect of the packing phase is specifically eliminated. Thus there seems to be no indication for correction of high E.S.R.s in anaemia.

Antisedimenting Effect of Anaemia

Among the cases shown in Table III were many in which the E.S.R.s were less than might have been anticipated from the severity of the associated disorder, especially Cases 68 and 80, both of which had extensive bilateral phthisis, and Case 79, in which ulcerative colitis, though healing, was still causing four to six loose stools a day.

Further support for this antisedimenting effect is given by the behaviour of the E.S.R. in Cases 61, 63, 69, and 76 In these patients as the anaemia responded to treatment the E.S.R. increased, without clinical evidence of increased activity of the disorder responsible for the abnormal sedimentation (see Table IV).

TABLE IV.—*Behaviour of E.S.R. During Treatment of Anaemia*

Case No.	Before Treatment		During Treatment	
	E.S.R.	Hb%	E.S.R.	Hb%
61	15	23	19	44
63	12	32	25	78
69	11	48	35	70
76	14	56	18	68

Consideration of the effect of the sodium citrate content of the Westergren blood sample also suggests that the suspension stability of the red cells in anaemia is increased. Ham and Curtis (1938) demonstrated in experiments on haemophiliac blood that sodium citrate has a marked retarding effect on sedimentation. Now, the addition of one part of 3.8% sodium citrate to four parts of normal blood (P.C.V. = 45%, say) in the Westergren technique results in a concentration of 1.2% sodium citrate in the plasma. In the case of anaemic blood (P.C.V. = 25%, say) there is a final concentration of 0.95% in the plasma of the Westergren specimen. Thus when a normal E.S.R is present in anaemia (see Tables III and IV) it occurs in spite of a lower sodium citrate concentration than in normal specimens and therefore in spite of a smaller citrate retarding effect.

During this study observations have been made on the effect of diluting Westergren blood samples with their own citrated plasma. The retarding effect of sodium citrate was best seen in dilution experiments on polycythaemic blood (P.C.V. = 75%, say), in which the sodium citrate concentration in the Westergren specimen is 1.9% and the E.S.R. is normally zero. In one representative dilution experiment on polycythaemic blood, 75% dilution of the sample with the citrated plasma resulted in an increase of the E.S.R. to 3 mm. in one hour and 11 mm. in two hours: compared with 40 mm. in one hour and 95 mm. in two hours when the same dilution experiment was carried out with a Wintrobe sample. Wintrobe's dry oxalate mixture produces no alteration in sedimentation rate (Wintrobe and Landsberg, 1935; Ham and Curtis, 1938).

In every dilution experiment in this study on normal blood, dilution has resulted in marked acceleration of sedimentation, confirming the findings of Fahraeus (1921) and many others. However, in every experiment on anaemic blood similar dilution has resulted in less acceleration of the E.S.R. than in the normal specimens (comparing samples of identical E.S.R. before dilution). Now in these anaemic samples there is a smaller concentration of red cells and dilution is carried out with plasma containing a lower concentration of sodium citrate (see above). For these two reasons one would expect that dilution of anaemic samples would show a greater acceleration of sedimentation than dilution of non-anaemic samples. That there is in fact less acceleration is felt to be further evidence of the increased suspension stability of the red cells in anaemia.

Table V shows the increases in sedimentation with various dilutions of blood samples with haemoglobin levels of 136%, 100%, and 58%. These results are representative of repeated similar experiments.

TABLE V.—*Effect of Dilution on Westergren E.S.R.*

Hb%	E.S.R.	Dilution			
		Nil	25%	50%	75%
136	In one hour	0	0	2	3
100		4	9	15	20
58		4	7	10	15
136	In two hours	0	1	3	5
100		10	23	40	55
58		12	20	30	40

Discussion

With a wealth of authoritative opinion in support, correction of the E.S.R. is now generally believed to be necessary and is widely practised. When such corrections are made, minor abnormalities of the E.S.R. are converted to normal and any possible significance is lost. When the E.S.R. is raised in the presence of anaemia the elevation is usually disregarded because "the E.S.R. goes up in anaemia." When a patient is found to be anaemic the E.S.R. is often not estimated, since "it will be up anyway."

On the contrary, this study suggests that the E.S.R. in hypochromic anaemia of simple origin has the same limits of normal as in non-anaemic blood and that minor increases in the E.S.R. in anaemia are of at least the same significance as similar increases in normal blood. The E.S.R. has its limitations like any other clinical test, but anaemia is not one of them.

It is, however, a little unexpected to find normal sedimentation rates associated with marked anaemia, since dilution of normal blood undoubtedly increases the rate. It has been pointed out that the red cells are not entirely passive in the processes of sedimentation. It may be that the small abnormal cells of hypochromic anaemia resist rouleaux formation, or that the plasma of anaemia is deficient in rouleaux-forming properties.

Summary and Conclusion

Reasons are given for doubting the current view that the E.S.R. in anaemia requires correction.

The impossibility of correction and the fallacies of correction methods are discussed.

The distribution of E.S.R.s in 367 normal women was found to be identical with that in 160 women suffering from hypochromic anaemia of benign origin. The modal E.S.R. in both groups was 3 mm. an hour.

The modal E.S.R. in 273 normal men was found to be 2 mm. an hour. This finding is thought to indicate that the higher average E.S.R. of women is due to some factor other than their lower average red cell count.

In 60 patients with haemoglobin values between 21% and 60%, E.S.R.s ranged between 1 and 9 mm. an hour. It is therefore evident that anaemia does not increase the E.S.R.

In 20 patients with haemoglobin levels between 23% and 64%, the E.S.R.s were between 9 and 19 mm. an hour. Adequate reasons for the raised E.S.R.s were present in all, indicating the significance of small increases in sedimentation in anaemia and emphasizing the dangers of correction.

Evidence is outlined for believing that the suspension stability of red cells is increased in anaemia.

These findings refer to the Westergren E.S.R. Similar but insufficient observations suggest that they also apply to the Wintrobe E.S.R.

Hypochromic anaemia neither invalidates the Westergren E.S.R. nor necessitates correction.

It is with great pleasure that I record my gratitude to Dr. R. Bodley Scott for his advice and encouragement, to Dr. Geoffrey Bourne and others for access to their clinical material, to Dr. H. F. Brewer for facilities in the Department of Clinical Pathology, to Mr. M. P. Curwen, of the Statistics Department, and to Mr. Norman K. Harrison, of the Photographic Department, St. Bartholomew's Hospital.

Nearly 15,000 more hospital beds are now available for patients in England and Wales than before the National Health Service began in July, 1948. This brings the number of staffed beds to 470,000, out of a total of about 514,000. Hospital nursing and midwifery staff has increased by 24,000—16,000 more full-time and 8,000 more part-time. Increases have been recorded among all grades, including student nurses, midwives, and pupil midwives. There are now 7,000 more student nurses, the total having risen to 49,000. This is a new record. Total full-time hospital nursing and midwifery staff is now nearly 135,000, and part-time 25,000. The increase in staff has enabled many more hospitals not only to bring empty beds back into use but to introduce as well a 96-hour fortnight and to improve working conditions generally. These figures were issued by the Ministry of Health early in November, and cover the period July 5, 1948, to June 30, 1950—the first 24 months of the Service.

PSYCHOLOGICAL TREATMENT IN SKIN DISORDERS

WITH SPECIAL REFERENCE TO ABREACTIVE TECHNIQUES

BY

H. J. SHORVON, M.B., B.S., D.P.M., D.A.
A. J. ROOK, M.A., M.D., M.R.C.P.

AND

D. S. WILKINSON, M.D., M.R.C.P.

(From the Departments of Psychological Medicine and of Diseases of the Skin, St. Thomas's Hospital)

During the last 30 years there has been an increasing realization of the place of psychological factors in the production or precipitation of certain skin disorders. Pioneer contributions to the subject were made in England by O'Donovan, and in America by Stokes. MacKenna (1944) attempted to correlate personality types with certain skin reactions, and Klaber and Wittkower (1939) and Wittkower (1946) have studied series of patients with specific skin disorders in an endeavour to assess the importance of psychological factors in their pathogenesis. Gillespie (1938) and Sulzberger and Zaidens (1948) have dealt with the probable psychological mechanisms involved. Useful general reviews of the growing literature on this subject have been published by Stokes (1932), Klauder (1936), and Wittkower (1948).

We are impressed by the relative lack of emphasis on treatment and by the paucity of detail on methods employed and the results achieved.

The tendency has so far been for psychiatrists to treat cases referred from dermatologists by systematic long-term individual or group psychotherapy, but because of its time-consuming nature this method is necessarily limited to few patients. Treatment by "drug abreaction" offers an alternative method, having the advantage of taking up much less time and so allowing for the treatment of many more patients.

It is universally recognized that the free discussion of significant events, or "getting things off one's chest," may result in some relief of pent-up tension. The therapeutic value of a mere recital of unpleasant experiences is slight; but, as Freud and others observed, if the revived traumatic incidents are relived with emotional intensity and vividness (or, in other words, if the patient "abreacts") a striking release and relief of tension may occur. The term "abreaction" was originally applied to the recalling and reliving of repressed events, but has for some time been given a wider interpretation to include both conscious and unconscious material. Its essential feature is the excitement attained during the discharge of emotionally laden ideas and incidents, and our technique is to stimulate further and to facilitate the release of this excitement by the use of drugs. The more intense the emotion aroused and its release, the more successful the abreaction.

Irrespective of its cause, tension is present in many skin disorders. Since in many patients its relief results in the amelioration or disappearance of the skin condition, we considered the use of abreactive techniques in the treatment of 50 dermatological patients. The results so far obtained seem to us of sufficient interest to warrant this communication.

The results of treatment in the 50 cases may be classified as follows: in 21 the skin cleared (but 3 have relapsed within one year); in 22 the skin condition improved; and in 7 there was no change.

Of the seven who showed no change, one was psychotic, one a woman of 65, two discontinued treatment, and three others are still under treatment.

It will be realized that this does not represent a final or complete analysis. The patients whom we treated by abreaction were suffering from a variety of skin conditions. Moreover, this series was experimental in the sense that different intensities and lengths of treatment were used. It must be stressed also that the patients had been selected in the first instance by dermatologists as being suitable for this form of therapy and that the promising results must in part be attributed to this. For that reason we shall emphasize the criteria to which we have strictly adhered in our more recent cases.

Our present results give an approximate impression only. After a longer follow-up period we hope to publish a detailed analysis, in which due attention can be given to such obviously important factors as the type of skin condition, its chronicity, and the nature and duration of previous treatment.

Selection of Cases

Abreactive techniques have been applied by us to a wide range of skin disorders, and from our experience and findings we have attempted to determine some practical criteria for the selection of suitable patients by the dermatologist. In assessing this, one point requires emphasis. Not all patients whose skin eruptions are psychologically determined require this particular method of psychological treatment. Many will respond to superficial psychotherapy, or similar methods within the power of the general practitioner or dermatologist, whereas some may need other specialized forms of psychological therapy.

Our criteria for the selection of patients are: (1) The cutaneous reaction is one in which either a psychological cause is generally accepted or one in which it seems likely, from a combination of positive psychological and negative organic findings. (2) The disorder is of sudden onset or apparently related to a specific, emotionally traumatic incident. (3) The patient should preferably be under the age of 40. (4) The patient must be psychologically accessible, psychotics and defectives being obviously unsuitable.

In occasional patients the skin disorder, although not obviously determined by psychological factors, may, because of associated psychological disturbances, be expected to benefit from non-specific abreactive treatments.

Technique

We have used intravenous barbiturates, such as sodium amytal or thiopentone, ether, intravenous methylamphetamine hydrochloride ("methedrine"), and a carbon dioxide mixture, alone or in various combinations, to facilitate emotional release. An intravenous barbiturate alone has little part to play in the abreaction of skin disorders, though Sargant and Slater (1940), when treating battle casualties after Dunkirk, recognized its value in certain cases with tension due to recent trauma. They found that the induced emotional outbursts were often effective in breaking up the recently acquired neurotic patterns of behaviour. It is much more difficult to bring about an excitatory abreaction under intravenous barbiturates in chronic cases, and most

dermatological patients requiring psychological treatment fall into this group. In an ancillary capacity barbiturates can, however, occasionally be used to relax an apprehensive patient before an ether or carbon dioxide abreaction is attempted, or to reinforce the effect of methylamphetamine hydrochloride. They also have some value in special instances, such as the uncovering of an amnesia or the preliminary breaking-down of a reticent patient's inhibitions.

Summary of Cases

Case No.	Age	Sex	Diagnosis	Length of History	Outstanding Personality Traits or Psychiatric State	Result
1	34	M	Psoriasis	2 yrs.	Obsessional	+
2	23	M	Pruritus ani	4 ,,	Mildly obsessional	Cleared*
3	34	M	Urticaria	18 ,,	Anxious	+
4	24	F	Seborrhoeic eczema	2 ,,	Anxious. Paranoid trends	Cleared
5	22	M	Atopic dermatitis	4 ,, (present attack)	Anxious	
6	42	M	Neurodermatitis	3 yrs.	Obsessional	No change (discontinued treatment)

49	32	F	Prurigo	2 ,,	Anxious	+
50	35	M	Generalized prurigo	7 ,,	—	Cleared

* "Cleared" = When the skin condition completely disappears and has so far not recurred. + = When improvement occurs in the skin condition or in associated pruritus (which occurred in some cases of psoriasis).

An intense excitatory abreaction with the release of tension, anxiety, and aggression can often be induced with ether even in long-standing cases. Our technique has been fully described in previous papers by Sargant and Shorvon (1945) and Shorvon and Sargant (1947). Briefly, incidents of emotional significance are selected from the patient's past history and used to start off the abreaction. He is excited under light ether (far short of anaesthesia) with an open mask, and then encouraged to take himself back to the situations in which these events have occurred. Should he succeed in doing so, his voice becomes louder and he begins to abreact, behaving as though the events were happening at that moment. He is deliberately encouraged to shout, cry, and struggle, and the physician is on the alert to play on incidents of high emotional content which may become evident for the first time only during the abreaction. It is not always necessary to abreact specific incidents accurately, and in practice one may deliberately distort events if by so doing an even greater excitement or anger results. The patient experiences a marked easing of tension if the abreaction has been a success. Many patients, however, fail to abreact under ether, particularly those with marked obsessional trends in their make-up. They tend to answer in the past tense, in an impersonal manner, and are acutely aware of their surroundings.

For such patients, repeated intravenous injections of methylamphetamine hydrochloride, 25 to 30 mg., can be very useful (Simon and Taube, 1946; Sargant, 1948). A pleasantly relaxed feeling with mental calm, euphoria, and confidence soon sets in. "It increases the clarity of things" and "the brain races away as in insomnia." If encouraged, the patient exhibits a pressure of talk and acceleration of ideas with a lack of reserve. The loquaciousness may continue for many hours, particularly if the effect is reinforced by sodium amytal (3 to 6 gr.—0.2 to 0.4 g.).

As one patient said, "It gives me the desire to get rid of the junk in my mind," and much valuable and previously inaccessible material may pour out in a short time. This facilitation may be punctuated by emotional outbursts, especially if an ether mask is applied when traumatic events are discussed. The total effect is that of a prolonged moderate abreaction or, in other words, a prolonged state of excitation in full consciousness. We have encountered no untoward side-reactions, but the pulse rate is often accelerated, the blood pressure is raised, and there is some thirst and dryness of mouth.

Since 1947 experiments have been made by Sargant, and later by other members of the psychiatric department of St. Thomas's Hospital, in the application of Meduna's (1948) carbon dioxide inhalation technique to facilitate abreaction. This technique, with modifications, is to be reported in a paper by Marshall, Sargant, and Shorvon. The inhalation mixture consists of 30% carbon dioxide and 70% oxygen, and is a rapid and safe method that can easily be given in an out-patient department. The treatment is usually carried out two or three times a week, and, as a rule, at least 20 are required. We have found it useful in pruritus ani, lichenified neurodermatitis, and Besnier's prurigo, but the results have been inferior compared with cases treated by abreaction under ether or methylamphetamine hydrochloride. It can, however, be of distinct value if used to attain the end-point of an ether abreaction in which the patient failed to reach a climax of excitement. The patient is thereby relaxed and

may experience much relief. If successful there is a gradual lessening of tension with an easing of skin irritation.

We have employed abreactive techniques in the treatment of more than 50 dermatological patients (see Table) and the following cases illustrate some of the points we wish to bring out.

Case 9

A man aged 33 gave a five-years history of extensive exudative neurodermatitis of the arms, legs, and back. It began soon after his landing in Burma in 1944, first on the left elbow and then on the back of his legs. The itching was intense. Lotions, ointments, sulphonamides, and *x*-ray treatments were tried, with little effect. Since demobilization he felt "full of frustrations" and was unable to keep up with his work. He is an obsessional individual with phobias and "thousands of compulsions," and declares he is never relaxed. He joined the Regular Army in 1937 and was a corporal at the outbreak of war, but in a few years rose to the rank of major in a glider regiment. He knew of no immediate precipitating cause of his eruption, but stated that he went through a worrying time at O.C.T.U. in 1942 and had only four days with his wife after their marriage in 1943 before they were separated by their respective duties in the Services. He was treated by ether abreactions, at first twice weekly and then once a week.

In the first treatment he did not abreact, but gave further details of his history. In the second treatment there was some abreaction over a glider crash in which he was involved four months before going to Burma. However, he abreacted violently on the subject of a woman living in the flat below who irritated him beyond measure because of her objection to the slightest noise. He had to remove his shoes at night and see to it that his child was quiet. After this abreaction he said he felt happier than he had been for months, but he still had some skin irritation. In the third abreaction there was a marked release of aggression in regard to this woman, and also concerning his employer, whom he blamed for constantly increasing his work. In the ensuing week his wife said he was a different man to live with, and no longer "flew off the handle at the least thing." The irritation was negligible and the skin condition was much improved. The fourth abreaction was on similar lines and he felt "on top of the world," but suffered a slight setback after appearing before a medical board.

In the fifth abreaction he displayed little emotion when describing in detail the death of his friend in the glider crash, nor when he related the shock he experienced on a further occasion. He had watched the departure of three friends for Burma in a plane in which he was prevented from travelling at the last moment and soon after learned of their death when the plane hit a mountain. Again, however, there was a violent outburst over his neighbour. The same happened in the sixth abreaction, and he now "ceased to kick and snarl or lose his temper when things went wrong." The greatest abreaction took place at the seventh treatment. On the way to Burma the patient landed at Cairo and expected to meet his wife, who was serving in Egypt in the W.A.A.F. about a hundred miles away. The wing-commander refused him permission and he was sent on to Burma, yet other men who had been waiting for a plane for some weeks could easily have changed with him. The eighth abreaction was mainly concerned with the wing-commander and his neighbour, but he then began to talk of his wife's commanding officer in Egypt, who had apparently made several attempts to get into her tent at night. "I wish I could get at him. She wrote and told me about it before I left for Burma." The ninth and final abreaction was similar. He claimed that he "felt a new man," that little annoyances passed him by, and that he had infinitely more patience. After six weeks the skin lesions had regressed to such a degree that for the first time for a year he was able to walk with comfort. He put on 21 lb. (9.5 kg.) in weight in the next six months; his skin cleared and has remained so for over a year.

This case is of interest in that the patient, although obsessional, abreacted under ether. This is unusual with obsessionals. There was a gradual unfolding of incidents causing tension and aggression prior to the onset of the skin eruption, but the abreactions were non-specific in the sense that much use was made of situations occurring long after the skin trouble began. The treatment consisted of a general release of tension and aggression.

Case 24

A woman aged 29 complained of generalized pruritus together with pruritus vulvae et ani. This began in 1937 and was persistent till 1943. It began again in 1948. The irritation started at the age of 17 when a boy of whom she was very fond, and with whom she had been going out for 18 months, suddenly left her for another girl. "I did not get over it." She had received many forms of treatment without relief. She married in 1941, but the irritation continued throughout her pregnancy in the following year. The symptoms cleared when her husband went abroad in 1943, but returned when she began to work in her husband's office in 1948. She had had all the accepted methods of treatment, including *x*-ray therapy, and also sedation with barbiturates and antihistaminics.

From her own account she was a nervous, worrying, bad-tempered type and was somewhat hysterical and mildly obsessional. For the unhappiness of her marriage she blamed her inability to forget her first boy friend. She experienced no sexual satisfaction. She was hostile to her child and felt that her husband did not trust her, and that for this further reason he had placed her in his office, where he, moreover, paid marked attention to the other girls.

In the first ether abreaction she cried a good deal over her love for her former boy friend, Wally, who liked flirting but "did not insist on intercourse." He failed in his marriage and attempted, during her husband's absence overseas, to get her to live with him. They indulged in kissing and masturbation, and she was symptom-free during this period. Her pruritus was worse after the abreaction. A second ether abreaction in the same week was much the same, and produced no improvement. One week later she was given an intravenous injection of 30 mg. methylamphetamine hydrochloride. She now stated that since the recurrence of pruritus vulvae in 1948 she had not had intercourse with her husband. She admitted that during his absence abroad she made every effort to persuade Wally to leave his wife and come to her. Her husband, on embarkation leave, intercepted a letter from Wally and "had a colossal row with her and ceased to trust her." After this abreaction there was a marked easing of pruritus for some days.

After a further week she was given another intravenous injection, and she discussed the many neurotic symptoms of her early years and her maladjustments at home. She showed a marked hostility to her mother, who was exasperating and fault-finding. She said that her pruritus recurred in 1948, when she found her husband was happy in his office but not at home. After this abreaction she felt much calmer and decided to leave her husband and child "while she straightened things out in her mind."

The third methylamphetamine hydrochloride abreaction was largely concerned with her attitude to her husband and a general discussion of her life-situation. From this time her tension eased and she returned to her husband and is now leading a normal life with little or no pruritus.

This case illustrates the common history of frigidity met with in many patients with pruritus vulvae and the indication that the pruritus is a defence against sexual intercourse. We have often noticed that pruritus ani in women may precede or be associated with pruritus vulvae, as in this case. It is significant that her symptoms cleared as soon as her husband went overseas. It also illustrated the successful use of intravenous methylamphetamine hydrochloride where ether abreactions failed. Inadequate emotional release sometimes results in an increase of tension, as happened with this patient under ether, but a successful release was accomplished by the use of intravenous methylamphetamine hydrochloride.

Case 8

A man aged 30 complained of persistent pruritus ani for nine years, beginning almost immediately after the evacuation of Dunkirk. Various local applications had been tried with very little or no success. He stated that after much stress he got away from Dunkirk in an overcrowded boat which was bombed and machine-gunned, and then capsized. He managed to swim back to the beach and was eventually evacuated to England, where he experienced disturbing battle dreams and jumped at the least noise. The air raids and flying bombs greatly upset him, but he completed his Army service.

On examination his perianal skin was macerated and erythematous. He showed an obsessional personality and was tense, anxious, irritable, and sweating.

Treatment was by weekly abreactions under ether. The first was vivid and emotionally violent. He described his journey towards Dunkirk in an abandoned lorry. This was stopped by military police, who pointed out that he was sitting on boxes filled with high explosives. "I leapt off and felt I had sat on something hot." During the dive-bombing on the beaches his friend sustained multiple shrapnel wounds in the buttocks and he applied the dressings. The abreaction became most intense when he re-enacted his swim back to the beach after his boat capsized. This was reproduced so faithfully that he made repetitive swimming movements on the couch, puffed and grunted, became cyanosed, and developed a fine froth at the mouth. The irritation practically cleared after this treatment, but his hands remained moist and clammy.

The second abreaction was more detailed. Several men were killed in the water and he reached the shore after much difficulty. He also saw a large ship bombed and set on fire at night and watched several trapped men, silhouetted against the glare, leap off the burning vessel. After this abreaction he "felt fine. No bother. The best since 1940."

Dive-bombing and scenes at Dunkirk were the main topics of the third abreaction, and the patient attributed his pruritus to immersion and no change of clothing. He had some irritation after this abreaction, which cleared with the fifth and sixth abreactions. The latter were largely concerned with his difficulties in swimming in the oil-covered sea. The patient was still free of pruritus a year later.

It is always open to doubt how much a particular localization may be due to predetermined factors and how much to the particular psychological associations. We do not wish to stress, therefore, the localizing associations, such as dressing his friend's buttock wounds, which occur in this case. Removal of symptoms, however, followed abreaction of these incidents, and it is interesting that the ether abreactions were successful in spite of the fact that the traumata occurred several years ago.

Case 5

A man aged 22 stated that he developed an intensely irritating rash three years ago, when his arms were scalded by boiling oil from the back-flash of a boiler. This happened in Australia some months after he joined the Navy, and he was eventually invalided out. Recently he became very anxious during his wife's pregnancy, as he had strong views on the "agony of childbirth." A generalized spread occurred during her confinement, and a further exacerbation followed when he thought he had a duodenal ulcer. Clinically he presented an unusually extensive picture of Besnier's prurigo. At the age of 10 he had been treated by systematic psychotherapy for Besnier's prurigo of the arms, which was said to have followed the loss of the tip of his finger; the skin cleared after six months.

An ether abreaction was attempted, and he gave a complicated and detailed description of the "accident." Suddenly he became very emotional and declared the whole story to be a lie. He described his increasing dissatisfaction with the discipline and restrictions of the Service. A mate had failed "to work his ticket" and bet him that he would not succeed. He then began to scratch the flexures of his arms to bring out his former rash. His determination to do so was increased when he found he had been drafted for Hong Kong. Soon afterwards the back-flash occurred, but the oil did not touch him. He made full use of this incident and malingered. After his discharge from the Navy he felt very guilty and has made repeated attempts to rejoin and "serve his time."

He experienced a marked relief in relating the true story for the first time, and the skin condition rapidly cleared.

From a dermatological point of view, this patient was suffering from an extensive atopic eczema. His experiences with this complaint in earlier life enabled him to employ it as a mode of reaction for future difficulties. It is of interest that, having produced it artificially, the intense guilt over his own action and the superadded anxiety were sufficient to exacerbate the skin condition. During long periods in civilian and naval hospitals his response to treatment had been entirely unsatisfactory. Confession under ether and removal of guilt resulted in immediate improvement, which has so far been maintained for one year.

Case 25

A woman aged 33 gave a history of "eczema" of eight years' duration, beginning on her honeymoon. A sore patch behind an ear spread to the eyelids, back of the neck, and both ears. After the death of her mother in 1942 it spread all over her body, and there were further exacerbations when her only brother was presumed to have died in Burma and when a cousin died suddenly in 1949 from heart failure in her home. The itching was intense. There was only temporary or no relief from an abundance of treatments, such as superficial *x*-ray therapy, local applications, injections of calcium, dieting, and visits to faith-healers and homoeopaths.

She had a very unhappy upbringing. Her father was a gambler, and she had to wait outside his workplace in an attempt to save some money for the family before he lost it. She was very fond of her mother. At school she was very shy and kept to herself. Her personality is obsessional with paranoid trends. She expressed a hatred of any form of duplicity or dishonesty, and the least slight put her into an irritable, sulky state for days. She stated that bad attacks of irritation coincided with emotional upsets or occurred when she was overtired and worried. She also said she was in a persistent state of frustration and suppressed anger because her rich, vulgar, and domineering mother-in-law had strongly objected to her marriage and had shown her much ill-will before it and since. She felt guilty over her mother's death, having taken her home against the advice of a hospital. She also felt she had caused the death of her mother by giving her a hot drink instead of ice to suck when she had a haemorrhage.

Several attempts at abreaction under ether produced little or no emotional release, but there was a better response when the treatments were completed with carbon dioxide inhalations. Many of the details of her history were elaborated and she brought out further causes of friction. She gradually began to assert herself with her mother-in-law and showed an increasing resentment towards her husband. She stated that the treatment gave her some relief of irritation and "took a load off her mind." Her skin condition improved in so far as the lichenification of her arms and neck cleared.

As the condition then remained static, intravenous methylamphetamine hydrochloride therapy was tried. With the first injection she became very talkative for the first time and remained so for most of the day. She then disclosed that a fortnight before the marriage her fiancé presented a false medical certificate to avoid military service. As most of her family were in the Services, this was a tremendous shock to her. "I would not have married him had I known it earlier." The rash began immediately after the marriage, and the honeymoon was a very miserable one. She was too ashamed and furious to go out, and hid in their room in the hotel. As soon as the honeymoon ended she made her husband go to Scotland Yard and confess. He then joined the Army, but she continued to hold his intended evasion of service against him. With the second injection she poured out many further accusations against her husband and his mother, and afterwards had a "showdown"

with him. From this time their relationship greatly improved and her skin condition cleared altogether. She has remained well for a year.

This case is of interest in that repeated ether and carbon dioxide treatments resulted in some relief of tension with improvement of a severe lichenified neurodermatitis, but it required intravenous methylamphetamine hydrochloride injections to bring out the crucial precipitating factors, the abreaction of which resulted in complete relief of the skin condition.

Discussion

It will be seen from the foregoing cases that a variety of skin disorders may be associated with specific or non-specific psychological factors, and may be relieved by treatment of these factors. It is pertinent to stress here that because some such cases may be cured or alleviated by this treatment it does not necessarily follow that they are caused by such factors (though in the cases chosen these probably were of primary aetiological importance).

In certain other cases the treatment we have described may greatly influence the patient's attitude towards his disease, enabling him to reduce to reasonable proportions symptoms which had come to assume an overwhelming and unreasonable significance for him. A patient with psoriasis, for example, who considered that his skin lesions were ruining his life, was helped to adjust himself to the disease, although this was not significantly modified by such treatment. In other cases, such improvement gives the dermatologist a better chance of succeeding in the treatment of the disease along conventional lines. This is especially so in many cases of eczema, in which psychological factors may perpetuate an eruption of quite other causation. Perhaps the most important cases of this type are those in which the eruption was initially determined by occupational factors.

We believe that, even in the presence of skin reactions of a type in which the possible psychological origin is accepted, a careful exclusion of organic causes is essential if disaster is to be avoided. This exclusion should be made at an early stage and not after the failure of unsuitable treatment over a period of months or years. Pruritus may, for example, be a symptom of a pre-reticulosis, and pruritus vulvae may lead to the discovery of diabetes. It is perhaps less often realized that, conversely, failure to appreciate positive psychological factors at an equally early stage may condemn a patient to months of ineffective treatment.

Although the abreaction was the principal therapeutic procedure employed in the cases described, psychotherapy was of course used to a limited extent. It was superficial in the sense that, though possible precipitating events were discussed and the patient's life-situation and reactions were reviewed, no prolonged analysis was attempted. Attempts were made to persuade the patient to see the part played by mental symptoms and traumatic episodes in the genesis of skin disorder. Environmental, domestic, and occupational difficulties were tackled where necessary, but it is unfortunately true that such difficulties sometimes proved insuperable barriers to effective treatment.

Though the cases we treated required, in our view, the use of abreaction therapy, we believe that most patients with psychologically determined disorders can be adequately treated by simple psychotherapy administered by the practitioner or dermatologist who is aware of the indications. Sneddon (1949) has discussed this aspect and has shown that much can be achieved in suitable cases. Even a brief psychiatric history and personality assessment should enable the dermatologist or practitioner to discover these factors and to realize their significance.

The importance of the skin itself and the constitutional limitations of the atopic, ichthyotic, and seborrhoeic types must constantly be borne in mind. Both these and the morale of the patient, as well as the social problems we have mentioned, naturally affect the prognosis. Although we do not claim that this method is the only one that may be employed or that all cases are cured or benefited by it, we have found it of definite value in a considerable proportion of all cases considered to require treatment by a psychiatrist. The particular advantages, from a practical point of view, are that treatment can be carried out in the out-patient department and that a limited number of consultations are needed compared with systematic psychotherapy and analytical methods. We have been impressed, from the dermatologist's point of view, by the rapidity with which results are obtained and, within the limits of our follow-up, by the infrequency of recurrences. The period of time needed to produce marked improvement is generally a matter of weeks or months, depending on the frequency of treatment and type of skin disorder. On the whole, patients with neurodermatitis respond after a few treatments, while those with pruritus ani or pruritus vulvae need correspondingly more in view of the greater complexity of the factors involved.

Our experience of patients treated by convulsion therapy and prolonged sedation has been far less encouraging. Some of the patients we have referred to had already been treated with prolonged and deep sedation with little or no effect. We have already pointed out that obsessional patients often fail to abreact. Similarly, severely depressed patients may require convulsive shock therapy and very agitated patients deep narcosis as an urgent matter.

We are not aware that the abreactive technique has previously been employed in the treatment of skin disease, and the eminently practical nature of the treatment and the encouraging results obtained lead us to regard it as a useful addition to the dermatologist's therapeutic armoury. It is probable that the other methods of psychological treatment will be found to have specific indications in dermatology, and criteria for these should be established. It is obvious that no single method will be applicable to all cases

Summary

The literature on the psychological aspects of skin conditions contains few references to treatment.

The application of the abreactive technique in treatment of certain skin disorders is described, and an attempt has been made to define the criteria for its employment.

Five illustrative cases are reported.

The value and limitations of psychological methods of treatment are discussed, and it is suggested that the abreactive technique offers a practical and useful method of treatment.

We would like to thank Dr. William Sargant and Dr G B. Dowling for their interest and encouragement, and our colleagues who have referred many of the cases to us.

HEREDITY AND LEG ULCERS

BY

S. T. ANNING, M.A., M.D., M.R.C.P.

Assistant Physician, Dermatological Department, Leeds General Infirmary

Accurate knowledge of the aetiology of any disease is necessary for its rational treatment. This applies equally to preventive treatment, and it was with this in mind that the present investigation was carried out to learn more about heredity in relation to gravitational ulcers of the leg.

Its place in the aetiology of these ulcers has never been soundly established, though many authors have expressed the opinion that it may be important. Weber, Rast, and Lutterotti (1930) described chronic ulceration of the legs following pneumonia in a man aged 25 with thrombo-angiitis obliterans whose father had suffered from similar ulcers, and Carleton (1948) reported a striking family history in two sisters with leg ulcers. Weber (1948) wrote that there certainly is a constitutional tendency to ulcus cruris in some families. Heredity undoubtedly plays a part in ulceration of the legs associated with purpura haemorrhagica, sickle-cell anaemia, congenital haemolytic icterus, splenic anaemia, Gaucher's disease, and Cooley's anaemia (Weber and Dorner, 1910; Weber, 1930; Taylor, 1939; Cummer and LaRocco, 1940; Witts, 1942; Woofter, Dick, and Bierring, 1945; Estes, Farber, and Stickney, 1948), but these conditions account for few of the leg ulcers seen here.

There is more evidence of the importance of heredity in the aetiology of varicose veins. Virchow (1855–61) recognized this, and Gay (1868) reported two affected families. Curtius (1928) published several pedigrees and Čičóvački and Stöger (1939) recorded one which showed that the condition is inherited as a dominant character. Ottley (1934) examined a series of 50 patients, and found that the inheritance was of a simple dominant type in 26 families; in another 10 either a recessive character was concerned or the usual dominant type was masked in predisposed individuals.

In patients with varicose veins a positive family history was found in 50–75% by Magnus (1921), 55% by Nicholson (1927), 65% by de Takats and Quint (1930), 56% by Jensen (1932), over 50% by Payne (1936), 43% by Larson and Smith (1943), only 6–10% by McPheeters and Anderson (1946), and 80% by Pratt (1950). A positive family history of varicosis might therefore be expected in many patients with leg ulcers resulting from varicose veins, and this has been noted by Bauer (1948).

Present Investigation

A series of 525 patients examined personally has been investigated to try to determine more precisely the place of heredity in gravitational ulceration.

Here the term "positive family history" indicates that ulcers or varicose veins are known to have been present in one or more parent, sibling, child, uncle, or aunt. Varicose veins rarely appear before the age of 20 (McPheeters and Anderson, 1946; Roberts, 1949), and in the present series ulceration before that age developed in only 17 patients (3.2%). Because of this and the difficulty in obtaining information about grandparents, pedigrees dealing with many generations are rarely obtained. Eighty pedigrees have been determined, but in many of them accurate information is limited to parents, siblings, and children.

It is not easy to discover the complete family history of patients with leg ulcers unless several members of the family can be examined, and this has seldom been possible here. Although the presence of ulcers and varicose veins in parents, siblings, and children may be known by the patient, accurate pedigrees which include other relations are difficult to obtain, as these conditions are not commonly disclosed.

Of the 525 patients (360 women and 165 men) examined, 29 were unable to give a family history, and of the remaining 496 a family history of ulcers or varicose veins was present in 256 (51.6%). As, however, the variety of causes of gravitational ulcer makes such figures of little value, an attempt has been made to break up the series into different aetiological groups. The accompanying Table shows the number of patients with a positive family history in each of these groups.

Details of Family History

Cause of Ulcer	No. of Patients	Family History Known	Negative Family History	Positive Family History				
				Without Details	History of V.V.	History of Ulcers Only	Total	%
Thrombotic:								
Post-partum thrombosis	111	103	48	15	30	10	55	53·4
Ante-partum thrombosis	28	28	11	9	5	3	17	60·7
Disease of leg:								
Injury without fracture	101	97	48	15	26	8	49	50·5
Injury with fracture	22	22	17	1	4	0	5	22·7
Infection of leg	20	19	15	2	2	0	4	22·2
Treatment of varicose veins	28	28	11	5	10	2	17	60·7
Operation on leg	9	8	3	2	3	0	5	62·5
Burns of leg	5	4	4	0	0	0	0	
Thrombosis — unknown cause	39	35	13	7	13	2	22	62·8
Recumbency:								
Medical illness	34	32	20	2	5	5	12	37·5
Operation—not on leg	19	18	9	2	7	0	9	50·0
Other causes	4	4	1	1	2	0	3	
Miscellaneous causes	5	5	1	0	3	1	4	
"Silent" thrombosis	9	9	6	1	1	1	3	33·3
Non-thrombotic:								
Varicose ulcers	32	29	3	2	22	2	26	89·9
Arteriosclerotic ulcers	6	6	2	0	0	4	4	
Arthritic ulcers	5	5	2	0	3	0	3	
Doubtful cause (with varicose veins)	44	40	24	4	8	4	16	40·0
Doubtful cause (without varicose veins)	4	4	2	1	1	0	2	
Total	525	496	240				256	51·6

In considering the incidence of positive family histories in the various groups in the table it must be remembered that varicose veins are common, and leg ulcers not uncommon, in the general population of this country. Roberts (1949) found, in the examination of 10,000 candidates applying for Post Office appointments, a mean incidence of 1.57% of men and 1.68% of women with varicose veins. All age groups were included, though most males were under 45 and most females under 25. In a social survey conducted in 1947 (General Register Office, 1950—personal communication) of 30,843 men and 38,503 women of all ages over 16 years, varicose veins were found in 1.03% of men and 3.13% of women. The highest incidence (4.18%) occurred in the 11,440 women aged 45–64 years. Less is known about the incidence of leg ulcers, but it has been stated (Annotation, 1950) that about 5 per 1,000 of the population are affected.

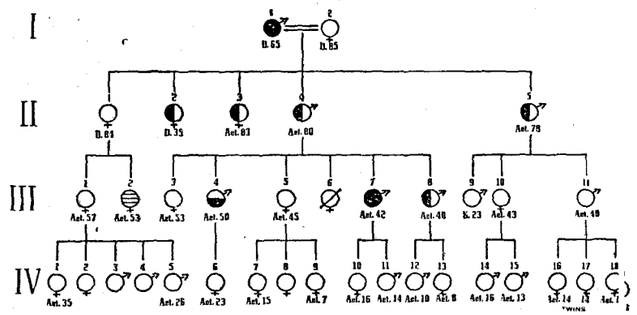
It has not been found possible, from these figures, to estimate the incidence of positive family histories to be

expected in the general population, and the determination of this incidence by questioning a random group has not been carried out.

The Thrombotic Group

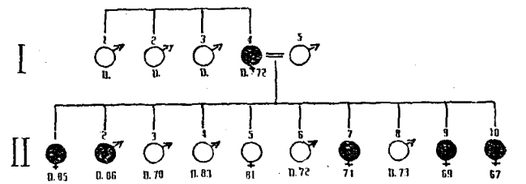
However, ulceration from thrombosis after fracture, burning, infection, or operation affecting the leg would seem to result from causes less susceptible to hereditary influences than some, and more likely to result from chance. (The group with injury of the leg without fracture has not been included, as it is heterogenous, the degree and mode of injury being very variable.) Of the 56 patients concerned, 25% gave a positive family history. As hereditary factors may have played some part in causing the thrombosis which occurred in these patients (and this seems to have been so in the operation group), it cannot be argued that this incidence of positive family histories represents that to be expected in the general population, yet it provides a useful comparison with the incidence found in other groups of patients with ulcers.

In the thrombotic group, 53.4% of patients with ulcers caused by post-partum thrombosis gave a positive family history. This incidence is significantly higher than that expected (25%), and it is worthy of note that the mothers of 10 of these patients and the sisters of 2 of the 10 had also suffered from post-partum thrombosis. Special precautions to prevent thrombosis seem to be indicated in parturient women with a family history of varicose veins, leg ulcer, or thrombosis, especially if the confinement be difficult (Anning, 1949).



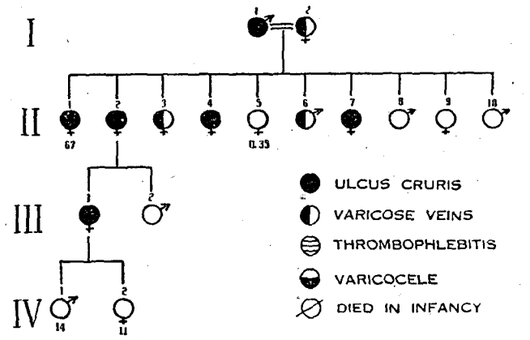
Among the other patients in the thrombotic group, those with ante-partum thrombosis, and thrombosis due to treatment (especially injection) of varicose veins, to operation on the leg, and to unknown causes, had a significantly higher incidence of positive family histories than that expected, and this is possibly also true of patients with thrombosis due to injury without fracture. In thrombosis from recumbency and in "silent" thrombosis, heredity seems to play a doubtful part.

The Non-thrombotic Group



In the non-thrombotic group heredity is clearly of major importance in varicose ulcers—that is, ulcers due to varicose veins alone—a positive family history being present in 89.9%. A family affected in this way is shown in pedigree 1. Here gross varicose veins were present, but ulceration occurred only in two members, probably because most of the affected members wore elastic supporting bandages or stockings. Sitting back on her heels, kneeling, caused thrombosis in one member (III, 2).

In varicose ulcers it is possible that not only congenital weakness of the wall of the veins but congenital absence of valves may also play a part (Eger and Casper, 1943; Curtis and Helms, 1947). The importance of defective valves in the deep veins in this type of ulcer has been stressed by Warwick (1931), Luke (1941), and Bauer (1948).



The number of patients with ulcers thought to be due primarily to arteriosclerosis is small, but of these a large proportion gave a family history of ulcers of the legs (without varicose veins), and such a family is shown in pedigree 2. Only the three youngest women in the second generation were examined. They each had cold extremities, cyanosis of the toes, tortuous radial arteries, impalpable dorsalis pedis arteries, and radiological evidence of calcification of arteries in the leg. There was hypertension.

PEDIGREE 1.—Ulcers due to varicose veins alone. (Key on Pedigree 3.)

PEDIGREE 2.—Ulcers of the legs (without varicose veins) due primarily to arteriosclerosis.

PEDIGREE 3.—Varicose veins, thrombosis from various causes, and ulcers.

It will be noted that, apart from the arteriosclerotic group, the proportion of patients with a family history of ulcers only is small compared with that of patients with a family history of varicose veins. A tendency to thrombosis occurs in some families, occasionally without primary varicose veins, but more commonly in association with them. (Here primary varicose veins must be distinguished from those appearing secondarily to the thrombosis.) Primary varicose veins seem to be the common factor in the family history, when positive, of most patients with leg ulcers of the post-thrombotic and the varicose types. A family with varicose veins, thrombosis from various causes, and ulcers is shown in pedigree 3. Here, in the first generation, the husband had a leg ulcer and his wife varicose veins; of their 10 children the eldest fractured her left tibia and fibula at the age of 46; thrombosis followed while the leg was in plaster-of-Paris and an ulcer appeared when she was 48; the second had a post-partum thrombosis followed by ulceration; the third had varicose veins; the fourth had thrombosis for no known cause and ulceration later; the sixth and seventh had varicose veins which were operated upon, an ulcer appearing after the operation in the seventh; of the third generation, one had an ulcer.

Conclusion

The presence of a familial tendency to ulceration, except in the arteriosclerotic group, is usually associated with the inheritance of varicose veins; this applies to post-thrombotic as well as to varicose ulceration. It must not be assumed, however, that varicose veins are present in an individual before thrombosis occurs, as this is not usually so. It means merely that thrombosis, unless caused by fracture or infection of the leg, seems more likely to occur in individuals with a family history of varicose veins.

Where thrombosis may occur, as in parturient women, patients recumbent for medical or surgical reasons, and those with fractures of or undergoing operations on the leg, special efforts should be made to prevent it if there is a family history of varicose veins, thrombosis, or ulcus cruris.

Summary

The influence of heredity in gravitational ulceration of the leg has been investigated in a series of 525 patients.

The significance of the family history has been considered in various groups of patients with ulcers from different causes.

The implications of the family history in regard to prevention of thrombosis are mentioned.

I am grateful to Dr. John T. Ingram and Dr. F. F. Hellier for allowing me to carry out this investigation on their patients, and to Dr. Percy Stocks and Miss Eileen M. Brooke for providing me with information from the General Register Office.

The London Area Mobile Physiotherapy Service (L.A.M.P.S.) is a voluntary society founded in May, 1948, to provide physiotherapy at home to those who cannot afford to pay, since it became clear that the National Health Service would, for some years at least, be unable to provide such a service. About 30,000 members of the Home Nursing Scheme have automatically come into the society, and some 250 private physiotherapists are providing the treatments, which in the year 1949–50 amounted to nearly 4,000.

TREATMENT OF POST-PHLEBITIC LEG AND APPLICATION OF VENOUS-PRESSURE MEASUREMENT*

BY

A. J. WALKER, M.B., F.R.C.S.

Formerly Chief Assistant, Surgical Professorial Unit, St. Bartholomew's Hospital; Surgical Tutor, General Infirmary at Leeds

Homans (1941) was the first to champion ligation of the superficial femoral vein in the treatment of the post-phlebitic leg. He argued that the condition was due to valvular incompetence in the main leg veins as a result of the thrombus recanalizing, and that ligation of the superficial femoral vein, harmless when performed for other conditions, was likely to do good. His lead was followed by Buxton *et al.* (1944), who recorded 21 cases, later increased to 26 (Buxton and Collier, 1945). Linton and Hardy (1947) published 34 cases (58 legs), later raised to 49 (84 legs) (Linton and Hardy, 1948), in which they stripped the long saphenous vein as well. Glasser (1949) and Sandegård (1949) published 91 (40 cases followed up) and 32 cases respectively, the latter selecting his patients for operation by the retrograde phlebogram method of Bauer (1948).

Bauer in his paper advocated the ligation of the popliteal rather than of the femoral vein and published the result of 24 cases, later increased to 196 (Bauer, 1950). I have set out the results claimed by these authors in Table I. Ulcers are claimed to remain healed in 70–100% of cases, bursting pain is usually cured, but oedema persists in a disappointingly high proportion of those treated, except in Bauer's hands.

Impressed by Bauer's arguments and results, we have employed his methods at St. Bartholomew's Hospital on a series of 30 legs. This paper presents the results of this treatment, and the application of venous-pressure measurements in the selection of cases. The division and ligation of the vein is done through a 3-in. (7.6-cm.) vertical incision in the upper half of the popliteal fossa. Afterwards the knee is kept extended for five days to aid healing, but early walking with a crêpe bandage is allowed. Rapid healing is ensured if the joint crease is not transgressed.

Material

Twenty-six patients were treated, 4 of the 30 ligations having been done bilaterally. Four patients, accounting for six of the ligations, showed no evidence of previous thrombosis, and these must be included in Bauer's (1948) and Luke's (1941) group with primary valvular incompetence of the deep veins. The histories varied from 2 to 50 years in duration, and the ages from 24 to 72. Four patients were older than Buxton's upper limit of 55 years, and I agree with Glasser (1949) that this upper limit is meaningless.

The chief symptoms were ulceration or eczema—usually painful—bursting pain, and oedema. Less common were coldness and cyanosis, nocturnal cramps, and varicose veins. Ulceration occurred in 15 instances (50% of total). In 12 cases the ulcers were notably painful, a feature which helped to distinguish them from varicose ulcers. The medial malleolus was the common site, and a varying

*A slight amplification of a paper read to the Section of Surgery at the Annual Meeting of the British Medical Association, Liverpool, 1950.

TABLE I.—*Comparison of Results Claimed by Various Authors after Venous Ligation for Valvular Incompetence*

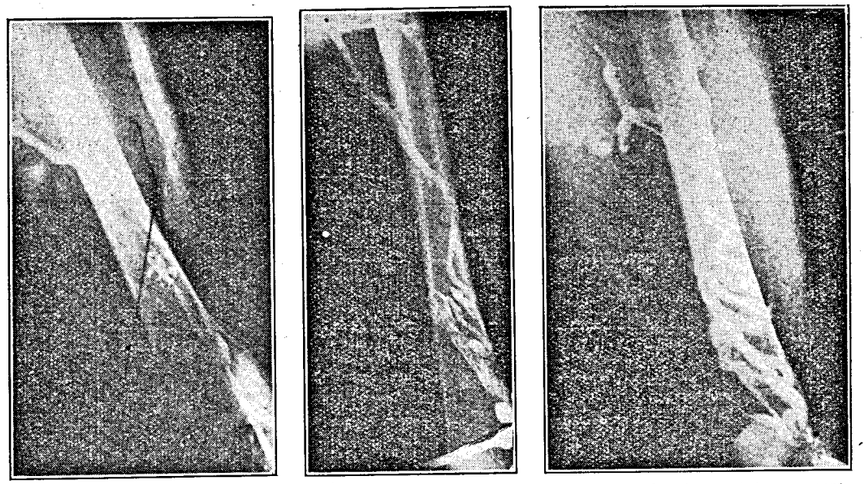
extent of pigmentation and subcutaneous sclerosis usually surrounded the ulcer. In two instances the skin changes were present without ulceration.

I cannot agree with Boyd (1950) that the presence of pigmentation and sclerosis necessarily means that secondary varicose veins are present, nor that these ulcers usually penetrate the deep fascia: the excision of these ulcers will readily show their superficial character. The extra pain associated with them cannot be attributed to greater infection as Boyd suggests: small clean ulcers can be excruciatingly painful. It is probably due to the greater pressure in the venules of the ulcer base.

Eczema occurred in only five legs. In four of these the eruption was painful. In two, the rash was confined to the feet, which is unusual, and in the others the leg was involved, as is more common.

Bursting pain is often described as one of the distinctive symptoms of deep venous incompetence. It was present in 20 legs (66% of total). Bursting as a descriptive term is perhaps not wholly appropriate. Although many patients do describe the pains as bursting in character, it has been referred to as an ache, a burning pain, a deep pain, and a tight feeling or a shooting pain. It is always located in the calf or lower leg, though in one case it was localized to an area of pigmentation and sclerosis above the medial malleolus. The commonest factor is that it comes on when the leg is dependent. It is always worst at the end of the day or after prolonged standing, but it may start directly the foot is put to the ground. In such cases it may wear off in a short while, only to restart as the day wears on. In others it is present all day. In some it is worse during exercise. It varies in severity from the annoying to the incapacitating. It is true to say that it is always relieved by elevation, but some patients state that they may feel it again when they get warm in bed. Of all the symptoms it is the one most easily treated. "Dependent pain" might be a more accurate term, but "bursting pain" graphically describes what is the probable cause—venous distension by blood at an abnormal pressure. In this it resembles the ache felt in varicose veins, but "bursting" pain is usually the more severe of the two.

Oedema occurred in 25 legs (83% of the total), but varied much in degree. It never extended above the knee, and was always worse after prolonged standing. Whereas in some a night's rest would cause disappearance of oedema, in the majority it was always present to some degree, but never to elephantoid proportions. The milder cases were controllable by elastic support, but in the worse legs elastic support of all types was badly tolerated and many patients with oedema would not wear their stockings and bandages towards the end of the day.



Authorities vary very much in their account of the frequency of superficial varicosities in the post-phlebitic leg. I agree with Luke (1941) that they are not usually a feature. They were present in nine cases (30% of the total), but in all except three cases the varices were scattered loops which did not fill from above. In two cases there were quite long varicose trunks in the leg, but in only one leg was the internal saphenous vein incompetent throughout its extent. In no case, however, did the veins empty when exercising with a light tourniquet below the knee, and in some they became tense.

Diagnosis

Apart from the history of a previous deep thrombosis, the diagnosis of deep venous disease was usually suggested by the finding of signs and symptoms such as those mentioned previously without there being any varicosities to account for them. It is not usually difficult to distinguish clinically between true varicose ulcers—associated with marked superficial varicosities and a "feeding" vein, no oedema, and but little pain—and the ulcers due to deep venous disease. The diagnosis of deep venous disease was confirmed in 25 cases by finding a venous pressure above 50 mm. Hg in the foot on exercise, with or without a light tourniquet below the knee to control the superficial veins as in Perthes's test, and a patent though often irregular main venous channel on ascending phlebography. The details of this technique are described below.

In 12 cases descending phlebography was used as well. Bauer's (1948) open technique was preferred to Luke's (1941) blind one, and reflux to the popliteal vein was demonstrated. If these indications were present the popliteal vein was tied. If, however, it was impossible to demonstrate patency of the femoral vein venous ligation was, of course, not possible. During the period that this work covers, four such patients were encountered. They are not included in this series. In three other cases, however, an additional phlebogram was taken by exposing the popliteal vein and injecting 20 ml. of diodone into it. In each of these three cases it was possible to demonstrate not only that the femoral vein was thrombosed but also that the blood was returning through a large collateral vein that ran up behind the femur and was probably derived from the profunda femoris veins. The foot venous exercise pressure was, of course, high; the valves in the collateral vessel must have been incompetent, and this new vessel was thus having the same effect on the venous return as would an incompetent femoral vein. These cases were treated as though it was the femoral vein which was incompetent, and they are included in the result of popliteal vein ligation. (The phlebograms from the popliteal vein are shown in Figs. 1–3.)

Boyd (1950) has argued that the information gained by pressure readings can be obtained more simply by exercising with a rubber band applied tightly enough below the knee to obliterate the superficial veins, as in Perthes's test. With this in position, if the deep veins are obliterated or incompetent the superficial veins should stand out after exercise and may ache. This is true so far as it goes, but most of these patients have no prominent superficial veins, and in them the test fails. Further, as is shown later, it is possible by means of the venous-pressure readings to exclude those patients whom experience in the method has shown will not benefit from operation. Of all methods of investigation of the venous function of the leg, this alone is quantitative.

FIGS. 1–3.—Phlebograms from the popliteal veins showing thrombosed femoral veins and incompetent collateral veins.

Results

Popliteal Vein Ligation.—Of the 30 legs treated 27 have been followed for from 3 to 15 months. This period is too short for any conclusions to be drawn from the ulcer cases. The effect on the other symptoms is definite enough, however, to encourage hope that the results in the healing of the ulcers will eventually prove similar. The results are summarized in the last column of Table I.

Ulceration.—Of 15 ulcerated-leg cases, only 13 have been followed. Two of these were unhealed on discharge from hospital, and both of these patients have refused to return for further treatment, and so have been excluded, leaving only 11 legs in which the treatment was concluded and the patients followed up. Four of these recurred. These four were among those with the worst pressure changes on exercise, and under such circumstances we have come to expect a bad result. They recurred at 3, 4, 8, and 12 months after operation. With one exception the recurrent ulcers were smaller than before and painless. In considering these patients with ulceration, too much significance must not be attached to the role of popliteal vein ligation in maintaining the ulcers in the healed state. Most of these patients continued to wear elastic support of one kind or another after the operation, and support by itself might produce similar results in the period under consideration.

Bursting Pain.—This was present in two-thirds of all legs. In the cases followed up, it was said to be unchanged in one case and considerably improved in three others. In all the rest (80%) it was abolished.

Oedema.—This is traditionally the most difficult symptom to treat. It was present in 23 legs followed up. It was improved to the extent that it was controllable by an elastic stocking in 11 legs, and was abolished completely, so that a stocking was unnecessary, in a further 3 legs.

Other Symptoms.—Nocturnal cramp is a feature of venous disease of the leg that has never been satisfactorily explained. It was present in only three legs and was abolished by popliteal vein ligation in each instance. Coldness and cyanosis were present in five legs. Three of these had previously had sympathectomy without permanent benefit; only one was improved by popliteal vein ligation. Eczema is a disappointing symptom despite local treatment. Of the five legs affected, three improved.

Subjective Improvement.—The 26 patients were asked whether they thought they had benefited from the operation. Eleven said they had, eight said they had not, and five were uncertain. Two cases were too recent for the result to be assessed. Of all the symptoms, pain, whether bursting pain, cramp, or pain in the ulcer itself, is the one most constantly relieved.

Treatment of the Post-phlebitic Ulcer

The chronicity of these ulcers is due to two factors—the disturbance of venous return and the local changes in the skin and subcutaneous tissues. A large number of deep thromboses must recanalize without any valvular incompetence developing. During the period of complete thrombosis, pigmentation, induration, and ulceration and scattered varices may develop, and persist when the venous function has returned to normal. I have studied five such cases. It would seem that the venous changes cause the pigmentation and sclerosis, which affects the powers of resistance and healing of the skin. These skin changes may be permanent.

To prevent recurrence of ulceration it is logical to treat both cause and effect not only by ligation of the superficial or deep veins, as indicated, but also, whenever this is possible, by exercise and grafting of the indurated area (Homans, 1917). I have performed this double treatment in only four of the present series, selecting those cases in which the ulcers were of long standing but the indurated area was not too extensive. The results so far are encouraging, but it is early yet to assess the result.

If not excised, it is important that the ulcer should be healed before the patient leaves hospital. Healing is achieved either by compression bandages or by elevation, and may be speeded at times by the use of local streptomycin to sterilize the area, and by grafting the ulcer. On discharge from hospital the patient should wear an elastic support to control

the veins in the neighbourhood of the ulcer site. In the presence of such persistent oedema, however, the support may not be well tolerated.

Venous-pressure Measurements in Selection of Cases

The method used to measure venous pressure has been described elsewhere (Walker and Longland, 1950). The apparatus used is shown in Fig. 4. A mercury manometer

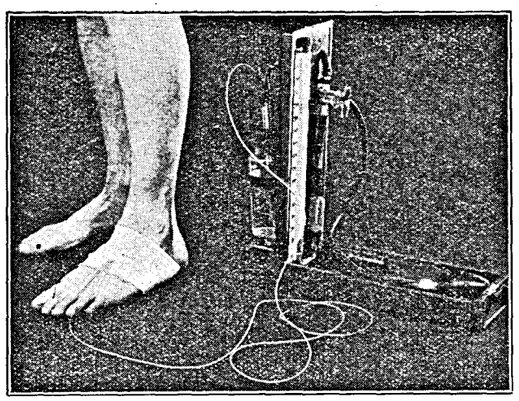


FIG. 4.—Apparatus for measuring venous pressure.

is connected by a three-way tap to a sphygmomanometer hand bulb and to a glass tube piercing the airtight cork of the reservoir bottle, which is sterile and is half filled with sterile heparinized saline. Also piercing the cork and extending below the fluid level is one end of a sterile polythene cannula several feet long. With the polythene cannula filled with saline from the bottle, its far end is tied into a vein which is exposed under local analgesia on the dorsum of the foot. Blood can then flow into the cannula, but by adjusting the pressure the flow can be checked. To measure the venous pressure, the pressure in the apparatus is raised above the expected venous pressure, and then, when the cannula is clear of blood, lowered very slowly. The pressure is read on the manometer at the instant blood appears in the cannula. Thanks to the flexibility of the tube, it is quite easy to take these readings with the patient exercising. The method of investigation is well within the capacity of the average house-surgeon.

Using this method, we have measured the venous-pressure changes on exercise in normal legs and legs with varicose veins on the post-phlebitic syndrome. Our results (Walker and Longland, 1950) agree with those published elsewhere (Smirk, 1936; Beecher, 1937; Seiro, 1938; Pollack *et al.*, 1949; Warren *et al.*, 1949; White and Warren, 1949; Hojensgard and Stürup, 1949). At rest, the venous pressure in the limbs is the pressure exerted by a column of blood extending vertically from heart level to the level of the point of measurement. In the standing position it varies in the foot between 70 and 100 mm. Hg, irrespective of the state of the leg veins, depending solely on the height of the patient. But directly the patient exercises, the pressure falls in a normal individual to less than 30 mm. Hg.

Pollack and Wood (1949) have shown that the degree of exercise has little influence on this result. If there are superficial varices present, then the pressure on exercise is reduced less, depending on the severity of the varicosities, to figures varying from 80 to 30 mm. Hg. If the reflux down the varices is prevented by placing a tourniquet below the knee the pressure on exercise is reduced further till it reaches the normal range. In contrast, if there is valvular incompetence or thrombosis of the deep veins, then the fall of pressure on exercise is even less than in varicose vein cases, and is unaffected by the below-knee tourniquet. In some cases the pressure may even rise. The pressures to be expected in the various groups are summarized in Table II.

TABLE II.—*Foot Venous Pressures in Erect Position*

Standing still—all cases	70–100 mm. Hg
Exercising—normals	0–30 " "
" —varicose veins	30–80 " "
" with light tourniquet below knee	0–30 " "
" —deep venous disease	50–110 " "
" with light tourniquet below knee	50–110 " "

It is reasonable to assume that the fall on exercise is proportional to the efficiency of the venous return of the whole limb, and that in legs with the least fall of pressure on exercise ligation of the main vein will merely divert the blood to other incompetent channels with no resulting benefit. In those with the greatest fall of pressure in exercise the collateral veins are presumably competent, and benefit is likely to be considerable. To test this assumption those cases in which the venous pressures were measured are so arranged (Table III) that those with the greatest fall of venous pressure on exercise are at the bottom and those with the least at the top. Opposite each case are recorded the results of the operation. These changes are recorded numerically as 3, 2, and 1, meaning that symptoms were unchanged, improved, or cured respectively. In the case of ulcer, 1 means that it has remained healed, 2 that it has recurred to a small degree, 3 that it has recurred to a size as large as before. As regards oedema, 2 indicates that the oedema is controllable by elastic support. Table III shows a steady improvement in

TABLE III.—*Changes in Symptoms After Popliteal Vein Ligation Compared With the Changes in Venous Pressure on Exercise, Before Ligation*

Case	Rise (+) or Fall (−) in Venous Pressure on Exercise	Bursting Pain	Pains of Ulcer or Eczema	Cramp	Ulcer*	Eczema	Cyanosis and Coldness	Oedema†	Overall Improvement	Remarks

* In cases of ulcers: 1 = remained healed; 2 = recurred to small degree; 3 = recurred as large as before.
† = 2 = Oedema controllable by elastic support.

results as the drop in pressure on exercise recorded preoperatively increases. If there is no pressure fall on exercise before operation the operation will probably be valueless, especially when ulceration, eczema, and oedema are the principal symptoms. As the drop in pressure on exercise becomes greater the outlook improves.

Discussion

Among patients who exhibit the post-phlebitic syndrome in varying degrees, not all are suitable for popliteal vein ligation, and this should not be practised indiscriminately if the best results are to be obtained.

Unsuitable cases are: (*a*) Those in which the main vein has not recanalized. These will be excluded by the ascending phlebogram. In doubtful cases a phlebogram from the popliteal vein may help. (*b*) Those in which venous function has returned to normal. These will show normal venous pressures. Their sole symptom is ulceration. (*c*) Those with maximal valvular incompetence. In these, exercise will produce little or no drop of venous pressure from the resting level and may even show it to rise.

When these cases have been excluded, note should be taken of the presenting symptoms in the remainder before operation is advised. The most consistently good results are obtained where pain is a prominent symptom, be it bursting pain, cramp, or painful ulcer or eczema. The results in treating oedema are less satisfactory, and experience suggests that where oedema is a predominant cause of complaint ligation may not abolish it. It is too early to say to what extent ligation will help to prevent recurrent ulceration, especially as most patients continue to wear elastic support and so complicate the problem. In suitable cases excision and grafting of the ulcers of patients whose veins have been tied may well prove helpful in producing a lasting cure. Venous-pressure measuring is a simple investigation and not purely a research weapon. Its routine use is a most valuable help in the selection of patients in whom popliteal vein ligation is contemplated.

Summary

A series of 30 legs, the seat of valvular incompetence of the deep veins, is presented; on these popliteal vein ligation was performed.

A simple method of measuring venous pressures at rest and during exercise is described. It is shown how these readings coupled with ascending phlebography can establish the diagnosis of valvular incompetency of the deep vein.

Treatment has been by ligation and division of the popliteal vein. Figures for the 3–15 months follow-up are presented, and are contrasted with the results of other authors.

It is shown how those results could be improved by the selection of cases by means of their venous-pressure changes.

The operation is most useful in those patients in whom pain is a prominent feature.

I am greatly indebted to Professor Sir James Paterson Ross, director of the Surgical Professorial Unit at St. Bartholomew's Hospital, for facilities to undertake the work, and for much helpful criticism in the preparation of this paper. Also to Mr. R. S. Corbett, Mr. J. P. Hosford, and Mr. E. G. Tuckwell for access to such of their patients as are included in this paper; and to Mr. R. S. Murley and my colleagues on the surgical professorial unit for advice and assistance; to the theatre staff for their patience; and to the photographic department for the radiographs.

USE OF DECAMETHONIUM IODIDE IN ANAESTHESIA FOR PERORAL ENDOSCOPY

BY

C. F. SCURR, M.B., D.A.
Anaesthetist, Westminster Hospital

In the early papers on the use of D-tubocurarine in anaesthesia, note was made that a combination of curarization with thiopentone–nitrous-oxide anaesthesia provided satisfactory conditions for peroral endoscopy. It is usually preferable to perform these examinations under local analgesia, but, as Dinsdale (1949) has pointed out, there may be indications for using general anaesthesia—for example, in children, in very nervous patients, or where there is difficulty in obtaining relaxation of the jaw.

Bourne (1947) contributed a paper on the use of D-tubocurarine for intubation. However, one authority has described its use for this purpose as a steam-hammer blow; thus a pointer is given to the main disadvantage of using D-tubocurarine in these cases—if an adequate curarizing dose is given, then depression of the patient persists for about three-quarters of an hour. Attempts to avoid this by reducing the dose of D-tubocurarine lead only to unsatisfactory results However, as Bourne points out. the toxic effects are less than when deeper anaesthesia with ether is employed.

Suitable anaesthesia for peroral endoscopy and intubation is, however, provided by the use of decamethonium iodide in conjunction with thiopentone—a combination which seems to avoid almost entirely the disadvantages of the D-tubocurarine–thiopentone technique.

The important desiderata for peroral endoscopy are relaxation of the jaw, an open glottis, and lack of reflex response. Relaxation of the jaw is usually stated to accompany anaesthesia with thiopentone; but this cannot be guaranteed, and very often the stimulus of introducing a laryngoscope will cause the jaw muscles to tighten. In the edentulous this factor is less important, but where there is a full set of long teeth, especially in association with some degree of inferior retrusion, profound relaxation is essential.

As Gray and Halton (1946a, 1946b) noted, D-tubocurarine is a potent preventive of laryngeal spasm. In an adequately curarized patient the cords are almost invariably seen to be well abducted, and this is essential for atraumatic intubation or bronchoscopy. This lack of spasm makes it possible to perform oesophagoscopy without intubation (Organe, 1947), as there is no anxiety about loss of control of the airway. It is preferable, however, to intubate such cases. A special advantage of curarization applied to oesophagoscopy is that the relaxation of the post-cricoid sphincter makes passage of the oesophagoscope a very easy procedure.

Decamethonium iodide prevents reflex motor response by producing a block at the myoneural junction of skeletal muscle. The use of topical anaesthesia to depress reflexes

on the afferent side is an important adjunct. For this reason we prefer to spray the throat in all cases with a 2% solution of amethocaine hydrochloride at the beginning of anaesthesia: in bronchoscopies 1 ml. of the solution is introduced into the trachea by means of a laryngeal cannula or by injection through the cricothyroid membrane. It is not known whether decamethonium iodide has any protective effect against possible cardio-inhibitory and other reflexes of the vago-vagal type; although it is uncertain how common or dangerous such phenomena may be, topical anaesthesia provides an additional safeguard in this respect. Notable advantages of the method are lack of explosion danger, greater safety than chloroform anaesthesia, low toxicity, and speed.

Technique

Suitable premedication, including atropine or scopolamine, is given one hour pre-operatively. The estimated dose of decamethonium iodide (ranging from 3 to 5 mg. in adults) is injected intravenously and is immediately followed by little more than a sleep dose of thiopentone (0.3–0.5 g.) given slowly through the same needle. An oral airway is inserted and the 2% amethocaine hydrochloride spray directed down it. Oxygen is then administered by inhalation or inflation for three to four minutes until the relaxant effect is maximal. This is an important point, as apnoea, should it occur, is well tolerated in the presence of full oxygenation of the lungs. A small additional dose of thiopentone is now given and the endoscopy is begun or the endotracheal tube introduced.

Maintenance is usually ensured by further doses of thiopentone given intermittently during the operation. Where an endotracheal tube is used nitrous oxide and oxygen are administered; trichlorethylene has occasionally been employed as a supplement. In rare instances where the operation has lasted more than 15 minutes, further doses of decamethonium iodide have been given as indicated.

Should respiratory depression or apnoea occur, it is the duty of the anaesthetist to maintain adequate oxygenation of the patient; this involves (1) the maintenance of a clear airway and (2) artificial ventilation. The former is secured by the instrument in bronchoscopy or by the tube in other cases. Adequate respiratory exchange should be ensured by gentle compression of the flanks and lower ribs (as in Schäfer's method) or, in the intubated cases, by rhythmic pressure on the rebreathing bag of the anaesthetic apparatus.

Discussion

The method described has been used in 50 operations for peroral endoscopy and in 250 cases for endotracheal intubation. The ages of the patients ranged from 3 to 82 years. Satisfactory operating conditions were obtained in all.

The dosage of decamethonium iodide has approximated to 0.5 mg. per stone (6.35 kg.) body weight. This high rate is important, as adequate curarization is an essential part of the technique. In no instance has delayed return of respiration been encountered. Recovery can always be confidently predicted within a 20-minute period from administration; however short the operation, the residual period elapsing before recovery can only be brief, and during this interval oxygenation can easily be maintained by ventilation with oxygen, simple anaesthetic apparatus being used. For this reason the antagonist—pentamethonium iodide—has never been employed. The unfortunate side-effect of ganglionic block by this drug renders its use inadvisable on most occasions; its employment in surgery is likely to be limited to the deliberate production of hypotension to reduce haemorrhage during certain operations —for example, fenestration. This technique is unsuitable where the administrator is not skilled in the care of the apnoeic patient or where adequate facilities and equipment are lacking. Dyspnoea is a contraindication to the use of the method.

Jaw clonus has been encountered occasionally during the induction period; this may be associated with the anti-esterase effect of decamethonium iodide. However, in all instances it has been transitory and has provided no obstacle to intubation.

No qualitative difference has been evident in comparison with other relaxants: an apparently greater ease of laryngoscopy noted early in the series is probably due to the fact that a relatively high dosage of the short-acting decamethonium iodide was employed. In contrast to the observations of Doughty (1950), irritability of the respiratory tract has not been greater than with other relaxants; our experience in this respect is confirmed by Harris and Dripps (1950).

It is believed that this method possesses definite advantages, especially over D-tubocurarine, in that the short-lived action of decamethonium iodide approximates closely to the average duration of these relatively short procedures.

I am indebted to my colleagues for access to their records in the preparation of this paper.

Medical Memoranda

A Toxic Effect of Thiouracil Hitherto Undescribed

The object of this communication is to set on record a hitherto undescribed side-effect of thiouracil.

CASE REPORT

The patient, a woman aged 48, during a period of intense business anxiety in November, 1947, became "nervy," developed palpitation, and lost 42 lb. (19 kg.) in weight during the next six months. In July, 1948, her doctor asked me to see her because she had a persistent tachycardia and had failed to regain her normal weight in spite of considerable improvement in her general condition with rest and sedatives.

She was a small-boned but not very thin woman, and weighed 7 st. 6 lb. (47.2 kg.) in her indoor clothes. In spite of some nervous agitation under examination she did not give the impression of being a neurotic subject. Her pulse was regular at 120, the thyroid gland was slightly enlarged, and she had a fine tremor of the outstretched hands. There was no exophthalmos or other abnormal eye sign, and her skin was not unduly moist. Her heart was normal and her blood pressure 160/74.

At that time I did not regard the clinical evidence of thyrotoxicosis as strong enough to justify a change in treatment. Six months later, however, though there had been no alteration in weight, her thyroid gland had enlarged and she had developed exophthalmos of the right eye; moreover, she complained of always feeling hot, and her skin was moist.

Treatment with methyl thiouracil, 100 mg. twice daily, was begun and considerable clinical improvement followed. After two weeks she complained of "difficulty in focusing her eyes," and her doctor noted that she had horizontal nystagmus to right and left. The dose of thiouracil was reduced to 100 mg. once a day during the next week, but she stated that she felt "light-headed" and that everything she looked at "seemed to be jumping about." After another four days she developed such intense vertigo that she could not stand or even sit up in bed unless she kept her eyes closed, and any attempt to get up and move about caused nausea and sickness. Gross nystagmus was present in all planes. Thiouracil was stopped and the more severe symptoms subsided during the next three days, but she remained unsteady and immediately became sick when she tried to walk. At no time was there any headache or skin rash, and apart from the symptoms described above she felt quite well.

Her general condition was good and the signs and symptoms of thyrotoxicosis were definitely improved—pulse 100, exophthalmos much less noticeable, skin normal, and no complaint of feeling hot. She was in fact very pleased with the effect of treatment and most anxious to continue to take the thiouracil in case symptoms should return. The only abnormal finding in a full examination of the central nervous system was a very coarse nystagmus in all planes. Romberg's sign was negative and the ocular fundi and tympanic membranes were normal. The condition of the heart and the blood pressure were unchanged, except that a few extrasystoles were noted.

During the next three weeks she gradually improved and was able to go out if accompanied. She still found reading difficult. Her thyrotoxic symptoms, however, increased again, and partly on this account and partly because of the unusual effects of the thiouracil treatment she was sent to Professor Himsworth. He agreed that the development of nystagmus could, in reason, be attributed only to the thiouracil, but could neither recall having encountered a similar case himself nor, in spite of wide inquiry, both in this country and abroad, find anyone else who had done so. He advised surgical treatment for the thyrotoxicosis without delay.

The patient was admitted to hospital on May 24, 1949; and on June 3 subtotal thyroidectomy was performed by Mr. John Griffith. During the first week after operation nystagmus increased, but by the fourteenth day, when the general condition was excellent and the pulse rate had become stabilized between 70 and 80, it became less marked and she made no complaint of visual disturbance. She was then discharged from hospital.

Sections of the excised gland were examined by the pathologist (Dr. R. W. Johnson), who reported that the appearances were typical of thyrotoxicosis.

When last seen, on July 15, 1949, six weeks after operation, she looked and felt well and had gained a stone (6.4 kg.) in weight. Nystagmus, however, was still present, being most marked when she looked to right and left, but also when the eyes were raised upwards. She said that she could read without difficulty but that "things jumped about" when she looked to either side. Apart from the nystagmus, examination of the central nervous system was negative as before, and there was no evidence of cardiovascular sclerosis or ear disease.

COMMENT

When thiouracil produces toxic effects they are generally manifest on or about the fourteenth day after the beginning of treatment. In the present case visual symptoms and nystagmus appeared at this time. These receded again with omission of the drug. There is therefore strong presumptive evidence that this was an effect of thiouracil. The absence of history or physical signs of disease of the central nervous system or of vascular sclerosis makes any alternative explanation improbable.

It might be suggested that the particular sample of thiouracil used contained an impurity which could be held to blame; some of the tablets were therefore sent to the manufacturers for analysis, but they were found to be in every way normal pure samples of methyl thiouracil.

In the circumstances it is of course impossible to give a prognosis, but as four months have elapsed since thiouracil was discontinued and signs and symptoms are still present it seems unlikely that complete recovery will now take place.

Acknowledgment is due to Dr. Fitzgerald Frazer for permission to publish these notes of his patient and for his own careful records of the case while she was under his care. I have also to thank Professor Himsworth for his interest and advice.

C. BARRINGTON PROWSE, M.B., M.R.C.P.,
Physician, Royal Sussex County Hospital, Brighton.

Fulminating Staphylococcal Pneumonia Treated with Massive Doses of Chloramphenicol and Penicillin

Fulminating staphylococcal pneumonia has in recent years shown itself to be a rapidly fatal condition despite penicillin therapy. We have recently encountered a case following influenza B infection in which the organism was resistant to penicillin. Early treatment with chloramphenicol was instituted, but the patient's condition deteriorated rapidly; however, with increased dosage he recovered after a critical illness.

CASE REPORT

The patient was a male nurse aged 39. His first symptoms were those of a severe febrile cold. After four days he developed a slight pain in the left side of his chest. During the next six hours this increased to such an extent that breathing became difficult; it was at this stage that he attended the casualty department of University College Hospital.

Physical examination showed a severely ill man with marked respiratory distress, temperature 100.6° F. (38.1° C.), pulse 100,

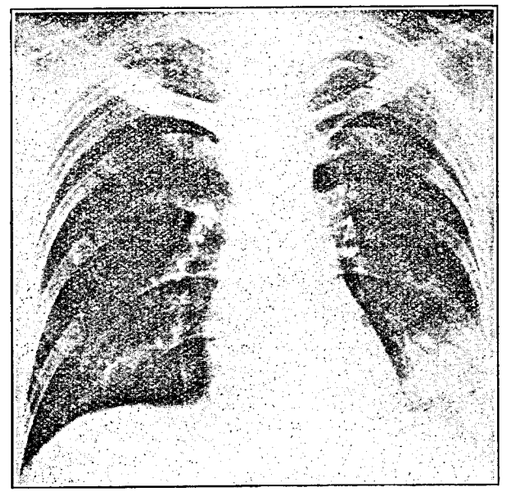

FIG. 1.—Radiograph taken on March 22.

respirations 26. Movement on the left side of his chest was considerably reduced and rhonchi were widespread. Radiographs of his chest taken at that time (March 22, 1950) showed consolidation in the anterior and middle basal segments of the left lower lobe (Fig. 1). A diagnosis of aspiration pneumonia was made, and after blood and sputum had been collected for laboratory examination he was given 2.5 g. of chloramphenicol

followed by 0.25 g. four-hourly. This drug was made available as part of an investigation into the treatment of aspiration pneumonia. Later, when it became obvious that this was in fact a case of penicillin-resistant staphylococcal pneumonia, the supply was maintained by the Ministry of Health.

During the first 24 hours of treatment there was a great deterioration in the patient's condition. He showed an ashen-grey cyanosis, his temperature reached a maximum of 102° F. (38.9° C.), and the physical signs in his chest indicated rapid spread of the pneumonic process. The left side did not move at all on respiration, the percussion note over it was stony dull, and breath sounds were inaudible. Radiographs at this stage showed (March 24) the left hemithorax to be completely opaque, but with no evidence of mediastinal displacement (Fig. 2). A report of the sputum culture described a predominant growth of *Staphylococcus aureus*, resistant to penicillin and moderately sensitive to chloramphenicol.

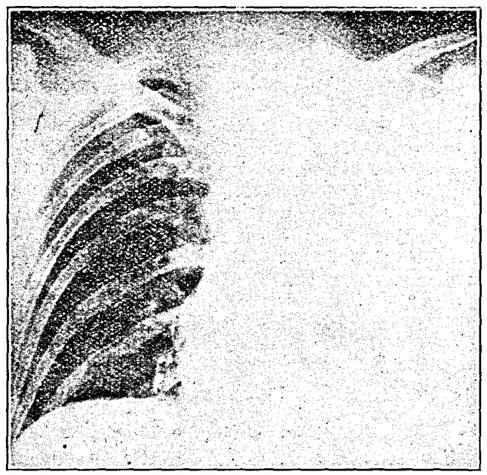

FIG. 2.—Radiograph taken on March 24.

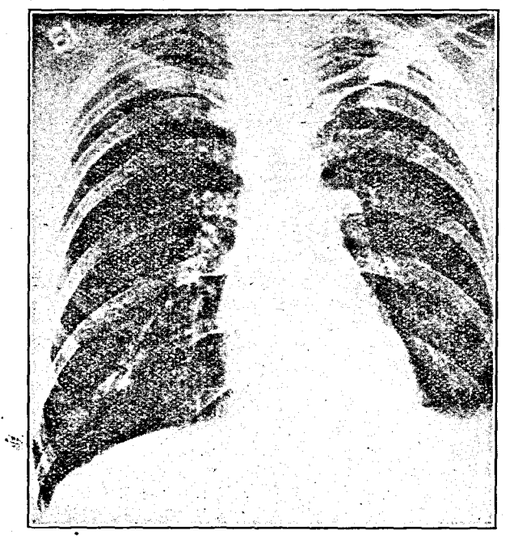

FIG. 3.—Radiograph taken on August 8.

In view of this report and of the patient's poor response to chemotherapy, the dosage of chloramphenicol was doubled and crystalline penicillin, 1,000,000 units three-hourly, was started; the patient was placed in an oxygen tent.

For 24 hours his condition remained critical, but thereafter he made steady, if slow, improvement. His temperature fell by lysis to normal in 14 days. Within 10 days of his admission radiographic evidence of resolution appeared and three weeks later was almost complete. He received in all 43 g. of chloramphenicol. Complement-fixation tests for influenza showed a titre of 1/4 for influenza B on admission and a titre of more than 1/128 six days later. Fig. 3 shows the radiographic appearance on August 8.

DISCUSSION

In the great influenza pandemics of 1889 and 1918–19 the staphylococcus was only occasionally found in fatal cases, although in localized outbreaks a high incidence was reported (Netter, 1892; Chickering and Park, 1919). In the smaller epidemics of recent years it has been found in a considerable proportion of the more serious cases (Stuart-Harris *et al.*, 1938). Wollenman and Finland (1943) and Stuart-Harris *et al.* (1950) have commented on the failure of fulminating cases to respond to chemotherapy.

The present case appeared on admission to be one of a moderately severe aspiration pneumonia. It was only after 24 hours on conservative doses of chloramphenicol that the condition gave rise to anxiety. At this stage he presented the prostration, respiratory distress, and ashen-grey cyanosis typical of a fulminating case of staphylococcal pneumonia. There seems to be little doubt that, without the very large doses of chloramphenicol and penicillin used, he would have succumbed to his infection within 48 hours of his admission to hospital.

SUMMARY

A case is described of fulminating staphylococcal pneumonia, secondary to influenza B, successfully treated with chloramphenicol and massive doses of penicillin.

Reference to the literature suggests that the association of influenza and staphylococcal pneumonia is an extremely fatal one.

I wish to thank the Virus Reference Laboratory, Colindale, for carrying out the complement-fixation tests for influenza, Professor M. L. Rosenheim for permission to publish this case, and Dr. J. D. Nabarro for advice in preparing the manuscript.

The Ministry of Health states that more blood was given to hospitals in England and Wales during the June quarter this year than in any three months since the war. Gifts totalled 128,392, making over 250,000 in the first half of this year. Over 35,000 new donors joined the National Blood Transfusion Service in the quarter. Blood consumption is 50 times what it was in 1938 and is still mounting. To meet these increasing demands without calling too often on existing donors, at least 200,000 more enrolments are needed. There are now 388,000 registered donors—a gain of 10,700 in the quarter and the highest total since 1945.

Reviews

SAINT AND PIONEER

Florence Nightingale, 1820–1910. By Cecil Woodham-Smith. (Pp. 615; illustrated. 15s.) London: Constable and Co. 1950.

I must confess to an early prejudice against Florence Nightingale. I thought she had created a tradition of nursing discipline which was rigid and inhuman, and my only knowledge of her life was derived from Lytton Strachey's astringent essay. My prejudice was first shaken when I saw her bust in the National Portrait Gallery and realized that she was not a misfavoured feminist but an extremely beautiful woman. It was further weakened by the feeling I have had that our attitude to sickness in the welfare State is becoming utilitarian, and that neither the medical nor the nursing professions will flourish without a renewed sense of their vocation. It has been finally destroyed by reading Mrs. Woodham-Smith's enthralling biography and realizing the condition of our hospitals less than a hundred years ago, the filth and lack of sanitation in the wards, the drunkenness, immorality, and inefficiency of the nurses, and the complacency of the medical staffs. It is against this background that Florence Nightingale's achievement is to be measured.

She was, indeed, a remarkable woman. She was beautiful, wealthy, and gifted, brought up in an age and society where women were expected to display an excessive sensibility. Although she had a passionate nature and attracted many suitors, she never married. From the age of 19 onwards her life was a prolonged battle with her mother, who was bitterly disappointed at her refusal to follow the conventional path to social success. Florence had had the feeling from early childhood that she was not like other people but was set apart. God had spoken to her at 17, as He was to do again three times afterwards; but what a heartbreaking business it was, finding the task for which she was called. After the first voice at 17, seven years passed before she decided that her call was for nursing, and it took another nine to persuade her family. Fortunately, she had a gift for making friends who were able to supply the understanding which she could not get from her parents, and gradually she began the study of hospitals and nursing which was to make her one of the foremost health experts in the world. Throughout this period her health suffered from the struggle, and she was subject to uncontrollable daydreaming. At the age of 29, after refusing Richard Monckton Milnes, she wrote:

"I have an intellectual nature which requires satisfaction and that would find it in him. I have a passionate nature which requires satisfaction and that would find it in him. I have a moral, an active, nature which requires satisfaction and that would not find it in his life. Sometimes I think I will satisfy my passionate nature at all events, because that will at least secure me from the evil of dreaming. But would it? I could be satisfied to spend a life with him in combining our different powers in some great object. I could not satisfy this nature by spending a life with him in making society and arranging domestic things."

Eventually she obtained her freedom and the superintendentship of the Institution for the Care of Sick Gentlewomen in Distressed Circumstances. A year later came the Crimean War and the invitation to take out a nursing contingent. This war witnessed the destruction of an army and the breakdown of its medical services as a result almost entirely of administrative incompetence. Once again human suffering reached its extreme limits, as it had done, alas, in so many previous campaigns. The collapse of the medical services would have been complete but for the personality, skill, and indomitable energy of Florence Nightingale. The Sanitary Commission described the defects of the Barrack Hospital at Scutari as murderous.

"Beneath the magnificent structure were sewers of the worst possible construction, mere cesspools, choked, inefficient, and grossly overloaded. The whole vast building stood in a sea of decaying filth. The very walls, constructed of porous plaster, were soaked in it. Every breeze, every puff of air, blew poisonous gas through the pipes of numerous open privies into the corridors and wards where the sick were lying."

But even worse was man's inhumanity to man, the quagmire of administrative difficulties, the obstructive group loyalties, the defence of the old regime, the intrigues, the mere inertia. No army medical department likes to be found incompetent, and it likes it even less when the main source of criticism appears to be an amateur. Nevertheless, she succeeded, and the mortality, which in six months had been 73% in eight regiments from disease alone, was brought to a lower level than in England. In achieving this she had created not only the modern nurse but the modern soldier.

She had a horror of publicity. All her life she hated having a likeness taken, which explains the shortage of photographs and portraits, and before she died she desired that the only memorial on her grave should be a small cross, on which are the words "F.N. Born 1820. Died 1910." At the end of the Crimean War, when a nation was waiting to welcome her, she slipped home unnoticed.

"Mrs. Watson, the housekeeper, was sitting in her room in the front of the house. She looked up, saw a lady in black walking alone up the drive, looked again, shrieked, burst into tears, ran out to meet her."

That scene, I think, is how a film on Florence Nightingale might end, and in a way the film would be right, for never before or after were her powers so fused and concentrated as during the Crimean War. She was now 36. During the next 50 years she was to do an immense amount of work in the reform of nursing at home and abroad and in the improvement of conditions of life in the Army and in India. She became an expert on hospitals, nursing, and sanitation, and a pioneer medical statistician, but she was never really happy, and it was as if her work was an obstacle to happiness rather than the means to it. Her health collapsed when she was 37, and though mentally energetic she lived the life of a physical invalid thereafter. She became, in fact, a highly productive neurasthenic who worked most of her collaborators to death. A further deterioration in her health occurred when she was 48, and thereafter she never had quite the same immense powers of sustained concentration.

Looking back on these fevered years of commissions and Blue Books, one is tempted to compare Florence Nightingale with Beatrice Webb. Both had something inhuman about them. "I never gave or took an excuse," said Florence. Mrs. Gaskell thought that she lacked a love for individuals, and most people who worked with Florence Nightingale were hurt in the end by something hard within her. In her just resentment against her mother she had once spoken of the devourer and the devoured, but her own treatment of Sidney Herbert is hard to forgive. Admittedly her mother was obtuse and cruel, but even as a child Florence never showed any affection for her. Beatrice was fortunate in finding an ideal partner in Sidney Webb, and in their tranquil union they accomplished an immense work, which

has left its mark on almost every aspect of British society. Florence momentarily reached a greater height, a height which in women is probably only possible for the saint or the celibate, but she had not the serenity of sainthood, and the later years, the neurasthenia, the cats, the girlish letters, and the decline into senility are painful to study.

Mrs. Woodham-Smith's biography is magnificent. It is crowded with figures like a Frith canvas and all are alive. Her writing is so transparent and her observation so dispassionate that her art reaches the highest level of achievement; the medium is forgotten and the past lives again. It is a big book of 600 pages, and busy doctors may feel that they need a holiday or an illness to read it; but however they make the time they will be well rewarded.

L. J. WITTS.

⁂ A hitherto unpublished letter from Florence Nightingale appears on page 1328.—ED., *B.M.J.*

CHROMATOGRAPHY

Progress in Chromatography 1938-1947. By Professor L. Zechmeister. (Pp. 368. £2 5s.) London: Chapman and Hall. 1950.

Many notable advances, for instance the introduction of partition chromatography, have been made in the decade that has elapsed since the publication of *Principles and Practice of Chromatography*, by Zechmeister and Cholnoky. The senior author—mistakenly, in the reviewer's opinion—has decided to issue a supplement instead of revising the original treatise. As an almost complete list of references to the application of chromatography to the separation of carotenoids, steroids, amino-acids, carbohydrates, etc., this book could hardly be bettered.

On the theoretical side, however, a list of references is of little use to anyone wishing to understand the broad principles of chromatography. Indeed, even practically it is difficult to learn from the many examples given those manipulative tricks on which the success of a chromatographic separation so often depends. The subject is developing rapidly, and the beginner (and indeed the expert) will gain greater understanding by listening to or reading transcripts of discussion between experts than by studying uncritical reviews. Luckily such a discussion on chromatographic analysis (*Discussions of the Faraday Society*, No. 7, 1949) is now available.

The book is well printed, with the exceptions of the plates, which are blurred, and the chemical formulae, which are too small. The price is too high for a list of references unleavened by critical commentary.

H. M. E. CARDWELL.

KÜNTSCHER NAILING

Marknagelung nach Küntscher bei Schaftbrüchen der langen Röhrenknochen. By Professor Carl Häbler. Second edition. (Pp. 302; 350 figures. M. 26.) Munich and Berlin: Urban and Schwarzenberg. 1950.

The first edition of this work appeared in 1943 under the title of "The Stable Osteosynthesis." In the second and much improved volume, now named "Küntscher's Medullary Nailing," the author illustrates in detail the use of the nail in all bones in which it has been found of value and elaborates the technical details of insertion. The method is not without danger, and if the local complications differ little from those arising during the other forms of internal fixation the general complications, notably fat embolism, are increased. Five personal cases (an incidence of 2.5%) are reported, all in fractures of the femur. Two occurred in operations on fresh fractures and three in late cases. Other authors have also reported deaths in cases of late medullary nailing, and, even if experimentally the dangers in fresh fractures can be shown to be small, in late fractures, where the pathology differs, there is certainly an added risk. As it is particularly in fractures of the femoral shaft that Küntscher nailing offers advantages over other methods, it is unfortunate that nailing this particular bone is most likely to produce fat embolism.

Efficient nailing is dependent on an accurate appreciation of the mechanics of the nail and the physical shape of the fracture. There is an abundance of diagrammatic detail which should be studied by anyone who approaches the procedure with a conviction that it is simple and a limited armamentarium.

Among the tables of results provided, a high figure is found for infection after open nailing of old healed fractures, and even if the use of the method in inexperienced hands is to be blamed, as the book suggests, more than one lesson may be learned from these figures. One is that the skin tension on restoring the full length to a limb may result in local skin necrosis and infection.

As in many Continental works, one has to work hard to discover the broad principles, for they are overlaid by a mass of case histories and individual operative details which is not always distinguished from the main text by typographical alterations. This book is the most complete one available on the subject, though its value as a reference book would be considerably increased by the provision of a detailed index.

J. G. BONNIN.

DESIRES AND NEEDS

Human Desires and Their Fulfilment. By K. W. Monsarrat. (Pp. 270. 12s. 6d.) Liverpool: University Press. 1950.

It is a commonplace for the psychiatrist that while human beings have needs and desires and strive for their fulfilment they are very often mistaken about their needs, desire inappropriate satisfactions, and go the wrong way to obtain them. It is part of Mr. Monsarrat's task to expose these errors and to offer the means of correcting them; but as he starts from first principles a very large amount of ground is covered before he reaches his conclusions.

The history of human modes of thought from a primitive vitalism through a belief in supernatural agencies to sophisticated and scientific thinking is surveyed. The author emphasizes the capacity of scientific, or analytical, thinking to provide meaningful answers, but points out its limitations. It is, in final analysis, invariably circular and never eliminates the subjective element. We can never know things in themselves but only their relations one to another and to ourselves. An examination of our basic knowledge of physics, biology, physiology, and psychology over several chapters shows that in every case we are concerned with relations and that the analytical view cannot take us further. But there are many other questions which seem to demand an answer. Some of them are inherently unanswerable and, on examination, based on a misconception of what is knowable. But the whole world of values is also involved, and Mr. Monsarrat does not accept the view, which at present prevails among scientific men, that analytical, or scientific, thought is unable to help us here. Haphazard attempts to solve these problems are playing havoc with human relations at the present day. "Science has in its files clear and indisputable evidence that mutual assistance to balance has been throughout terrestrial history the one and only relation which has given equilibrium to collections of associated units on any plane." The doctrine of the necessity of conflict, with values in terms of power, as exhibited in the works of a number of philosophers, especially Hegel and Marx, is emphatically rejected; and what one might call the doctrine of love is held up, not only as appealing to a loftier view of the world, but, more importantly, as being scientifically well founded.

This book is not easy reading. But the author is no doubt right, first that no thoughtful man can safely burke these issues, and secondly that science has somehow or other got to learn to handle in a logical and dispassionate way data in which values are involved. Some preliminary assumptions are inevitably involved. Mr. Monsarrat's definition of what constitutes a "higher" state is very similar to one recently proposed by Julian Huxley, and of a kind to appeal to biologists and medical men.

ELIOT SLATER.

PHYSIOTHERAPY

Manual of Massage and Movements. By E. M. Prosser, T.M.M.G. (Pp. 388; 287 figures. 15s.) London: Faber and Faber. 1950.

Ever since its first appearance 13 years ago this volume has provided a mine of information for physiotherapy students. Massage is discussed in five chapters, none of them very satisfactory. For example, stroking movements over the back are stated to be useful in debility and depression because of their effect on the peripheral nervous system; over the abdomen in gastric atony and intestinal stasis; along the limbs in anaemia, and over the scalp in alopecia. A similar mixture of fact and fancy colours the views on kneading, which is said to be called for in: upper motor neurone disease, oedema, anaemia, debility, rheumatoid arthritis, insomnia, convalescence after poliomyelitis or a fracture, securing a greater flow of urine and bile, nerve-palsies, incipient flat-foot, and haematomata. It is only fair to point out that most other textbooks on massage make yet more extravagant claims; by contrast, therefore, this book represents a comparatively factual approach.

The author considers exercises in the next 17 chapters. The action of gravity and the nature of levers is admirably set out. The fundamental starting positions are well described, and the muscles involved in them, and in the exercises derived from them, are listed. Excellent line drawings enhance clarity and are of obvious value to students, but the fact that the scapula is rotated on full elevation of the arm is ignored throughout. Sometimes too many variations of one exercise are elaborated; for example, 25 drawings illustrate different methods of performing flexion and extension at the hip. Nothing could be clearer or more factual than this—the main—part of the book (apart from an extraordinary statement about tuberculosis on page 302).

But practical questions cannot be ignored. Does rehabilitation, as carried out to-day, employ these measures often enough to make detailed knowledge of these variants essential to students? Can exercises be taught in the abstract without reference to their indications—for example, after meniscectomy at the knee, for relief of the thoracic-outlet syndrome? Many contemporary methods of active rehabilitation of this sort are omitted. It is true that the student who has grasped the fundamental facts of posture and muscle work possesses the basic knowledge enabling her to vary her methods according to the needs of to-day. But she would obviously be greatly aided by a more modern approach to exercise therapy. As matters now stand, however, this popular and authoritative work is indispensable to every candidate for the examinations of the Chartered Society of Physiotherapy.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY DECEMBER 9 1950

EUTHANASIA

The Voluntary Euthanasia Legislation Society was founded in 1935, and its first public meeting was held in B.M.A. House in that year. Dr. C. Killick Millard was its honorary secretary and Lord Moynihan its first president. The society had the backing of a number of distinguished men in the Church and in the medical profession. Soon after it had come into being it promoted a Bill which was introduced in the House of Lords in 1936. Last year considerable interest was once more raised in this matter when a medical man in the U.S.A. was on trial for murder because of a "mercy killing" of a patient said to have incurable cancer. Last week a further debate in the House of Lords on the motion of Lord Chorley showed that the interest in this question is by no means abated, and also, too, that the House of Lords is still unwilling to take any steps towards putting a Euthanasia Bill on the Statute Book.

The procedure laid down in the Bill of 1936 was briefly as follows: The patient desiring euthanasia must be over 21 years of age and suffering from an incurable and fatal disease accompanied by severe pain. Application for euthanasia must be made by the patient in writing, on a special form, in the presence of witnesses. The application, accompanied by a medical certificate, must then be sent to a euthanasia referee appointed by the Minister of Health. Before granting permission for euthanasia the referee "must satisfy himself, by a personal interview with the patient and otherwise, that the requisite conditions have been fulfilled and that the patient fully understands the nature and purpose of the application."[1] After the euthanasia referee sends the permit to the patient there is to be a lapse of seven days before the permit is put into execution. Meanwhile the nearest relative has been informed that permission has been granted, and may then appeal to a Court of Summary Jurisdiction on the grounds that one or more of the conditions have not been fulfilled. Euthanasia is to be administered by the medical practitioner named in the permit and in the presence of witnesses. The Bill provided that the Act should be in the hands of the Minister, who should have power to make regulations "(*a*) for the issue to medical practitioners of licences to administer euthanasia; (*b*) prescribing the duties of euthanasia referees and the fees payable to them; (*c*) prescribing the procedure to be followed in administering euthanasia; (*d*) prescribing the various forms to be used."

This bare description of the official procedure to be followed by someone whose anguish of mind would make any objective judgment of his own fate almost impossible is likely to raise less enthusiasm for euthanasia than the eloquent and learned speeches made by distinguished members of the House of Lords in 1936 and again last week. Lord Ponsonby in 1936 based part of his case on instances of suicide "which were not only innocent and laudable but very noble."[2] The introduction of the verdict of "Suicide while of unsound mind" was, he argued, a practice which showed that the law was being stretched. He thought, too, that it was putting far too great an onus on a doctor to leave in his hands the decision to administer a merciful dose of narcotic. Lord Ponsonby pleaded that "we are not opening any door, we are merely unlocking it. We are drawing the bolts by which prejudice and tradition have kept it closed. We want to be as merciful with one another as we are to our own animals."[3]

The view of the medical profession was put in two admirable speeches in 1936 by Lord Dawson and Lord Horder. As cancer was uppermost in people's minds and the one condition from which the relief of euthanasia would be sought above all others, Lord Dawson pointed out that it would be incorrect to say that most cases of cancer were characterized by agonizing pain. He thought that during the past 50 years there had been a gradual change in medical opinion. Looking back 50 years, he said he thought it was true to say that then the medical profession "concentrated all its endeavours on the maintenance of life, despite the nature of the illness and even despite sometimes the imminence of death."[4] But now the opinion was growing "that one should make the act of dying more gentle and more peaceful even if it does involve curtailment of the length of life." He emphasized that their first thought in the face of incurable disease should be to assuage pain, even if this did involve shortening of life. The Archbishop of Canterbury (the late Lord Lang) thought it was "a situation which must be dealt with from inside, by the confidential relations of the doctor and the patient; not from outside by the procedure which is contemplated in this Bill."[5] Lord Horder, who in essence said last week what he said so well in 1936, observed "that the good doctor is aware of the distinction between prolonging life and prolonging the act of dying." He viewed with misgiving the "suggested intervention of the bureau as replacing that complete confidence and understanding which is one of the most satisfactory of all human relationships." In last week's debate Lord Horder emphasized again that this matter of euthanasia was not really one for the doctor to settle, but that as a doctor he hoped he could give some guidance to those discussing such a settlement; and he made a statement which has special relevance at a time when so many advances are being made in therapeutics. "As to incurability of a disease in general, incurability is the measure at the moment of the doctor's experience of incurability, and those who have the most experience use the term incurability least often, because in Medicine we talk more and more of controlling disease rather than of curing it."[6] Lord Uvedale stressed the possibility of error in diagnosis and saw the practice of euthanasia as something that would disrupt the bond of sympathy and affection existing between the doctor and the patient in a late stage of a disease. Three other medical Peers —Lord Webb-Johnson, Lord Haden-Guest, and Lord Amulree—put the weight of their experience in the same scales against legislation on the practice under discussion.

The subject of euthanasia is one that is bound to stir up emotion and prejudice. It is not something that can be decided by controlled experiment, nor would the legalization of voluntary euthanasia be likely to show an effect on the suicide rate. When the World Medical Association met in New York in October of this year doctors from different parts of the world declared themselves to be in a majority against the introduction of such a practice into Medicine. While it is true that it will be the community at large that has the decision in its hands, the doctors who would have to execute the community's wishes in this matter must have a say out of proportion to their numbers. No one can fail to be impressed by the fact that men of great responsibility in the medical and other learned professions firmly believe that such a measure as voluntary euthanasia should be introduced as a benefit not to be withheld from the man or woman dying from a painful and incurable disease. Yet in the two debates in the House of Lords medical men of the highest eminence and unrivalled experience have given cogent expression to what surely must be the medical man's instinctive attitude. When faced with disease and injury the doctor's job is to relieve pain and to set in motion all methods of treatment that may help him and the patient to bring disease under control. And so little is yet firmly known of the natural history of disease, especially perhaps of cancer, that the pressure on the doctor by patient and relative to seek a way out by euthanasia would introduce a new and disturbing element in the doctor's assessment of a case. Those many medical men who are opposed to legislation on this subject will see much point in the observation made by the Earl of Iddesleigh when he said: "There is something very terrible about this reversal in the morale of the sick-room." A part of the morale of the sick-room in which a person lies dying resides surely in the general belief that the good doctor will distinguish between prolongation of life and the unnecessary prolongation of the act of dying.

CHLORAMPHENICOL NOW AVAILABLE

We print on page 1326 a Ministry of Health statement that from December 11 chloramphenicol will be generally available on prescription. This drug is one of three new antibiotics which have been developed in the United States, and all of them are available without restriction in that country. Owing to shortage of dollars they cannot be made so in Great Britain until manufactured here. The production of chloramphenicol, which is the synthetic form of "chloromycetin," has been undertaken in England with commendable energy, and supplies are now adequate for its release. Plans for the home production of "aureomycin" and "terramycin" are unlikely to mature for some time. Fortunately the indications for all three antibiotics are broadly the same, though there are a few absolute exceptions to this rule and a number of differences in relative efficacy for particular infections. In the Ministry of Health statement of indications for chloramphenicol the expression, "More effective than any of the therapeutic agents at present generally available," presumably refers only to the present position in this country. It is doubtful whether the action of the drug even equals that of aureomycin in primary atypical pneumonia. If experimental infection with this virus in cotton rats is any guide to its behaviour in man, then, according to the findings of Eaton,[1] aureomycin is much the more effective of the two.

An outstanding merit of chloramphenicol is its action in typhoid fever, which naturally comes first on the list of unqualified indications. On the other hand, treatment with the drug does not prevent the persistence of a

carrier state, nor is it of the slightest value in trying to abolish this. Smadel,[2] in a review of the pioneer work on the treatment of typhoid and typhus in which he himself played so large a part, proposes an explanation for this anomaly. The action of chloramphenicol—and indeed of all three newer antibiotics—unlike that of penicillin and streptomycin, is simply to inhibit bacterial growth: organisms are not actually killed even when exposed to high concentrations. It is thus easy to picture the survival of bacilli despite treatment which is fully effective in terminating the disease. According to Rammelkamp[3] the same thing happens when aureomycin is given for haemolytic streptococcal throat infections, for, though the clinical results equal those obtainable with penicillin, the organism is not eliminated. Chloramphenicol is also indicated for salmonella enteritis. But here again a carrier state is apt to persist: it did so in seven out of nine such cases carefully studied at the Children's Hospital, Washington.[4] Among other intestinal infections, only ulcerative colitis is mentioned in the Ministry's statement—as a disease not to be treated with chloramphenicol. There is no mention of infantile gastro-enteritis or of dysentery.

Other unquestionable indications for chloramphenicol—undulant fever, rickettsial infections, psittacosis, and lymphogranuloma inguinale—are all rare conditions. It has been obtainable for these purposes for some time past, and the new uses to which it will now be put, such as the treatment of urinary and respiratory-tract infections generally, are of a less specific nature and call for some discrimination. To direct such treatment intelligently will also require help from the laboratory. It is as well that this is pointed out in the Ministry's statement where urinary-tract infections are listed, particularly since two of the causal organisms mentioned are often resistant to the drug. Although it is excreted in high concentration in the urine much of it is in a combined and consequently inactive form, and sensitivity of the organism to 25 μg. per ml. is a minimum requirement if treatment is to have any prospect of success. Of 19 strains of *Ps. pyocyanea* tested by McLean and his colleagues[5] only six were inhibited by this concentration or less, the remainder being more resistant. Hewitt and Williams[6] and Garvey and his colleagues[7] report respectively 93 and 21 cases of urinary-tract infections treated with chloramphenicol, and in both papers unsatisfactory results are recorded in infections due to *Ps. pyocyanea* and, to a less extent, *Proteus*. *Bact. coli* and *Bact. aerogenes*, on the other hand, were found sensitive both *in vitro* and *in vivo*.

It is to be hoped that the drug will not be used indiscriminately for urinary-tract infections. Laboratory evidence of its potential efficacy should be obtained first, and the same is true of multiple infections elsewhere, particularly in the air passages. As a general rule chloramphenicol is more effective than aureomycin for Gram-negative infections, whereas the reverse holds for Gram-positive infections. Thus, as the statement says, the drug indicated for penicillin-resistant staphylococcal infection is aureomycin. In so far as this applies also to pneumococci and streptococci generally—and the indications are that it does—chloramphenicol cannot be expected to give results as good as those obtainable with aureomycin in miscellaneous infections in which such organisms are concerned. There will doubtless be a strong temptation to try chloramphenicol when penicillin has failed in fever of unascertained cause, but this sort of blind therapy is to be deplored until every possible diagnostic aid has been exhausted. Even should fever abate during treatment the diagnosis is still unmade, and there is no knowing how long the drug should be continued. It will be most unfortunate if chloramphenicol comes to be regarded by the public as the latest wonder drug, and to be demanded by patients themselves because they have read sensational accounts of its powers. There is no appeal for economy in the Ministry of Health's statement, but it should perhaps be known that the drug is expensive: adequate treatment costs at least a pound a day.

Chloramphenicol is taken by mouth. Since excretion is comparatively slow, four doses a day are enough. The total daily dose used has been 4 g. or even more in severe infections and sometimes less in less serious conditions. No serious toxic effects have been reported except the occasional occurrence of granulocytopenia. Vascular collapse occurring during the treatment of typhoid fever with chloramphenicol has been attributed to the rapid liberation of potent endotoxins.[8] Minor unpleasant effects are anorexia and dryness of the mouth. Administration to children who cannot swallow capsules presents difficulty, since the drug is exceedingly bitter.

PROFESSOR E. D. ADRIAN, P.R.S.

Since the Royal Society was founded in 1662, eight of the 48 presidents have been medical men, the last being Sir Henry Dale, who was elected president 10 years ago. The medical profession is proud that once again one of its distinguished members has been elected to this, the highest, office in British science, and will extend its warmest congratulations to Professor E. D. Adrian, who was elected P.R.S. on November 30.

Adrian has been professor of physiology at Cambridge since 1937, when he succeeded Joseph Barcroft. World-wide recognition was given to his work when in 1932 he shared with Sir Charles Sherrington the Nobel Prize in

[1] Article signed A. V. H. in *St Bart's Hosp. J.*, April, 1937.

physiology and medicine, and in 1942 he became one of those select few to join the Order of Merit. Among his many other distinctions was the award of the Gold Medal of the Royal Society in 1934 and of its Copley Medal in 1946. Adrian, who was a King's scholar at Westminster School, showed that this was not necessarily a bad introduction to science when he achieved what is believed to be a record of obtaining first-class honours in five separate subjects in the Natural Science Tripos at Cambridge.[1] After an interlude at St. Bartholomew's Hospital and the Hospital for Nervous Diseases at Queen's Square, Adrian returned to Trinity College as a Fellow in 1913. There he began with Keith Lucas his investigations into the fundamental nature of the activity of the nerve cell, which made his laboratory a centre of research in electro-physiology. During the war of 1914–18 Adrian and Keith Lucas were looking into the possibility of using the thermionic valve for the detailed investigation of the electrical activity which is associated with nervous action. After Lucas's death in 1917, while flying, Adrian carried on those researches which have so vividly illuminated the nature of nervous activity. It was not until he had reinvestigated the discoveries of Berger that all the implications of changes in brain potentials were fully and widely appreciated, which led, among other things, to the clinical use of the electro-encephalogram.

Adrian inherited and enriched the Cambridge tradition of manual dexterity and subtlety in experiment. His lectures to Cambridge students on the physiology of the nervous system were enlivened by constant reference to clinical neurology, reflecting his experience in this specialty during the 1914–18 war. Professor A. V. Hill,[1] writing in 1937, summed up Adrian's work thus: "To have given a new quantitative basis to nervous behaviour, to have shown that afferent or efferent effect in any given neurone depends on the pattern in time of the impulses which travel in it, is the great achievement of Adrian's recent work. In it he and his pupils have explored the activity of the single neurone, the single sensory end-organ, the single muscle group, their excitation, their adaptation, their fatigue." By his work on the basis of sensation and on the nature of nervous activity, Adrian has broken down still one more barrier which lies between man and the knowledge of his own nature.

TUBERCULOSIS AS A PRESCRIBED DISEASE

Dr. Edith Summerskill, Minister of National Insurance, stated in Parliament last week that she has accepted the recommendation of the Industrial Injuries Advisory Council that tuberculosis should be a "prescribed" disease. Section 55 of the National Insurance (Industrial Injuries) Act, 1946, lays it down that "a disease or injury may be prescribed . . . in relation to any insured persons if the Minister is satisfied that (*a*) it ought to be treated, having regard to its causes and incidence and any other relevant considerations, as a risk of their occupations and not as a risk common to all persons; and (*b*) it is such that in the absence of special circumstances the attribution of particular cases to the nature of the employment can be established or presumed with reasonable certainty." When the Industrial Diseases Subcommittee of the Industrial Injuries Advisory Council was asked to consider and advise on the question whether tuberculosis (and other communicable diseases) should be prescribed as an industrial disease of nurses and other health workers it was set a very difficult task. However, in spite of the difficulties the council has succeeded in bringing out a concise and informative report[1] with a number of cut-and-dried recommendations on which the Minister has already acted. It is doubtful if any will disagree with the general recommendations that diseases due to tuberculous infection might properly be prescribed under the Act in so far as they affect persons "having close and frequent contact with the infection by reason of their employment." The conditions under which the disease may be presumed to be due to the nature of the employment are clearly laid down. But the council was quite definite in stating that the attribution of particular cases of the disease to the nature of the employment could not be established, as distinct from presumed, with reasonable certainty except on rare occasions. In reaching decisions of such importance the council was helped by the evidence put before it by many expert witnesses. Earlier this year the Council of the B.M.A. approved a memorandum[2] on this subject prepared by a committee under the chairmanship of Dr. R. R. Trail, and this memorandum was formally submitted to the Industrial Diseases Subcommittee of the Industrial Injuries Advisory Council. The recommendations of the latter body are in close agreement with those of the B.M.A. committee.

It is of course to be expected that some of the points of detail in this report will give rise to controversy. In fact there will be many who will agree with the interesting and practical note by Mr. T. A. E. Layborn, dissenting from a recommendation of the council that the disease may be presumed to have been contracted at work for as long as two years after employment ceased. He also considers that there should be a definite minimum qualifying period of six months' employment (the council's recommendation is six weeks) before the presumption is permitted that the infection was a result of previous employment. No doubt some will question the council's view that it is impracticable at present to insist that claimants under the Act should have had a pre-employment tuberculin test. Other problems which the council had to face were the definition of tuberculosis and what is meant by "close and frequent contact." Those who consider that the primary infection is all-important and that subsequent disease is due to endogenous exacerbation will support Mr. Layborn's comment that "circumstances quite unconnected with nursing and

[1] *Tuberculosis and Other Communicable Diseases in Relation to Nurses and Other Health Workers*, Ministry of National Insurance, 1950.
[2] *British Medical Journal*, 1950, 1, 484.

other health work are responsible for the great majority of cases of the disease," and they may feel that the council has not given sufficient weight to this view. Nevertheless the wisdom of the report outweighs these debatable details, and it will bring much satisfaction to all tuberculosis workers. Though industrial injury benefits are higher than those for ordinary sickness under the National Insurance Act, there is some uncertainty about the effect of "prescribing" tuberculosis on nursing recruitment. Some potential entrants to the profession may now have a greater sense of security, while others may be put off by the possible danger. The council has shown good judgment in refusing to recommend "block" prescription of other communicable diseases. It appreciates that the recommendations about tuberculosis will have wide repercussions, and it prefers to await developments before extending the concessions.

EMOTIONS AND THE SKIN

Clinical reports on the association between urticarial rashes and emotional changes have been quite frequent since 1935. A recent report by Graham and Wolf[1] is interesting, because clinical examination was combined with experimental investigation. The subjects were 17 women and 13 men who had had repeated attacks of urticaria, showing either as superficial weals or deeper and more diffuse swellings. Some had an itching blotchy erythema with pronounced dermographism. A fairly complete life history was obtained from each patient, with particular attention to exposure to possible antigens and the emotional aspect of situations in which attacks of urticaria were known to have occurred. The patients were then asked to discuss these situations, while observations were made on skin temperature and the reactive hyperaemia threshold. To carry out the latter test a weight is applied to the skin long enough to cause a zone of erythema (due to dilatation of the minute vessels) to appear after removal of the weight, the time being measured. This is a test of the tonus of the vessels and not of their calibre. Skin temperature, on the other hand, is dependent on the dilatation or constriction of the arterioles. Room temperature was kept constant throughout the experiments. In a number of cases the authors also tested the sensitivity of the skin to pilocarpine and histamine introduced electrically by iontophoresis. In 29 out of the 30 cases there was an invariable relation between past attacks of urticaria and the emotional state at the time. Curiously, there was no important association with foods or other antigens. The nature of the emotional state was also specific. Emotions of anxiety, hostility, grief, or dejection were not directly associated with attacks of urticaria, but the prominent emotional state was one which might be called resentful frustration. At the time when the attack happened the patients had felt themselves "on the spot" in some way and unable to do anything about it. The authors' experiments confirmed this impression. They recorded the emotional state on graphs—through self-consciousness, anxiety, tears, and dejection to resentment—as the patient discussed his preoccupations in the course of the interview; and, whereas other emotions caused little change, when resentment was felt the skin temperature rose, the tonus of minute vessels fell, and the patient might even start to scratch. Other emotions were not entirely without effect; anxiety tended to cause an increase in minute vessel tone and delay of flushing after pressure, and dejection was associated with a fall in minute vessel tone and also a fall in skin temperature, probably due to arteriolar constriction.

The authors make an interesting point when they say that, while they were able to establish a relation between urticaria and a particular mental state, they were often unable to understand just why the patient had taken that emotional attitude. Often enough when the patient explained that "there was nothing I could do," it seemed to the observer that, in fact, a good many things could have been done. The patients, as a whole, not only failed to express hostility but tended not even to feel it. In the past they had adopted rather a passive attitude to punishment from parents or superiors. Some of the women found hostility unacceptable in terms of their standards of proper behaviour. An attack of urticaria sometimes occurred while a patient was pondering on his problems, but at such times there was an absence of aggressive fantasies. On the other hand there was no general lack of initiative and energy of character; the passivity was shown only in meeting external hostility. Physiologically urticaria is due to an increased tendency to vascular dilatation both in the arterioles and in the minute vessels. Graham and Wolf do not find it necessary to postulate the local liberation of histamine. The permeability of the vessels increases as they dilate, until the point is reached where exudation occurs. Local stimulation—for instance, the rubbing of a collar—may decide the actual place of appearance.

To a certain extent these experiments run counter to prevailing clinical opinion, which would ascribe an important role to the emotion of hostility in provoking urticaria. It is in any case a little difficult to distinguish between hostility and resentment. Nevertheless it is investigations of this kind that aid in the exploration of psychosomatic relationships. Elsewhere in this issue we publish a report by Drs. H. J. Shorvon, A. J. Rook, and D. S. Wilkinson on the treatment of skin disorders by inducing emotional release through "drug abreaction." Much has yet to be learned about the indications for this treatment, but the fact that such encouraging results have already been obtained not only confirms the importance of psychological factors in precipitating certain skin disorders but shows that psychiatric treatment is far from impracticable. An interesting finding was that after abreaction some patients were able to reduce to reasonable proportions symptoms which had come to assume an overwhelming significance for them. Increasing knowledge of the pathogenesis of such obscure conditions as the neurodermatoses should help in another direction. One of the greatest weaknesses of psychiatric observations is that they have to be expressed so largely in ill-defined qualitative words and phrases. If we could redefine such psychological expressions as "anxiety" and "depression" in physiological terms and begin to measure differences between patients and in the same patients at different times it would go far to clear away present obscurities.

REFRESHER COURSE FOR GENERAL PRACTITIONERS
THE TREATMENT OF VARICOSE VEINS

BY

REGINALD T. PAYNE, M.D., M.S., F.R.C.S.

I heard two beggars that under an hedge sate,
Who did with long talk their matters debate.
They had both sore legs most loathsome to see,
All raw from the foot well most to the knee.
"My leg," quoth the one, "I thank God is fair."
"So is mine," quoth the other, "in a cold air,
For then it looketh raw and as red as any blood,
I would not have it healed for any world's good.
No man would pity me but for my sore leg,
Wherefore if I were whole I might in vain beg.
I should be constrained to labour and sweat,
And perhaps sometime with scourges be beat."

ROBERT CROWLEY, *Epigrams, c.* 1550.

Idiopathic varicose veins are common in all sections of the community, and every general practitioner is faced with the problems of diagnosis and treatment. Sometimes he must take full responsibility, while in other cases treatment can be carried out successfully only in conjunction with a specialist. The results will be gratifying if diagnosis is accurate and the scope of treatment recognized.

The consultant tends to see the most advanced cases and other people's failures. In some there has been a non-recognition of threatening complications or the true origin of a dermatitis. In others treatment has failed because of ignorance of the anatomical territories of the internal and the short saphenous veins. Some failures are due to the giving of injections in quite unsuitable cases, others to giving inadequate injection treatment in suitable cases. The treatment of ulceration, phlebitis, etc., may prove unsuccessful through the omission of necessary surgical measures.

The treatment and management of limbs in which there is varicosity or enlargement of the superficial veins secondary to obstruction or thrombosis of the deeper veins are not considered here. Such cases should be eliminated by a careful history and a full clinical examination.

Diagnosis

Treatment should not be undertaken without an adequate medical history and a careful examination.

History.—It is important to know the patient's age, the age at which the veins developed, their speed of progress, the effect of any pregnancies, the nature of any complications, the details of past treatment, and the nature of the present disability. The character of the patient's work and other physical activities should be ascertained.

Past History.—Information must be sought about the patient's previous health. Has there ever been typhoid fever or any other possible cause of deep thrombosis? Is there a history of skin disease, of peripheral arterial disease, or of other disability of the lower limbs?

Family History.—A family history of varicose diseases occurs in approximately two-thirds of the cases, and a bad history has an important bearing upon the question of treatment. The practitioner who embarks upon the treatment of a familial case in which the veins have started at an early age and have progressed rapidly with successive pregnancies will gain little credit from injection treatment.

Physical Signs.—A general examination is advisable if systemic disease is suspected. Both lower limbs must be examined and the general condition of the skin and subcutaneous tissue determined. More detailed information about the size, thickness, and tortuosity of the veins can be obtained by palpation. Varicosity of the short saphenous vein (Fig. 1) is apt to be overlooked, and examination for this should always include the region behind the external malleolus.

The various tests for venous incompetence should be carried out. These include the determination of a well-defined impulse on coughing or percussion of the vein, and Trendelenburg's test. Special attention should be directed to the skin. There may be thinning in relation to actual varicosities or congestion of the lower and inner part of the leg when the internal saphenous vein is incompetent.

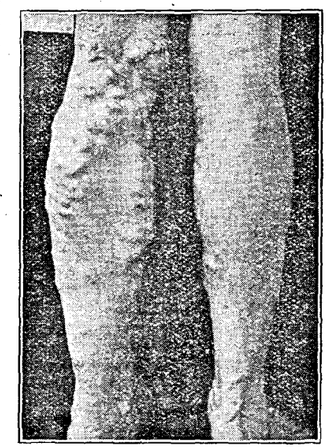

FIG. 1.—Posterior aspect of legs showing varicosity of left internal and short saphenous veins.

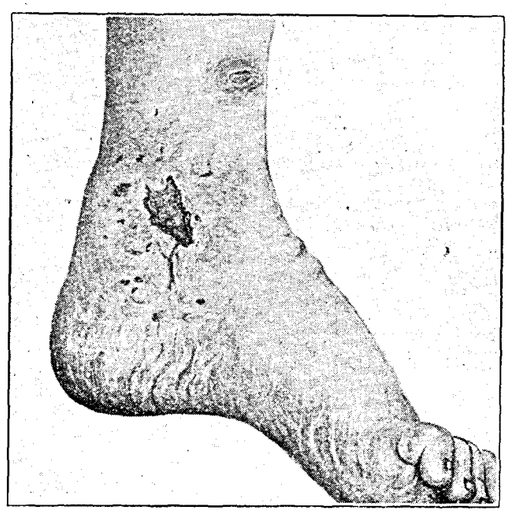

FIG. 2.—Chronic varicose ulceration in region of right external malleolus, associated with incompetence and varicosity of short saphenous vein.

Details of any phlebitis, eczema, ulceration, or oedema must be noted, and the relationship of these complications to the underlying veins determined (Fig. 2). The horizontal position is best when examining an area of suspected phlebitis.

It is advisable also to know whether the arteries are clinically normal in the feet, and the latter should be examined for deformities such as hallux valgus, corns, etc. The type and suitability of shoes should be noted.

Principles of Treatment

The practitioner must know what may be reasonably expected from the various methods of treatment. Relief may be obtained in uncomplicated cases by supports, by injections, by operation, or by a combination of operation and injection. Varicosities below the knee, especially when thin-walled, respond well to injections. If, however, the internal saphenous vein is incompetent in the thigh, or if the veins are relatively straight and thick-walled, then thrombosis will be uncertain and recanalization likely. Operation, or operation and injection, will be needed in these cases.

In complicated cases it is essential to know the extent and nature of the underlying varicose veins. If these are of a type likely to respond to injections, then injection will have to be incorporated in the scheme of treatment. If, on the other hand, the veins require operative treatment, then the complications will have to be dealt with and the appropriate surgical treatment carried out. The ideal to be aimed at is the cure of complications, the obliteration of incompetent veins, and the restoration of a limb which requires no permanent support.

External supports are indicated only in uncomplicated cases when other treatment is not possible or advisable, or as a temporary measure during injection treatment. The various types of crêpe bandages can be extremely helpful, but all too frequently these are applied in such a way as to give little support to the limb. Elastic stockings must fit accurately, and should be fitted by the suppliers. Measurements for them should be taken first thing in the morning.

Injection Treatment

Many drugs have been used as sclerosing agents, but quinine–urethane is one of the most certain. It must be used only by those familiar with intravenous technique, as leakage into the tissues may produce necrosis. The veins should be distended by a light rubber tourniquet, and then the patient should lie horizontally on a couch in a comfortable position. Treatment should start in the distal veins and one injection should be given at each sitting. The initial dose should be 0.5 ml., and subsequent dosage should not exceed 2 ml., depending upon the size of the vein. Local reactions are usually moderate, except when the veins are very thin-walled or very large. Mild general quinine reactions occasionally occur in women. Large veins should be treated at intervals of five to seven days, while smaller veins may be treated at intervals of two or three days. A crêpe bandage may give support during the treatment of large veins.

Cases for operation will not normally come under the care of the general practitioner, but post-operative injections may be required. Occasionally excellent results are obtained in those borderline cases in which surgery would appear to be preferable but in which for one reason or another it is decided to test the efficacy of injections.

Phlebitis

Phlebitis in the lower limbs is invariably due to varicose veins and is secondary to venous stagnation and nutritional impairment of the vein wall. The diagnosis will be established by the history and by the presence of varicosities and a tender subcutaneous swelling, with fixation and discoloration of the overlying skin. Oedema may be marked in massive thrombophlebitis.

The objects of treatment are: (1) to prevent spread of the thrombosis in the superficial varicose veins; (2) to prevent spread of the thrombosis to the deep veins with the risks of pulmonary embolus; (3) to control oedema; (4) to improve the circulation; (5) to control infection if present; and (6) to prevent recurrence.

Anticoagulants will not be discussed here, as these will not normally be used in cases under the general practitioner's care. The following are the main types of phlebitis.

Local.—In mild or moderately severe cases the leg should be enclosed in "elastoplast" and a pad incorporated immediately above the upper limit of the thrombosis. Moderate activity should be permitted, although fatigue must be avoided. The elastoplast should be changed at weekly intervals and should be continued until the local inflammatory changes have disappeared.

Spreading.—Ligation of the internal saphenous vein at the saphenous opening may be indicated in cases with ascending thrombosis in the thigh.

Recurrent and Chronic.—Most of these cases show saphenous incompetence in the thigh, and operative treatment is necessary after the acute attack has subsided.

"Sock" Phlebitis.—In this condition there is much periphlebitis with extensive woody induration of the tissues of the lower part of the leg. Resolution occurs with prolonged elastoplast treatment, but operative treatment of the veins is usually required to prevent recurrence.

Infective Thrombophlebitis.—These cases are usually streptococcal and associated with high fever, rigors, and acute inflammatory signs. Penicillin and saphenous ligation are indicated.

Diagnosis may be difficult when the veins are embedded in a large amount of fat. Conditions such as thrombophlebitis migrans, thrombo-angiitis obliterans, etc., should be considered when thrombosis occurs in apparently normal veins.

The use of external supports may be needed temporarily after the acute phase has subsided. When operation is indicated this should be carried out during a quiescent interval. If injections are indicated these should not be started until at least six months after the attack of phlebitis.

Eczema or Dermatitis

Typically varicose eczema starts in the lower third of the leg, in relation to old-standing areas of congestion, but it may develop over varicosities anywhere or be secondary to ulceration (Fig. 3). Long-continued eczema leads to sensitization of the skin and involvement of other parts of the body. Recurrence is inevitable if the varicose origin of the eczema is not recognized.

Curative treatment involves treatment both of the eczema and of the veins. It is essential to decide whether the veins can be cured by injections or by operation. Elastoplast should not be used on patients with eczema.

Mild Cases.—Local treatment will usually cure small areas of dry eczema. An ointment of equal parts of zinc oxide ointment and soft paraffin should be applied daily and the affected region covered with as little dressing as possible. The old ointment should be cleaned off with liquid paraffin at each daily redressing. Some cases respond well to "siccolam," but very little must be applied and the new ointment should be put on the top of the old. No other dressing is necessary. A mild "sphagnol" ointment often proves helpful, and *x*-ray treatment is invaluable in old-standing cases. If injections are indicated these may be carried out during the treatment of the eczema.

Severe Cases.—When the eczema is extensive or severe, treatment should be on the above lines, but combined with a period of absolute rest in bed, with the lower end of the bed elevated. In many cases there are indications for operation. This can be carried out under penicillin cover after rest and local treatment have controlled the eczema.

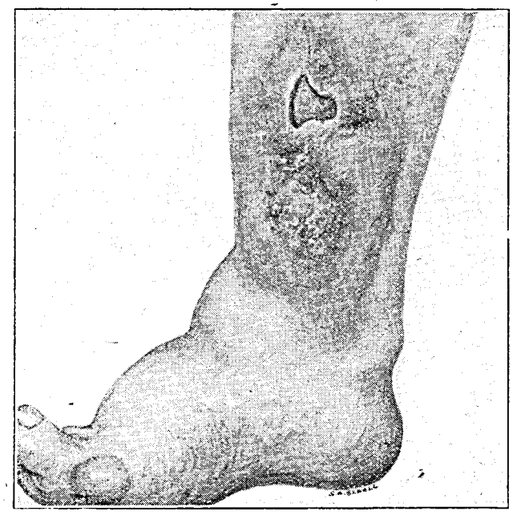

FIG. 3.—Chronic varicose ulceration with scarring, pigmentation, and eczema.

Varicose Ulceration

There are many methods of treatment of varicose ulceration. I have gradually come to the conclusion that long-standing cases are best treated by operation if sound healing of the ulceration and a useful limb requiring no external support are to be secured. The special indications for operation are either incompetent veins in the thigh, incompetent communicating veins in the calf, or incompetent thick-walled veins.

Cases Suitable for Injection.—If the veins are of a type suitable for injection, then treatment must be built around this, and small and early ulcers may be cured by this measure alone. Most cases, however, require a combination of injections and external support. Injections should start distally and as near the ulcerated area as is safe, and the limb should be enclosed in elastoplast below the knee. This should be changed weekly and a further injection given. Elastoplast treatment should be continued for about three weeks after the ulceration has healed and it should be followed by the use of a crêpe bandage for a further three to four weeks.

Cases Suitable for Operation.—The ulceration is healed by postural treatment before carrying out surgery. This involves a period of absolute rest in bed, with the lower end of the bed raised on 8-in. (20-cm.) blocks. The ulcerated area should be dressed with an ointment of equal parts of zinc oxide ointment and soft paraffin, and covered with light gauze dressing. Fresh ointment is applied daily after cleaning off the old ointment with liquid paraffin. The oedema and pain rapidly clear up, and a foul infected ulcer is converted to a clean granulating wound which heals steadily. Penicillin cover has made operation possible immediately healing has occurred. This method of treatment may also be used as a preliminary to injections or permanent supports.

The various types of adhesive dressings cannot be considered, nor can the treatment of very complicated cases be discussed in which there is ulceration, eczema, chronic phlebitis, and bone change. There are two points which may be of some value to the general practitioner. The first is that, although penicillin applications may sterilize an ulcer, they will not necessarily lead to healing, and may, exceptionally, cause a generalized skin eruption. Secondly, rashes may follow the prolonged use of ointments containing sulphonamides.

Haemorrhage

External haemorrhage may arise either spontaneously from thin-walled and congested malleolar varicosities, or it may result from injury. In either case the blood loss may be rapid and considerable. Immediate elevation of the limb must be followed by a firm local dressing. Ulceration may develop at the site of the haemorrhage. Subsequent treatment of the veins is indicated.

Internal haemorrhage may occur. Spontaneous cases result from the rupture of minute subcutaneous vessels, and active treatment is rarely needed. Traumatic haemorrhage may occur when a large vein is torn but the skin remains intact. A small haematoma may resolve satisfactorily with elastoplast treatment, but a large one may require evacuation. Traumatic thrombosis may lead to an extending phlebitis.

Pregnancy

Varicosities usually start about the second or third month of pregnancy. Rapid progress often occurs when there is a bad family history of varicose diseases, and especially when varicosities have started at puberty. Uncomplicated varicosities do not cause oedema, but may be associated with other causes of swelling of the lower limbs. The degree of discomfort produced is partly an individual factor and partly related to the speed of development of the varicosities. Generalized skin congestion and discoloration may be marked. Vulval varicosities and piles may also develop.

Active treatment is not often advisable, because success is unlikely owing to the speed of development of the condition. If local symptoms are marked or if the veins are large, then crêpe bandages or elastic stockings should be worn and an afternoon rest taken if possible. Injection treatment should be regarded as quite exceptional, and quinine should not be used. The veins usually show considerable improvement after delivery, but they never return to the condition they were in before the pregnancy. After the baby has been weaned active treatment should be carried out in keeping with the general principles already indicated. Every subsequent pregnancy tends to aggravate existing varicose veins, and thus increases the risks of subsequent complications. If active treatment has been carried out and a further pregnancy is desired, then such treatment should be completed well before the pregnancy starts, and should be safeguarded by wearing a below-knee stocking throughout the pregnancy.

In a leading article in the *Journal of the American Medical Association* (September 9, 1950, p. 182) it is estimated that the minimum cost to medical students of attending medical school for one academic year, including the cost of tuition, other fees, books, equipment, all essential living, and travel, ranges from $567 (£202 at the present rate of exchange) to $2,252 (£804), with a median of $1,473 (£526).

Walter Stoneman, London.]

PROFESSOR E. D. ADRIAN, O.M., M.D., F.R.C.P., P.R.S.

Professor E. D. Adrian, who in 1937 succeeded the late Sir Joseph Barcroft in the chair of physiology at Cambridge, was elected President of the Royal Society on November 30, being the ninth medical man to occupy this position (see also leading article at p. 1320).

DISTRIBUTION OF CHLORAMPHENICOL (CHLOROMYCETIN)

From December 11 all doctors will be able to prescribe chloramphenicol ("chloromycetin") for their private or N.H.S. patients. The Ministry of Health has issued the following statement (see leading article on p. 1319):

Owing to improvement in supplies, chloramphenicol (chloromycetin) will be generally available on prescription from December 11. The following provisional lists are intended as a guide to practitioners in prescribing this antibiotic.

There are certain infections (list 1 below) in the treatment of which chloramphenicol is more effective than any of the therapeutic agents at present generally available. Apart from these there is a variety of infective conditions (list 2 below) in which the value of treatment is less certain; preliminary trials both in this country and abroad have given variable results, and further experience is needed before chloramphenicol can be recommended as routine treatment in these diseases. In certain diseases (list 3 below) there is no satisfactory evidence that chloramphenicol has any therapeutic value.

1. *Infections in which the Therapeutic Value of Chloramphenicol is Superior to that of Sulphonamides or Penicillin.*—Typhoid and paratyphoid fevers (excepting carriers), brucellosis (undulant fever); rickettsial diseases—i.e., typhus, scrub typhus, Q fever; psittacosis; lymphogranuloma inguinale; atypical (virus) pneumonias; urinary tract infections resistant to sulphonamides and penicillin (these include infections due to resistant strains of *B. coli, B. proteus, Ps. pyocyanea,* and *Str. faecalis.* Sensitivity of the organism to chloramphenicol should be determined).

2. *Infections in which Therapeutic Benefit from Chloramphenicol has been Reported but not Fully Substantiated.*—Whooping-cough, salmonella food-poisoning, *H. influenzae* meningitis.

3. *Infections in which there is no Satisfactory Evidence of the Therapeutic Value of Chloramphenicol.*—Influenza, the common cold, poliomyelitis and encephalitis, tuberculosis, syphilis, ulcerative colitis.

Chloramphenicol is probably effective in a number of pyogenic infections, such as bacterial pneumonias, gonorrhoea, and peritonitis, but it is doubtful whether it is as effective as penicillin or sulphonamides. In bacterial endocarditis due to organisms which are penicillin-resistant, chloramphenicol is probably inferior to a combination of streptomycin and penicillin. An exception to this is bacterial endocarditis due to penicillin-resistant *Staph. pyogenes*; for this, as for any severe penicillin-resistant staphylococcal infection, "aureomycin" is the antibiotic of choice.

It should be noted that chloramphenicol in the powdered form has an extremely bitter taste. It is not, therefore, easily administered to young children who will not swallow capsules.

THE BLAIR-BELL MEDAL

PRESENTATION TO PROFESSOR MUNRO KERR

The first Blair-Bell medal of the Royal Society of Medicine, awarded quinquennially for the advancement of science in gynaecology or obstetrics or both in the preceding five years, was presented to Professor J. M. Munro Kerr in the presence of a distinguished company on November 30. The medal was designed by Mr. Carter Preston.

Lord Webb-Johnson, President of the Royal Society of Medicine, said that he had not known Blair-Bell as well as he would have liked, but he well knew his brother, who wore himself to death in the service of the wounded in the first world war. It was a delight to see many members of Blair-Bell's family present on this occasion. The medal was a beautiful example of the engraver's art. On one side it bore an excellent portrait of Blair-Bell, and on the other a design to represent Juno Lucina, the chief goddess of childbirth. He spoke of his great admiration and affection for the first recipient of the award.

Mr. V. B. Green-Armytage, President of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine, and Professor Hilda Lloyd, President of the Royal College of Obstetricians and Gynaecologists, then presented Professor Munro Kerr to Lord Webb-Johnson. In doing so, Mr. Green-Armytage said that for over 50 years Professor Munro Kerr had adorned and embellished their profession; during that time he had stimulated countless students—undergraduate and postgraduate—and had earned the regard and affection of countless colleagues. When it was learned that Professor William Blair-Bell had left £500 to the Royal Society of Medicine to establish a medal to be given every five years to the man or woman who had done most to advance science in gynaecology and obstetrics it was the unanimous vote of their Section of the Society that the first recipient should be their guest of that evening.

Professor Munro Kerr, after receiving the medal at the hands of Lord Webb-Johnson, said how deeply he was touched and how greatly he prized the honour. When he heard that this honour had been given him he wondered what some of his old colleagues now in the Elysian fields would say about it. Probably they would say that it was only what was to be expected in the case of a Scot, long-lived and persistent.

He appreciated the medal the more because it had been handed to him by a great surgeon. The relationship between surgeons and gynaecologists had not always been so friendly and amicable as it was to-day. When he looked back to the 'eighties, at the time when he was a student, he recalled that gynaecologists were recruited from old obstetricians who had very little experience of abdominal surgery. They had one such in Glasgow, a very erudite man, and a good obstetrician, who had been a medallist in anatomy, though when he came to know him he was an accepted authority on seaweed.

He thanked Mr. Green-Armytage, a friend of many years' standing, and Lord Webb-Johnson for the kindly words with which they had introduced him to the company, and he associated with the thanks Mr. Geoffrey Edwards, the secretary of the Society, who had arranged this occasion and who himself was celebrating his 25 years' association with the Society.

Reports of Societies

SYMMETRICAL CORTICAL NECROSIS OF KIDNEYS

At a meeting of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine on November 17, with Dr. V. B. GREEN-ARMYTAGE in the chair, a paper was read on symmetrical cortical necrosis of the kidneys.

Professor H. L. SHEEHAN, of the Department of Pathology, University of Liverpool, said that the great majority of these cases arose from concealed accidental haemorrhage in pregnancy. In studies of a large series of kidneys in women who had died after concealed accidental haemorrhage, some of them a few hours after the haemorrhage and others a few days later, all the stages of different renal lesions could be seen, from very slight and minor degrees of damage up to complete cortical necrosis. The cause of the kidney damage was ischaemia, due to temporary arrest of the circulation to the renal cortex at the time of the accidental haemorrhage or soon afterwards, followed, on the restoration of blood flow, by the development of necrotic changes and the formation of thrombi.

He divided the renal lesions into nine grades. The first grade, illustrating the slightest lesion, was a condition of proteinuria, brought about by a spasm of the afferent arterioles which lasted, perhaps, a quarter of an hour. All that resulted from the spasm was a certain amount of damage to the filtration mechanism of the glomeruli. To the naked eye the kidney in this grade showed no marked abnormality, and there was usually a return to normal within one or two days. The second grade was signified by colloid degeneration in the epithelium of the proximal convoluted tubules and colloid casts in the intermediate zone. Here again the patient had a spasm affecting the afferent arterioles, lasting for possibly an hour. The epithelium of the tubules was partially damaged and developed a series of degenerative changes. Usually with a Grade 2 lesion there was a return to normal within two or three days.

In the third grade there was necrosis of the proximal convoluted tubules. Here the spasm lasted a good deal longer, probably for two or three hours; there was necrosis of the proximal convoluted tubules, though the other structures of the kidney, being less sensitive, survived. In most of the tubules the epithelium began to regenerate after about three days. At this grade there was obviously a severe impairment of renal function. The fourth grade was marked by benign thrombosis of the glomerular capillaries. The spasm of the afferent arterioles here continued longer, and the tubular necrosis was more widespread. The thrombi, however, did not occlude the capillary lumen. The fifth grade showed focal cortical necrosis, with the glomeruli themselves damaged, and thrombosis in the arterioles. The initial spasm in the greater part of the cortex lasted from two to four hours, and in the few small foci from eight to ten hours. The subsequent course was healing of the small focal lesions if the degree of proximal tubular necrosis was not too great to allow the patient to survive.

The sixth grade he had entitled "minor cortical necrosis." It was here that arterial lesions as distinct from lesions of the arterioles began to play a part. Spasm lasted in the distal part of the arteries for eight or twelve hours, killing the glomeruli and parts of the cortex in the area. When the arteries relaxed, and the blood opened up with sufficient pressure, there quickly developed necrosis and dilatation in these dead arteries. The seventh grade consisted of patchy cortical necrosis. The spasm developed about the mid-point of the intralobular artery. After relaxation of the spasm thrombi appeared in the necrosed artery at about 18 or 24 hours. So much kidney tissue was lost as a result of the widespread and prolonged ischaemia that chances of recovery were very poor.

The eighth grade was marked by gross cortical necrosis, with spasm occurring low down in the intralobular artery, cutting off the whole blood supply to the cortex, all structures in the ischaemic area being necrosed. When arterial spasm relaxed, the whole arterial tree dilated, and necrotic changes and thrombus of the usual sort developed. The final grade showed gross cortical necrosis of a most severe kind. In a schema which Professor Sheehan showed, out of 1,000 cases of concealed accidental haemorrhage it was estimated that 105 had changes corresponding to Grades 4 to 9. Among these 1,000 cases there were 64 deaths on the first day, 44 deaths later in the puerperium, and 892 recoveries.

In the ensuing discussion Dr. A. M. JOEKES described 10 cases of cortical necrosis of the kidneys, five of them fatal, and three with prolonged and two with short-term oliguria. In the five non-fatal cases the course of recovery of renal function was identical. Ability to concentrate urine was recovered in anything up to a fortnight after onset. There was no fundamental difference in the ischaemia resulting from cortical necrosis, nephron necrosis, or tubular damage; the difference was only one of degree. He stressed the impossibility of diagnosing with certainty a complete cortical necrosis; therefore all cases must be treated on the assumption that there was a recoverable renal lesion.

Professor KENNETH FRANKLIN said that he had wondered whether other renal troubles of pregnancy had not some aetiological basis common to them and to cortical necrosis. Changes apparently comparable had been induced in animals by various experimental procedures. In rabbits experimental renal cortical necrosis was definitely induced by ischaemia. The renal effects occurring in cases of concealed accidental haemorrhage ranged from quite minor changes to full necrosis. There was a certain measure of renal cortical blood-flow diversion a little before term. The contraction of the abdominal muscles with the onset of labour must also be borne in mind. It could be visualized how, under the various influences which were brought to bear, cortical necrosis or some other renal lesion might develop.

Professor J. F. HEGGIE said that he had seen similar changes to those described by Professor Sheehan. He noted that Professor Sheehan had not suggested a cause for the spasm, and it was very difficult to prove or disprove that spasm occurred, though many writers on the subject had described spasm on the strength of the aetiological evidence.

Mr. G. J. SOPHIAN gave a review of recent literature on the subject. He thought that the work of Trueta and his colleagues had made possible a more rational explanation of what occurred, and it was this which had suggested to him the hypothesis which he had been advancing since 1947 concerning the causation of the major renal disturbance which underlay pregnancy toxaemia. In the laboratory animal faradic stimulation of the renal nerve could result in some degree of cortical necrosis, with visible changes in the cortex. He showed sections illustrating changes noted in the kidney of the rabbit following renal ischaemia.

Dr. R. H. PARAMORE commented on the three main theories put forward—toxins, reflex nervous stimuli, and increased activity of abdominal muscles in parturition—and directed attention to the last of these as having an importance hitherto neglected.

The Ministry of Health has prepared a booklet entitled *Allocation of Pension* explaining the superannuation scheme to medical practitioners and others about to retire from the National Health Service. Copies have been sent to hospital boards and executive councils so that it may be seen by doctors who are about to retire, and it may also be obtained from H.M. Stationery Office for 6d.

Nova et Vetera

FLORENCE NIGHTINGALE'S VIEWS ON THE AGE AT WHICH A YOUNG LADY SHOULD BECOME A NURSE

The letter from Florence Nightingale printed below was written to Sir William Richmond, R.A., about the daughter of a friend of his. It is interesting to record that the subject of this letter, in later life, worked with great devotion among the Kentish hop pickers.

The original lettef, which we publish by kind permission of the present owner, Dr. Arthur M. Ware, is written in pencil.

Oct. 17/87
10, South Street,
Park Lane, W.

My dear Sir,

Your wishes are law to me. And your account of the young lady of 18 who wishes to devote herself as a Nurse is so very interesting.

But have you thought whether 18 is not too young, both physically and morally ?

There are sacred secrets belonging to the sick which 18 could not and ought not to be able to understand—and there are secrets the very reverse of sacred, the secrets of vice, about Patients which their Nurse *must* know if she is not to be made a fool of; and which one shrinks from any young woman, gentle or simple, knowing. (Alas ! the "simple" know them far too soon.)

A gentlewoman, or gentle girl, would either be shocked and run away. Or she would be hardened, which is the worse evil of the two. Then about the physical side—we do not take any one into our Training School at St. Thomas' Hospital under 23—tho' I think we strive to make it a home where the mother of any girl need not object to seeing her daughter.

Whatever you take out of a woman in Nursing life before 23 or 24 you more than take out of her at the other end; indeed you may reckon two years for every one at this end that she loses at the other. Even in Children's Hospitals I believe they take no Probationers under 20. (It is true that the present Matron of St. Thomas' (just appointed) who was Matron of the Great Edinburgh Infirmary for 13 years, came to us before she was 20, and has been in the Service ever since. But the exception proves the rule (This lady is a pearl of the finest water), and I think even she would have better health, had she entered later.)

We even prefer not admitting *gentlewomen* earlier than 26 or 27, for two reasons: one that gentlewomen are younger in *knowingness* than those who have had to rough it: the other that posts of superintendents will be theirs if they persevere in the life* and 24 is too young to superintend.

Having laid these things, as an old Nurse and Trainer, before you and Mrs. Richmond, I will gladly see the young lady whenever we can make an appointment.

Pray do not think that I cry down Hospital life. To me it is the most sacred, the holiest of all. What is the highest character worth but to use it for those who have none ? What is holiness for but to spend it for those who are unholy ? And the lovely things one sees among Patients, the return of good feeling among those who for years have never heard a "good word" would alone make the life a delightful one.

Pardon me for not having answered your note before. I have been so driven both by work and illness since I came back that I have scarcely had time to breathe, and shall be. But in November I hope to have a little more time and to make an appointment to see your maiden fair.

May she run her noble career in life is the earnest wish of yours ever faithfully,

FLORENCE NIGHTINGALE.

How can I thank you enough for your picture of me; for my sister is more than delighted with it ! ! That is what genius can do.

F. N.

W. B. Richmond, Esq.

*i.e., after their year's probation.

Bejel is a childhood-acquired, non-venereal, syphilis-like disease due to treponema and widespread among the semi-nomadic populations of the eastern Mediterranean area. It responds to penicillin, and a Unicef-W.H.O. project in conjunction with the Iraq Government to control it opened in Bagdad in October under the direction of Dr. E. H. Hudson, of Ohio University, Athens, Ohio, an authority on treponematosis.

Correspondence

Economy in the Health Service

SIR,—You deserve the gratitude of all responsible citizens for your excellent leader (December 2, p. 1262). The N.H.S. is facing financial disaster, and in the very near future. This year it is estimated to cost £483m.: if this runs true to form, the actual cost should be well over £500m. Drastic economies *may* save this much-desired service, but it is idle to believe that careful administration and the mere elimination of discovered waste can produce the kind of economies that will bring expenditure permanently within the nation's capacity.

It has been suggested in authoritative circles that some small charge will have to be made throughout the Service; but the nature of the charge and how it is to be imposed are not clear. The issue cannot much longer be shirked. We must be realists and crystallize these rumblings about economy into clear and definite action to produce a better health service at a lesser cost. So I shall venture further and mention at least five sections of the Service in which substantial economies could, and should, be made. These are the administrative, dental, ophthalmic, pharmaceutical, and hospital sections.

The costliness of the dental and ophthalmic services is a matter for grave concern. It may be politically expedient, but it is scientifically wrong and economically unsound to provide dentures and spectacles for octogenarians while allowing the teeth and eyes of the rising generation to be neglected. It is our duty to see that priorities are restored. Dental and ophthalmic benefits were in existence before 1948 under the N.H.I., and were free from abuse. Under this system the patient paid half of the cost for teeth and spectacles; and it may be that we should reconsider this well-tried method for patients who are in full employment.

The pharmaceutical service is worthy of the closest scrutiny. Unfortunately, many people have regarded the N.H.S. as a source of free supplies and not, as they should have done, as a guarantee that no man, woman, or child shall be debarred from receiving free of charge costly, life-saving, and disease-preventing drugs, and drugs necessary for certain chronic illnesses. The Australian Government has profited by our costly mistakes and has prepared a list of these important drugs, some 140 items, which shall be free on a doctor's prescription: but the inessentials of medicine are not included and the public cannot "run riot in the chemist's shop." We should do well to free the N.H.S. in this way from abuses which cannot meet with the approval of responsible citizens.

The cost of the hospital services (£238m.) has shown an alarming increase and is mounting daily. Yet there are no more beds in the hospitals: in fact, there are 50,000 empty beds as compared with 1939. The great cost has been attributed to the increase in administrative, clerical, and medical staffs, and to the present inefficient system of financing the hospitals. The result has been a tremendous increase in the maintenance rate per bed, which in many hospitals has more than trebled since 1948. There should be ample scope here for substantial economies. Furthermore, though the N.H.S. has been widely advertised as a free Health Service it has never been advertised as a free hotel service. So for those who can afford it, and there must be few who cannot in this country of full employment, a reasonable charge of £1 per week should be made for board while in hospital: with over 500,000 hospital beds in the country this should effect a saving of at least £20m. a year.

The need for retrenchment is urgent. Economies on the above lines would, I feel confident, produce a more efficient health service, free from abuse and exploitation on the part of both patient and practitioner. The Minister has invited our representatives to put forward suggestions for economies (*Supplement*, July 8, p. 19), but neither the Council nor the G.M.S. Committee has yet taken any steps in the matter. It may soon be too late to save the Service.—I am, etc.,

Guildford. J. O. M. REES.

Displaced Registrars

SIR,—It seems that the conscience of the profession is causing discomfort. The hardness of the bargain which the negotiating committee drove with the Minister is being gradually realized, and matters are being brought to a head by the difficulty of defending the secret merit award scheme and by the suggestion that the awards should be devoted to medical charities. Your leading article (November 18, p. 1158) points out that the proposal of the Ministry of Health to discard 1,100 registrars is due to financial reasons and not because there are already sufficient consultants in the Service. The suggestion has also been made that the period of service for senior registrars should be extended, but it would probably be more satisfactory to establish a grade of assistant consultants. Some of the money might be provided from the merit awards. This money was granted for the improvement of the Service, and, if it is not desired by the consultants and is not having the effect expected, it should be devoted to some other part of the Service. I can think of no more worthy way in which it could be spent than in providing salaries for assistant consultants.—I am, etc.,

Liverpool. H. H. MACWILLIAM.

SIR,—In your leading article (November 18, p. 1158) you make the point that this hard decision to discard over a thousand registrars is due to the financial impossibility of creating the new consultant posts which are considered necessary to the proper running of the Service. I am glad you did so, because it is a vital point. Many of the major difficulties confronting the Service at the moment are essentially financial. The extension of hospitals and building of new ones, the provision of more nurses and better care for the tuberculous and the aged sick, the building of health centres, the increase in the capitation fee and better pay for doctors in the Forces, all call for a great deal more money.

The necessity for rearmament has of course imposed economy on the country. But prior to this it seemed at least doubtful whether the public were prepared to spend any more money on the Service. It would seem very desirable that the profession should emphasize whenever possible that if the country wants a good Service it must be prepared eventually to pay more for it. Any failure on our part to do this may prove a disservice to the future of medicine in this country.—I am, etc.,

London, N.18. DAVID FERRIMAN.

SIR,—Your leading article (November 18, p. 1158) quotes 1,100 as the number likely to have their appointments terminated by M.O.H. Memorandum R.H.B. (50) 106. This is a considerable understatement. Apart from the 1,100, whose posts are ruled as above establishment, the great majority of the remainder have been registrars since July 5, 1948, and their appointments will also be automatically terminated. The total number of registrars to be discharged from the National Health Service is likely to be over 2,000. Many of these men are in their late thirties and have young families.

A return to service in the armed Forces is unlikely to appeal to the majority of registrars, who have already served through the war. Moreover, it is no solution to the problem to suggest that many will find openings in general practice. It is as hard to enter general practice as a principal to-day as it is to become a consultant.

Does the Minister of Health think that the National Health Service will benefit from the sudden loss of these men ? Surely they are the very people, young, keen, and well qualified, who should be making the Health Service a success. Unless some suitable employment within the National Health Service is offered before this memorandum is implemented, large numbers of registrars are certain to become unemployed next year.—I am, etc.,

Bath. K. G. PASCALL.

SIR,—So great was my pleasure in following your reasoned arguments (November 18, p. 1158) on the fate of registrars that I should be glad if you will allow me to stress one aspect of their training touched upon by you. No consultant who has been through the ranks of general practice has any doubt that the added training he thus received is of incalculable value to him in determining the advice he shall give. Can it possibly come to be regarded, not as a disadvantage, but as a normal part of his training that the potential consultant shall have a background of general practice ? If so, it might then be regarded as normal that the general-practitioner registrar should have a right to promotion.

Can the difficulty envisaged by you, of arranging for the future of 1,100 registrars, be overcome by judicious placing of them in general practices where they will have not only an opportunity but a right to appointments as clinical assistants at recognized hospitals ? If they can be given a reasonable prospect of promotion over a period of five years, at the rate of 200 promotions a year, to consultant status, would not the consultant body be all the richer for their experience ?—I am, etc.,

Bangor. LEONARD LANCASTER.

SIR,—The Ministry of Health circular "Registrar Grades: Review of Appointments" was discussed at recent meeting of the Welsh Regional Registrars Group. A unanimous resolution was passed that the following criticisms be placed on record:

1. That the proposals are entirely unacceptable in that no satisfactory solution of the registrar problem is offered.
2. That the instruction to hospital boards in paragraph 9 (ii) (that registrar and senior registrar appointments be reviewed annually and where necessary terminated in the implementation of the reduced establishments) will involve flagrant breach of contract in many cases where appointment has already been made for two or three years in accordance with the terms and conditions of service.
3. That the proposals in paragraph 11 (*b*) are particularly unacceptable to registrars.
4. That paragraph 12 merely adds insult to injury.

—I am, etc.,

G. R. VENNING,
Acting Secretary, Welsh Regional Registrars Group.

Registrar House

SIR,—The efficiency of hospital services will suffer so much from the displacement of registrars that the registrars can surely turn the situation to their personal advantage, and let us give them every help and encouragement. I suggest that they form themselves into groups, acquire a house near their hospital for consulting-rooms, minor out-patient surgery, etc., and call it Registrar House. They should enlist the support (financial, if necessary) of their present chiefs, and coach them in the best way of referring cases for that extra attention and prompt treatment for which many of the public will gladly pay (not to be overdone !). The consultants and not-yet-displaced registrars should co-operate to maintain the liaison necessary to provide those facilities which can be found only in the hospitals. I feel sure that the authorities would turn a blind eye to a little outside practice by registrars during the last weeks before they are discarded, while a little unobtrusive advertising would be overlooked—say a joint notification of the address to the local practitioners.

For certain conditions the service provided at Registrar House would be so much more efficient and prompt than the hospital provides that it should be an immediate success. Indeed, perhaps the securely (?) established consultant might make it a condition of early financial help that he should have a future claim on a room in Registrar House if things become intolerable elsewhere.—I am, etc.,

Oxford. W. RITCHIE RUSSELL.

Exercises in the Bath

SIR,—Sir Leonard Hill's enthusiastic approbation (November 18, p. 1153) of Mr. Togna's under-water exercises is surely misleading. He judges their value by the oxygen consumption per pulse-beat, upon which basis Mr. Togna's oxygen intake with a pulse frequency of 66 per minute is equal to that of a famous marathon runner with a cardiac rate during exercise of 118.

But this gives an erroneous impression of the real criteria, the total oxygen consumption per minute. Sir Leonard says that

"Togna's theory was established in effect by the experiments of Professor G. P. Crowden." Crowden showed, as would have been expected, that simple exercises performed in water involved little exertion, as indicated by the oxygen intake and, of course, the small increase in cardiac rate and blood pressure. With a simple arm- or leg-bending exercise the increased oxygen requirement per minute is about twice as great in the air as in the water, while in another type of exercise in which the trunk is raised and lowered the increase in oxygen requirement in water is only one-third of that for the same exercise performed in the air. To quote Togna's own figures, the cost of action done in air for one minute at the rate of 70 movements to the minute raised the pulse rate from 60 to 180 and the oxygen requirement to 3,470 ml. per minute. The cost of the same action vigorously done in the bath for five minutes at the rate of 60 movements per minute raised the pulse rate from 60 to 88 and the oxygen requirement to 1,401 ml. per minute.

It was only to be expected that the lay press, with the advocacy of a popular medical journalist, has not been tardy to represent that all the advantages of strenuous exercise, especially—*on y revient toujours*—weight reduction, may thus be served with none of the disadvantages, in particular circulatory stress. It is proper to concede that no harm results from such a misconception. The corpulent middle-aged and elderly who are disinclined or unable to take strenuous exercise will have the physical pleasure of effortless splashing about in warm water and the psychical advantage of believing that they are even surpassing their more vigorous self-exhausting brethren.—I am, etc.,

London, W.1. ADOLPHE ABRAHAMS.

SIR,—Sir Leonard Hill's interesting article (November 18, p. 1153) was no doubt intended as a serious contribution to therapeutics and perhaps geriatrics. One would therefore wish for rather more detail. Sir Leonard implies that the chief benefit lies in the removal of the effect of gravity; if this is so, why is swimming classed with "exercises in air" as inferior? Unless the temperature of the water is the deciding factor the difference between exercises and swimming must be in the precise nature of the exercises, and one would like to know more about them. From experiment in a normal bath I can assert that it is difficult to carry out any exercises except the simultaneous employment of opposing muscles—e.g., flexors and extensors of the limbs—and this I should have thought could have been done lying "in air" with no particular complication by gravity.—I am, etc.,

London, W.1. NORMAN J. AINSWORTH.

A Clinical Test for Free Blood

SIR,—The amount of free blood that can be present in the peritoneal cavity without advertising itself often comes as a surprise to the surgeon. For the last 15 years I have made it a practice in case of doubt to tilt the patient by raising the foot of the bed 18 in. (45 cm.). Unilateral or bilateral shoulder pain is usually felt within half an hour, and is a remarkably constant sign when free blood is present. No doubt the idea has occurred to others, but it is apparently not in general teaching and usage. This is my only justification for placing on record such a simple procedure.—I am, etc.,

Luanshya, Northern Rhodesia. A. C. FISHER.

Family Planning for the Rhesus-negative Mother

SIR,—Doctors practising obstetrics must be frequently asked nowadays to advise Rhesus-negative mothers on the number of their family. The glamour of exchange transfusion, and other measures aimed at combating the effects of erythroblastosis foetalis, have been much publicized. Unfortunately the impression left in the minds of many Rhesus-negative women is that their baby, whether it be their first or their fourth, is almost certain to be stillborn or at best will live only to become the inmate of a mental hospital.

I am anxious to publish the following two cases to show how wrong is this impression.

Case 1.—Mother, Group B, Rhesus-negative, gave birth to:—1932, girl: normal, Group B, Rhesus-positive; 1934, girl: normal, Group B, Rhesus-negative; 1935 (February), 1935 (August), 1935 (December), eight-week miscarriages; 1937, girl: died after discharge from hospital, no icterus, no evidence of erythroblastosis foetalis; 1940, girl: normal, Group B, Rhesus-positive; 1948, boy: normal, Group B, Rhesus-negative; 1950, girl: Rhesus-positive, Coombs-positive, jaundice; apparently completely normal after exchange transfusion.

The husband's blood in this case is Rhesus-positive, and, in the light of the Rhesus grouping of the children, must be heterozygous.

Case 2.—Mother, Group A, Rhesus-negative, gave birth to:—1929, girl: normal, Group O, Rhesus-positive; 1930, girl: normal, Group A, Rhesus-positive; 1932, boy: normal, Group A, Rhesus-positive; 1934, boy: normal, Group O, Rhesus-positive; 1936, boy: normal, Group O, Rhesus-positive; 1938, boy: normal, Group O, Rhesus-positive; 1940, boy: normal, Group A, Rhesus-positive; 1942, boy: normal, Group O, Rhesus-positive; 1947, boy: normal, Group A, Rhesus-positive; 1950, girl: normal, Group A, Rhesus-positive.

Genotyping was carried out by Professor Mourant on the husband's blood, and was reported as Group O, probable Rh genotype, Rh_1Rh_1 (CDe/CDe). In his report Professor Mourant added that the Rh grouping might be R_1R^1 (CDe/Cde), but the children's Rh groups are against this. This case shows that an apparently homozygous Rhesus-positive man mated to a Rhesus-negative woman can produce ten healthy normal children, without the formation of antibody in the wife's serum and without any of the effects of erythroblastosis in the offspring.

Case 1 serves to illustrate the fact that to forecast the future without knowledge of the Rhesus grouping of the husband is useless. Even with this grouping, unless his genotype is known (or the Rhesus grouping of the existing children, from which his genotype can be assumed), no prognosis for future pregnancies can be given.

Case 2 shows that, where the outlook appeared to be as unfavourable as possible (Rhesus-negative wife, homozygous Rhesus-positive husband), the couple managed to have ten normal healthy children.

To sum up, it would appear that no Rhesus-negative woman should be advised against embarking on further pregnancies unless the Rhesus grouping (and possibly genotyping) of her husband's blood has been done. Even when these facts are obtained and appear to point to a bad prognosis, occasionally couples can rear large families of healthy normal children. The only completely certain case where avoidance of further pregnancies can be confidently recommended (and where some authorities would be prepared to terminate and sterilize a woman) is when the Rhesus-negative wife has antibodies in her serum, a history of one or more previous erythroblastotic infants, and a homozygous Rhesus-positive husband.—I am, etc.,

Taplow, Berks. JOHN HENDERSON.

Hygiene of Urinal Bottles

SIR,—The stench peculiar to a ward of elderly men is an aesthetic challenge hitherto neglected by the medical profession. Analysis of this smell in a geriatric hospital showed that although strongly noticeable on the male side it was not apparent in wards for women, whether ambulant, bedridden, clean, or incontinent. Yet the female wards were of precisely similar construction and had the same standard of nursing, cleanliness, and ventilation. It was not the smell of stale tobacco-smoke lingering on bed-linen, etc., nor was it due to sex differences in composition of sweat, or incidence of bromidrosis and ringworm of the feet, for the malodour was not present in all male wards. The source of offence was traced to the male urinal bottle.

The urinal bottles available at present are made of glass, porcelain, enamelled iron, or stainless steel. Incrustations accumulate in all, but the opaque utensils have the added disadvantage that vigorous action is rarely taken to remove what is not seen. Enamelled iron bottles, being cheap, are very widely used, but as they soon chip to expose rusty metal they rapidly become unsightly and unhygienic; in the long run they are uneconomical and on all grounds should be abolished. A stout transparent plastic urinal bottle would be ideal, but, until such

becomes available, glass or stainless steel are the materials of choice.

After some weeks of use, even though rinsed carefully, the bottle becomes fouled with a hard brown incrustation overlaid by a furry deposit. This accretion is the source of the foul smell. The hard brown crust is composed of mineral salts, chiefly calcium phosphate, stained with urinary pigments. From the furry slime overlying it a rich variety of organisms can be isolated, including β haemolytic streptococci (Lancefield group C), *B. proteus communis*, achromobacters, aerobic spore-bearers, and micrococci. Once it has formed, this accretion is extremely tenacious and can be removed only by strong caustics. Washing alone, however meticulous, does not prevent its recurrence. The problem was solved by applying a modification of the method used for sweetening vats in the brewing industry.

The routine recommended is as follows:

(1) Initially all bottles which have been in use are cleaned by soaking in concentrated commercial hydrochloric acid (approximately 33%) for 30 minutes. After washing in several changes of water, and finally rinsing in a bottle-washer or under a tap, they are ready for use. New, unused utensils do not, of course, require this initial cleansing.

(2) Used bottles are collected from the patient's side four-hourly (clean ones being issued in their place) and their contents emptied down the sluice.

(3) About 2 ml. of an acid detergent mixture, consisting of "izal" liquid cleanser 1% with commercial hydrochloric acid ("spirits of salt") 1% in water, is inserted into the urinal bottle and about ¼ pint (250 ml.) of water added.

(4) The mouth of the bottle is then covered with a rubber pad and the vessel shaken vigorously for 30 seconds.

(5) The contents are poured down the sluice, and

(6) the bottle is rinsed in the standard bottle-washer or under the tap.

It must be emphasized that the acid-detergent mixture does not remove long-standing accretions, but does prevent incrustations from forming in utensils initially clean. The method has proved effective in practice over the past twelve months and ensures a sterile, inodorous urinal bottle.

I am grateful to Mr. W. Trillwood, chief pharmacist to the United Oxford Hospitals, for his assistance, and to Dr. R. L. Vollum, director of the Public Health Laboratory Service, Oxford, for the bacteriology.

—I am, etc.,

Oxford. P. D. BEDFORD.

Atelectasis and Bronchiectasis in Pertussis

SIR,—Dr. A. W. Lees's paper (November 18, p. 1138) is a useful contribution to our knowledge of the incidence, distribution, and duration of segmental and lobular atelectasis in pertussis. The rarity with which permanent bronchiectasis occurred in his series is surprising when one considers the frequency with which one encounters bronchiectatics who date their respiratory illness to an attack of whooping-cough in infancy or childhood. Of course, such a difference may well be due to the selected material one observes in a chest department or, as your annotator justly remarks (p. 1162), to the mildness of the pertussis epidemic investigated by Dr. Lees.

My sole criticism of an otherwise valuable paper rests on Dr. Lees's tacit assumption that Lander and Davidson are necessarily correct in their hypothesis about the genesis of bronchial dilatation—viz., a more negative intrapleural pressure results not merely in the compensatory phenomena of lung emphysema and diaphragmatic and mediastinal movements but also in *widening of the calibre of the bronchi* in the affected atelectatic areas. Now the latter part of this thesis may be partially correct, but I very much doubt if it represents the entire story. It fails to offer an adequate explanation why one encounters "reversible" bronchial dilatation in children whose intrapleural pressure readings remain substantially within normal limits throughout their pertussis illness. Similarly, Lander and Davidson's views do not offer a satisfactory explanation for the *absence* of bronchial dilatation (as a compensatory mechanism) *outside the areas of lobar atelectasis*, even when the intrapleural pressure is substantially lowered.

Perhaps it is because of this very doubt existing in Dr. Lees's mind that he remains so guarded in his appraisal of the merits of artificial pneumothorax as a therapeutic weapon "to counter the mechanical stresses dilating the bronchi." Clearly, if Lander and Davidson's hypothesis on the aetiology of bronchiectasis is only a partial explanation, then the entire principle underlying collapse therapy in potential bronchiectatics is invalidated. In any event, it appears contradictory to advocate postural drainage, percussion, and bronchoscopic suction as therapeutic measures to facilitate expulsion of secretions, while simultaneously advocating a technique which must entail compression and constriction of the bronchial lumen and result in the retention of bronchial secretions which were initially responsible for the atelectasis.—I am, etc.,

Halifax. BERTRAM MANN.

SIR,—Bronchiectasis has still its full share of what Sir Thomas Browne called "vulgar and common errors." Dr. A. W. Lees (November 18, p. 1138) is to be congratulated on investigating one, for which Laennec is somewhat to blame, that pertussis is a common cause. My own experience, like that of Dr. Lees, does not support this view. Some years ago the then superintendent of the North-eastern Fever Hospital gave me the opportunity of seeing all those patients who had survived very severe or complicated whooping-cough during the preceding two or three years. Clinical and radiological examination suggested that all had recovered completely, so that there was no single case in whom bronchography could be justified.

The histories of proved cases of bronchiectasis referred for admission to the Invalid Children's Aid Association's special hospital school (the Meath Home) sometimes contain the statement that the symptoms date from pertussis, or from pertussis and measles consecutively. In nearly every such case a more careful questioning of the parents reveals that in fact there had been respiratory symptoms before the pertussis. The accurate history is that pertussis had aggravated respiratory symptoms already present.

Dr. Lees appears to accept what may be another error, that the prognosis in a severe case is poor without surgical intervention. The mother of one of my most severe childhood cases recently wrote me that the boy, having passed A1 into the Army and after intensive training, was just off to Malaya. I was able to save him from what might have been a medically disastrous adventure. The exact role of surgery in the treatment of childhood bronchiectasis has still to be defined. It is misleading to attack this difficult problem with the assumption that the prognosis is known to be bad, when recent follow-up studies have cast doubt upon this.—I am, etc.,

London, W.1. ALFRED WHITE FRANKLIN.

Intraperitoneal Intestinal Anastomosis

SIR,—I do not wish to discuss the merits of this operation, but would like to point out a few practical principles concerning colostomy closure which, judging from the difficulties which one so frequently sees recounted, are not as fully appreciated as they might be. Failure to close a colostomy is usually due to obstruction at the site of closure, assuming that obstruction at a distal level, and particularly that due to faecal masses in the rectum, has been ruled out before closure is undertaken. Obstruction at the closure practically always means inadequate crushing of the colostomy spur.

Before closing the peritoneum in a Mikulicz resection the two limbs of colon which are to form a double-barrelled colostomy should be sutured together for a full 3 in. (7.6 cm.), and this should be done in such a way that the mesentery is well clear of the spur, and so that there is no possibility of a loop of small bowel finding its way between the walls of the colon subsequently to being crushed. If this is done, then with reasonable care there is no difficulty in crushing a spur of adequate depth; such extensive "gun-barrelling" will necessitate a considerably more extensive colonic mobilization than is required when intraperitoneal anastomosis is carried out, if the operation is to be as radical as it must be.

The type of enterotome used is important. There are many unsatisfactory types of enterotome in use. All enterotomes which are hinged on the scissor principle are fundamentally unsound; their maximum crushing power is close to the hinge, and thus at the upper end of the colostomy spur, and they may slip off when this is crushed, leaving the deeper part intact. Many enterotomes are too short. A satisfactory enterotome should be capable of crushing a spur to a depth of 3 in. The blades should be brought together by being screwed along a bar, and should be arranged so that they converge slightly towards their distal ends. This arrangement ensures a controlled but powerful crushing force which is maximal at the lower end of the spur. The question of teeth is probably not important. Short teeth are harmless and make slipping of the enterotome less likely, but are not absolutely necessary. Such an enterotome, applied carefully, will seldom need more than two applications to crush the spur adequately. A second application is sometimes needed, as it is not always possible to obtain a safe application to the full depth of the spur until the latter has been partly crushed. In this connexion it is important when applying the enterotome to make sure that the tip is freely movable, thus ensuring that it cannot include any structure on the posterior abdominal wall.

Mr. W. Garden Hendry (November 18, p. 1148) states, "An extraperitoneal closure in the presence of a partially crushed spur is always difficult and unsatisfactory. . . ." I would add that it should not, and need not, be attempted. Before closing the colostomy it should be possible to pass an index finger to its full length before the remains of the crushed spur are felt. If closure is attempted under these circumstances there need be little fear of breakdown.

Certainly, keeping to these principles and using an enterotome of the type indicated, I have as yet had no case of even temporary leakage, or of the subsequent development of obstructive symptoms.—I am, etc.,

Northampton. J. H. C. PHILLIPS.

SIR,—Mr. W. Garden Hendry (November 18, p. 1148) has performed a useful service in drawing attention to the undoubted advantages of immediate anastomosis after resection of the colon. However, four of his 15 cases were operated upon for growths of the caecum. Primary anastomosis has long been the established method of completing a right hemicolectomy. The comparative safety of the procedure lies in the fact that in the presence of a caecal growth the vitality of the colon is not impaired by the effects of obstruction, whether acute or chronic. These affect only the small intestine, and experience gained from resections for strangulation teaches that the healing powers of small intestine, in contrast to those of the colon, are not appreciably reduced by obstruction.

In six of his remaining cases Mr. Hendry availed himself of proximal decompression by a caecostomy or colostomy. This again, it is fair to say, has been a common practice for many years and it has given good results. Still, one of the cases in this group developed a faecal fistula and remains with a colostomy and three others have undergone a second operation for closure of the caecostomy.

Mr. Hendry is to be congratulated on the five cases in which he successfully performed an immediate colonic anastomosis without a caecostomy or colostomy. He is on sure ground when he refers to the saving in time and inconvenience to the patient of this method when compared with the Paul–Mikulicz procedure. But I cannot endorse his strictures on the latter method when he writes of the difficulties of crushing the spur, of the painfulness of the process, and of the multiple attempts at spur crushing and colostomy closure. This is quite contrary to my experience.

In a series of 34 resections carried out on the Paul–Mikulicz principle I have had three deaths before the colostomy was closed. One was from bronchopneumonia in a patient aged 79 and one occurred in a young man suffering from severe cachexia. The third death resulted from a technical error and was the only one related to the method in question. In the absence of an enterotome I used a pair of Kocher's forceps to crush the spur. Penetration by the sharp teeth of this instrument caused a local peritonitis with formation of adhesions. The patient died from perforation of a gangrenous strangulated loop of small intestine. In the remaining 31 cases the spur was crushed and the colostomy closed at the first attempt. A good many of the wounds have suppurated for a short time. In one or two cases there has been a small faecal fistula which closed spontaneously in a few days. I have not observed subsequent stricture formation nor evidence of defective colonic function which Mr. Hendry supposes must result from fixation of the colon to the abdominal wall. I doubt if after intraperitoneal anastomosis the colon often retains substantially more mobility than after an extraperitoneal completion of the anastomosis.

Finally, I must join issue with Mr. Hendry over his statement that "it [intraperitoneal anastomosis] can, of course, be a good deal more radical than an extraperitoneal excision." Disregarding his confusion of terms, by which he implies that it is the anastomosis instead of the excision the extent of which is in question, it needs to be stated emphatically that the method of anastomosis to be used should in no way influence the extent of the excision. This, except in purely palliative operations, must be decided solely by the extent of the pathological process. In cases of carcinoma this means the extent of glandular involvement. Only when such excision is completed need the surgeon concern himself with the question of which type of anastomosis will give the best result. I can assure Mr. Hendry that, because of the great mobility of the colon to which he himself refers, provided there are 6 in. (15 cm.) of free bowel distal to the resection an extraperitoneal anastomosis can be performed in any circumstances in which an intraperitoneal anastomosis would be feasible.—I am, etc.,

Edgware. FRANK FORTY.

SIR,—It was with great interest that I read Mr. W. Garden Hendry's article (November 18, p. 1148) on fifteen cases of intraperitoneal anastomosis in colectomy. I have practised this method for the last twenty years and can inform him that I have never carried out one single case of the Paul–Mikulicz technique in my surgical history. When I was working at the New York medical centre in 1932, Dr. Eugene Poole was the chief advocate of the extraperitoneal method. He was an excellent surgeon, and admittedly got good results; but, so he informed me, the average time a patient was in hospital was just over ten weeks—a serious consideration for a working man, as Mr. Hendry points out. Having closely followed Poole's work for three months, I came to the conclusion that with careful technique in carrying out the end-to-end or end-to-side anastomosis there was no real need to swing over to the extraperitoneal method. In those days the sulphonamide compounds were unknown, so a prescribed pre-operative course of other antiseptics was used. Salol by mouth and lower bowel washouts with 1/8,000 permanganate of potash or albargin seemed to be satisfactory.

My technique is much the same as that described by Mr. Hendry, but I would like to make the following comments:

(1) In right-sided hemicolectomy—e.g., for Crohn's disease—I have found that the easiest method of anastomosis is end (ileum) to side (transverse colon).

(2) In resections of the left side of the colon, sigmoid, rectosigmoid, or descending colon I have found that a very effective method of protecting the anastomosis is to pass a large old-fashioned type stomach tube up through the anus into the bowel and beyond the anastomosis. The tube is then stitched to the anal margin. This device prevents the accumulation of gas in the distal bowel and so saves any strain on the junction. It is left in for five to six days and can be kept free by running saline through a funnel. Side holes cut in the tube are an additional measure which may be of assistance in preventing blockage.

(3) I have not used suphonamide powder on the actual suture line, as so far I have not found it necessary. As an added precaution I am in favour of it.

(4) Drainage should be instituted in all cases, as with the somewhat doubtful suture materials at one's disposal to-day a possible faecal leak cannot be ruled out.

(5) I prefer to lock every third loop of the through-and-through suture.

(6) The post-operative use of streptomycin is to be strongly advocated. I have had five cases of slight faecal leak which have caused no serious set-back and which cleared up within seven to ten days.

Following on Mr. Hendry's article I trust that more surgeons will attempt this method of anastomosis. I feel sure that they and their patients will be highly gratified with the results.—I am, etc.,

Burnley. STANFORD HOWARD.

Tuberculin Jelly Test

SIR,—The modification of the tuberculin jelly test which I described in a recent article in the *Journal* (July 15, p. 141) was developed to enable the useful range of the test to be extended into the teens and possibly beyond. As several cases have been brought to my notice of severe reactions in very young children in whom this modified technique has been employed, may I say that I would not advise its use, and do not think it necessary, in children under 5 years of age? Their skins are so sensitive that the original jelly test without flour-paper should be quite adequate. If flour-paper is used then some severe reactions may result.—I am, etc.,

London, N.W.3. W. POINTON DICK.

Transmission of Kala-azar

SIR,—As pointed out by your correspondent, Dr. B. J. Bouché (November 4, p. 1060), the sandfly theory has been severely mauled in the past few years. As there have been no serious attempts at resuscitation since September, 1945, I think we may assume that it is dead and has been decently, if unobtrusively, buried by its friends. May we hope that the obituary notice will duly appear in the next generation of textbooks?—I am, etc.,

Sheffield. R. H. MALONE.

Four Brothers with Duodenal Ulcer

SIR,—Although a familial history of peptic ulcer is quite usual, I have recently encountered a remarkable tendency to chronic duodenal ulceration in the male members of one family. Of nine children seven are male, all of whom are miners by occupation. I have myself in the course of the last fifteen months carried out a partial gastrectomy in three of the brothers for chronic duodenal ulceration. In each case the ulcer was on the first part of the duodenum, was extremely chronic, and in two of the three was associated with severe pyloric stenosis: in fact, the first brother to come under my care was admitted as an early case of alkalosis. Besides these three who have been treated by partial gastrectomy, one has been operated upon for a perforated duodenal ulcer some twelve years ago, and yet another is at present undergoing investigation elsewhere for severe indigestion, and has been told he is suffering from "stomach trouble." Of the two remaining brothers, one is symptom-free, and the other has mild indigestion, but has not thought it worth his while to seek medical advice. Therefore, of the seven male members of this family, three have had gastric resections for severe duodenal ulcer, one has had a perforated duodenal ulcer, one is at present under treatment for gastric trouble, one has slight symptoms, and only one is completely free. Both sisters are fit and well, as are the parents and near relatives. The ages of the seven brothers range from 31 to 53.

It would appear as though the tendency to duodenal ulceration in this instance is not hereditary. The fact that they are all miners (even allowing for the increased instance of peptic ulceration among miners) would not seem to account for such a high percentage of duodenal ulceration; nor have the three cases upon which I have operated exhibited any signs of undue apprehension—indeed, they have all three been excellent patients, and were certainly not of the anxious worrying type so commonly associated with a duodenal ulcer.—I am, etc.,

Barnsley, Yorks. ANDREW G. BUTTERS.

Amphetamine in Barbiturate Poisoning

SIR,—The widespread use of the barbiturate drugs, with consequent increase in the incidence of acute poisoning resulting from them, whether accidental or intentional, adds importance to a recent article on the problem from the pen of Dr. J. D. N. Nabarro (October 21, p. 924). A desire to have the results of his clinical experience in this matter elucidated prompts my letter. The author cites several cases from which the reader can only conclude that amphetamine sulphate has commendable therapeutic value in acute barbiturate poisoning. He follows with the suggestion that the drug is directly indicated (to the exclusion of the at present more widely advised picrotoxin) if rapid rousing of the patient is desired, as in the case of the asthmatic (Case 2); and he goes on to say, "Many of the properties of amphetamine referred to make it questionable whether the use of this drug in barbiturate poisoning is ever justified."

Dr. Nabarro renders a clinical service by drawing attention to the untoward properties of a drug which has such widespread applications, and he clearly regards as important the cardiovascular side-effects in question. But how important are they, and how frequently do they occur? The enormous quantities of "dexedrine" and "benzedrine" which are now taken prove conclusively that these drugs are not ordinarily associated with significant side-effects at all. But, even agreeing with Dr. Nabarro that cardiovascular toxicity occurs, surely it is better to risk a possible though rare cardiac arrhythmia while leaving a coma quickly, than to avoid the arrhythmia and invite the delayed bronchopneumonia.

It is unreasonable to discard a drug of proved value in the treatment of barbiturate poisoning because it has side-effects, especially when, as Dr. Nabarro says, "no undesirable results seem to have followed the large amounts of amphetamine administered," and more especially when he goes on to admit that picrotoxin quickly induces dangerous "preconvulsive muscular twitchings." Surely the association of an untoward drug effect with the cerebral rather than with the cardiac component of the human being does not necessarily lessen its significance. In short, far from being a "useful ancillary drug," as Dr. Nabarro says, in the treatment of such cases, amphetamine sulphate is the drug of choice for acute barbiturate poisoning; it is picrotoxin which is ancillary.

Finally, none of my comments contradict or are contradicted by Chakravarti, who wrote: "In relation to its toxicity benzedrine is the most potent substance for arousing narcotized mice, being more potent than cardiazol or picrotoxin; on the other hand, as an antidote to lethal doses of the same narcotic, benzedrine is quite useless."—I am, etc.,

London, N.W.3. H. CREDITOR.

Dangers of Penicillin Snuff

SIR,—It was with some concern that I read recently in the press of the extensive and frequent usage of penicillin snuff in the treatment and the prevention of the common cold at a Midlands factory. In the course of a personal research during the past six years on the aetiology and treatment of the common cold I have used this method of treatment, and from personal clinical observations I am of the opinion that the following are some of the risks involved:

1. In some patients frequent inhalation of penicillin snuff produces a degree of penicillin sensitization which on subsequent use causes an allergic rhinorrhoea. This in effect defeats its own object.

2. I have observed patients who have been thus sensitized develop anaphylactic shock and/or severe acute urticaria when penicillin therapy has been used for other infections at a future date. In these cases patients have been denied the benefit of penicillin therapy in much more dangerous infections for what is a relatively trivial complaint.

3. By repeated inhalation of penicillin snuff the organisms responsible for the secondary stage (muco-purulent catarrh) of the common cold eventually become resistant, and not only has the treatment no effect but if any other part of the body becomes infected with these organisms penicillin treatment is ineffective.

From clinical experience, my own opinion is that penicillin snuff is only of value in converting the secondary stage of the common cold to the primary stage of simple rhinorrhoea, which in itself can be controlled by instillation of a mixture of a vasoconstrictor and antihistaminic.

The works medical officer will find that he will reduce the incidence of the common cold in susceptible persons if they are given regular dosages of glucose and vitamin C, thereby avoiding the risks I have pointed out.—I am, etc.,

Whitburn, Co. Durham. FRANK CORT.

Vasomotor Collapse after Chloramphenicol

SIR,—Several of our colleagues have reported that in treating cases of typhoid fever with chloramphenicol they have encountered in some cases a critical fall of temperature, with feeble or imperceptible pulse, profuse sweating, cold extremities, etc. Recently we have come across two such cases, which are described below.

(1) A male 30-year-old Indian Hindu was admitted with a history of eight days' continuous temperature with headache and prostration. The patient was restless and toxic, with temperature 103° F. (39.4° C.), pulse 106, respirations 26 per min., tongue coated and moist, but no rash and no enlarged glands. The lungs showed occasional rhonchi on both sides, and the liver and spleen were both just palpable. Blood count: total W.B.C., 8,700 per c.mm.; differential count: neutrophils 72%; lymphocytes 28%; monocytes 0; eosinophils 0. Malaria parasites 0. Blood on culture did not show any growth.

The patient's temperature continued between 102° and 104° F. (38.9° and 40° C.), and on the tenth day of fever the Widal reaction showed agglutination with *B. typhosus* (H) positive in 1-in-125 dilution, the Weil-Felix reaction was negative, and chloramphenicol was started, 1.5 g. at first, followed by 500 mg. every two hours. (The patient was not weighed, but he was a muscular man of average build and would have weighed about 10 stone.)

After about 24 hours and after 7 g. of chloramphenicol his temperature fell sharply to 96° F. (35.6° C.), associated with symptoms of collapse. He had profuse and continuous sweating, and his pulse was very feeble at the wrist. Heart sounds were very weak, and the rate varied between 120 and 140 per minute. Blood pressure was 60/45 mm. Hg. There was also retention of urine. There was no evidence of intestinal haemorrhage or perforation. The stools continued to be of normal colour subsequently. He was in that condition for nearly 36 hours and gradually recovered with stimulants and supportive treatment. The subsequent course was uneventful and he did not have a relapse. He had a total of 9 g. chloramphenicol.

(2) A female Hindu, aged 12 years, was first seen on the fifth day of a clinical relapse of paratyphoid A fever. She had continuous temperature for 12 days, when the blood showed agglutination positive with *B. paratyphosus* A in a dilution of 1 in 250. She was then treated with chloramphenicol, 1 g. followed by 250 mg. three-hourly, when her temperature came down in three or four days' time. Chloramphenicol was continued for four days after defervescence, 250 mg. four-hourly. She remained well for 12 days and then started with fever again. At this time her temperature ranged between 101° and 103.6° F. (38.3° and 39.8° C.), with pulse 100 per minute, blood pressure 100/60 mm. Hg. The abdomen was slightly distended, but no other abnormal signs were seen. Blood count: total W.B.C. 5,400 per c.mm. (neutrophils 68%, lymphocytes 26%, monocytes 4%, eosinophils 2%). No malaria parasites.

Chloramphenicol was started again on the sixth day of relapse; 250 mg. was given every two hours. After 36 hours, when 4.5 g. had been given, there was a sharp fall of temperature to 95° F. (35° C.) with symptoms of collapse. She had profuse perspiration and pulse imperceptible at the wrist. Her condition improved with stimulants, but the temperature continued subnormal for about 72 hours, when it rose again to 101° F. (38.3° C.). The fever continued for another six days and gradually came down to normal. There was no rigidity of the abdomen and no free fluid. The stools continued to be of normal colour.

A limited search of the published reports on the trial of chloramphenicol in typhoid and paratyphoid fevers shows only one report[1] of sudden fall of temperature to subnormal level with circulatory collapse. That case ended fatally. As mentioned above, several physicians in Calcutta have also noticed similar complications, sometimes with fatal result (personal communication). In a series of 17 cases of typhoid fever (excluding the second case above, which was seen outside) treated by us in hospital during the last three months with chloramphenicol, the temperature came down by lysis in two to four days' time without any evidence of collapse in 13 cases. Case 1 (above) had a sudden fall of temperature with circulatory collapse. Three other cases had a rapid fall of temperature, which reached subnormal level with severe sweating, but did not have circulatory collapse.

Stephens thinks that the sudden fall of temperature with circulatory collapse may be due to a reaction of the nature of a Jarisch–Herxheimer reaction. The sudden liberation of the endotoxins of bacilli destroyed by chloramphenicol may cause a depression of the vasomotor centre. This explanation, however, seems unconvincing. It is desirable that the pharmacological action of chloramphenicol should be more carefully studied, with particular reference to any possible antipyretic action and depressant action on the vasomotor centre.—We are, etc.,

P. K. CHATTERJEE.

Pethidine in Anaesthesia

SIR,—Having read an article by Dr. H. F. Griffiths (*Journal*, September 30, p. 763), I tried his technique out on a case, with the following results. The subject was a mental patient aged 60 years, of fairly muscular build, and was referred by the neuropsychiatrist for a left inguino-scrotal hernia.

The patient was sitting up on the stretcher and boisterous when wheeled into the anaesthetic room one hour and fifteen minutes after having been given two-thirds of a bulb of "omnopon" ¾ gr. (44 mg.) and scopolamine 1/150 gr. (1 mg.). He was held down and thiopentone sodium given, dose 0.5 g. Anaesthesia was continued with nitrous oxide, 5½ l. per minute, and oxygen 1½ l. per minute. When placed on the operating table 25 mg. of pethidine hydrochloride was given intravenously. The surgeon complained of a tensed abdomen, and 5 mg. of "tubarine" was given intravenously. About fifteen minutes after the commencement of the operation the surgeon again complained of rigidity, when a trickle of ether was added to the anaesthesia. About ten minutes after this the patient ceased breathing and artificial respiration was given by squeezing the rubber bag for rebreathing. A good colour was maintained and his pulse was regular, with good tension and volume, at 80 per minute.

After a further ten minutes an endotracheal tube was passed under direct vision and oxygen given by artificial respiration. As there was no evidence of automatic breathing being resumed 2 ml. nikethamide and 1 ml. lobeline were given intravenously, when immediate automatic respiration was resumed. The operation was meanwhile being continued, and the patient left the theatre with normal respiration and pulse.

Is it possible that the respiratory arrest was due to the trickle of ether, which was not used in the technique described by Griffiths, or to the premedication?—I am, etc.,

Colombo, Ceylon. T. W. VANNIASINGHAM.

Producing Anaesthesia of Trigeminal Nerve Distribution

SIR,—Dr. Wilfred Harris (November 4, p. 1015) is not alone in his difficulties over producing third-division trigeminal anaesthesia after alcohol injection of the Gasserian ganglion, or surgical section of the sensory root in the middle fossa, for we, and many other neurosurgeons, have had a similar experience. In recent years we have been dividing the trigeminal sensory root in the middle fossa through an intradural approach, and have thereby obtained a clearer view of the ganglion and its root *in situ*, for in the usual extradural operation stripping of the dura is apt to rotate the ganglion and to distort its normal structure and relations. As a result of our experience with this operation we have come to recognize the fact that in not a few instances the third division is separated from the first and second by a fibrous tissue septum in the ganglion, which may extend far into the sensory root; in fact, these two portions of the root may have a separate arachnoidal sheath. Wide variations in the point of trifurcation of the ganglion have been noted by others.[1] It would not be surprising, therefore, that when injecting the ganglion, or dividing its sensory root, one might enter one of these compartments and destroy the fibres running in it, while leaving the other unaffected. It has been our experience after such procedures to obtain only first- and second-division anaesthesia on a few occasions, and more rarely the reverse has been true.

Failure to obtain third-division anaesthesia after sensory root section near the pons is more difficult to explain. It has been the experience of one of us (B. H.) that careful preservation of a bundle of fibres, thought to be the motor root, in the middle fossa operation has resulted in first- and second-division anaesthesia only, while section of this bundle at a second operation has resulted in third-division anaesthesia (and motor paralysis). Is it not possible that in some cases the third-division sensory fibres are closely applied to, or incorporated in, the motor root, and that this state of affairs may persist right up to the side of the pons? Perhaps the anatomists can supply the answer, and if this contention is true it may be that deliberate sacrifice of the motor root will have to be accepted in such cases.—We are, etc.,

Birmingham. BRODIE HUGHES.

Teething

SIR,—Like Dr. H. M. Tietze (December 2, p. 1281), I was brought up to regard the diagnosis of "teething" as the refuge of the destitute, and when used irresponsibly I believe it still is. However, I have modified my views since observing my own child. He invariably had loose stools for a few days before eruption of a tooth—so much so that the diagnosis of "another tooth" was absolute on onset of this symptom. I feel that our teachers appreciated this, but rightly felt that missing a case of gastro-enteritis was a more serious matter than not diagnosing teething in the appropriate case.

It may be that teething is a physiological process, but so is menstruation, and one cannot deny that the latter process is often accompanied by symptoms which are very disturbing. I therefore think it is wise to avoid the diagnosis of teething if possible, but one should recognize its possibilities.—I am, etc.,

London, E.17. P. R. SAVILLE.

Lower-segment Caesarean Section Modified

SIR,—I have learned recently of an unusual modification of the standard technique employed by some operators when difficulty is encountered in extracting the foetal head through the transverse incision in the lower uterine segment. An incision is made vertically into the upper segment from the mid-point of the transverse incision, resulting in the formation of a T-shaped opening through which the child is extracted. Furthermore, I am told that this procedure was advocated in the circumstances mentioned by an examiner at a recent examination at the Royal College of Obstetricians and Gynaecologists.

It appears to me that, following retraction of the uterus, satisfactory apposition of the cut edges must be extremely difficult, particularly at the points of junction of the two incisions, and a weak scar would be likely to result. At present I have attending my hospital antenatal clinic a patient whose last labour was terminated in this way on account of foetal distress. I am therefore interested to know if any of your readers have experience of the conduct of labour following such an operation.—I am, etc.,

London, W.9. JOHN P. ERSKINE.

Should First M.B. be Passed at School?

SIR,—It was with interest and appreciation that I read of the protest made by Dr. Robert Birley (*Journal*, November 4, p. 1052) on the restrictions imposed on boys' education by the unwarranted insistence of the universities on First M.B. passes at school.

In its present form the First M.B. is about the most archaic type of examination in an already overburdened and outmoded curriculum. For the universities to transfer to the schools the obvious pressure put on them to retain the absurdly weighted "training programme" of modern medical schools is a sorry reflection on the weakening independent status of universities. At the very time when an opportunity presents itself, at the conclusion of the specialized efforts of school certificate and matriculation examinations, to "educate" in the widest sense a potential member of a supposedly learned profession, the wretched boy is to be driven even further into the confined niche of a super-technical apprenticeship.

It surely cannot be a matter of indifference to the profession that a vital stage in education is being by-passed, in the opinion of many, for the sake of superfluous cramming.—I am, etc.,

Princes Risborough, Bucks. F. H. M. DUMMER.

Obituary

SIR WILLIAM THOMSON, M.D., F.R.C.P.

Sir William Thomson, professor of medicine at Queen's University, Belfast, died at home on November 26, aged 65 years. He had occupied the chair of medicine for 27 years, and his death has robbed the Belfast medical school of a well-loved and outstanding personality.

William Willis Dalziel Thomson was the son of the late Dr. W. Thomson, J.P., of Anahilt House, Hillsborough, Co. Down. He was educated at Campbell College, and became a student at the old Queen's College, Belfast. He had a remarkable undergraduate career, obtaining the B.A. of the Royal University of Ireland with first-class honours and an exhibition in 1907 and graduating M.B., B.Ch. at the Queen's University, Belfast, in 1910 with first place, first-class honours, and a scholarship—a record which it would be difficult to surpass. This promise of a great career to come was not confined solely to intellectual achievement, for he took an active part in student life and was elected president of the Students' Representative Council in 1908, thereby becoming a member of the Senate of the University. He won many prizes, including the Hutchinson-Stewart Scholarship and the Dunville Studentship. After graduation he spent a year in residence at the Fever Hospital, Purdysburn, and later became demonstrator first in physiology and later in pathology at the university. His studies then led him further afield, to Dublin, London, Paris, and Budapest. One of his first papers, on the subject of blood urea and published in 1914, was an outcome of his work with Widal in Paris. In 1912 he took the D.P.H. and in 1913 the B.Sc.(Belfast) with first-class honours. He proceeded M.D., winning a gold medal, in 1916. In the summer of 1915, as a temporary captain in the R.A.M.C., he worked with the late Sir Almroth Wright on war nephritis in the research laboratory attached to No. 13 General Hospital at Boulogne. The results of this research were later published in the *Quarterly Journal of Medicine*. While in France he came to know many eminent medical men. In 1916 he gained experience of chest wounds through his association with Sir Bertrand (later Lord) Dawson, which may have contributed to his later interest in diseases of the lungs. In the same way it seems probable that it was the example and teaching of Gordon Holmes, with whom he formed a friendship at this time, that determined his abiding and profound interest in clinical neurology.

[Walter Stoneman, London.

Such was the background against which W. D. Thomson emerged at the end of the first world war. For a time he was a member of the staff of the Mater Hospital, and he was elected assistant physician at the Royal Victoria Hospital in 1918, the year in which he became a Member of the Royal College of Physicians of London. His appointment to the chair of medicine followed the retirement of the late Professor James Lindsay in 1923. A year later he was full physician and assumed charge of wards 1 and 2—the medical unit in the hospital with which his name and reputation have since been inseparably linked. He was

elected a Fellow of the Royal College of Physicians in 1928. Unfortunately at this stage in his career serious illness overtook him, the malady proving intractable and at times threatening life and calling forth all his powers of endurance. For long periods he had to give up practice. After great suffering he made a splendid recovery, and all his friends were delighted to see that subsequently there were no signs of recurrence of the old enemy. Honours and increasing responsibilities followed: he was elected president of the Northern Ireland Branch of the British Medical Association in 1932 and of the Irish Medical Schools' and Graduates' Association in 1936. He delivered the Lumleian Lecture before the Royal College of Physicians on "Primary Carcinoma of the Lung" in 1939, and the year 1937, when the British Medical Association met in Belfast, saw him President of the Section of Medicine. After the end of the second world war Thomson took an active part in committee work and in the negotiations entailed in the organization of the hospitals under the new Health Act. He was a member of the Hospitals Authority and other important committees from their inception. On the retirement of Professor C. G. Lowry he became a member of the General Medical Council. He continued to serve on several important committees of the B.M.A., including the Central Medical War Committee, until 1946. Two further distinctions awaited him: the presidency of the Association of Physicians of Great Britain and Ireland in 1949 and his elevation to a knighthood in the last New Year Honours. He received the accolade from the King on March 29, 1950.

Dr. R. S. Allison writes: Sir William Thomson was an unassuming personality and incapable of airing his accomplishments. This gifted scholar, who in spite of his snowy hair seemed to grow no older, never failed in his consideration for others. "W. D.," as he was always affectionately known, had no guile and was incapable of dishonesty either in his professional work or in his dealings with his fellow men. Tall and commanding in his person and with characteristic bushy eyebrows, he was renowned for his toleration and for his gift for seeing the important issue behind the façade of trivial or petty detail. But, while he was generous and quick to support a worthy cause, he had profound contempt for anything that savoured of charlatanism or deceit, and if he considered a decision unjust or improper he had no hesitation in saying so and in exerting his influence to put it right. He was a natural leader of men. He never gave orders; instead he would suggest that such and such a thing should be done. Where another man might rage at some mistake or omission he would simply take his subordinate gently by the arm and smilingly make an appropriate suggestion, or, if the occasion warranted it and he knew his man, poke a little fun. He was a good companion and liked a story, especially one which had local colour. He and Lady Thomson kept open house, and to be a guest at their table was an unforgettable experience. These were some of the qualities that drew so many to him and made him at one with his students, house-physicians, registrars, and colleagues—all of whom he treated alike. He was one of the greatest clinical teachers this school has ever known, for he had the gift, while not trying to over-simplify a subject, of presenting it in such a way that its chief characteristics became apparent. As has been said of Boerhaave of Leyden, "he led his pupils by the hand to clinical medicine." Any task he set himself he undertook with characteristic single-minded devotion. During the last 12 years, when he had good health, he became greatly attracted to gardening, and visiting examiners and others will recall with pleasure being entertained at his country house, "Seven Tides," Donaghadee. Here, out of bare pasture land and on an exposed site facing the sea, he succeeded in raising a remarkable collection of trees, rare shrubs, and plants which, together with his flowers, it was his delight to demonstrate.

In 1914 he married Josephine, daughter of the late Mr. Humphrey Barron, J.P., and their life together was ideally happy. Throughout his earlier illness his wife unstintingly devoted herself to his care, and there is no doubt that this contributed materially to his recovery. Their only child, Humphrey Barron Thomson, who had graduated in medicine in 1939, at once volunteered for service with the R.A.M.C., and in 1942 was killed by the Japanese. His parents bore this sorrow unflinchingly. How great was the effort to remain composed only their closest friends knew.

It is difficult, now that Thomson's presence has been so swiftly withdrawn, to realize the incalculable loss we have suffered; a loss that will be shared by his patients, his students, and colleagues alike. He will go down in the annals of our school as a man of genius, and yet of great simplicity, for though he rose to one of the highest places in the community he himself never seemed to be conscious of it and remained throughout his life steadfast in his humanity, gentleness, and honesty. Our deepest sympathy is extended to his widow.

H. L. T. writes: "W. D." was known by his initials to the medical profession throughout the British Isles, and everywhere he was truly loved. He rose to the top of his profession as a physician, and as he mounted the ladder of success those whom he passed by felt neither rancour nor jealousy. Nor would he have felt any himself if others had been preferred to him. For he possessed to a remarkable degree a quality of charm, almost feminine in its gentleness, which spread its influence to those around him. Yet his character was by no means weak. He would always listen to others, but he formed his own opinions and held firmly to what he believed to be right. The correctness of his judgment was so recognized that he was able to direct the policy of the medical school which was his life's interest and which he raised in reputation as he rose himself. He was welcome everywhere. If where he went he met only acquaintances, he left them as his personal friends. He died with his harness on his back. Much as he loved the country and his garden, perhaps this is what he would have chosen. A happy warrior indeed, his memory will be long and widely revered.

E'en as he trod that day to God so walked he from his birth,
In simpleness and gentleness and honour and clean mirth.

Professor F. J. Nattrass writes: I should like to record a brief tribute to Sir William Thomson—"W.D." to all his friends. I had the privilege of knowing him intimately, both as a fellow pilgrim to medical schools at home and abroad and through several years examining in Belfast. He occupied a position which seemed to me unique: more than anyone I have met, he was the centre of all medical affairs, educational and administrative, in the area he served. This is not surprising, as he was the object of universal respect and affection—a very fine physician, a man of great charm and modesty, an outstanding orator, a beloved teacher. His courage and cheerfulness, and that of his wife, were maintained in spite of prolonged illness in his earlier years, and the loss of their only child, a young doctor killed in cold blood after capture by the Japanese. He will be deeply missed by a great company of friends in England and Scotland as in his native province.

H. B. RUSSELL, M.D., M.R.C.P.

Dr. H. B. Russell, for many years in charge of the electrocardiographic department at St. Thomas's Hospital, died at his home at Greatstone-on-Sea, Kent, on November 27 from a cardiac condition which he had most courageously suffered for a long time.

Henry Bret Russell was the son of Dr. Alexander Russell, F.R.S. He was educated at St. Paul's School, and from there went straight to St. Thomas's. He took the Conjoint qualification in 1917 and graduated M.B., B.S. in 1919. Among the posts he held at his hospital was the important one of resident assistant physician. Later he became resident medical superintendent at the Hospital for Sick Children, Great Ormond Street. In 1920 he proceeded M.D. and became a member of the Royal College of Physicians. At a very early stage he developed an interest in electrocardiography, working under the late Sir Maurice Cassidy. With his illustrious father's help he made many practical suggestions to the manufacturers of electrocardiographic equipment. Until his death he also worked as physician in charge of the electrocardiographic department of the Royal Masonic Hospital.

Russell, who was consulting physician to the Queen's Hospital for Children, Hackney, was particularly interested in heart disease in childhood, and he published a book on this subject with Dr. C. K. J. Hamilton as co-author. In another sphere he assisted Sir Maurice Cassidy and, later, Dr. Isaac Jones in the medical department of the Metropolitan Police, being appointed deputy physician in 1926. Here his sterling qualities and wide knowledge of human nature made his services greatly valued. Russell had a kindly heart and a gay disposition in spite of a disabling congenital joint condition. Although a first-class physician he himself felt that he would have been happier using his very mathematical mind away from medicine. When driving a car he would often work out all types of arithmetical problems with the numbers he saw on the registration plates of passing cars. He had a great love for the Highlands and for travel in general, and was never happier than when starting out with a map and compass on a long motor tour. He was a keen Mason, being a past master of the Cheselden Lodge, in which he had held the posts of secretary and treasurer. He was also a member of the Cheselden Chapter and held London Grand Rank. His passing will be deeply felt by the many real friends he had made.

JAMES N. MEENAN, M.D.

Dr. J. N. Meenan, professor of medicine at University College, Dublin, died suddenly at his home on November 20 in his 72nd year.

James Nahor Meenan was born in Co. Tyrone and came to Dublin from Clongowes Wood College in 1897 with an already established reputation as a brilliant classical student. Entering the old Cecilia Street School of Medicine, he steadily maintained that reputation throughout his course of professional study, and when he graduated M.B. in 1903 he won the Chancellor's Gold Medal. In his final year at St. Vincent's Hospital he also won the Bellingham Gold Medal in clinical medicine, which award then carried with it the coveted succession to the post of resident house physician for the ensuing year. From Vincent's he passed on to the resident physician's post at Cork Street Hospital. When in 1905 the post of assistant physician became vacant at St. Vincent's Hospital Meenan's appointment was a choice approved by all. From the outset his capacity as a teacher was outstanding. A man of great modesty and of retiring habit, Meenan had come, almost involuntarily, to be a prominent figure in Dublin medical life. He had passed through every grade at his hospital till he had become the active doyen of its staff, enjoying there the trust and affection of students and staff alike. At University College his course had run on parallel lines. His first appointment there had been as lecturer in hygiene—he took the D.P.H. in 1903. From the chair of medical jurisprudence he succeeded to that of systemic medicine in 1926; later he became the representative of the medical faculty on the governing body of the college. In 1934 the honorary degree of M.D. was conferred on him by the National University of Ireland. A signal tribute was paid to him when in 1947 the then president of the college—the late Dr. Arthur Conway—retired through illness and the senate of the university requested Meenan to undertake the duties of acting president until the successor to Dr. Conway was selected. As a consultant, Meenan's opinion was widely sought throughout the country. He was consulting physician to St. Patrick's College, Maynooth, to the National Maternity Hospital in Dublin, and to Cork Street Fever Hospital. An original member of the General Nursing Council (Ireland), he was one of the two nominated members appointed to the Medical Registration Council by the Executive Council of the Irish Government in 1927. Few matters of public medical policy did not bear traces of his influence in Ireland. His readiness to assist and encourage his juniors was proverbial, and to the unexpected end his generous interest in former pupils was unfailing. At the funeral service, held in St. Vincent's Hospital, the enormous attendance of mourners, representative of every element in the community from the presidency downwards, must have brought solace to his widow and family in their bereavement.—W. D.

Dr. DAVID BLAIR, who at one time was mental superintendent of the Lancashire County Mental Hospital, at Prestwich, died in Edinburgh on November 10. He studied medicine at Glasgow University, graduating M.B., C.M. in 1894 and proceeding M.D. in 1899. Before his appointment as medical superintendent at Prestwich he was deputy medical superintendent at the County Mental Hospital, Lancaster. Blair was a Scotsman of many parts. He was of striking appearance, and his tall erect figure, friendly voice, and courteous manner were familiar to staff and patients alike. He was lecturer in mental diseases at Manchester University, but besides having an extensive knowledge of psychiatry as a science he showed above all the human touch when dealing with patients. This was particularly striking when he was showing patients to his classes of undergraduate or postgraduate students, who were always impressed by his sympathy with and understanding of a man or woman suffering from a distressing illness and requiring help and guidance. Possessing the imagination to see the advances possible in psychiatry, he was able to carry out many improvements in his hospital and had planned many others. He welcomed the passing of the Mental Treatment Act of 1930, and it was he who inaugurated one of the first psychiatric clinics under the auspices of the Lancashire Mental Hospitals Board. He did a considerable amount of original work, being specially interested in the problems of mental deficiency and endocrine disturbances, and he made several contributions to medical journals. At the Annual Meeting of the British Medical Association in Liverpool in 1912 he was vice-president of the Section of Neurology and Psychological Medicine, and he was a representative of his Division on several occasions. In 1934, the year of his retirement, the Royal Medico-Psychological Association held a most successful meeting at his hospital at Prestwich. He retained his interest in the work of these Associations for many years longer.

While Blair retained what might now be thought to be an old-world idea of the dignity of the profession of medicine, he was too kindly in disposition to be a very strict disciplinarian, and if he erred at all it was in always believing the best of people and in attributing to them the worthiest of motives. He was somewhat of a philosopher and a keen classical scholar. He was renowned for his hospitality, and many former colleagues and friends will remember his Christmas parties and tennis afternoons. Although it is sixteen years since he retired, his memory is still respected by all those who knew him. He was an approachable and generous colleague and a humanitarian with a wide interest in social and individual problems.—A. McG. and G. T.

DR. HENRY DEAN HAWORTH, for many years in general practice in Nelson, died suddenly in that town on November 4, aged 69. He was educated at Manchester Grammar School and Manchester University. As a student he won the Dauntesey medical scholarship in 1899 and the Platt physiological exhibition a year later. He graduated M.B., Ch.B. in 1903, proceeding M.D. in 1907. Before going to Nelson he held several appointments in Manchester and Salford, including those of house-physician at Manchester Royal Infirmary and senior house-surgeon at Salford Royal Hospital. In 1906 he was a research fellow in public health at the Victoria University, Manchester, and he took the D.P.H. in 1907. During the first world war he served with the R.A.M.C. Shortly after he commenced practising in Nelson he was appointed honorary physician to the Victoria Hospital, Burnley, a post which he retained until his death, though he had retired from general practice. As a consultant Haworth's opinion was always worth having in any case he was called to see. Immaculate in dress and appearance, he was always bright and cheery and a comfort to all his patients. He worked hard and was always very punctual. He took an active part in local affairs, being chairman of the Burnley Division of the B.M.A. in 1934–5. His interests, however, were not confined to his medical work. He was a keen social welfare worker, and particularly had the aged sick at heart, being a prime mover in arranging Christmas cheer, outings for the disabled, and camps for poor children. Educational matters interested him greatly, and he was a governor of Nelson Grammar School. At one time he was a member of the Nelson Town Council, and by his forthrightness he got much useful work done in the town during his membership. Beyond all these activities, he was a lover of music. An accomplished musician himself, he was for many years associated with Nelson Clef Club and was president of the Nelson Arion Glee Union, a male voice choir which obtained many honours under his presidency. He died suddenly while waiting to open a choral concert. The sympathy of his many friends and colleagues will be extended to his widow.—A. J. McC.

DR. ISAAC GEORGE BRIGGS died in Green Lane Hospital, Auckland, New Zealand, on November 2, aged 58. He was born in Birmingham, and educated at Bromsgrove School, Birmingham University, and the London Hospital. He qualified in 1927, afterwards practising in Greenford, Middlesex. Later he decided to become a barrister, and was called to the Bar at the Inner Temple. In the period between 1936 and 1939 he made several voyages to India as a ship surgeon, and on the outbreak of war he joined the R.A.M.C., in which he served as a major. After retiring from the Service he was appointed registrar at the Hospital for Head Injuries at Oxford. In 1942 he joined the Nuffield organization and was responsible for the laying out and equipping of one of its medical centres. In addition to his legal and medical activities, Briggs was the author of several books, the best-known being *How to Start in General Practice*, *The Surgeon Goes to Sea*, and *They Gave Me a Crown*. In 1947 he went to New Zealand and practised in Auckland, where he remained until his death. It is a tribute to his personality that during his comparatively short residence in that country he made many friends. He will be sincerely mourned by all his patients and medical associates, whose sympathy is extended to his widow.—F. J. G.

Medical Notes in Parliament

Legalizing Euthanasia

Lord CHORLEY on November 28 called attention to "the need for legalizing voluntary euthanasia." He recalled that in 1936 the late Lord Ponsonby had introduced a Voluntary Euthanasia Legalization Bill, but that a second reading had been refused: he wanted to bring the matter again into discussion and hoped the Government would try to solve the administrative difficulties so that the necessary legislation could be introduced.

The Bill of 1936 had laid down that the sufferer must be not less than 21 years of age, must be of sound mind, must be suffering from illness involving severe pain and of an incurable and fatal character, and must make application in writing on a set form. He had to sign the application himself in the presence of two witnesses, and it had to be supported by two medical certificates, one from his own doctor and the other from a medical practitioner with special qualifications for dealing with cases of this kind. The application had to be made to a referee appointed by the Minister of Health, who was bound to go personally to see the sufferer. Having satisfied himself, the referee would make the necessary order and the euthanasia would be administered in the presence of an official witness by a medical practitioner from a special panel maintained for the purpose.

From time to time sympathetic judges had said that the law ought to be altered to enable voluntary euthanasia to be applied. When the 1936 Bill was before the House of Lords the late Lord Dawson of Penn had made an eloquent plea for voluntary euthanasia although he voted against the Bill. He had said that it was something which belonged to the wisdom and conscience of the medical profession and not to the realm of law.

It seemed to Lord Chorley that Lord Dawson proposed to leave the decision over euthanasia to the discretion of the doctors. Many people held that doctors, moved by compassion, did take the law into their own hands; but many doctors had religious scruples against doing anything of the sort. Surely it was wrong that the wretched patient's chance of escape from his sufferings should have to depend on the accident of who was his doctor, or that society should place the burden of the decision upon the shoulders of an individual doctor.

Lord DENMAN said there was a growing force of public opinion in favour of euthanasia. Members of the Government and of the Front Opposition Bench were in the list of supporters of the Voluntary Euthanasia Legislation Society. In 1936, after the debate, he had discussed the subject with Lord Dawson, who said: "This Bill that you advocate is really unnecessary, because we already do what you seek to do under the proposals in the Bill." Lord Denman said that while it might be possible for an eminent physician like the late Lord Dawson to do as he liked in a matter of this kind, it was different for the ordinary general practitioner, who had to take the risk of prosecution and possibly of professional ruin.

The ARCHBISHOP OF YORK said the duty of prolonging life was not the same as prolonging dying. But if once Parliament began to adopt legislation of this kind it would put its foot on a very slippery slope. If the right was granted in connexion with excessive pain, why should it not also be granted to those who were born feeble-minded or physically so crippled that they could be of no service, and why should it not also be applied to those in mental asylums? In Germany euthanasia was applied at first to very few, but eventually to a large number who were regarded as useless mouths in a time of emergency. The value attached to human life would be reduced if by law it was possible year by year to kill a large number of people. From experience gained through visiting old people, often incurably ill, he doubted whether the regulations to which Lord Chorley had referred would be a sufficient safeguard. It was impossible to know what pressure might be brought to bear on people behind the scenes. When the mind had been weakened by morphine and pain it was difficult to know whether the patient fully understood what he was asking for.

Whose Agony?

Lord HORDER said that in 1936 he had pointed out that it was not a doctor's job to settle this matter. The doctor tried to cure the patient's disease, and, if this was impossible, to prolong his life, relieving pain, whether physical or mental. A good doctor distinguished between prolonging life and prolonging the act of dying. On the other hand, in his experience, the attitude of most patients was that of the soldier who wished to face the enemy: during a morning depression the patient might favour an application for euthanasia, but later in the day he thought differently, or had forgotten what happened in the morning. Their lordships must distinguish between the trials of the patient and the trials of the relatives and friends. He recollected being addressed by a tense-faced relative. "But, Doctor," said the son, "this agony must not go on." Lord Horder said he had done right in looking him straight in the eye and asking, "Whose agony?" Upstairs an old man lay slowly and peacefully dying, but downstairs people could not stand and wait.

Lord IDDESLEIGH said euthanasia had been rejected by orthodox Jews from time immemorial, by Christians since the ninth century, and by Mohammedans since the flight of the Prophet. He could conceive nothing more dangerous than to create by Act of Parliament another class licensed to bring death, and nothing more psychologically disruptive than to give that function to doctors, known to all as bringers of life and health.

Extension of Liberty

Lord ESHER said euthanasia was an evolutionary extension of liberty giving to the individual new rights to which up till now he had no access. It was argued that the doctors were against it. They all knew that when Miss Florence Nightingale was trying to reduce the sum of human misery the doctors were against her, and that when Mr. Bevan brought forward his great measures of public health he had not noticed any affection for them among the doctors.

Lord AMULREE said that it would be bad if the patient felt that one day the doctor would come in as executioner. In the last 20 years much had been done towards the relief of pain, not merely by the use of narcotics but by minor surgical operations and other treatments.

Lord UVEDALE OF NORTH END said it was notorious that doctors were occasionally wrong in diagnosis. In one case he had consulted with two of the most eminent members of the profession and they had agreed that the patient had only six months to live. That patient died years afterwards from an entirely different complaint. He thought that before euthanasia could be properly carried out the matter would have to go before a medical jury, and even that jury might come to a wrong conclusion.

Relief from New Treatments

Lord HADEN-GUEST said that no progress whatever had been made since 1936 by the advocates of euthanasia in assembling arguments which might bring conviction to an unprejudiced audience. Since 1936 there had been almost a revolution in the introduction of new methods of treatment, and a greater and more powerful armoury of drugs was in the hands of the medical profession to deal with pain and to relieve suffering. He said that he had practised in this country and in South Africa, but could not recall examples of terrible pain which called for euthanasia. At the recent meeting of the World Medical Association a resolution had been passed against euthanasia. One might say that a great majority of the whole medical profession in the world was against euthanasia. He asked the House to remember that once a law was passed there was nowadays an arrangement through which it could be extended by regulation and order. If euthanasia was to be applied it might be extended to mentally defective children, hopeless lunatics, or any of the mentally and medically unfit.

Lord WEBB-JOHNSON said members of the medical profession were unanimous in rejecting the proposal. If the idea of euthanasia had been accepted in the past patients now being relieved by modern treatment might have been quietly put away. He instanced cancer of the prostate, one of the most distressing and painful diseases, in many cases of which suffering was removed and life prolonged not by drastic treatment but by pills swallowed twice a day. Further, although a patient might apply for a form and sign it one day, he might wish to revoke it. He asked what the procedure would then be.

The EARL OF HUNTINGDON said he respected the reluctance of the medical profession, but thought that Parliament had to consider the patient. He had been told that the number of incurable cancer cases in England was about 60,000; he knew of at least three poor people who for months suffered agonizing pain through not having enough of the drugs, and cried out for release but were not given it.

The Legal View

The LORD CHANCELLOR said from the legal point of view the consequences of passing any Bill like the one which had been discussed would be most serious. He suggested that the right solution had been put by Lord Dawson of Penn when he had said:

"I read that it is lawful to use drugs to alleviate pain, even though it be foreseen that these may shorten life, provided that the alleviation of pain and not the shortening of life is the primary purpose of the drug."

If the House accepted this as the medical ethic it must leave to the conscience of the medical profession its carrying out in accordance with its traditions. If they placed such a Bill on the Statute Book he foresaw a defence in future, "I made a mistake about this. I did not get the right form so I knocked the old lady on the head." This doctrine of putting people out of what was called their misery might have very serious repercussions on the criminal law. There could be no adequate safeguards where one human being was allowed to start killing another.

Lord CHORLEY said that it was perhaps to be expected that medical peers would be more conservative than other doctors, and it was the fact that over 200 eminent members of the medical profession were strong supporters of these proposals. He pointed out that the resolution of the World Medical Association had been against the sort of thing which had been practised in Germany and not against voluntary euthanasia with safeguards.

Lord HADEN-GUEST interposed to say that the resolution had been equally directed against the course which Lord Chorley advocated.

Lord CHORLEY replied that there was nothing in the resolution about death being voluntary and nothing at all about safeguards. What the doctors who put it forward were trying to prevent was that euthanasia should be left completely to the discretion of the doctor. It was because the advocates of the proposal felt that human life was sacred and human personality was sacred that they said there ought to be this means of relief. He did not propose to divide the House, and asked permission to withdraw his motion.

The motion was then withdrawn.

The Durham Affair

This matter (see *Journal*, November 25, p. 1229) was raised again by Mr. WINSTON CHURCHILL on November 29 and by Mr. J. GRIMOND and Miss IRENE WARD on December 4.

Mr. HERBERT MORRISON in reply said that Parliament had left the choice of officers and their conditions of service to the county council except for very limited classes where Ministerial approval was needed. The Durham County Council had already been informed that the Government strongly deprecated the council's proposal to make membership of an association or union a condition of service. The Government or individual Ministers had no authority to take further action, but where their approval was sought to the termination of some appointment, or there was a breakdown, or threat of breakdown, in services for which the council had statutory responsibility, Ministers could intervene to secure the proper maintenance of the service, and would if necessary do so.

Mr. GRIMOND asked whether it was intended to introduce legislation to prevent public bodies from enforcing a closed shop.

Mr. MORRISON said he thought there were peaceful ways of resolving this difficulty and that they would be unwise to make declarations about legislation at this moment.

Mr. ANTHONY EDEN asked whether some form of discussion between the Government and Durham County Council was proceeding, and whether the House could expect a further statement before the Christmas recess.

Mr. MORRISON repeated his contention that it would be far better to try to settle the matter by persuasion, but said that, if necessary, another statement would be made.

Tuberculosis Insurance for Nurses

Dr. EDITH SUMMERSKILL stated on November 28 that she had decided to accept the recommendation of the Industrial Injuries Advisory Council that nurses and certain others who come into close and frequent contact with tuberculous infection should be insured under the National Insurance (Industrial Injuries) Act. She added that the precautions which nurses and other health workers were able to take to-day were such that the chances of contracting tuberculosis were very small. Fewer nurses had contracted tuberculosis in sanatoria than in practically any other work.

Displaced Registrars

On November 30 Mr. K. PICKTHORN and other members addressed questions to Mr. Bevan suggesting that he should suspend and reconsider his recent circular about appointments of senior registrars and registrars.

Mr. BEVAN replied that this circular, which had been grossly misrepresented, was issued after full consultation with the profession's representatives. Its object was in the interests of the profession itself—to secure a proper relationship between the numbers of training posts for future specialists and the number of specialist posts likely to be available. In estimating the latter it allowed for a reasonable annual expansion over mere replacements in present posts. The numbers of training posts would be reviewed as and when further expansion occurred in later years. The urgency of the circular was that the number of trainees had already risen to nearly twice the number needed to produce the specialists likely to be required and about four times the pre-war number, a situation thoroughly unfair to all concerned. He added that the circular was not prompted by economy. Indeed, it provided for alternative appointments if necessary for the work of the hospital.

Mr. J. K. VAUGHAN-MORGAN then asked what prospects of suitable employment were open to those 1,100 hospital registrars who would become redundant.

Mr. BEVAN replied that each existing senior registrar and registrar would complete his present year of appointment. Afterwards a senior registrar whose appointment was not renewed but whose services were still needed might be offered a similar temporary hospital appointment for one year. Others could, as had always been the case, apply to set up in general practice, possibly supplemented by a part-time clinical assistantship at a hospital.

Universities and Colleges

UNIVERSITY OF DURHAM

Professor J. Z. Young, F.R.S., will deliver the eighth Rutherford Morison Lecture at the Royal Victoria Infirmary, Newcastle-upon-Tyne, on Monday, January 15, at 5.15 p.m. His subject is "Experiments in Learning."

UNIVERSITY OF LONDON

Professor Alan Moncrieff has been appointed a representative of the university at the Conference of Home Universities to be held in London on December 15 and 16, and Professor J. H. Dible a delegate of the university at the fifth centenary celebrations of the University of Glasgow from June 17 to 24, 1951.

The following have been appointed, or nominated for appointment or reappointment, as representatives of the university on the governing bodies indicated in parentheses: Dr. C. F. Harris (British Postgraduate Medical Federation); Dr. E. C. Warner (Charing Cross Hospital); Dr. Penry Rowland (Colchester Royal Grammar School: Estates Governor); Dr. A. J. W. Beard (King's College School, Wimbledon); Mr. P. H. Mitchiner (Reigate Grammar School).

The Special Advisory Board in Postgraduate Medical Studies has been reappointed for a further period of three years from October 1.

The John Marshall Fellowship in Surgical Pathology for 1950, which is of the value of £700 a year for two years in the first instance and which is tenable at University College Hospital Medical School, has been awarded to Dr. D. E. H. Phillips (University College Hospital Medical School) as from October 1.

The Sanderson-Wells (Senior) Prize for 1950, of the value of £20, has been awarded to Dr. Alexander Swan (King's College Hospital Medical School) for his essay on "The Influence of Diet on the Occurrence of Dental and Parodontal Disease in Man." The Sanderson-Wells (Junior) Prize for 1950, of the value of £10, has been awarded to A. F. C. Coppin (St. Thomas's Hospital Medical School) for his essay on "Methods of Assessing the Adequacy of Human Diets."

The title of Reader in Anatomy in the University has been conferred on Richard John Harrison, D.Sc., M.B., B.Chir., in respect of the post held by him at Charing Cross Hospital Medical School.

UNIVERSITY OF WALES

The following candidates for the degrees of M.B., B.Ch. at the Welsh National School of Medicine have satisfied the examiners at the examination indicated:

MEDICINE.—A. G. Alexander, L. M. Charles, S. I. Davies, A. R. Harris, S. J. S. Polwin, D. St. J. D. Rees, Dilys Rees, D. B. Scourfield, T. B. Stephens, A. P. Thomas, D. S. Wood.

PHARMACOLOGY.—A. Cunningham, W. Harrop-Griffiths, Norma A. Lloyd, E. H. Massey, J. Parry-Jones, D. C. Powell, Jeanne G. Roper.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

Professor H. L. Sheehan will deliver the Weild Lecture in the Hall of the Faculty (242, St. Vincent Street, Glasgow) on Wednesday, December 13, at 5 p.m. His subject is "Renal Cortical Necrosis." Medical practitioners are invited to attend the lecture.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

The following were admitted to the Membership of the College on November 3: N. P. Bector, W. G. D. Caldwell, W. W. Ghali, D. E. Mellon, G. H. A. Chamberlain.

ROYAL COLLEGE OF SURGEONS IN IRELAND

On December 1 the Fellowship of the College was conferred on C. R. F. McDowell.

EPIDEMIOLOGICAL NOTES

Poliomyelitis

Notifications of poliomyelitis in the week ending November 25 were paralytic, 111 (110); non-paralytic, 19 (39); total, 130 (149). The figures for the previous week, compared with which there was a total decrease of 19, are in parentheses. Uncorrected notifications for the corresponding weeks in 1947 and 1949 totalled 145 and 193 respectively. Total uncorrected notifications for 1950 to and including the week under review are 8,251. The corresponding figures for 1947, 1948, and 1949 are 8,821, 2,212, and 6,327.

Kent, Devon, Gloucester, Lancs, Surrey, and the West Riding produced the largest numbers of notifications and contributed together some 38% of the total notifications.

The seasonal downward trend in weekly notifications is maintained.

Smallpox Not Confirmed

A coloured student in a hostel in Chelsea M.B. was removed to hospital on November 28 as a suspected case of smallpox. Laboratory investigations and clinical developments have now removed all suspicion of smallpox.

Industrial Accidents and Diseases

According to the *Ministry of Labour Gazette* (November, 1950) the number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in October was 117, compared with 220 in the previous month, and 114 in October, 1949. The largest number of deaths in any single category was 31 for workers underground in coal mines. In the 13 weeks ended July 1, 88 persons were killed underground in coal mines, and in the 13 weeks ended September 30, 182. The last figure includes 109 deaths in the disasters at Knockshinnoch and Cresswell collieries.

The following cases of industrial diseases in the United Kingdom were reported during October: lead poisoning, 5; mercurial poisoning, 1; anthrax, 3; epitheliomatous ulceration, 20 (pitch 7, tar 12, oil 1); and chrome ulceration, 14; total, 43.

Discussion of Table

In England and Wales increases occurred in the number of notifications of measles 1,275, whooping-cough 405, scarlet fever 180, acute pneumonia 93, dysentery 63, and diphtheria 21, while the only decrease in incidence of any size was acute poliomyelitis 76.

The largest rises in the number of notifications of measles were Yorkshire East Riding 264, London 222, Surrey 203, Yorkshire West Riding 303, and Kent 78, and the largest decline was Gloucestershire 66. A rise in the incidence of whooping-cough was reported from every region except the South Midland; the largest increases were Yorkshire West Riding 69, London 55, and Lancashire 36. A small rise in the number of notifications of scarlet fever was reported in every region except London, where the number of cases was the same as in the preceding week. The notifications of diphtheria were more numerous than for any week since March. The largest of the local rises were Lancashire 10, Glamorganshire 6, London 5, Durham 4; the largest fall was 7 in Warwickshire. A small rise in the incidence of acute pneumonia was fairly general throughout the country, the largest increases being Yorkshire West Riding 28 and London 20.

The notifications of dysentery were the largest for over six years. The chief centres of infection during the week were London 74 (Lambeth 53); Surrey 66 (Surbiton M.B. 59); Lancashire 66 (Liverpool C.B. 15, Southport C.B. 10, Prestwich M.B. 10); Leicestershire 40 (Leicester C.B. 30); Northumberland 34 (Rothbury R.D. 19, Newcastle-upon-Tyne C.B. 10); Yorkshire West Riding 28 (Morley M.B. 12); Essex 25 (Romford M.B. 14, Leyton M.B. 9); Durham 21 (Darlington C.B. 14); Glamorganshire 16 (Cardiff C.B. 16); Shropshire 13; Cheshire 13. The largest outbreak of food-poisoning was 62 notifications in Lancashire, Formby U.D.

A fall in the notifications of acute poliomyelitis occurred throughout the country. The largest returns were Gloucestershire 13 (Bristol C.B. 6); Yorkshire West Riding 12 (Sheffield C.B. 4); London 10; Cheshire 9; Devonshire 8; and Surrey 8.

In *Scotland* decreases were recorded in the number of notifications of measles 83, whooping-cough 42, acute poliomyelitis 13. There was a rise of 55 in the notifications of acute primary pneumonia. Although the notifications of dysentery were only 7 more than in the preceding week a considerable change in the regional distribution occurred. The notifications of dysentery in Glasgow rose from 57 to 103; the only other centres of importance were Lanark county 18 and Edinburgh 9.

In *Eire* decreases in the number of notifications of diarrhoea and enteritis 22 and whooping-cough 23 were the only large fluctuations in the trends of infectious diseases.

In *Northern Ireland* a fall of 63 in the number of notifications of measles was the chief feature of the returns. The fall in the incidence of measles was general throughout the country. The only case of acute poliomyelitis was notified in Down county.

Week Ending November 24

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,483, whooping-cough 4,334, diphtheria 61, measles 11,343, acute pneumonia 490, acute poliomyelitis 130, dysentery 626, paratyphoid fever 7, and typhoid fever 3.

No. 46

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended November 18.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland. *Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for:* (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland. A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1950 (a)	(b)	(c)	(d)	(e)	1949 (Corresponding Week) (a)	(b)	(c)	(d)	(e)

Rate per 1,000 total births (including stillborn)			33					21		

* Measles is not notifiable in Scotland, and the returns are therefore an approximation only.

† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

‖ Includes puerperal fever for England and Wales and Eire.

¶ Primary pneumonia no longer notifiable in Eire.

Medical News

U.S. Government Grants for Visiting America

Under the terms of the Smith-Mundt Act there are now available grants in dollars to assist faculty members at the university level, advanced scholars, and research workers to visit the United States for the purposes of research or teaching in the year 1951–2. Applications will be accepted in the following fields of study: American studies (History, Economics, Government), Education, Science and Technology, American Literature and Journalism, Administration and Management. The grants will vary in amount, and each will be calculated to assist the candidate to maintain an adequate standard of living. Grants will be awarded for a term of study of not less than six months but preferably of twelve months. Expenses of travel may be met by a Fulbright travel grant (see below). To be eligible for an award the candidate must be a British subject resident in the United Kingdom. The selecting committees will award the grants on the basis of evidence of character and scholarly achievement, as shown in the applications, the academic record, and the plan of study proposed by the applicant. Each applicant will be required to state a plan for study or a specific project which can be materially assisted by a period of from six months to a year in the United States as a research scholar or teacher. It is expected that the applicant will establish his own affiliation with an American university or research institution. Application forms may be obtained from the United States Cultural Office, Room 22, 5, Grosvenor Square, London, W.1, and the closing date is January 15, 1951.

Fulbright Travel Grants, 1951–2

Once again applications for these financial aids to assist visits to America may be made to the United States Educational Commission in the United Kingdom, 55, Upper Brook Street, London, W.1. A full statement of the conditions of grant appeared in the *British Medical Journal*, 1949, 2, 1424 (issue of December 17).

Liverpool Medical Institution

The first pathological meeting of the session was held on November 9, with the president, Dr. David Johnston, in the chair, when Dr. C. V. Harrison read a paper on "The Pathology of Pulmonary Hypertension." The paper was restricted to a consideration of primary pulmonary hypertension, in which no cause could be found in the left heart, the lungs, or the thoracic cage. Seven such cases were encountered amongst 5,000 necropsies at the postgraduate school. One of the seven was caused by multiple tumour emboli occluding most of the smaller pulmonary arteries, and another four showed visible multiple thrombotic emboli. In a group of rabbits experimentally subjected to repeated showers of small pulmonary emboli, lesions like those seen in the human cases appeared over a period of months, and gave rise to a statistically significant right ventricular hypertrophy which disappeared if the embolization was stopped. Hence repeated small pulmonary emboli should be looked for in cases of apparently primary pulmonary hypertension. The inaugural Florence Blair Bell memorial lecture was delivered by Sir Stanford Cade on November 16 on "Chemotherapy of Cancer." The address paid tribute to the personality of Blair Bell, his memorable service to the Royal College of Obstetricians and Gynaecologists, of which he was the first president, and to his work as professor of gynaecology and obstetrics in the University of Liverpool.

North of England Obstetrical and Gynaecological Society

At a meeting held in conjunction with the Birmingham and Midland Obstetrical and Gynaecological Society in Nottingham on October 13 Professor Hilda Lloyd was in the chair, and Mr. Percy Malpas read a paper on the problem of postmaturity. Mrs. A. E. Marrow described three interesting cases of volvulus associated with pregnancy. Mr. P. C. Barkla, of Nottingham, described a case in which the foetus had assumed several bizarre positions throughout pregnancy and it had always been extremely easy to convert it from a transverse or oblique position to a vertex. The child was ultimately found to have extraordinarily atonic muscles. Mr. H. Agar reported a case of stab wound of the abdomen, produced by an irate husband hurling a bread knife at his pregnant spouse.

The wife was an eighth gravida, and the wound seemed to be quite trivial at first. Her pulse rate rose, the general condition deteriorated, and laparotomy was decided upon. At operation it was found that the wound had involved the uterine musculature and impinged upon an anteriorly situated placenta. The amniotic cavity contained a large amount of blood, and one of the vessels near the origin of the cord had been incised and had led to exsanguination and intrauterine death of the foetus.

An interesting case of leaking ovarian tumour was described by Mr. L. M. Park.

A New Science Centre

Mr. Herbert Morrison announced in the House of Commons on November 21 that the Government is to build a British science centre in London to house the Royal Society and other scientific societies at present using the cramped quarters of Burlington House, Piccadilly. It will be some years before the actual buildings can be put up, but the central site to be acquired will be named early in 1951. It is planned to provide sets of rooms not only for the present occupiers of Burlington House but also for others such as the Physiological and Biochemical Societies, and the Royal Anthropological Institute, who are either without any dwelling or scattered throughout London. Hospitality will also be offered to many of the smaller clubs and societies. In addition the Patent Office and its library, and the Government scientific offices, such as the Department of Scientific and Industrial Research and possibly the Medical Research Council, will be moved to the same group of new buildings so as to provide an integrated and easily accessible capital city of science.

Scottish General Nursing Council

New members include Professor G. M. Wishart (dean of the Faculty of Medicine, Glasgow University), Dr. A. D. Briggs (medical superintendent, Stobhill General Hospital, Glasgow), Dr. W. G. Clark (medical officer of health, Edinburgh), and Dr. Mary Esslemont (general practitioner, Aberdeen). Thirteen of the 26 members of the council are registered nurses working in Scotland, elected by a nursing vote.

Royal Dental Hospital "At Home"

The Royal Dental Hospital of London School of Dental Surgery in Leicester Square was "at home" on November 25. The building was full of interesting exhibitions and demonstrations, including a demonstration of malocclusion, its aetiology and principles of treatment, by members of the junior teaching staff, and a film in colour of bilateral mandibular osteotomy. The most popular event was a Brains Trust, for which the lecture theatre was crowded out. The question master was Dr. A. B. MacGregor, and there were four members of the trust who were never caught out by any question, although they sometimes answered questions in opposite ways.

Swiss Beds for British Patients?

As announced recently in the House of Commons, the Department of Health for Scotland is sending a clinical team to Switzerland now, to study the medical facilities available there for the treatment of patients suffering from pulmonary tuberculosis. The party consists of Dr. M. A. Foulis, physician-superintendent, Robroyston Hospital, Glasgow; Dr. R. Y. Keers, medical director, British Red Cross Sanatoria in Scotland; Miss G. M. M. Carter, matron, East Fortune Sanatorium, East Lothian; and Dr. I. M. Macgregor, medical officer, Department of Health for Scotland.

In Brief

Dr. A. Q. Wells, of Shipton Manor, Kidlington, Oxford, has been nominated a Sheriff for Oxfordshire, and Dr. R. Davies Jones, of Llys Hafren, Llanidloes, a Sheriff for Montgomeryshire, North Wales.

Dr. G. Campbell has been elected president, Dr. J. G. H. McNabb captain, and Dr. R. J. Sandys treasurer, of the London Irish Medical Golfing Society.

Dr. Grantly Dick Read has been appointed honorary lecturer in the Department of Philosophy (Philosophy of Science Section) of the University of Witwatersrand. It will be recalled (see *Journal*, 1949, 2, 187) that he now practises in South Africa.

Dr. Honorio Delgado, director of the department of psychiatry and neuropathology at the Faculty of Medicine at Lima, and Peruvian delegate to the International Congress of Psychiatry in Paris and the Hispano-American Congress of Intellectual Co-operation in Madrid, visited Britain under the auspices of the British Council between November 28 and December 8. He is at present engaged in setting up Peru's first institute of neuropsychiatry and mental hygiene.

Wills

Dr. Margaret E. Bryson, of Bushey, Herts, and St. Briavels, Glos, left £10,023; Dr. J. S. S. Steele-Perkins, J.P., of Exeter, former consulting surgeon at the Royal Devon and Exeter Hospital and Exeter Dispensary, left £18,995; Colonel J. P. Cameron, C.S.I., C.I.E., I.M.S., of Camberley, Surrey, Inspector-General, Civil Hospitals and Prisons, Assam, 1931–5, and commandant, Middleton Park Convalescent Hospital for Head Injuries, 1940–5, £11,054; Mr. D. W. Daniels, F.R.C.S., of Mansfield, Notts, £14,633; Dr. O. A. P. Clark, of Worthing, and formerly of Kingston-on-Thames, £8,779; Dr. R. C. Mott, of Parkstone, Dorset, £11,066; Lieutenant-Colonel W. D. Hayward, I.M.S., of Kingsdown, Deal, £12,109; Dr. David Moodie, of Goodmayes, Essex, formerly practising at Aldridge, Staffs, and in Durham, £17,571.

COMING EVENTS

Association of Psychiatrists

A general meeting will be held at 8 p.m. on Monday, December 11, at B.M.A. House, Tavistock Square, London, W.C.1, to consider, among other matters, the recent Ministry of Health document on registrar establishments. All psychiatrists in the region, whether members of the Association or not, are invited to attend.

Scientific Film Association

A meeting of the Medical Committee of the Scientific Film Association will be held at the Royal Society of Medicine, 1, Wimpole Street, London, W., on Monday, December 11, at 5 p.m., when some films on pathology will be shown, with Professor R. Cruickshank in the chair.

Association of Sea and Air Port Health Authorities

The meeting on Wednesday, December 13, will be held at the Royal Sanitary Institute, 90, Buckingham Palace Road, Victoria, S.W.1, and not at the London School of Hygiene as previously announced.

Ophthalmology Lecture

Professor L. J. Witts, Nuffield Professor of Clinical Medicine in the University of Oxford, will deliver a lecture on "Ocular Aspects of Blood Dyscrasias" at the Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C., on Thursday, December 14, at 3 p.m. The lecture is open to those attending courses in the College and to all other medical practitioners, dental surgeons, and advanced students.

Remedial Work Among School-children

A conference on school remedial work will be held in London from January 2–4, 1951, by the Ling Physical Education Association in co-operation with the Society of Medical Officers of Health (Schools Health Service Group). Particulars may be obtained from the General Secretary, Ling Physical Education Association, Hamilton House, Bidborough Street, London, W.C.1.

Course on the Use of B.C.G.

On March 16 and 17, 1951, at the British Medical Association (Scottish Branch), 7, Drumsheugh Gardens, Edinburgh, 3, the National Association for the Prevention of Tuberculosis is holding lecture seminars and demonstrations. The fee is three guineas, and particulars may be obtained from N.A.P.T., 65, Castle Street, Edinburgh, 2.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday

●INSTITUTE OF NEUROLOGY, National Hospital, Queen Square, London, W.C.—December 11, 5 p.m., "*Congenital Diplegia*," by Dr. P. R. Evans.

MEDICAL SOCIETY OF LONDON, 11, Chandos Street, Cavendish Square, W.—December 11, 8.30 p.m., pathological meeting.

●ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.—December 11, 3.45 p.m., "*Principles of Immunity in Relation to Surgical Practice*," by Lord Stamp.

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—December 11, 4 p.m., "*Optics*" (Revision), by Mr. H. N. Reed.

●ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—December 11, 5.30 p.m., "*Anatomy of the Eye and Orbit*," by Professor T. Nicol.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE, 28, Portland Place, London, W.—December 11, 4.30 p.m., "*Studies on Child Health: Historical Background, the Unborn Child*," Harben Lecture by Sir Leonard Parsons, F.R.S.

UNIVERSITY COLLEGE, Gower Street, London, W.C.—December 11, 4.45 p.m., "*Aspects of Protein Structure*," by Dr. A. Elliott and Dr. W. E. Hanby.

Tuesday

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C., December 12, 5.30 p.m., "*The Definition and Assessment of Respiratory Function*," by Dr. K. W. Donald.

CHELSEA CLINICAL SOCIETY.—At South Kensington Hotel, 47, Queen's Gate Terrace, London, S.W., December 12, 7 for 7.30 p.m., "*Health and Education East of the Iron Curtain*," discussion to be opened by the Very Rev. Dr. Hewlett Johnson.

●CIBA FOUNDATION, 41, Portland Place, London, W.—December 12, 5 p.m., "*The Role of Suprarenal Cortical Function in Disorders of Childhood*," by Sir Stanton Hicks (Adelaide).

EDINBURGH POSTGRADUATE BOARD FOR MEDICINE.—At University New Buildings (Anatomy Lecture Theatre), Edinburgh, December 12, 5 p.m., "*Renal Cortical Necrosis*," by Professor H. L. Sheehan.

●INSTITUTE OF DERMATOLOGY, Lisle Street, Leicester Square, London, W.C.—December 12, 5 p.m., "*Pathology*," by Dr. J. O. Oliver.

INSTITUTE OF UROLOGY (UNIVERSITY OF LONDON).—At St. Paul's Hospital, Henrietta Street, London, W.C., December 12, 5 p.m., "*Epididymitis. Cystic Swelling of the Scrotum*," by Mr. J. D. Fergusson.

PADDINGTON MEDICAL SOCIETY.—At St. Mary's Hospital, Praed Street, London, W., December 12, 8.30 p.m., "*Restraint in Surgery*," by Professor C. A. Pannett.

●ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.—December 12, 3.45 p.m., "*Hormones of Adrenal Cortex*," by Professor N. F. Maclagan.

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—December 12, 5 p.m., "*Science and Art of Refraction*," by Dr. T. H. Whittington.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE, 28, Portland Place, London, W.—December 12, 4.30 p.m., "*Studies on Child Health: The Newborn Child and the Infant*," Harben Lecture by Sir Leonard Parsons, F.R.S.

Wednesday

●INSTITUTE OF DERMATOLOGY, Lisle Street, Leicester Square, London, W.C.—December 13, 5 p.m., "*X-ray Technique*," by Dr. C. W. McKenny.

INSTITUTE OF UROLOGY (UNIVERSITY OF LONDON).—At St. Paul's Hospital, Henrietta Street, London, W.C., December 13, (1) 3.30 p.m., demonstration of x-rays by Mr. Harland Rees; (2) 5 p.m., "*Tumours of the Testicle*," by Mr. H. G. Hanley.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.—December 13, 4 p.m., "*Dublin's Surgeon-Anatomists*," Thomas Vicary Lecture by Mr. William Doolin.

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—December 13, 4 p.m., "*Clinical Ophthalmology*" (Revision), by Mr. R. A. Burn and Mr. R. P. Crick.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW, 242, St. Vincent Street, Glasgow.—December 13, 5 p.m., "*Renal Cortical Necrosis*," Weild Lecture by Professor H. L. Sheehan.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE, 28, Portland Place, London, W.—December 13, 4.30 p.m., "*Studies on Child Health: The Older Child, a Glance into the Future*," Harben Lecture by Sir Leonard Parsons, F.R.S.

ROYAL MICROSCOPICAL SOCIETY.—At B.M.A. House, Tavistock Square, London, W.C., December 13, 5.30 p.m., "*Mouldlike Growth in Certain Bacteria*," by Mr. M. H. Mannering and Miss P. Davis.

ROYAL SANITARY INSTITUTE, 90, Buckingham Palace Road, London, S.W.—December 13, 2.30 p.m., discussion: "*Blowflies in Slaughterhouses*," to be opened by Mr. A. A. Green.

SOCIETY OF CHEMICAL INDUSTRY: FOOD GROUP.—At Burlington House, Piccadilly, London, W., December 13, 6.15 p.m., meeting of Nutrition Panel. "*Factors in Distribution Affecting the Quality and Nutritive Value of Foodstuffs*," speakers, Dr. J. Sword, F.R.I.C., and Miss A. M. Copping, B.Sc.

SOCIETY OF CHEMICAL INDUSTRY: BIRMINGHAM AND MIDLAND SECTION.—At University Mason Theatre, Edmund Street, Birmingham, December 13, 6.30 p.m., joint meeting with Fine Chemicals Group, "*Dextran Blood Plasma Substitute*," by A. R. Lockwood, B.Sc., A.R.I.C. A discussion will follow.

Thursday

ALFRED ADLER MEDICAL SOCIETY.—At 11, Chandos Street, London, W., December 14, 8 p.m., "*Initiation*," by Dr. Edward F. Griffith. Discussion to be opened by Dr. E. N. Snowden.

BRITISH INSTITUTE OF RADIOLOGY, 32, Welbeck Street, London, W.—December 14, 8.15 p.m., "*Presentation of the Radiograph—Photographic, Photomechanical, and Display*," by Dr. R. G. W. Ollerenshaw.

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C., December 14, 5.30 p.m., "*The Definition and Assessment of Respiratory Function*," by Dr. K. W. Donald.

EDINBURGH CLINICAL CLUB.—At B.M.A. Rooms, 7, Drumsheugh Gardens, Edinburgh, December 14, 8 p.m., "*Pitfalls in Practice*," by Dr. Douglas Robertson.

HONYMAN GILLESPIE LECTURE.—At University New Buildings (Anatomy Theatre), Teviot Place, Edinburgh, December 14, 5 p.m., "*Reflections from a Provincial Deanery*," by Dr. J. G. McCrie.

●INSTITUTE OF DERMATOLOGY, Lisle Street, Leicester Square, London, W.C.—December 14, 5 p.m., "*Bites and Stings*," by Dr. E. J. Moynahan.

INSTITUTE OF UROLOGY (UNIVERSITY OF LONDON).—(1) At St. Peter's Hospital, Henrietta Street, London, W.C., December 14, 3 p.m., ward round by Mr. A. W. Badenoch; (2) At St. Paul's Hospital, Henrietta Street, London, W.C., December 14, 5 p.m., "*Congenital Defects of the Testis and Epididymis*," by Mr. D. I. Williams.

LIVERPOOL MEDICAL INSTITUTION, 114, Mount Pleasant, Liverpool—December 14, 8 p.m., "*The Pathology of Captive Wild Animals*," by Dr. R. E. Rewell.

LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—At London Jewish Hospital, Stepney Green, London, E., December 14, 3 p.m., clinical meeting.

LONDON UNIVERSITY, Senate House, Bloomsbury, W.C.—December 14, 5.30 p.m., "*Food and Folly*," Sanderson-Wells Lecture by Sir Stanton Hicks (University of Adelaide).

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.—December 14, 3 p.m., "*Ocular Aspects of Blood Dyscrasias*," by Professor L. J. Witts.

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—December 14, 5 p.m., "*Methods of Examination*," by Mr. C. M. Shafto.

ROYAL SOCIETY, Burlington House, Piccadilly, London, W.—December 14, 4.30 p.m., "*The History of Microdissection*," Wilkins Lecture by Professor F. J. Cole, F.R.S.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—At 26, Portland Place, London, W., December 14, 7.30 p.m., "*A Review of Investigations on Scrub Typhus in Burma and Malaya*," by Dr. J. R. Audy.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, Hyde Park Corner, London, S.W.—December 14, 4.30 p.m., lecture-demonstration on neurology by Dr. A. Feiling.

TORQUAY AND DISTRICT MEDICAL SOCIETY.—At Torbay Hospital, December 14, 8.30 p.m., "*Surgical Aspects of Hypertension*," by Mr. Norman Lake.

Friday

BIOCHEMICAL SOCIETY.—At Department of Biochemistry and Chemistry, the Medical College of St. Bartholomew's Hospital, Charterhouse Square, London, E.C., December 15, 2 p.m., 292nd meeting. Scientific papers will be read.

BRITISH INSTITUTE OF RADIOLOGY, 32, Welbeck Street, London, W.—December 15, (1) 5 p.m., meeting of medical members; (2) 6.30 p.m., "*Radiation Chemistry with Emphasis on Dosimetry*," to be introduced by F. T. Farmer, Ph.D. Paper by M. J. Day, M.A.

EDINBURGH UNIVERSITY, University New Buildings (Surgery Lecture Theatre), Edinburgh.—December 15, 2.30 p.m., "*The Surgical Exposure of the Pancreas*," Macarthur Postgraduate Lecture by Professor Ian Aird.

INSTITUTE OF OPHTHALMOLOGY, Judd Street, London, W.C.—December 15, 5.30 p.m., "*Clinical Perimetry*," by Mr. G. I. Scott.

●MAIDA VALE HOSPITAL MEDICAL SCHOOL, London, W.—December 15, 5 p.m., clinical neurological demonstration by Mr. Valentine Logue.

●ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.—December 15, 3.45 p.m., "*Some Practical Applications of Bacteriology to Surgery*," by Lord Stamp.

●ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—December 15, 5.30 p.m., "*Physiology of the Eye*."

Saturday

ASSOCIATION OF BRITISH NEUROLOGISTS.—At National Hospital, Queen Square, London, W.C., December 16, 10 a.m., "*Basic Problems in the Pathology of Disseminated Sclerosis and Demyelinating Disease*," Florence Tong Lecture by Dr. E. C. Lumsden.

APPOINTMENTS

HOWELL, T. E., M.B., B.S., Principal Medical Inspector of Mines, Ministry of Fuel and Power, 7, Millbank, London, S.W.

Dr. Howell, who was born in 1900, worked for some years in the coal-mining industry before beginning the study of medicine, and obtained a first-class mine manager's certificate. His medical training was at Guy's Hospital, London, and he qualified in 1934. After a period in general practice he returned to Guy's as registrar and chief clinical assistant to out-patients. In 1938 he joined the Factory Department of the Home Office as Medical Inspector of Factories in charge of the South-western Region, and after five years, during which time he was also Lecturer in Industrial Medicine at Bristol University, he joined the Ministry of Fuel and Power as Deputy Chief Mines Medical Officer. For several months during 1946 he was loaned to the Ministry of Labour to deal with difficulties in connexion with recruitment of miners for work in the Ruhr coalfields, and he recently represented the Ministry of Fuel and Power at a Congress of Industrial Medical Officers in Vienna.

Dr. W. T. Joseph has been appointed an Official Member of the Legislative Council of the Virgin Islands.

GILLORAN, JAMES LEITCH, M.B., Ch.B., D.P.H., Assistant County Medical Officer, Cumberland County Council.

HAYWARD, J. B. W., M.B., Ch.B., Medical Director in Charge of Mass Radiography Unit at Gloucester, South-western Regional Hospital Board.

KERSHAW, G. R., M.R.C.S., L.R.C.P., D.P.H., Area Medical Officer, Warwickshire County Council, Medical Officer of Health, Borough of Nuneaton and Bedworth Urban District Council.

LYCETT, C. D., L., M.D., D.P.H., Deputy County Medical Officer of Health, Staffordshire County Council.

MCDOWALL, GEORGE D., M.B., Ch.B., F.R.C.S.Ed., Assistant Surgeon, Ear, Nose, and Throat Department, Royal Infirmary, Edinburgh.

MARTIN, KENNETH W., M.B., B.S., F.R.C.S., Senior Registrar, St. Peter's and St. Paul's Hospital, to work at St. Paul's Hospital, Endell Street, London, W.C.

NICOL, WILLIAM, M.B., Ch.B., D.P.H., Assistant Medical Officer of Health, Birmingham.

O'BEIRNE, MICHAEL S., M.B., B.Ch., B.A.O., D.P.H., M.R.C.P.I., Medical Officer, Arklow, Co. Wicklow, Eire, and Medical Officer Maternity and Child Welfare Clinic, Arklow.

PARSONAGE, M. J., B.Sc., M.B., M.R.C.P., D.C.H., Assistant Physician, Department of Neurology, General Infirmary at Leeds, and Consulting Neurologist to hospitals under the control of the Leeds Regional Hospital Board.

PRINCESS TSAHAI MEMORIAL HOSPITAL, Addis Ababa, Ethiopia.—*Medical Superintendent and First Surgeon*, S. W. Allinson, M.B., F.R.C.S., D.L.O. *First Physician*, Edward Davison, M.D., D.P.H. *Second Surgeon*, H. C. Fletcher-Jones, M.B., F.R.C.S.

ROWLEY-HARVEY (formerly Davies), SADIE MARGARET, B.Sc., M.B., B.Ch., C.P.H., Area Medical Officer of Health, No. 10 Area, comprising Abergavenny Borough, Abergavenny Rural, Pontypool Rural, and Usk Urban Councils, Monmouthshire.

TINKER, CECILY M., M.D., M.R.C.P., Senior Registrar, Lancaster House Chest Clinic, Southend-on-Sea.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Heining.—On November 14, 1950, at Beckenham, to Joan Marie (formerly Brotherton), wife of Dr. E. W. Heining, a son—Timothy Edward Dalrymple.

McCullough.—On November 28, 1950, to Dr. and Mrs. J. K. H. McCullough, 12, Middleton Hall Road, Kings Norton, Birmingham, a son—Philip Hugh.

DEATHS

Elliot.—On November 18, 1950, at Woodlands, Fleet, Hants, Andrew Elliot, M.D., M.R.C.P., D.P.H.

Finsterbush.—On November 15, 1950, at 237, Oxford Road, Reading, Edmund Finsterbush, M.D.

Foott.—On November 17, 1950, at Southsea, Hants, Frank Williamson Foott, L.R.C.P.&S.I.&L.M., aged 82.

Harris.—On November 20, 1950, Charles Edward Smith Harris, M.B., Ch.B.

Jones.—On November 21, 1950, at "Little Seeleys," Beaconsfield, George Arthur Jones, L.S.A.

Lindenstein.—On November 14, 1950, at Selly Oak Hospital, Birmingham, Louis Lindenstein, M.D., aged 71.

Macevoy.—On November 17, 1950, at Pensylvia, Sticklepath, Devon, Henry John Macevoy, M.D., late of Brondesbury, London.

McQueen.—On November 23, 1950, at Cumloden, Ridgacre Road, Quinton, Birmingham, Alexander Dairymple McQueen, M.B., Ch.B., aged 74.

Malcolmson.—On November 24, 1950, at a nursing-home, Edinburgh, Alexander Mowat Malcolmson, M.D., 305, St. John's Road, Corstorphine, Edinburgh.

Rolleston.—On November 19, 1950, at Ketton, Stamford, Lincs, Christopher Rolleston, D.M., M.R.C.P., D.P.H., aged 73.

Smith.—On November 16, 1950, at 34, High Street, Markyate, Herts, James Ernest Sutcliffe Smith, M.B., B.S., aged 73.

Sutton.—On November 15, 1950, at 57, Glenmore Road, Minehead, Somerset, Frederick Reginald Sutton, M.D., aged 79.

Swaffield.—On November 19, 1950, at 2, Deancry Street, London, W., Walter Henry Swaffield, M.D., F.R.C.S.Ed.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Value of Pasteurization

Q.—*What is the effect of pasteurization on the food value and digestibility of milk? Is there any evidence that pasteurization reduces the incidence of tuberculosis, and has it ever been shown to cause an increase of other diseases (e.g., in institutional observations)?*

A.—Pasteurization of cows' milk by the official Holder method laid down by the Ministry of Health leads to the destruction of about 10% of vitamin B and 20% of vitamin C. Carefully controlled observations on rats, mice, calves, and children have failed to reveal any change in the biological value and digestibility of the protein, in the availability of the calcium and phosphorus, in the amount of vitamin A or D, or in the total energy or nutritive value of the milk for the growing animal. The slight destructive effect on vitamins B and C is of little practical significance, because vitamin B is about 10 times as abundant in cows' milk as in human milk, and because vitamin C is present in such small quantity in cows' milk and is so readily inactivated by exposure to light that in infant feeding it must be supplemented by orange juice or some other abundant source of vitamin C. Pasteurization by the high-temperature short-time method, which is also officially recognized by the Ministry of Health, has not been studied so fully, but there is reason to believe that the minor changes it produces in milk are even less than those caused by the Holder method.

The best factual evidence that the use of pasteurized milk reduces the incidence of tuberculosis is afforded by the observations of R. M. Price (*Canad. J. publ. Hlth*, 1934, **25**, 13) at Toronto. Working at the Hospital for Sick Children, she determined the type of infecting bacillus in a series of 300 cases of non-pulmonary tuberculosis in children under 14 years of age. Of these, 15% were found to be infected with the bovine tubercle bacillus. Inquiry revealed that every one of these children came from parts of Ontario where the milk was drunk raw. In Toronto itself, where compulsory pasteurization had been in force since 1915, not a single case of infection with the bovine type was discovered in spite of the fact that 4% of the churn milk and 26% of the bulked milk entering the city contained tubercle bacilli.

There is no evidence that the use of pasteurized milk causes an increase in the incidence of other diseases. On the other hand there is a good deal of evidence to show that its use is followed by a reduction in the incidence of tuberculosis of bovine origin, of undulant fever, and of epidemic milk-borne disease such as scarlet fever, septic sore throat, diphtheria, enteric fever, dysentery, and gastro-enteritis. A classic illustration of the effect of pasteurization in reducing disease is afforded by the experience of a children's institute on Randall's Island, New York, where a mortality rate of 44.36 per thousand per annum was promptly reduced to one of 19.8 after all the milk was pasteurized, no other hygienic measures having been put into operation.

Sunlight and Pulmonary Tuberculosis

Q.—*Does direct sunlight harm patients convalescent from pulmonary tuberculosis or with healed fibrotic lesions?*

A.—There is some evidence that exposure of the chest or back to direct sunlight may cause a flare-up in patients whose tuberculosis is only quiescent. There is no evidence that exposure of other parts of the body to the sun, short of burning or "cooking," has any deleterious effect. If the lesions are really healed, exposure to sunlight is not detrimental, but it is extremely difficult to say which lesions are completely healed, and, to be on the safe side, it is best to tell patients to refrain from exposing their back and chest to direct sunlight. This of course does not apply to the very short periods of exposure involved in sea-bathing, but to lying or standing about in the sun with the back or chest uncovered.

Heredity and Peptic Ulcer

Q.—*To what extent do familial and hereditary factors play a part in the aetiology of peptic ulcers?*

A.—It has for long been noticed that relatives of peptic ulcer patients often have ulcers or complain of dyspeptic symptoms, and some families with a remarkable number of dyspeptics in them have been recorded. It has not, however, been possible to conclude from this that peptic ulcers are hereditary. The difficulty is that ulcers are so common that it is by no means unlikely for several members of a family to be affected. For example, if 10% of men develop a peptic ulcer at some period of their life, it can be shown that three out of four male relatives would be expected to develop ulcers in four of every 1,000 families. The difficulty cannot be overcome by comparing the family histories of ulcer patients with the histories given by other hospital patients, for it has been shown[1] that patients with a given disease are more likely to know about its occurrence among their relatives than are other patients who do not themselves suffer from the disease. This is only to be expected, but it is surprising how often it has been overlooked in the past.

The only satisfactory proof of the existence of hereditary factors in a common disease is obtained by comparing the incidence of the disease in relatives of sufferers with its incidence in the general population, and this can be done only when accurate information about the prevalence of the disease is known. It has recently been possible to do this for peptic ulcer, and the results[2] confirm that there is a distinct hereditary factor. It seems probable that peptic ulcers occur about twice as often in "ulcer families" as would be expected[3] and, what is particularly interesting, it appears that the site of the ulcer—whether in stomach or duodenum—is usually the same in all members of the affected family. This does not, of course, mean that environmental factors are not also significant. On the contrary, we know that they are important in the production of both gastric and duodenal ulcers. What is inherited is the liability to have an ulcer, but whether one actually develops must be largely dependent on the conditions to which the subject is exposed.

Trauma and Tuberculous Meningitis

Q.—*Has any relationship been established between trauma and the onset of tuberculous meningitis?*

A.—The general opinion on the pathogenesis of tuberculous meningitis is that the meninges are not infected directly from the blood stream but from the cerebrospinal fluid, which is itself infected from a cerebral or meningeal tuberculoma probably by rupture of a tubercle into the subarachnoid space. This view is supported by J. Schwarz in a comprehensive survey of the subject (*Amer. Rev. Tuberc.*, 1948, **57**, 63). The lesion is usually a sequel to a primary infection, but it can develop in patients in whom the primary focus has apparently healed but in whom there is an active focus of a post primary character.

In the literature on tuberculous meningitis, the influence of trauma as a predisposing factor is rarely mentioned. A. R. Rich (*The Pathogenesis of Tuberculosis*, 1944, pp. 630–3, Chas. C. Thomas, Baltimore) considers that there is evidence that the disease may follow directly upon a head injury. He makes the point that the lesion follows within a short period of the injury. Schwarz, however, does not think that the number of cases of tuberculous meningitis preceded by injury is of statistical significance, but qualifies that opinion by the statement "that repeated cerebral traumata are probably more

frequent in childhood than in other age groups," implying that head injuries may cause the infection to spread to the meninges.

Vagotomy

Q.—*What are the effects of vagotomy? How is a "medical" vagotomy performed?*

A.—The secretion of acid in the stomach is controlled partly by a hormone and partly by the parasympathetic nervous system through the vagus nerves. It has been shown that complete section of the vagi considerably reduces both acid secretion and the motility of the stomach. Beneficial results can therefore be expected in cases of duodenal ulcer, particularly where severe pain is a leading feature.

The vagi can be cut either above or below the diaphragm. Owing to anatomical abnormalities complete section is not always possible below the diaphragm and a transpleural approach is more certain, but this has the disadvantage that the lesion in the duodenum cannot be inspected. In practice an abdominal route is usually used, and by pulling on the oesophagus the nerves are severed as high as possible.

The reduction in gastric motility leads to gastric retention, and the operation is contraindicated if there is any narrowing of the duodenum. Movement of the small intestine is increased, and chronic diarrhoea may follow the operation. Pyloric narrowing may require a gastro-enterostomy to be combined with the vagotomy, and conversely vagotomy may be tried on patients who have recurrent ulceration following a short-circuit. In this way the formidable operation of gastrectomy following gastro-enterostomy may be avoided.

Belladonna paralyses the nerve endings of the vagus, and if given in sufficient quantity will reduce the secretion of hydrochloric acid. Starting with 5 minims (0.3 ml.) thrice daily, the dose should be increased by a minim at a time until the largest dose that the patient can tolerate without side-effects is given. Dryness of the mouth and blurring of vision are the principal side-effects which often militate against the successful use of belladonna. A less toxic preparation is atropine methyl nitrate in doses of 5 mg.

Faecal Incontinence in Childhood

Q.—*What are the likely causes of faecal incontinence of recent origin in a boy of 8 years? How should the condition be treated?*

A.—Probably the commonest cause is gross constipation, but in this case the incontinence is always associated with diarrhoea, due to local irritation caused by the hard scybala. The diagnosis can often be made on the history of the child's not having had a motion for several days at a time, and then having watery motions with incontinence. It is confirmed readily by rectal examination during the phase of diarrhoea, when the rectum is found to be enormously distended and loaded with hard faeces. On abdominal palpation hard faecal masses can also often be felt. Constipation of this degree is usually a behaviour problem, of which the commonest cause is undue concentration by the parents on the child's bowels. All the child's motions are inspected to see if they are "adequate," and he is compelled to stay in the lavatory if the product does not come up to the parents' desires. Occasionally the constipation may be due to a painful local lesion, such as anal fissure. If there is no associated diarrhoea, the faecal incontinence is again almost certainly a behaviour problem. It may be due to the treatment described above, but it is more likely to be due to an emotional disturbance of recent onset, such as jealousy of a new baby, domestic unhappiness, or worries at school, either because of difficulties in a particular subject or with a particular teacher, or because of bullying. The problem is perpetuated by punishment of the child in the form of smacking or of efforts to shame him.

The treatment must be directed towards the cause, and can only be very briefly outlined here. The first essential is to deal with the parental attitudes and anxieties. On no account must the child be punished or shamed for the incontinence. His greatest need is love, security, and encouragement. If the incontinence is due to hard scybala, these must be removed by saline purgatives and daily enemas, but it is essential to stop these as soon as that has been achieved. The child must then be left to look after his own bowel actions without any anxiety being shown about their sufficiency. If there is no constipation, the precipitating cause must be discovered by a really careful history in order to determine exactly what happened just before the onset of the incontinence, and in particular what is going on in the home or school to upset the child. There is no place for drugs, other than the saline purgatives mentioned above, in the treatment of the condition.

Sensitivity to Antibiotics

Q.—*(1) What concentration of an antibiotic should be used to determine the sensitivity of an organism? (2) What relation has the in vitro sensitivity of the organism to the serum concentration of antibiotic necessary for successful therapy?*

A.—(1) To obtain accurate information about the sensitivity of an organism to an antibiotic, it is necessary to use not one but a series of different concentrations of the antibiotic in separate tubes of culture medium. The result of such a test may be to show that the organism is inhibited by, for example, 0.02 unit of penicillin per ml., but not by 0.01. The various agar diffusion methods yield similar information, although this can be expressed only approximately in the same terms.

(2) The outcome of treatment certainly depends on whether the concentration found inhibitory *in vitro* is attained and indeed somewhat exceeded in the blood in consequence of the dosage given. Although this has been more or less self-evident since the earliest therapeutic use of penicillin, the fact that *in vitro* results are directly applicable to conditions *in vivo* has recently been experimentally proved by Eagle, Fleischman, and Musselman (*J. Bact.*, 1950, **59**, 625). They inoculated mice and rabbits with pneumococci, one hour previously having administered different doses of a slowly absorbed procaine–penicillin preparation giving sustained blood levels which were accurately determined. The doses required to save half the animals were those giving serum concentrations two to five times greater than the minimum effective concentration *in vitro*. This two- to five-fold difference is accounted for by plasma binding and by the concentration gradient between the blood and tissue fluids: in other words, the concentrations active *in vitro* and *in vivo* are evidently about the same.

The same considerations apply to sensitivity tests with other antibiotics, although the techniques differ owing to such factors as the instability of "aureomycin" or the marked dependence of the action of streptomycin on the size of the inoculum and the composition of the medium.

NOTES AND COMMENTS

Rectal Prolapse.—Mr. J. R. M. WHIGHAM (London) writes: With regard to rectal prolapse ("Any Questions?" November 18, p. 1184), I think the operation recommended by R. R. Graham (*Ann. Surg.*, 1942, **115**, 1007) is worth a mention. The principle of the method is based on the assumption that a complete rectal prolapse is essentially a sliding hernia of the anterior wall of the rectum. The rectum is approached from above, the peritoneal sac is removed, and the anatomical defect in the pelvic fascia repaired. I have found the results satisfactory and the operation well borne even in a patient as old as the one mentioned.

Correction.—In our report of Mr. Brock Chisholm's statement to the press (*Journal*, November 4, p. 1049) it was said that two Ethiopian medical students were studying medicine in the Sudan. We understand that this is not the case. Two Ethiopian undergraduate medical students are studying in the Lebanon and two in Egypt. Five nurses from Ethiopia are studying under W.H.O. Fellowships in Uganda.

APPENDICITIS

BY

Sir CECIL WAKELEY, K.B.E., C.B., D.Sc., P.R.C.S., F.R.S.Ed.

Senior Surgeon and Director of Surgical Studies, King's College Hospital; Surgeon to the Royal Masonic Hospital and Belgrave Hospital for Children; Consultant Surgeon to the Royal Navy

AND

PETER CHILDS, M.A., D.M., M.Ch., F.R.C.S.

Surgeon, South Devon and East Cornwall Hospital, Plymouth; late Surgical First Assistant, King's College Hospital

[WITH SPECIAL PLATE]

Appendicectomy is one of the commonest surgical operations performed, especially as an emergency. The Registrar-General's figures show that "in the period 1935–8 the number of deaths from appendicitis remained very constant, successive annual totals being 3,178, 3,053, 3,039, and 3,027. In the next three years a rapid fall occurred, to 2,733 in 1939, 2,465 in 1940, and 1,970 in 1941, but this was followed by a stationary period with 2,038, 1,976, and 1,965 deaths. In 1945 a further fall began, bringing the number to 1,774 in that year." The report continues, "These two changes were contemporaneous with the introduction on a considerable scale of sulphonamides and penicillin respectively. Non-civilian deaths included in the above totals in years 1939–45 were 11, 87, 97, 111, 90, 84, 71" (Registrar-General for England and Wales, 1949).

Development

The stages in development of the appendix are shown in Fig. A.

At the fifth week of foetal life the caecum appears as a small outgrowth of the wall of the primitive midgut, which is not yet differentiated into small and large intestines. This outgrowth is the same diameter throughout, equal to that of the intestine But about the eleventh week it increases in length. Even at this early stage the process differentiates into a basal fifth and a distal four-fifths, which grow differently. The basal portion grows equally with the large bowel, whereas the distal portion grows greatly in length but little in diameter. Thus at the end of foetal life the caecum is conical in shape, with its wide base joining the ascending colon and the narrow end tapering gradually into the vermiform appendix. Such a caecum is termed infantile, and persists for some time after birth. In 3% of cases such a type of caecum is found throughout life.

At the sixth or seventh month of foetal life the terminal part of the ileum adheres to the medial wall of the caecum for some distance. In addition, two folds of peritoneum—one anteriorly, one posteriorly—pass between the two parts. In such a way is future

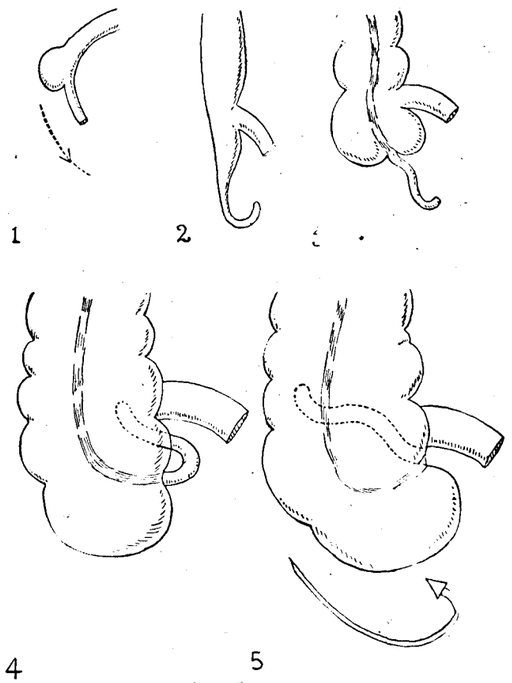

FIG. A.—Early development of the appendix, showing its tendency to become retrocaecal.

growth of the caecum regulated. As the caecum begins to expand the medial part of the wall cannot enlarge as much as the rest. The lateral part grows much more rapidly, and eventually forms the apex and most of the body of the caecum, while the original apex with the vermiform appendix is pushed into one or other of the sites mentioned below.

The level of the caecum varies at different periods of foetal life. At the eleventh or twelfth week it lies immediately beneath the liver and to the left of the median plane. Gradually it travels to the right across the descending part of the duodenum, and lies on the right side, and downward, to reach its adult position at birth or some time later. Descent may be imperfect, giving a high caecum, or excessive, in which case the caecum lies in the pelvis (Cunningham, 1931).

Anatomy

The general anatomy is well known and requires no discussion (Fig. B). But the site in which the appendix

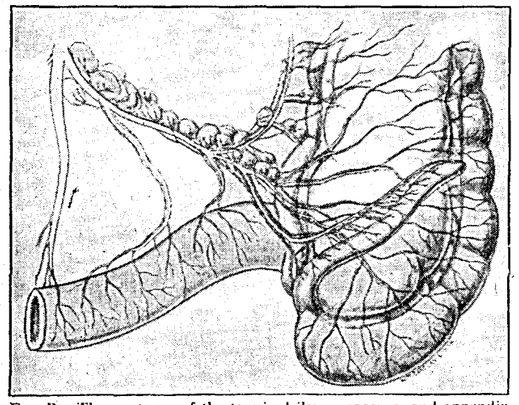

FIG. B.—The anatomy of the terminal ileum, caecum, and appendix as seen from behind.

finally settles is of importance, as the symptoms, signs, and complications of appendicitis are in some degree related to the site of the appendix.

Wakeley and Gladstone (1928) analysed 5,000 cases taken from the operating theatre, post-mortem room, and dissecting-room. Their findings are shown in Table I

TABLE I.—*Position of Appendix in 5,000 Cases (Wakeley and Gladstone)*

	No. of Cases
Anterior or pre-ileal	47 (0·94%)
Splenic or post-ileal	25 (0·5%)
Pelvic, on psoas muscle, near or hanging over brim of pelvis	1,606 (32·11%)
Subcaecal, beneath the caput caeci	101 (2·02%)
Post-caecal and retrocolic	3,219 (64·38%)
Ectopic	2 (0·04%)

In a consecutive series of 430 operations for appendicectomy performed at King's College Hospital during 1947 and 1948 the position of the appendix was noted in 171; the results are given in Table II.

TABLE II.—*Position of Appendix in 171 Cases at King's College Hospital*

	No. of Cases
Anterior or pre-ileal	7 (4·1%)
Splenic or post-ileal	13 (7·6%)
Pelvic, on psoas muscle, near or hanging over brim of pelvis	42 (24·5%)
Paracolic	7 (4·1%)
Post-caecal and retrocolic	101 (59·1%)
Ectopic—in umbilical hernia	1 (0·6%)

It is not only the site which is important surgically. In the case of the post-caecal and retrocolic appendices the relation of the appendix to the peritoneal reflection is important, for on this depends, to some extent, the likelihood of dissemination of infection into the general peritoneal cavity. Figs. C, D, and E show some of the possible relations.

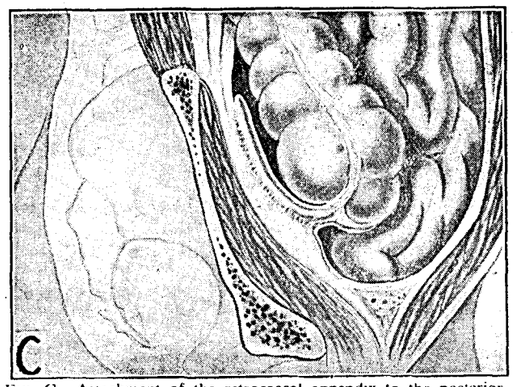

FIG. C.—Attachment of the retrocaecal appendix to the posterior abdominal wall in the right iliac fossa.

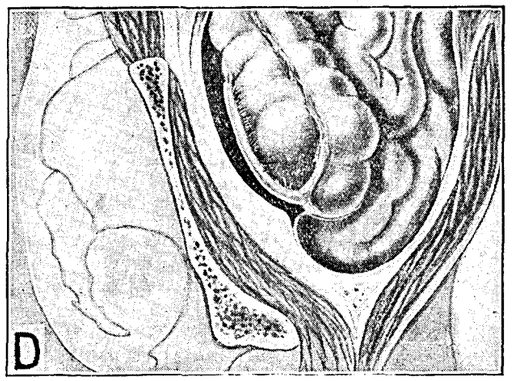

FIG. D.—The retrocaecal appendix attached to the posterior wall of the caecum

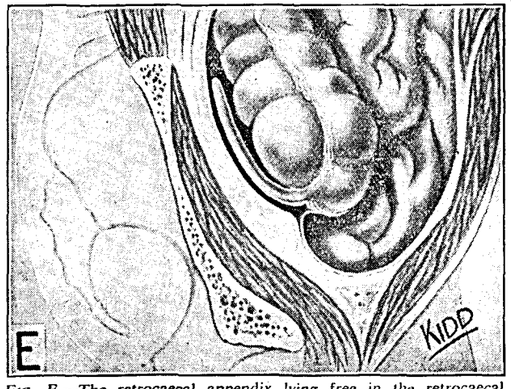

FIG. E.—The retrocaecal appendix lying free in the retrocaecal fossa.

Material.—During the 31 months, February, 1947, to August 31, 1949, 217 appendicectomies were performed by one of us. There were no deaths. It has been thought worth while to review the pathology of the appendix as illustrated in this series and to discuss the treatment of appendicitis.

SIR CECIL WAKELEY AND P. CHILDS: APPENDICITIS

FIG. 1.—Case 40. Mucosa intact; no abnormality in the outer coats apart from vascular dilatation in the subserosa. (× 25.)

FIG. 2.—Case 206. Intense congestion of vessels of the subserosa. Muscle coat oedematous and mucosa intact. (× 25.)

FIG. 3.—Case 17. Showing the earliest changes of an acute inflammatory reaction in subserosa and muscle coats. (× 25.)

FIG. 4.—Complete destruction of the mucosa; all outer coats are heavily infiltrated with polymorphonuclear cells. (× 25.)

FIG. 5.—Section of the distal part of the appendix shows complete replacement of lumen and mucosa by fibro-adipose tissue. (× 25.)

Pathology in "Acute" Appendicitis

Table III sets out the pathology found in 168 appendicectomies performed as emergencies.

TABLE III

	No. of Cases
Acute suppurative appendicitis:	
Uncomplicated	61
Non-perforated, with early general peritonitis	4
Non-perforated, with abscess	2
Perforated, with general peritonitis	6
Perforated, with abscess	2
Associated with faecaliths	4
Associated with "kinking" of appendix and localized peritonitis	1
Associated with faecalith, perforation, abscess, and local peritonitis	3
Acute gangrenous appendicitis	3
With early general peritonitis	2
With faecalith and established general peritonitis	3
With abscess	1
Late general peritonitis due to acute suppurative appendicitis	2
Appendix abscess drained	4
Acute suppurative appendicitis with evidence of past inflammation	9
Vascular dilatation in the outer layers of the appendix	1
Chronic appendicitis	10
Normal appendices	15
Containing faecaliths	16
Adherent	4
Removed from children under the age of 13	10
Containing worms	1
Misdiagnoses (pyelitis, lymphoid hyperplasia of terminal ileum, pneumonia)	3
Unknown pathology	1

The earliest case operated on was that of a medical student aged 28 (Case 40). He gave a history of only 2½–3 hours, but the signs and symptoms were typical of appendicitis and he had vomited much. The pathologist's report on his appendix is interesting (Plate, Fig. 1): "An appendix 9 cm. in length. Its mesentery is very fatty. The serosal surface is congested, but the lumen is patent throughout, and the mucosa is normal. Section shows an intact mucosa and no abnormality in the outer coats apart from vascular dilatation in the subserosa. There is no inflammatory infiltration."

The exact significance of this vascular dilatation is difficult to determine. It may, in view of the shortness of the history, represent the earliest stage of inflammation. It is impossible to be dogmatic about this, but it is worth noting that in the "acute" series five cases, and in the "elective" series two cases, in which the pathologist reported macroscopically and microscopically no evidence of inflammatory change, it was noted at operation that there was abnormally marked injection of the serosal vessels of the appendix.

Whatever may be the significance of vascular dilatation, 7 of the 61 cases of acute suppurative appendicitis indicated clearly that the infection of the appendix did not begin in the lumen. In none of these appendices was the lumen in any way obstructed, nor was there evidence of involvement of the mucosa. Typical reports from pathologists are as follows:

Case 206.—A boy aged 12½ (Fig. 2). "Section shows intense congestion of the vessels of the subserosa, which is heavily infiltrated by polymorphs and covered in a few areas by fibrinopurulent exudate. The muscle coat is oedematous, and is infiltrated by moderate numbers of polymorphs. The mucosa, which is intact, is least involved by this acute suppurative process, which appears to have started in the outer layers."

Case 17.—A boy aged 15 (Fig. 3). "Section showed the earliest changes of an acute inflammatory reaction in the subserosa and muscle coats."

The shortest history in these seven cases was 12 hours, the longest four days. All patients were between 8 and 22 years of age. None complained of nausea, and there was slight vomiting in only two cases.

Two pathological reports among the remaining 54 cases of uncomplicated acute suppurative appendicitis were as follows:

Case 89.—A man aged 29, 18 hours' history. "*The proximal* third of a 9-cm. appendix is covered with fibrinous exudate. The lumen is patent throughout and there appears to be some diffuse superficial ulceration of the mucosa. Section shows *acute suppurative appendicitis* with extensive mucosal ulceration and oedema, and polymorphonuclear infiltration of all the coats of the organ."

Case 71.—A man aged 41, 12 hours' history. "The lumen of an 11-cm. appendix is patent throughout. The proximal 2 cm. shows congestion and ulceration of the mucosa. Elsewhere the mucosa is intact, but the organ is dilated. Section through the proximal part shows early ulceration of the mucosa and diffuse and focal polymorph infiltration of the outer coats."

In none of these cases was there evidence of a causative obstructive lesion. But Case 71 does illustrate how inflammatory swelling of mucosa in the proximal part may cause obstruction secondarily.

The length of history in these 54 cases lay between 8 and 48 hours. The age incidence was as follows:

0–10 years	8 cases	41–50 years	4 cases
11–20 "	21 "	51–60 "	1 case
21–30 "	15 "	61–70 "	1 "
31–40 "	4 "		

Where the disease had progressed beyond the stage illustrated by these 54 cases we found complications.

Acute suppurative appendicitis was found with early general peritonitis in four cases, in which a seropurulent fluid was disseminated throughout the general peritoneal cavity; the bowel was injected along its whole length. A typical pathological report was as follows (Fig. 4): "The distal half is covered with inflammatory exudate, and shows mucosal ulceration. Section shows complete destruction of the mucosa, and all the outer coats are heavily infiltrated with polymorphonuclear cells."

The history in all four cases ranged from 24 hours to 3 days. All the appendices were lying free in the peritoneal cavity, one being anterior and pre-ileal and three being subcaecal.

The acute suppurative appendix can, without perforation, give rise to an abscess. This was found in Case 23, that of a girl aged 4¾ with a 48-hour history, in whom a small abscess was walled off by omentum round an unperforated appendix. And in Case 47, a woman aged 39, with an eight-day history, an abscess was found round an appendix which the pathologist described as follows: "The distal third of an appendix 7 cm. long is surrounded by a ragged mass of haemorrhagic tissue. The lumen is patent and there is no obvious ulceration of the mucosa. Section through the distal part shows it surrounded by a mass of haemorrhagic granulation tissue which is heavily infiltrated by polymorphs. The inflammation extends through the muscle coats into the submucosa, but the mucosa is intact."

In six cases perforation of acute suppurative appendices occurred, and general peritonitis ensued, with free pus in the peritoneal cavity. In Case 85, a man aged 37 with a five-day history of pain in the right iliac fossa, the pathologist's report was: "The specimen consists of an appendix 5 cm. long. The mucosa is extensively ulcerated, and perforation has occurred in the middle third of the organ, where its wall is completely necrotic."

The length of history in these cases ranged from 36 hours to 5 days. A feature worthy of note was looseness of and frequency of motions in four of the six cases. This symptom was associated with both pelvic and retrocaecal appendices. The ages of the patients were 7, 11, 15, 36, 37, and 50 years.

In two cases of acute suppurative appendicitis, one retro-ileal with a 36-hour history, the other subcaecal with a 56-hour history, perforation of the appendix occurred with localization and formation of an abscess. Adjacent loops of small bowel formed the abscess wall.

Abscess formation is a complication of acute suppurative appendicitis, but abscess formation may itself be complicated by general peritonitis. In Case 1, that of a woman aged 62, a diagnosis of general peritonitis was made preoperatively. At operation this was found to be due to spread from an abscess cavity lying behind the caecum; while in Case 5, that of a girl aged 17½ with an eight-day history of abdominal pain, general peritonitis was found to be due to spread from an abscess which had formed round a pelvic appendix.

Four acute suppurative appendices were complicated by the presence of faecaliths. The histories ranged from 24 to 48 hours. Vomiting was a marked feature in two cases, where the faecalith was clearly obstructing the lumen. Colic was pronounced in the third case. In the fourth case neither colic, nausea, nor vomiting was complained of.

In Case 132, that of a man aged 32 with a four-day history, the patient complained of copious vomiting and much colic, and an acute suppurative appendicitis, with a kink obstructing the lumen, and local peritonitis of the adjacent bowel were found. The appendix was lying retrocaecally.

Acute gangrenous appendicitis was found in three cases —two girls aged 17 and 14 years, and a boy aged 6. The histories ranged from 24 to 48 hours, and the appendix was in one case retro-ileal, in one pelvic, and in one retrocaecal. There was a localized peritonitis round the appendix in all three cases; in two of the cases faecaliths were obstructing the lumen. In Case 131, that of a boy aged 6 with a 24-hour history, the pathologist reported: "The lumen of a 7.5-cm. appendix is obstructed 2.5 cm. from the tip by a hard pellet of laminated faecal material. Beyond this point the wall is gangrenous, the serosa is covered by fibrinous exudate, and the lumen is filled with pus." In all these cases persistent vomiting was a marked feature.

In two cases acute gangrenous appendicitis led to early general peritonitis, with foul-smelling seropurulent fluid free in the peritoneal cavity, in 36–60 hours. In Case 60 the pathologist reported: "The appendix, 6 cm. in length, shows the typical naked-eye appearances of late acute suppurative appendicitis. Section shows almost complete destruction of all the coats of the organ." In one of these cases the appendix was retrocaecal, in the other pelvic. In one vomiting was a marked feature.

Two cases of acute gangrenous appendicitis in association with a faecalith perforated and gave rise to well-established general peritonitis, after 48 hours in one case and five days in another. In both cases vomiting was a marked feature. One appendix was pelvic, the other retrocaecal. In Case 111, that of a man aged 32 who gave a history of three days' abdominal pain but who had not vomited at all, the pathologist reported: "The mucosa of the proximal half of the appendix is dark and ulcerated. The wall is thickened and the serosa covered by exudate. Beyond this the lumen is obstructed by a faecalith, and beyond this faecalith the wall is thin, completely necrotic, but not yet perforated.

In Case 40, that of a man aged 72 with a five-day history, a gangrenous retrocaecal retroperitoneal appendix was found surrounded by an abscess.

In four cases of appendix abscess which were drained only, the appendix was removed at a later date. In Case 204, that of a woman aged 49, the pathologist's report on the appendix removed one year later was: "The wall of the appendix is thickened, and the lumen of the terminal ¾ in. (1.9 cm.) is obliterated. No section was made."

In Case 55, that of a man aged 46, the pathologist reported six months after the abscess was drained (Fig. 5): "The middle part of an appendix 4 cm. long is replaced by a thin fibrous cord, and the distal part of the lumen is obliterated. Section of the distal part shows complete replacement of the lumen and mucosa by fibro-adipose tissue."

Perhaps the most intriguing finding is in Case 29, that of a boy aged 3 years who had an appendix abscess drained, and four months later had his retrocaecal appendix removed. The pathologist reported: "The specimen consists of an appendix 4 cm. in length. There is some patchy congestion of the serosa. The lumen is patent throughout. The mucosa and muscle coats show no naked-eye abnormality. Section shows an intact mucosa with no evidence of past or recent inflammatory change in the submucosa or subserosa."

There were nine cases in which acute suppurative appendicitis was found in appendices showing evidence of previous pathological change. In Case 195, that of a woman aged 63 who had a long history of dyspepsia and a recent history of 48 hours' pain in the right iliac fossa, there was localized peritonitis, and free pus was found round an anterolateral paracolic appendix, the lumen of which was obliterated, while the tip was patent, the site of acute suppurative appendicitis, and perforated. She had not vomited. In contrast, in Case 129, that of a woman aged 43 with a 24-hour history, acute suppurative appendicitis was found in the proximal part of the appendix, the tip of which was not inflamed. She had vomited much, and had looseness and frequency of bowel motion. In two other cases the distal part of the appendix was obliterated by fibro-adipose tissue, while the proximal segment was the site of an acute suppurative process. In two others there was proximal obliteration of the lumen, with a distal acute suppurative process. In three cases there was thickening of the wall with subserosal and submucosal fibrosis. In at least one of these cases there was no previous history of abdominal pain.

In the 10 cases reported as chronic appendicitis by the pathologist, the lesions found were: submucosal fibrosis in six cases; subserosal fibrosis in five cases; and obliteration of the lumen, in part, in seven cases.

In Case 92, that of a woman aged 34 with a history of previous attacks and a recent history of 24 hours, the report was: "The middle quarter of an appendix 5 in. (12.7 cm.) long is almost obliterated, and reduced to a thin cord. There is slight dilatation beyond this, and it contains mucoid material. Section shows well-developed submucosal and subserosal fibrosis." Such an appendix might well have developed into a mucocele of the appendix.

Pathology in "Chronic" Appendicitis

Table IV shows the pathology of the appendix in those cases in which it was removed as an elective procedure (39 cases).

TABLE IV

Acute suppurative appendicitis	4
Chronic appendicitis	9
Vascular dilatation of outer layers of the appendix	2
Normal appendix	12
Normal appendix containing faecaliths or inspissated faeces	7
Normal appendix associated with kink	1
Normal appendix associated with adhesions	4

There were four cases in which the appendix showed acute suppurative appendicitis.

Case 80.—A woman aged 41 had had attacks of pain in the right iliac fossa on and off for four years. Her first attack began with pain in the right iliac fossa, and later she felt sick and vomited several times. The second attack was two years later. It lasted for two days with pain which was not so severe as in the first attack. She felt some nausea but did not vomit. Her tongue felt "rough," her appetite was poor, and she felt constipated. Since then she has had frequent mild attacks of similar character at intervals of three to six months, and in the last attack she had some diarrhoea.

Examination on admission showed only one abnormal finding —namely, tenderness in the right iliac fossa. Operation showed the appendix to be adherent in the pelvis. The pathologist reported: "The lumen of the 6-cm.-long appendix is patent throughout. The mucosa and outer coats show no macroscopic abnormality. Section shows a very early stage of acute suppurative appendicitis with focal polymorphonuclear infiltration in places. The lumen contains purulent exudate, and there is oedema of the outer coats."

In the other three cases intermittent pain in the right side was the only prominent symptom, and tenderness in the right iliac fossa the only sign. In one case the barium meal and follow-through examination was negative, and in one the radiologist reported chronic appendicitis. In all three the pathologist reported acute suppurative appendicitis with ulceration of mucosa.

In the nine cases reported by the pathologist to be chronic appendicitis the lesions found were: obliteration of the lumen by fibro-adipose tissue, five times; submucosal fibrosis, five times; and subserosal fibrosis, three times.

In both the "acute" and the "chronic" series there were appendices which were normal macroscopically and on histological examination. The significance of such "lily white" appendices has been discussed elsewhere (Childs, 1949).

Mode of Infection

In this series of cases evidence is heavily in favour of infection by the blood stream. Those appendices showing early changes have changes in the outer layers. Inflammation and ulceration of the mucosa occur relatively later in the disease.

Mechanical obstruction of the lumen of the appendix does not seem to play any part in the initiation of acute appendicitis. When acute suppurative infection occurs in an appendix which shows evidence of previous inflammation it is as likely to be found proximal to an obliterated part of the lumen as it is to be found distal (See Cases 195 and 129 above). When the infection is distal to an obliteration of the lumen the mechanical obstruction produces a secondary effect. It causes a rise in tension in the distal part, and perforation may result therefrom. It is our impression that faecaliths play no part in the initiation of disease; but when the appendicular tissues around a faecalith become swollen and infiltrated the faecalith acts as an immovable object and causes pressure necrosis and perforation. It is significant, too, that faecaliths are so often found in association with acute gangrenous appendicitis.

Those cases of acute suppurative appendicitis in which there is no perforation but a localized or generalized peritonitis or an abscess also point to blood-stream infection; for in these cases it is sometimes found that the mucosa of the appendix is not involved in the inflammation.

In none of our cases has there been any evidence to suggest spread of infection from within the lumen of the appendix.

Diagnosis

It is not our intention here to recapitulate the signs and symptoms of appendicitis. They are well known. But we do wish to emphasize one or two points. In a case of uncomplicated appendicitis there is no place for "expectant" treatment. The case is one of acute appendicitis requiring urgent operation, or it is a case of chronic appendicitis in which operation may be performed as an elective procedure. There are several features of the presentation of the case which may help in the making of a decision:

(*a*) Where symptoms which were intermittent have become constant or more frequent, or where there has been sudden and definite aggravation of the symptoms, operation should be regarded as urgent.

(*b*) Where fetor of the breath is appreciated, pungently but not constantly, just as one appreciates the scent of roses on a summer evening, operation must be considered urgent.

(*c*) Absence of pyrexia has no significance, but when slight pyrexia is associated with the signs and symptoms of appendicitis operation must be looked upon as urgent.

(*d*) Where vomiting and looseness of the bowel are prominent features of the history operation should be regarded as urgent.

(*e*) When pain is experienced in the left iliac fossa and maybe spreads upwards to the left costal margin, but is associated with tenderness in the right iliac fossa, the appendix will be found lying in the pelvis and extending across the midline. Operation should be considered urgent in such cases.

(*f*) In children, if it is thought that they may have appendicitis, operation is always urgent.

(*g*) The path of development of the appendix must be remembered. Where the caecum is undescended an appendicitis may give rise to pain and tenderness high up under the costal margin; or the caecum may have descended into the pelvis, and tenderness may be found only per rectum.

Treatment

1. *Chronic Appendicitis.*—Elective appendicectomy was performed through a muscle-split incision in the right iliac fossa. This incision was used in females as well as males whenever the diagnosis was assured. The wound was closed without drainage and the patient was allowed—nay, rather encouraged—to walk the next day, and if home circumstances were satisfactory the patient was sent home on the third or fourth post-operative day. A paramedian incision was used only rarely, when it was thought desirable to explore the abdomen.

2. *Acute Appendicitis.*—Urgent appendicectomy was performed through a muscle-split incision in the right iliac fossa. The muscle split incision can readily be converted, for greater ease of access in difficult cases, into a muscle cut as used by the Newcastle school and originally described by Rutherford Morison. The peritoneum was closed without drainage. The skin was also closed without drainage unless it was thought that it might have been contaminated. In the event of complications being found at operation, treatment was modified as follows:

(*a*) If there was an appreciable quantity of seropurulent fluid in the abdomen, with an early general peritonitis, the peritoneal cavity was cleared of this, so far as was possible, by sucker and gauze mops, particular attention being directed to the pelvis and the right paracolic gutter. The peritoneum was closed without drainage, but the wound was drained. The patient was treated post-operatively with continuous gastric suction, nothing by mouth, and intravenous saline and glucose-saline, until the gut moved again spontaneously.

(*b*) Where appreciable involvement of adjacent viscera by local peritonitis was found the appendix was removed, 10 g. of sulphathiazole and penicillin powder dusted over the affected area, the peritoneum closed without drainage, and the patient

treated post-operatively with continuous gastric suction, nothing by mouth, and intravenous saline and glucose-saline. Only in the more severe cases were systemic penicillin and sulphadiazine given.

(c) Where an abscess was found surrounding the appendix the appendix was removed whenever possible, the cavity cleared of sloughs (and faecaliths, if present), 10 g. of sulphathiazole and penicillin powder was dusted into the cavity, and the peritoneum was closed without drainage, but the wound was drained. The patient was given penicillin and sulphadiazine systemically, post-operatively. And if the abscess was not completely retrocaecal, post-operative suction and intravenous drip therapy was used.

3. Where the patient presented as a case of well-established late general peritonitis it was not possible to be certain pre-operatively that the appendix was the cause. Paramedian incision was used in these cases; a drainage-tube was placed in the pelvis and a stab drain into the right iliac fossa, and the wounds were closed. The patient was given systemic penicillin and sulphadiazine and treated with gastric suction and intravenous drip therapy. The appendix was removed through a muscle-cut incision in the right iliac fossa later.

4. Where the patient presented with an appendix abscess, a muscle-split incision in the right iliac fossa was used. The appendix was not removed unless it was readily accessible. If the appendix was not removed a drain was placed into the abscess cavity after it had been cleared of pus and sloughs (and faecaliths, if present). If the appendix was removed the cavity was dusted with penicillin and sulphathiazole powder, and the peritoneum closed without drainage, though the wound was drained.

Complications

In our series there were no deaths. Table V gives a list of the complications which developed post-operatively.

TABLE V.—*Post-operative Complications*

Respiratory	Slight	3
	Moderate	7
	Severe	1
Wound infection	Slight	6
	Severe	6
Persistent sinus		1*
Pelvic abscess		3†
Thrombophlebitis in calf		1
Penicillin urticaria		2
Irritation of skin due to penicillin		1
Prolapse of omentum along drainage-tube track		1

* Actually shown by lipiodol injection to be a fistula leading through the appendix into the caecum following drainage in an eight-day case of general peritonitis. There was no faecal discharge.

† All cases of general peritonitis—1 developed on fifth day and discharged P.R. on tenth day; 1 developed on seventh day and discharged P.R. on eleventh day; 1 developed on 24th day and resolved by 36th day.

Mortality before the Advent of Sulphonamide and Penicillin Therapy

Bailey (1932) reported a mortality of less than 1% in those cases of acute appendicitis operated on within 12 hours of onset. If operation was delayed until 36 hours after onset the mortality rose to 11–18%. Peritonitis was the cause of death in more than 80% of fatal cases. Christopher and Jennings (1932) reported a mortality of approximately 5% in cases of acute appendicitis.

Holcomb (1932) reported 5 deaths in 153 (3.3%) cases of acute appendicitis. One death occurred in a case of acute suppurative appendicitis, three in cases with perforation and general peritonitis, and one in a case with gangrenous appendicitis and general peritonitis. Rayner (1933) had 17 deaths in 347 cases (4.9%); the proportion of "early" cases in the series (that is, within 24 hours of onset) was 25%. Garlock (1934) reported a mortality of 4.6% in 433 cases. Nuttall (1934) quotes McNeill Love: operation on first day, 1.1% mortality; on second day, 2.8% mortality; on third day, 10.3% mortality.

Comment

In 1932 Shipley and Bailey were advising strongly against the use of drainage-tubes inside the peritoneal cavity. They increase the formation of adhesions and the liability to the production of post-operative obstruction. They need only be used, in our experience, in those cases in which the appendix is not removed.

Peritonitis was the commonest cause of death in days gone by. Provided the appendix is removed or the site of the appendix is drained, few patients need now die of peritonitis if systemic sulphonamide and penicillin therapy is used, the bowel is put completely at rest by the use of continuous gastric suction, and intravenous fluids are given to maintain the electrolyte balance until the bowel moves once again of its own accord.

Since McNeill Love (1933) advocated expectant treatment for cases of appendicitis with localized peritonitis, the following have been added to the surgeon's armamentarium: sulphonamides, penicillin, intravenous drip therapy, and gastric suction.

This new armamentarium has increased the safety of immediate operation in the presence of localized peritonitis. In the above series of cases, expectant treatment was practised only three times; in all three cases—two of abscess and one of appendix mass—the local signs indicated spread during the time the patient was watched, and operation was therefore performed.

Conclusions

Early diagnosis and early operation remain the most important factors in reducing mortality due to appendicitis.

If the diagnosis is appendicitis, and if it is clearly not chronic, operation is urgent. There is no place for expectant treatment.

Sulphonamide and penicillin should be used locally in the peritoneal cavity if there is an abscess or much local peritonitis, but the peritoneal cavity should never be drained if the appendix has been removed. Sulphonamide and penicillin should be given systemically whenever inflammation is widespread.

If there has been soiling of the general peritoneal cavity, or involvement of loops of small bowel in local peritonitis or in the wall of an abscess cavity, treat the patient with continuous gastric suction and intravenous drip therapy post-operatively until the bowel moves again of its own accord.

Always drain the wound if there is danger of contamination.

We wish to express our thanks to Mr. E. G. Muir, under whom some of these patients were admitted; Professor H. A. Magnus and his pathological department; Mr. W. Smith, of the photographic department, for the photomicrographs; and Miss Fern and her Record Office staff.

CARE OF THE TUBERCULOUS IN THE HOME*

BY

F. R. G. HEAF, M.D., F.R.C.P.

Professor of Tuberculosis, University of Wales

At the end of 1948 there were approximately 210,000 cases of tuberculosis on the dispensary registers; 180,000 of these were respiratory tuberculosis, and about 100,000 of them were expectorating tubercle bacilli. Every one of these cases was a potential source of spread of the disease. At the same time approximately 30,000 beds were occupied by patients suffering from respiratory tuberculosis; about one-third of these patients would not be infectious, so that 20,000 of the positive cases were in-patients, leaving 80,000 patients, most of whom were expectorating tubercle bacilli, among the general population. This is a minimum figure, as mass radiography surveys show that there are at least three unknown cases with active disease among every 1,000 adults between the ages of 15 and 45. If these are taken into account another 57,000 persons must be added, making a grand total of 137,000 cases of respiratory tuberculosis with active disease under domiciliary conditions. It is the care of this great army of infectious and potentially infectious persons that is the problem we have before us.

It will not be denied that every case with a positive sputum constitutes a public health problem, and in most instances a medical one, too, so that the subject is of major importance in any tuberculosis scheme. Curiously enough, the attention given to it bears little relation to its magnitude and significance. The problem has come into prominence in recent years because of the shortage of institutional beds. We have been forced to treat patients in their homes, and we are finding out that much can be done to benefit them: in some instances actual recovery can be effected without resorting to institutional care. The number of patients treated in their homes who return to normal life and work without danger of spreading tuberculosis to their fellows is increasing every year. This is a most significant change in tuberculosis administration, and will have a profound effect upon the future development of public health programmes.

Approach to the Problem.—The problem may be approached from two points; first, from consideration of the requirement of the individual to recover or maintain a good state of health; and, secondly, from the need of the community as a whole to be protected from the risk of contracting the disease. In other words, we have the curative aspect and the preventive aspect, neither of which must be allowed to eclipse the other.

The Curative Aspect

Although the results of domiciliary treatment are becoming known, most persons suffering from tuberculosis are still recommended for a period of sanatorium treatment. It is possible that this slavish adherence to the prescribing of this form of treatment has become a habit, and a more enlightened approach to the management of all cases might be established by asking ourselves in every case if sanatorium treatment is really necessary. In present circumstances, whatever the answer may be, most patients will be treated at home for a long period. It is only recently that the problem of pre-sanatorium domiciliary care has become a matter of importance, and we must realize that it has come to stay for a number of years. It is therefore worthy of close attention and detailed study.

*Read in opening a discussion at a combined meeting of the Sections of Diseases of the Chest and Tuberculosis and of Preventive Medicine at the Annual Meeting of the British Medical Association, Liverpool, 1950

Pre-sanatorium Period

When tuberculosis has been diagnosed the management of the case will depend greatly on the social circumstances; but, whatever these may be, it is essential that the family appreciates the implications of the diagnosis and that certain obligations fall on all its members to play their part in assisting the patient towards recovery. In this matter it is highly probable that the general practitioner can be of considerable help, as he usually has a better acquaintance with the individual peculiarities of each member of the family, and knows best how to deal with them. It is important, however, that the chest physician and the general practitioner agree on the line of treatment to be pursued. A most unfortunate situation would arise if the former advocated rest in bed and quiet, whilst the other recommended basking in the sun on the hill-tops. It is hoped that neither of these physicians will cause unrest and discontent by arguing with the patient and members of the family about the National Health Service Act, and enlarge upon the fact that there are not enough sanatorium beds to allow for the immediate admission of patients to institutional treatment. However much we may fume within ourselves, such agitation does nothing but harm if passed on to the patient.

It will be agreed that during this pre-sanatorium period, which may be as long as nine months, the one important lesson the patient has to learn is the need for rest of both mind and body. Every instruction and piece of advice to the family must be designed to promote an atmosphere of calm patience in the home, thus providing the foundation on which treatment depends—treatment that quite often reduces the duration of the subsequent period at a sanatorium and sometimes eliminates the necessity for it altogether. I would say that three essentials in successful home treatment are (1) the full co-operation of the patient and the family; (2) freedom from financial anxiety; and (3) the possibility for the patient to obtain the necessary rest in bed. There are other essentials; but these are of primary importance, and without them success cannot be obtained. Adequate physical rest is complementary to peace of mind, and the spectre of want can easily destroy both.

In some homes it is impossible to create an atmosphere that is conducive to recovery. The experienced chest physician will soon become aware of this and not attempt the impossible. Patients in these households must be sent to sanatorium or hospital to escape the nerve-racking of such conditions, the most frequent cause of which is overcrowding. Where this exists, domiciliary care is extremely difficult, and priority of admission to an institution should be given to all such cases. If this is not done, money and labour will be wasted, for domiciliary treatment costs money and involves a great deal of work for the staff of the chest clinic.

It is a big mistake to think that treatment of patients at home can be organized without considerable expenditure, and both regional hospital boards and local health authorities must be prepared to vote money so that the necessary facilities may be provided. It is cheaper than sanatorium treatment, but that does not mean that it costs nothing. Money must be found to provide an adequate

ambulance service, sufficient home helps, good equipment for the chest clinic, and enough health visitors and handicraft instructors to give every patient the full attention he needs. Home helps are the key to the problem of relieving the patient of domestic worries. We all know how difficult housekeeping has become these days. If the patient happens to be the mother of the family, she can obtain no rest without a generous provision of labour in the form of home helps. To start a scheme of domiciliary treatment without home helps is like running an engine without oil.

Domiciliary care becomes increasingly difficult with the lowering of the standard of living and the morals of the home. In fact, in certain areas the factors that we know to be the predisposing causes of tuberculosis are present to such a degree that it is useless to try to establish domiciliary care until they are removed. In this problem, as in others connected with tuberculosis, we must be realists and deal with fundamentals, otherwise we shall waste much money in attempting to achieve the impossible.

Special Treatments

There are, however, homes in which domiciliary treatment can be carried out with success; and where this is so the enthusiastic physician will often be of the opinion that, although adequate rest has been secured for the patient, more can be done by the application of special treatments in the form of collapse therapy, postural rest, and antibiotics and chemotherapeutics. It must be realized that the inability to exercise close supervision over the patient introduces an element of risk into the administration of special treatment in the home. If there is sufficient staff at the chest clinic to provide frequent visits to the patient, and a good ambulance service to ensure the attendance of the patient at the clinic for adequate radiographic control, then much can be done to reduce these risks to a minimum.

Active domiciliary treatment throws a great strain on the chest clinic and a considerable amount of extra work on the staff. We all know that with collapse therapy certain complications often arise. Adhesions need cutting, fluid has to be aspirated, phrenic operations may be necessary, and, occasionally, emergency admission to hospital must be provided owing to the development of an empyema or a bronchial fistula. These complications can be avoided by inducing a pneumoperitoneum instead of a pneumothorax, but even here it is usually necessary to have the services of a surgeon.

Existing Schemes

Three different schemes have been developed to provide special treatment in the home during the pre-sanatorium period. In Glasgow in 1943, under the direction of A. Maclean and J. S. Gemmill, four beds were reserved in Baird Street Auxiliary Hospital, to which selected patients awaiting admission to sanatorium, and suitable for collapse therapy, were admitted. Artificial pneumothorax was induced on the day of admission, and the first and second refills were given on the following days. Some hours after the second refill the patient was sent home by ambulance, and rest in bed continued at home; refills were given at the hospital on the fifth or sixth day after induction and subsequently at weekly intervals. A report on 150 consecutive cases treated in this way shows that 20 to 33 months after induction the result was satisfactory in 82 cases, and in 65 (43%) recovery was obtained without any institutional treatment (Maclean and Gemmill, 1948). Sputum conversion occurred in at least 36%.

A modification of the Glasgow scheme has been adopted by Wynn-Williams, Shaw, and Mashiter (1950) in Bedfordshire, where selected patients suitable for collapse therapy, and others in need of emergency treatment, are given priority of admission to sanatorium, but when they are ambulant for two hours they receive their discharge to enable treatment to be carried on at home, with medical supervision at the chest clinic or sanatorium. In this scheme chronic cases with good home conditions are not admitted to institutional beds, but are given necessary treatment at home. In selected cases phrenic crush, pneumoperitoneum inductions, and bronchoscopies are performed on out-patients.

Heller (1949), at Hounslow, induces artificial pneumothorax or pneumoperitoneum, and is not averse to giving streptomycin while the patient is under domiciliary treatment. Phrenic crush is performed on selected cases in the out-patient department. Of the 50 cases in which artificial pneumothorax treatment was attempted, a successful induction was obtained in 33, and the disease was arrested in 11 and made quiescent in 19. Five of the artificial pneumothorax cases developed fluid. Pneumoperitoneum was induced in 150 cases and had to be abandoned in only 11. Eight of the artificial pneumothorax cases were treated entirely at home, and 25 were admitted to sanatorium for short periods for adhesion section.

James Cuthbert (1950) by careful selection of cases has had good results when admitting patients to hospital for successive periods of from three to five nights for the induction of a pneumoperitoneum with a phrenic crush, later for artificial pneumothorax induction, and, finally, if necessary, for adhesion section. In this way collapse therapy is established without undue risk while the patient is at home, and the danger of the development of progressive disease during the waiting period before sanatorium treatment is considerably diminished.

Toussaint has carried out domiciliary collapse therapy for a number of years, and at Tottenham he has been giving artificial pneumothorax and pneumoperitoneum treatment whilst the patient remained at home. He has had very encouraging results, achieving quiescence in 60% of cases. The organization of the scheme is worthy of close study, as it is a model of its kind. While in no way detracting from the value of the work, it must be noted that the Willesden Chest Clinic is very well staffed, the Central Middlesex Hospital is most co-operative in every way, the services of a thoracic surgeon are readily available, the area served by the clinic is mainly of the artisan and lower-middle-class type, and, most important of all, a large number of home helps are available. These conditions and facilities are not always easy to obtain, but that does not mean that we should be deterred from extending the trail that has been blazed by the enthusiastic work of an energetic chest physician. To-day domiciliary treatment is a necessity, and Toussaint has shown us what is needed to produce good results.

Administration of Special Treatments

It will be agreed that, although the administration of special treatments under domiciliary conditions may not be a method of choice and has been adopted only because the bed situation causes such a long waiting period for admission to sanatorium, it can nevertheless be carried out successfully and be of benefit to the patient. Those who have practised it are unanimous on four points: (1) it throws a very heavy strain on the staff of the chest clinic: (2) the chest clinic must be well equipped; (3) it is necessary to have a good and efficient ambulance service at the disposal of the chest physician; and (4) the latter must have complete control of the patient during domiciliary treatment and during periods of admission to sanatorium or hospital for special procedures. There must therefore be close co-operation between the chest physician and the medical superintendent of the hospital.

To these points I would add that the services of a thoracic surgeon must be available when required, and the local health authority should show a sympathetic interest in the work and provide the means to enable the patient to procure adequate rest at home. I would emphasize that in all domiciliary treatment there must be complete agreement and mutual co-operation between the local health authority and the regional hospital board, as each of these bodies has a special responsibility in the matter, and if quibbling about payments and providing services is allowed to arise, administration of the scheme will be difficult and probably impossible.

Very little has been written on the administration of streptomycin and P.A.S. under domiciliary conditions, but there is no doubt that these drugs are being tried on an extending scale now that both are cheaper and are available to all. There is no objection to the use of P.A.S. in domiciliary treatment, except that the drug's efficiency when used alone is still debatable; but streptomycin is in a quite different category, and if indiscriminately prescribed can do more harm than good. The use of streptomycin should be controlled by drug-sensitivity tests, and a careful watch should be made for the development of complications. These precautions are difficult to maintain under domiciliary conditions, but the neglect of them may mean on the one hand the infection of other individuals with drug-resistant bacilli, and, on the other, distressing sequelae to treatment. It is therefore permissible to use streptomycin in home treatment only in the circumstances in which these conditions can be met.

Lesions of the respiratory tract are an exception to this rule. Cases of tuberculous laryngitis, particularly those with dysphagia, and cases of tuberculous tracheobronchitis or bronchitis, respond so remarkably to streptomycin that its use under domiciliary conditions is justified. I think, however, that it would be a wise policy for all general practitioners wishing to use the drug in respiratory tuberculosis to consult the chest physician before starting treatment.

Prevention

As we are still considering the management of the patient prior to admission to an institution, it is necessary to refer to prevention of the spread of the disease. The diagnosis of active tuberculosis in one member of the family places the others in the category of contacts, requiring full medical examination, including tuberculin-testing. This should be carried out on adults as well as children, and the negative reactors should receive B.C.G. vaccination. This is not the time to discuss the need or practicability of segregation, but one is inclined to the view that, although segregation is desirable, vaccination without segregation is better than no vaccination at all.

In addition to the well-known precautionary measures that should be taken to prevent the spread of infection, I should like to put in a plea for a more systematic development of facilities for educating the family, and in particular the housewife, in domestic economy and the special points in household management that are associated with the presence of a tuberculous person. There must be much that the average housewife could learn which would improve the nutrition of the family and add to the comfort and well-being of the patient and others in the house.

I would also ask for biological and biochemical research into the reason why some members of a household develop the disease while others escape active infection and in some instances even fail to exhibit tuberculin sensitivity though they have been living in contact with an open case for a long period. The detailed study of family units would reveal facts which would be helpful in solving some of the problems of the pathogenesis of the disease.

Post-sanatorium Treatment

The problems of the post-sanatorium period of domiciliary treatment differ considerably from those associated with the person awaiting admission, for the patient will either have recovered sufficiently to need rehabilitation or be a chronic invalid, ambulant for only short periods or completely bedridden. The patient may be infectious or non-infectious, but it is well to remember that the ambulant infectious case spreads the disease to a much wider circle than the bedridden one; therefore our preventive measures must not neglect control of the habits of the ambulant person. It is probable that the bedridden patient can do little harm if he has a room to himself and is not allowed contact with children and Mantoux-negative persons.

The problem of the prevention of the spread of infection should be simpler in the case of the patient who has received sanatorium treatment, as we should be able to assume that he has had a thorough instruction during the course of treatment. In view of the frequency with which the child of an ex-sanatorium patient develops tuberculous meningitis even in a reasonably good home environment, some doubt may be expressed on the efficiency of this tuition. The fault may be in ourselves in that we do not instruct the patient carefully and thoroughly enough for him to retain the essentials of the precautionary measures we wish him to put into practice in his home.

Evidence that control of infection in tuberculous households is possible is found in the fact that no case of meningitis or miliary tuberculosis has developed among the children of the tuberculous households in our village settlements; showing that there need be no danger from living with open cases of tuberculosis if there is willing co-operation and understanding of the problem by the patient and members of the family. We must therefore ensure that they are all properly instructed.

In addition to prevention of spread of infection, the ambulant or semi-ambulant case presents many problems. The presence of an idle person with a well-developed invalid complex is a great trial to the other members in any household, particularly if there is any degree of overcrowding. Sheltered employment for such patients relieves the situation to a considerable degree. It is unfortunate that the development of organized schemes to provide rehabilitation that leads to employment has been so slow. This is mainly due to the reluctance of local health authorities to shoulder the responsibilities which the Act permits them to assume with regard to aftercare, which, of course, includes rehabilitation.

The value of diversional therapy to bed patients is well known, yet there is little enthusiasm for the development of home handicrafts. I admit that this is an expensive venture and must not be expected to bring in any financial return. It is difficult to organize, and to be successful it should be controlled from the chest clinic, if possible in connexion with a municipal workshop. All this involves

considerable expenditure; but does not the comfort and welfare of these patients, whom we are forced to treat at home through lack of beds, mean nothing to those responsible for their domiciliary care? Cannot some of the money which would have been expended on them had they been admitted to a sanatorium at anything from £6 to £10 a week be expended on developing efficient domiciliary treatment?

In answering these questions we come up against the difficulty that the money not being expended on institutional treatment is the concern of the regional hospital boards, and the cost of domiciliary care is largely borne by local health authorities, so that the adjustment is complicated. It is another instance in which the dual control operates against the benefit of the patient.

During the post-sanatorium period rehabilitation is of the highest importance. The National Health Service Act places this responsibility on the local health authority. The National Assistance Act provides for financial relief in cases of need and has made the National Assistance Boards responsible for the provision of the benefits that were scheduled in Memorandum 266T of the Ministry of Health. Under the Disabled Persons Emp'oyment Act, 1944, the development of sheltered industries can take place on a commercial basis, and the Ministry of Labour and National Service can give adequate financial assistance, both to the disabled individual under training and to the rehabilitation centre, for the provision of facilities to overcome the loss of working power which the disability has caused. The stage is therefore set for the development for the tuberculous in this country of the finest rehabilitation service in the world if we will only take full advantage of the powers that are provided in the Acts mentioned.

Drawbacks of Dual Control

It is not always realized how great is the change in environment for a patient who is discharged from a sanatorium and returns to an urban home. The frequency of relapse during the first year after discharge from the sanatorium shows how serious the strain can be, and how unfitted some patients are to withstand the stresses and anxieties of normal life. It is one of the disadvantages of sanatorium treatment that recovery takes place in conditions that are totally different from those under which the patient normally lives. For such a patient the first few months of domiciliary care should always be regarded as a transitional stage during which the closest clinical observation is maintained and wherever necessary sheltered employment provided until stabilization under home conditions is assured. In this way many relapses could be prevented, but it can be done only through the recognition by regional hospital boards and the local health authorities that rehabilitation is an essential part of treatment. Rehabilitation does not begin when sanatorium treatment ends, but both run concurrently from diagnosis until the disease is arrested.

It has been stated on many occasions that the most urgent need in tuberculosis at the present time is an adequate supply of nurses. This, indeed, is a necessity in order to provide more beds for institutional treatment, and also more efficient domiciliary care; but on the administrative side there is just as urgent a problem—the reuniting of the tuberculosis services so as to restore the relationship between prevention, diagnosis, treatment, and rehabilitation that existed before the National Health Service Act.

To try to organize treatment of tuberculosis apart from prevention and rehabilitation is to admit a complete lack of appreciation of the fundamental characteristics of the disease. Tuberculosis is most deceptive and insidious in its manifestations; it has a serious influence on the industrial life of the population, and causes repercussions throughout social relationships, and yet at the same time it is one of the most individualistic of disabilities. For these reasons the treatment of a case of tuberculosis should not be, as it is at present, the responsibility of one authority, leaving another authority to deal with the important aspect of prevention and aftercare.

Reorganization of the Services

The need for a reorganization of the existing administration of our tuberculosis services is urgent, and the care of the tuberculous in the home emphasizes very clearly the necessity for an amalgamation between the local health authorities and the regional hospital boards with respect to this disease. Let it be clearly understood that domiciliary treatment has come to stay. Experience has shown that in certain circumstances domiciliary treatment can shorten, and sometimes eliminate, institutional treatment, and it is reasonable to suppose that the clinical improvement obtained in the normal environment of the home will be more permanent in character than that derived under the abnormal surroundings and routine of the sanatorium. By domiciliary treatment the great difference between sanatorium life and home life is avoided, and the patient escapes the hazard of having to acclimatize himself to home conditions.

We therefore must plan for the development of domiciliary treatment, and create the machinery whereby the regional hospital board and the local health authority can jointly deal with the tuberculosis problem in their areas. The employment of the chest physician by either body should be on the same terms, and there should be an easy exchange of information and a mutual interest in each other's activities. This can best be established by the formation of a joint tuberculosis panel, consisting of members of the board of governors of teaching hospitals, regional hospital boards, and the local health authorities. It may be that there is no authority under the Act to give such a body preceptive powers, but it could be an authority to which all debatable tuberculosis problems in the region could be referred for advice. This would go some way towards adjusting the present disjointed administration.

A more satisfactory solution is to admit that the National Health Service Act as at present administered is inadequate for dealing with tuberculosis, because it does not take into consideration the peculiarities of the disease, and to press for an Amending Act to create a tuberculosis administration that would enable a service to be developed that could reduce the mortality and morbidity of the disease to an insignificant figure. Until this is done we shall proceed in a wasteful, discontented, and disorderly manner without hope of any real progress. The necessity for this action is of increasing importance in view of the international situation. In the event of war it is essential that our defences against tuberculosis shall be strong enough to withstand the strain that such conditions place upon them.

Conclusion

I would stress that domiciliary treatment can be beneficial, but to carry it out successfully requires money, good equipment, staff, and all those facilities that enable the patient to take the necessary rest at home. The higher the standard of living and the better the morals of the family, the more successful will be the result. Pre-sanatorium treatment differs from post-sanatorium care, but both should be of interest to the regional hospital board and the local health authority. Without the mutual co-operation of these two bodies there is little hope of the development of efficient domiciliary care and treatment. In fact, there is urgent need for a complete revision of our tuberculosis administration and the creation of a special service which the peculiar characteristics of the disease demands.

THE CONTENT OF HAEMOPOIETIC FACTORS IN LIVER EXTRACTS

RELATIONSHIP TO CLINICAL RESPONSE

BY

RONALD H. GIRDWOOD, M.B., Ch.B., F.R.C.P.Ed.
Lecturer in Medicine, University of Edinburgh

AND

KATHLEEN M. CARMICHAEL, M.B., Ch.B.
Assistant, Department of Medicine, University of Edinburgh

With Statistics by B. WOOLF, M.A., Ph.D., F.R.S.E.
Lecturer in Medical Statistics, Department of Public Health and Social Medicine, University of Edinburgh

In recent years there has been considerable discussion about the potency or otherwise of liver extracts available in this country for the treatment of the megaloblastic anaemias. This has been referred to by Mollin (1950), who has given clinical evidence of a decline in the potency of commercial liver extracts during the period from 1943 to 1948.

Since vitamin B_{12} was isolated from liver almost simultaneously in Great Britain (Lester Smith, 1948; Lester Smith and Parker, 1948) and in the United States (Rickes *et al.*, 1948), it has become clear that this substance is the main therapeutically active material present in refined liver extracts used for the treatment of pernicious anaemia, and vitamin B_{12} is therefore generally considered to be what was formerly known as the "specific anti-anaemic factor." Ungley (1949) has reported on the therapeutic activity of vitamin B_{12} in a series of 53 patients with pernicious anaemia, and Cuthbertson *et al.* (1949) and Shaw (1949a) have assayed certain liver extracts for vitamin B_{12} content and discussed the relationship of this to their clinical activity. A detailed review of the clinical and experimental uses of vitamin B_{12} and related factors has been made by Girdwood (1950).

The object of the present investigation was to estimate the vitamin B_{12} and pteroylglutamic acid (folic acid) content of various liver extracts that had been prepared commercially between the years 1945 and 1950, and to compare the vitamin B_{12} activity as assayed by microbiological methods with the clinical response on the basis of the results of Ungley (1949), who used vitamin B_{12} itself as the therapeutic agent in cases of pernicious anaemia and put forward a formula to indicate the rise in red cells that might be expected to occur with various doses. In addition, by the kind co-operation of certain manufacturers of liver extracts it was found possible to compare a few of our vitamin B_{12} estimations with the results obtained by these commercial houses. Estimation of vitamin B_{12} was carried out in all instances by measuring the turbidity produced by the growth of organisms in a vitamin-B_{12}-deficient medium to which had been added various dilutions of the liver extracts to be tested. These were compared with a standard obtained by measuring the growth sustained by adding known amounts of vitamin B_{12} to the same culture medium.

Methods

The patients were typical cases of Addisonian pernicious anaemia with histamine-fast achlorhydria and a megaloblastic bone marrow. There was no evidence of steatorrhoea or of any abnormality of dietetic habits. A control period without treatment preceded the injections of liver extract, and during this period there was no evidence of spontaneous remission. All the haematological investigations were carried out by one of two experienced research technicians whose results were in close agreement.

The liver extracts were kept in a refrigerator from the time of issue for clinical testing except where otherwise noted.

The microbiological assays for vitamin B_{12} were carried out by an unpublished modification of the method of Hoffmann *et al.* (1949), using *Lactobacillus leichmannii* as the test organism. Hoffmann and his co-workers in one of their methods added thioglycollic acid to the culture medium to prevent loss of vitamin B_{12} activity as a result of autoclaving, but we preferred to omit the thioglycollic acid and to add the samples aseptically after the medium had been autoclaved. It has been shown (Cuthbertson and Lester Smith, 1949; Shaw, 1949b; Winsten and Eigen, 1949) that liver extracts contain substances other than vitamin B_{12} capable of sustaining the growth of *L. leichmannii*. These can be separated by methods which include partition chromatography and by destroying the vitamin B_{12} by alkaline hydrolysis and then re-estimating the ability of the extract to support growth of the test organism. We tested our liver extracts by the latter method, and showed that substances other than vitamin B_{12} were responsible for only a negligible fraction of the growth-supporting activity of the samples tested, except in the case of the extract produced by Manufacturer C, 1948 (Table III), where 25% of this activity was due to substances other than vitamin B_{12}.

In each instance our vitamin B_{12} assay figure is the mean of three readings, and, as will be seen from Table I, the readings were in close agreement. The discrepancies within a group of triplicates are approximately proportional to the absolute value of the mean. The logarithms of the readings were therefore taken for statistical treatment.

TABLE I.—*Results of Vitamin B_{12} Assays on 16 Liver Extracts, Using a Tube Method with L. leichmanii as Test Organism*

Extract No.	Results of Three Assays (μg./ml.)			Mean
1	7·5	7·7	7·6	7·6
2	5·4	5·5	5·4	5·4
3	4·1	5·5	4·7	4·8
4	4·4	3·4	4·9	4·2
5	4·3	4·0	3·7	4·0
6	3·95	3·3	3·75	3·7
7	2·85	2·3	2·9	2·7
8	1·9	2·0	2·3	2·1
9	2·05	2·2	2·0	2·1
10	2·0	2·2	1·8	2·0
11	1·3	1·6	1·3	1·4
12	1·3	1·2	1·25	1·25
13	0·92	0·99	0·82	0·91
14	0·47	0·45	0·45	0·46
15	0·36	0·34	0·35	0·35
16	0·24	0·27	0·24	0·25

The logarithmic standard error of the mean is 0.02302, and the 5% fiducial limits are ±0.04698. This implies that the standard limit of the mean is about ±5.3% of the assay result, and it can safely be taken to be within the range 90 to 111% of the true mean in 19 cases out of 20.

In addition to our own results, we were fortunate in having assays performed for us on a few extracts by three commercial firms, and the results of these tests are shown in Table II.

TABLE II.—*Comparison of Vitamin B_{12} Assay Results With Those of Three Manufacturing Firms (μg/ml.)*

Extract	Manufacturing Firm	*L. leichmannii*, Tube Method			*L. lactis* Dorner, Plate Method
		Own Assay	Firm X	Firm Y	Firm Z
1 ..	Z	3·7	3·1	3·8	5·56
2 ..	X	0·46	0·27	—	—
3 ..	X	7·6	14·4	7·2	10·2
4 ..	X	4·0	1·4	—	2·1

The pteroylglutamic acid estimations were carried out by the method of Teply and Elvehjem (1945), using *Streptococcus faecalis* as the test organism, and measuring the growth of the organisms by turbidity estimations in a Spekker photoelectric absorptiometer.

In the paper by Ungley (1949), Campbell gives a formula to express the expected red cell rise when a dosage of 5, 10, 20, 40, or 80 μg. of vitamin B_{12} is given. Campbell's formula was calculated from the actual rise of red cells over a period of 15 days in 63 cases receiving vitamin B_{12}. In our calculations we have the slight inaccuracy that in most instances the red cell count had been done on the 14th rather than the 15th day (the day of injection being calculated as Day 0). The difference in red cell level between 14th and 15th days was extremely small in the few instances where a count was done on both days.

Statistical examination reveals that Campbell's formula is not wholly satisfactory. In the first place, for reasons given in the original paper, he considered it advisable to omit all data derived from the administration of very low doses of vitamin B_{12}, and to reject a discrepant observation within the range of doses he included (a patient who showed an exceptionally large red cell rise with 5 μg. of vitamin B_{12}). In the second place, none of the three regression coefficients in the formula he actually uses is statistically significant. In fact, he gives two formulae—one linear with respect to initial erythrocyte count and log. dose, and the other containing also a product term. The simpler formula, which he rejects, actually has the higher statistical credentials. To be on the safe side we have calculated our own results in terms of both formulae. As given by Campbell, these formulae are not convenient for the calculation of the expected responses at doses other than those he used. We have therefore used algebraically equivalent forms, in which the dose is expressed in ordinary logarithms to base 10. The two formulae are:

(a) $I_{15} = 0.684 - 0.131\ E + 0.814\ P - 0.056\ PE$
(b) $I_{15} = 0.913 - 0.199\ E + 0.641\ P$

where

I_{15} = Expected increase in red blood cell count (millions per c.mm.) on the 15th day
E = Initial red blood cell count (millions per c.mm.) on day of injection
P = Logarithm of number of μg. of vitamin B_{12} injected.

Ungley has pointed out that the formula used in his paper is unsatisfactory for doses of 2.5 μg. or less of vitamin B_{12}. For this reason we have divided our findings into two groups according to whether the dosage of vitamin B_{12} given was greater or less than 4 μg.

Results

The results of our assays for vitamin B_{12} and pteroylglutamic acid on 15 extracts that were tested clinically on 20 patients are given in Table III. All but one of these had been marketed as a high potency extract. In Table IV

TABLE III.—*Vitamin B_{12} and Pteroylglutamic Acid Content of Liver Extracts*

Manufacturer	Date of Manufacture	Vitamin B_{12} Content (μg./ml.)	P.G.A. Content (μg./ml.)

TABLE IV.—*Vitamin B_{12} Content of Liver Extracts and B_{12} Preparations Purchased Commercially in 1950*

Preparation	Country of Origin	Manufacturer's Statement of Vitamin B_{12} Content or Potency	Content According to Our Assay
Vitamin B_{12} ..	U.K.	20 μg./ml.	16·5 μg./ml.
,, ,, ..	U.K.	10 μg./ml.	10·0 μg./ml.
Liver extract ..	U.K.	20 μg./ml.	3·75 μg./ml
,, ,, ..	U.S.A.	15 U.S.P. units	1·5 μg./ml.

are given the results for four preparations of stated potency purchased in 1950. The American extract was provided by a patient who visited the United States.

In Tables V and VI are given the actual red cell rises when these extracts were used clinically, the expected cell rises according to each of the above formulae, and the differences between the observed and the calculated rises Table V refers to the 12 cases receiving 4 μg. or more of vitamin B_{12}, and Table VI to the eight patients who had less than this amount. It will be seen that the expected values on the two formulae are closely similar. Table VII summarizes the results of the comparison of observed and expected values. In the 12 cases in the first group the mean red blood cell rise was 1,068,000. The mean discrepancy on each of the two formulae was very small. The spread of values about the mean, conveniently measured by the standard deviation, was 0.508. Use of either formula reduces the standard deviation to about 0.45. This means that the formula is of some value for prediction but the reduction of standard deviation in these few cases is not statistically significant. On the other hand, in the second (low-dose) group, to which Campbell's formula is not supposed to apply, the predictive value of the formula is considerable and statistically significant.

We therefore combined the two groups, and the predictive value of the formulae on all the cases is shown at the bottom of Table VII. The standard deviation is reduced by about 22%, although, at 0.47, it is still considerably higher than the value of 0.33 claimed by Ungley and Campbell. Formula (b) seems slightly better than formula (a).

TABLE VII.—*Comparison of Observed and Expected Values for Red Cell Rise*

	Observed Red Cell Rise	Observed Minus Expected Red Cell Rise	
		Using Formula (a)	Using Formula (b)
Dosage of vitamin B_{12} 4 μg. or more (12 cases):			
Mean (mills./c.mm.)	1·068	−0·011	−0·059
Standard deviation ..	0·508	0·466	0·448
Dosage of vitamin B_{12} less than 4 μg. (8 cases):			
Mean (mills./c.mm.)	0·706	+0·153	+0·061
Standard deviation ..	0·738	0·531	0·510
Both groups (20 cases):			
Mean (mills./c.mm.)	0·923	+0·055	−0·011
Standard deviation ..	0·609	0·482	0·473

It seemed worth while to obtain from our data the best-fitting formula, for comparison with that put forward by Ungley. The analogue of his formula (b) worked out as :

$$I_{15} = 1.474 - 0.542\ E + 0.665\ P.$$

It is remarkably similar to that of Ungley, differing mainly in the increased importance given to the influence of the patients' initial counts on the final result. We believe that, by omitting his cases receiving a low dosage of vitamin B_{12}, Ungley artificially minimized the importance of this factor.

It is important to stress that, as is suggested by Table II, different results might have been obtained and different conclusions reached had the vitamin B_{12} assays been carried out by other workers using various modifications of the assay methods.

As has been found by previous workers (Stokstad and Jukes, 1946), the pteroylglutamic acid content of the extracts was in all instances therapeutically negligible.

In order to see how small a dose of vitamin B_{12} might be effective, we gave one patient, suffering from classical Addisonian pernicious anaemia, a single injection of 0.4 μg. of vitamin B_{12} itself after a control period. It will be seen from the Graph that we seem to have selected by chance a patient who was able to show some response even to this small dosage, for the red cell count rose by 670,000 per c.mm. in 13 days, and there was a partial

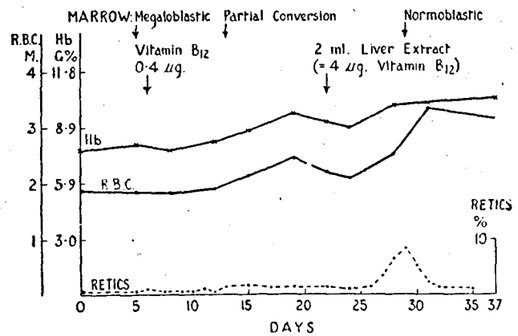

Chart showing response to vitamin B_{12} in a case of pernicious anaemia (man aged 73).

conversion of the bone marrow towards the normoblastic state, as evidenced by condensation of the nuclei of the megaloblasts.

Discussion

The results of this investigation indicate that the vitamin B_{12} content of all 15 batches of liver extracts manufactured between the years 1945 and 1950 and tested both microbiologically and clinically was low or very low. For comparison we have the figure of 25 μg./ml. for an American liver extract given by Mollin (1950). On the other hand, we have not included in the series a British liver extract, marketed in 1948 but not tested clinically by us, which we found to have a vitamin B_{12} content of 14 μg./ml. It is of interest that we obtained similar results

on assaying two samples of the same batch of one extract manufactured two years previously, one ampoule of which had been kept in a refrigerator and the other sent back to us from the Fiji Islands.

It has been suggested by Rickes *et al.* (1948) and by many workers since then that 1 U.S.P. unit of activity is approximately equal to 1 μg. of vitamin B_{12}, and the aim of manufacturers has been to market high-potency extracts containing 15 U.S.P. units of activity. How far the extracts considered in the present paper fall short of this target is evident. It should be realized that it was not the fault of British manufacturers that the vitamin B_{12} content of their products was low at a time when clinical testing was the only method of assay available to them, and individual variation to the same dose was so great that it would no doubt be possible to show the presence of "15 U.S.P. units of activity" in many of the above extracts if those testing them persevered long enough to find a sufficiently sensitive patient. Nor should it be thought that all American extracts are superior to British ones. Personal experience by one of us of the clinical results obtained in the United States by various liver extracts has convinced us that low-potency extracts were not uncommon across the Atlantic, too, when microbiological assay methods were not available, and from Table IV we see that a "high-potency" extract marketed in 1950 by a reputable American firm contained only 1.5 μg./ml.

The relationship between the actual red cell rise and the expected rise when liver extracts are used clinically, and calculating from Ungley's results with vitamin B_{12} itself, is obviously of importance. One should not, however, attach too much importance to formulae, especially those based on the relatively meagre data here considered, even if Ungley's findings and those of the present series are considered together. The random errors are so high, and the other relevant factors not taken into account are probably so important, that the formulae can do little more than indicate a qualitative relationship. All one can say with confidence at the moment is that the data indicate that the red blood cell rise is greater the lower the initial state of the patient and increases with increase of dose, and give some idea of the order of magnitude of the influence of these factors. We must add, however, that a statistical analysis of all available data may give one a fair idea of the quantitative importance of these influences. A study of this nature is planned.

In view of this, our conclusions must be guarded, but it is true to say that we have produced no evidence to support the view that the results in these cases cannot be explained on the assumption that the haemopoietic responses are due to the vitamin B_{12} content of the extracts. In order to suggest that the activity of a liver extract was not due solely to its vitamin B_{12} content it would be necessary to show a consistent and definite difference in response to the injection of that particular extract given to a relatively large number of patients. When the actual response is much greater than the expected response the chief possibilities are: (*a*) that this is a case that, by reason of some individual variation as yet not understood, responds unusually well to the dosage given; (*b*) that a spontaneous remission has coincided with the test; (*c*) that there is some substance present in the liver extract that has a haemopoietic effect and is not a growth factor for *L. leichmannii* or any other test organism used; (*d*) that the liver extract contains, in addition to vitamin B_{12}, inhibitors for the growth of *L. leichmannii*; or (*e*) that some of the vitamin B_{12} is present in a conjugate form that does not support the growth of *L. leichmannii*.

The significance of these factors is not yet understood. An artificially produced hydrogenation product of vitamin B_{12} has been named vitamin B_{12a} (Kaczka *et al.*, 1949), and it is possibly the same as vitamin B_{12b} isolated in crystalline form by Pierce *et al.* (1949) (Brockman *et al.*, 1950). More recently, vitamin B_{12c} has been isolated (Buchanan *et al.*, 1950), but so far there is no published evidence of the presence in liver of forms active clinically and not microbiologically, although reference to the possible existence of such forms has been made by Lester Smith (1950).

The problem of whether liver extract is active haemopoietically only by virtue of its vitamin B_{12} content may also be approached by comparison of the results of maintenance therapy. Recently Meacham *et al.* (1950) have reported that a vitamin B_{12} concentrate in a dosage equivalent to 1 μg. daily, but given every three or four weeks, did not maintain optimal blood levels in pernicious anaemia patients. They attribute this to inadequate dosage of vitamin B_{12}, but further work of this nature is indicated and other possible explanations require investigation, including the possibility that vitamin B_{12} is absorbed and excreted less rapidly if injected in the form of a liver extract.

It is of some interest to know how many patients would be required to assay a liver extract or vitamin B_{12} preparation clinically to any desired degree of precision. An answer to this question may emerge from our further statistical study. On the basis of the formulae used in this paper, for what they are worth, one can make the following rough estimates. If the true potency of a preparation be put at 100, then, using 4 patients, one would expect, in 19 times out of 20, to get a result only within the range 30 to 330; 16 patients would give an accuracy, in 95% of cases, between about 60 and 160; 64 patients between 80 and 125; while to get within 10% of the true result 250 or more subjects would be required. The same order of magnitude of error emerges from the results of the present series using liver extracts and from those of Ungley (1949) using vitamin B_{12}.

When microbiological assay is carried out, however, it is important that the method should be standardized, since, as we have seen in Tables II and IV, quite marked discrepancies may occur. At present the best practicable method of testing liver extracts for haemopoietic activity would appear to be by the combination of clinical tests on a few patients and microbiological assay by an agreed standard technique

Summary

The vitamin B_{12} content of 15 batches of British liver extracts prepared for commercial use between 1945 and 1950 and tested microbiologically by a tube method using *L. leichmannii* as the test organism was low, varying from 0.25 μg./ml. to 7.6 μg./ml. The pteroylglutamic acid content was negligible.

The actual rise of red cells in 20 pernicious anaemia patients treated with these liver extracts was compared with the calculated response according to the vitamin B_{12} content. Too much importance should not be attached to formulae, especially in view of the relatively meagre data available, but the results give no evidence to suggest that the haemopoietic responses cannot be attributed to the vitamin B_{12} content of the liver extracts.

Clinical testing alone of liver extracts or vitamin B_{12} concentrates may give very inaccurate information, but, although it is possible to obtain consistent results with a single microbiological method of vitamin B_{12} assay, there may be considerable variation between the results obtained by workers using different microbiological methods. Hence it is important that a standard method be agreed upon.

We are very grateful to Professor L. S. P. Davidson, Dr. W. A. Alexander, and Dr. T. R. R. Todd for access to clinical material in their wards, and to Professor L. S. P. Davidson and Professor F. A. E. Crew for their interest in this work. We wish to thank Dr. Augustus Gibson, of Messrs. Merck, Inc., Rahway, New Jersey, for supplying us with crystalline vitamin B_{12} for use as a standard. One of us (R. H. G.) was in receipt of a grant from the John Risk Bequest, and grateful acknowledgment is made for the assistance given in defraying the expenses of the investigation.

THE MANUBRIO-STERNAL JOINT IN RHEUMATOID ARTHRITIS

BY

ANDREW BOGDAN, M.D.

AND

JUSTIN CLARK, M.D., M.R.C.P.

(From the Rheumatism Unit, Westminster Hospital)

[WITH SPECIAL PLATE]

Examination of the manubrio-sternal joint in a series of patients has shown that rheumatoid involvement of this joint is not uncommon. Five examples are outlined here to indicate the clinical and radiological features.

Case Reports

Case 1.—A married woman aged 55 gave a five-year history of rheumatoid arthritis, still active, and showing typical clinical and radiological involvement of feet, wrists, fingers, and right elbow. The manubrio-sternal joint became painful two years after the onset of the disease, and the patient noticed that there was swelling and tenderness over the joint. The pain came in bouts lasting two to three days; between the bouts there was a residual ache. During the bouts the pain was aggravated by coughing and sneezing, and inhibited deep respiratory movement. Examination of the joint confirmed the presence of soft-tissue swelling and tenderness (Fig. A). Radiographs showed irregular destruction of the articular margins of the joint (Plate, Fig. 1). The sedimentation rate was 31 mm. (Wintrobe corrected) at the end of one hour.

Case 2.—A married woman aged 52, who gave a twenty-two year history of rheumatoid arthritis, starting with pain, swelling, and tenderness over the manubrio-sternal joint, showed clinical and radiological evidence of active disease in almost all the peripheral joints. The manubrio-sternal pain had lasted for one month only, and had not recurred. Examination showed no clinical abnormality of the joint, but a radiograph revealed gross narrowing and irregularity of the joint space, with marked irregular expansion of the articulating ends of the bones (Fig. 2). The sedimentation rate was 30 mm. (Wintrobe corrected) at the end of one hour.

FIG. A.—Swelling over the manubrio-sternal joint (Case 1).

Case 3.—A girl aged 16 gave a one-year history of swelling, aching, and stiffness of the proximal interphalangeal joints of the right index and middle fingers and of the left index finger. Examination of these joints showed soft-tissue swelling and tenderness, with tenderness of some of the other proximal interphalangeal, metacarpo-phalangeal, and wrist joints. Radiographs of these showed only soft-tissue changes. For three weeks prior to attending the clinic she had experienced a constant tight sensation over the front of the chest, in the region of the manubrio-sternal joint, aggravated by deep inspiration and yawning. She had no cough or other chest symptoms. There was definite tenderness over the manubrio-sternal joint, which persisted for one month. A radiograph of the manubrio-sternal joint showed no abnormality.

Case 4.—A married woman aged 52 gave a nine-year history of rheumatoid arthritis affecting all the peripheral joints and the cervical spine. She was severely crippled. For the past two years she had had intermittent pain in the region of the manubrio-sternal joint aggravated by deep breathing, coughing, and yawning. Examination showed swelling and tenderness of the manubrio-sternal joint. Radiographs showed irregularity of the joint space, erosion of the joint margins, and irregular expansion of the articulating ends of the bones (Fig. 3).

Case 5.—A married woman aged 53 gave a twelve-year history of rheumatoid arthritis with involvement of the knees, shoulders, elbows, wrists, fingers, and ankles, with typical radiological changes. Pain in the region of the manubrio-sternal joint was first noticed six months before attending the clinic, and became her chief symptom. The pain occurred in attacks lasting up to twenty-four hours, and was aggravated by yawning and coughing. A striking feature of the pain was its tendency to occur on exertion, especially on walking uphill, after which it often lasted several hours. When severe, she found difficulty in taking a deep breath. This pain, which had the same quality as her arthritic pains elsewhere, was relieved by aspirin. There was marked tenderness over the manubrio-sternal joint. A radiograph of the joint showed no abnormality. Examination of the cardiovascular system, cardioscopy, and the electrocardiogram were normal. Blood Wassermann and Kahn reactions were negative. The sedimentation rate was 31 mm. (Wintrobe corrected) at the end of one hour.

Anatomy

The manubrio-sternal joint is of the cartilaginous type, the articular surfaces being covered by a layer of hyaline cartilage and connected by a disk of fibro-cartilage. A limited amount of movement is permitted, and occurs with each thoracic respiratory movement. It is stated that in rather more than 30% of people conversion into a synovial

joint takes place by absorption of the central part of the disk (Johnston and Whillis, 1949). The incidence of ossification of the disk was found to average 10% and was commoner in women than in men. There was no correlation between incidence of ossification and age (Trotter, 1934).

Discussion

The above cases are examples of the effect of rheumatoid arthritis on the manubrio-sternal joint. In the early stages there is pain, swelling, and tenderness at the joint site, and in more advanced cases radiological changes. It may be the first manifestation of rheumatoid arthritis (Case 2). The pain may be constant or may show periodicity. In all the above cases it was aggravated by respiratory movements, and in particular by coughing, sneezing, yawning, and deep inspiration, and hence may occur on exertion. It may be severe enough to inhibit full inspiration. The pain has to be distinguished from other causes of chest pain. In Case 5 its precipitation by exertion simulated angina of effort.

Soft-tissue swelling was prominent in two cases. Tenderness oyer the joint was present in all the cases; as an isolated finding, however, it was not considered sufficient to justify the diagnosis, because this area may be sensitive in normal people, particularly those with a prominent sternal angle.

Radiological changes present in three cases included soft-tissue swelling, irregularity and narrowing of the joint space, erosion of the articular surfaces, and irregular expansion of the articulating ends of the manubrium and sternum. Progression to bony ankylosis was not observed in any of the cases. When bony ankylosis occurs in normal people the radiographs show that the continuity of the bony surfaces is quite smooth (Fig. 4). The joint was best visualized in coned lateral views; routine lateral chest films were usually not satisfactory. The joint picture may be obscured by superimposition of calcification in the second costal cartilage or in the presence of a depressed sternum.

Rheumatoid arthritis commonly affects synovial joints, especially those at the periphery, where considerable mobility is a feature. In contrast, the manubrio-sternal joint is usually cartilaginous and the site of very limited movement.

Involvement of the manubrio-sternal joint is well recognized in ankylosing spondylitis, and was noted in 7 out of 65 cases (Hart, Bogdanovitch, and Nichol, 1950). Osteoarthritis of this joint has been described (Rolleston, 1892–3). There is reference to two cases of osteochondritis (Brailsford, 1934).

Summary

Rheumatoid arthritis of the manubrio-sternal joint is described, with particular reference to five illustrative cases.

The pain may be the first symptom of rheumatoid arthritis. It is mainly related to respiratory movements, and has to be differentiated from other causes of chest pain.

The radiological changes, when present, are best seen in coned lateral views of the joint. The chief features are irregular narrowing of the joint space, with irregular expansion of the articulating bone ends.

We should like to express our thanks to Dr. F. Dudley Hart for encouragement and permission to publish these cases from the Rheumatism Unit of Westminster Hospital. We are also indebted to Dr. W. D. Nichol for his help with the radiology; also the Department of Medical Photography. We are indebted to Miss F. E. Stevens for her invaluable secretarial assistance.

ERYTHEMA NODOSUM AS INITIAL MANIFESTATION OF BOECK'S SARCOIDOSIS

BY

F. E. CRAWLEY, M.D., M.R.C.P., D.P.H.

Consultant Chest Physician, South and Central Liverpool

[WITH SPECIAL PLATE]

In chest clinics there is increasing awareness of growing appreciation among the profession of the fact that erythema nodosum is often a manifestation of tuberculous infection, and the formerly widely held opinion that this disorder is of rheumatic origin is fast disappearing. It is less widely recognized that the determination of the cause often provides an intriguing exercise in diagnosis for the chest physician who is aware of the multiplicity of disorders with which erythema nodosum has associations, and which tend to be discussed in the more specialized journals to the loss of those whose reading is confined to the more widely circulating publications.

Consideration is primarily given to investigations of tuberculosis as the cause, for it is now commonly considered that the eruption occurs during primary infection at the time when the patient first develops hypersensitivity to tuberculin. In Scandinavia, Wallgren (1938) has shown that 95% of his series of 800 cases gave positive tuberculin skin reactions, though that high percentage is not generally found in this country, where 54% of the cases of Bruce Perry (1944) were tuberculin-positive. In Scandinavia, where primary infection occurs at a later average age than here, 30% of primary infections were associated with the eruption; but in Ireland, where the age of onset of primary infection is earlier, Dunlevy (1949) has shown an incidence of only 2.8%.

Causes other than tuberculosis appear, therefore, to be more frequent in this country than in many others. Collis (1932) revealed that some tuberculin-negative patients showed pronounced skin sensitivity to streptococcal nucleoprotein, and Rotnes (1936) recorded a case in which the eruption appeared on 14 occasions, mostly after attacks of tonsillitis.

Sulphonamide sensitivity is not infrequently a cause, and it may be difficult to decide whether a patient with streptococcal tonsillitis under treatment with sulphonamides has developed erythema nodosum as a result of the streptococcal infection or of the treatment. Similarly, in patients with pyrexia of unknown cause under treatment with sulphonamides, the eruption cannot be attributed to the drug without the exclusion of tuberculosis and other conditions. During the recent war it was commonly recognized that meningococcal septicaemia was a far from infrequent cause.

In California, infection with *Coccidioides immitis* has resulted in a considerable number of cases, but none seem to have been recognized in this country, and

other infrequent causes here and elsewhere are syphilis, gonococcal septicaemia, lymphogranuloma inguinale, leprosy, lymphadenoma, and iodides, bromides, and other drugs. It is difficult as yet to determine the importance of Boeck's sarcoidosis as a factor in the aetiology of the disorder, but, in this country, Kerley (1942, 1943) and, in Scandinavia, Löfgren (1946) and Bjerkelund (1947) have described cases in which sarcoidosis was considered to be responsible.

Below is given the history of three cases in which there are thought to be grounds for arriving at the diagnosis of sarcoidosis.

Case 1

A married woman aged 30 had an attack of erythema nodosum in June, 1949. There had been no preceding illness of any kind. Her chest was *x*-rayed at a general hospital when the erythema had subsided and again in mid-August, both films showing gross bilateral hilar glandular enlargement and a small shadow in the left subclavicular area. She had no cough and was breast-feeding her few-months-old baby, and, apart from some lassitude, had no symptoms.

In view of the radiological appearances she was referred to the chest clinic late in August. Her weight was 10 st. 7 lb. (66.7 kg.); there was no evidence of glandular or splenic enlargement, no history of uveitis or parotid swelling, and no skin eruption; the E.S.R. (Cutler) was 12 mm. in one hour, and the differential white cell count showed 48% neutrophils, 5% eosinophils, 1% monocytes, and 46% lymphocytes. Examination of the chest revealed a slightly impaired percussion note in the hilar region on both sides posteriorly and a marked signe d'Espine. The *x*-ray film (Plate, Fig. 1) showed gross bilateral lobulated hilar glandular enlargement, an irregular faint shadow in the first left interspace, and hard streaky shadowing in the right upper zone. A Mantoux test performed with 1 in 1,000 O.T. was negative.

On October 11 she weighed 10 st. 4 lb. (65.3 kg.) and felt well; her E.S.R. (Cutler) was 7 mm. in one hour, and Mantoux 1 in 1,000 was again negative. There was now a small cluster of papules on the left side of the forehead and one small gland palpable above the head of the right clavicle. A laryngeal swab contained no tubercle bacilli on culture. An *x*-ray film showed some diminution in the size of the glandular enlargement, but the striations were increased in the right lung and were now also evident on the left. A film of both hands revealed no abnormality in the bones.

On November 25 she felt as well as she had done for years, and weighed 10 st. 5 lb. (65.8 kg.); the papules and gland were unchanged; Mantoux 1 in 100 was negative; W.R., Kahn, and G.C.F.T. tests were negative; and serum proteins totalled 7.55 g. %. Rather copious fine rales were audible at the right base, but she denied having any cough. An *x*-ray film showed further diminution in size of the hilar glandular enlargement, but the left subclavicular shadow and the striations in both lungs were unchanged and a few pinhead faint shadows were evident in the right upper zone.

Case 2

A married woman aged 28 had an attack of erythema nodosum in July, 1949, and two weeks previously had had a slight sore throat but had not received any treatment. After four weeks in bed she was referred to the chest clinic on August 30. She then felt perfectly well and weighed 14 st. 1 lb. (89.4 kg.).

General examination and questioning showed no evidence of splenic or glandular enlargement, skin eruption, or history of eye trouble or parotid swelling. No abnormal signs were found on examination of the chest, but *x*-ray films (Fig. 2) of the lungs showed considerable bilateral lobulated glandular enlargement and faint irregular striations in both lower zones. A Mantoux test with 1 in 1,000 O.T. was negative.

The patient was asked to attend for further investigation a few days later, but went for a holiday to another county and was not seen until November 1. She was then feeling perfectly well and weighed 14 st. 3 lb. (90.3 kg.), but whilst on holiday in early September she had a recurrence of erythema nodosum. Her E.S.R. (Cutler) was 10 mm. in one hour; the differential count was 66% neutrophils, 3% eosinophils, 4% monocytes, and 27% lymphocytes; the W.R., Kahn, and G.C.F.T. tests were negative; a laryngeal swab showed no tubercle bacilli on culture; radiographs of the hands revealed no abnormality; and chest films showed no alteration in the picture. Mantoux 1 in 1,000 was again negative, but on November 8 a Mantoux test with 1 in 100 O.T. produced a positive reaction of 1½ in. (3.75 cm.) diameter.

On November 29 she weighed 14 st. 1 lb., and felt perfectly well; the serum proteins amounted to 7.9%, and the E.S.R. (Wintrobe) was 12 mm. in one hour. Radiologically the bilateral hilar enlargement was much less, but a few fine faint floccular shadows were scattered in both lungs, especially in the right mid-zone.

Case 3

A youth aged 18 was seen on June 3, 1949, two weeks after the onset of erythema nodosum. There had been no preceding illness other than a slight cold in the head a week before the eruption appeared. He still had a slight cough and some nasal catarrh. His weight was 10 st. 4 lb. (65.3 kg.). No abnormal signs were found in his lungs, but an *x*-ray film (Fig. 3) showed marked enlargement of the left and slight enlargement of the right hilar shadow. A Mantoux test with 1 in 1,000 O.T. was negative.

He was persuaded to attend for further investigation on October 21. He had felt perfectly well and had been at work from the week after his previous visit. His weight was still 10 st. 4 lb. There was no enlargement of spleen or of glands other than a few in both axillae, but these were apparently secondary to many cuts and abrasions on the hands, sustained at work. There had been no previous trouble with his eyes and no history of parotid swelling. His E.S.R. (Cutler) was 3 mm. in one hour; the Mantoux test, 1 in 1,000, was again negative; the white cell count was 8,800 per c.mm., and the differential count 67% neutrophils, 2% eosinophils, 1% basophils, 2% metamyelocytes, 2% monocytes, and 26% lymphocytes. Serum proteins were 7.55 g. %; the W.R., Kahn, and G.C.F.T. tests were negative; a laryngeal swab showed no tubercle bacilli on culture and there were no abnormal signs in the lungs. *X*-ray films of the hands showed no abnormality, and lung radiographs revealed considerable diminution in size of the left hilar shadow.

When seen again on December 2 he remained well, and weighed 10 st. 7 lb. (66.7 kg.), Mantoux 1 in 100 was negative, and a film of the lungs showed an almost normal hilar shadow on the right but a moderately increased shadow on the left. At no time was there any evidence of infiltration in the lungs.

Discussion

The tuberculin sensitivity was not recorded in the cases described by Kerley (1942, 1943), who based his diagnosis on the radiological appearances of massive glandular enlargement in the lungs, with or without lung infection. In his earlier series of 12 cases, all adults, eight showed benign infiltration of the lungs, and the hilar glandular enlargement in 10 was bilateral and in two on the left only. He states that in lymphadenoma it is exceptional to see the bronchial glands involved in the early stages, that bilateral lymphatic obstruction has not been described in this disease, and that the large lobulated bronchial glands have not been described in lymphosarcoma or the leukaemias.

In the studies of 185 patients over 15 years of age with erythema nodosum, Löfgren (1946) considers that in adults a non-tuberculous cause is more common than in children. Two of his sarcoidosis cases were diagnosed with the supporting evidence of biopsy, and in one of

these there was a positive tuberculin reaction to 1 in 100 O.T. He found that on testing with increasing strengths of tuberculin the skin sensitivity of erythema nodosum patients increases rapidly after the initial threshold had been passed. This may account for the marked reaction to 1 in 100 O.T. in Case 2. This effect does not appear to be due to sensitization produced by the serial testing, as others using stronger test dilutions in much greater number have not produced Mantoux conversion by this means. Löfgren classed all his six cases with bilateral hilar glandular swellings with miliary infiltrations as sarcoidosis, and a further nine with bilateral glandular enlargement and negative reactions or reaction to 1 in 1,000 or 1 in 100 O.T. as probable sarcoids. Most estimates of the incidence of negative reactors to tuberculin in sarcoidosis give figures of 60–70%, the remaining positives tending to be weak reactors. In the case described by Bjerkelund there were a negative reaction to 1 in 100 tuberculin, bilateral hilar glandular enlargement, and only two small pea-sized infiltrations near the hilum.

In sarcoidosis one-quarter to one-half of the cases show an eosinophilia, rarely over 10–15%, and the findings in Case 1 may be significant. In the active phase an increase in serum proteins is often noted and may exceed 9 g. %, the result in Case 3 being possibly a little further supporting evidence.

Whilst it may be regretted that histological proof of the diagnosis could not be obtained, it was not considered justifiable to ask the patients to submit to the inconvenience of the necessary investigations, but on the above criteria the three cases could be regarded as sarcoidosis.

Summary

The many different causes to be considered in the differential diagnosis of erythema nodosum are discussed and three cases are described in which the cause appears to be sarcoidosis.

A new approach to Shakespeare's plays is being made in the United States. In an experimental course sponsored by the Institute of Arts and Sciences at Columbia University in New York modern psychiatric techniques are applied in studying the characters in nine Shakespearian plays: *Othello, Hamlet, Macbeth, Romeo and Juliet, A Midsummer Night's Dream, Antony and Cleopatra, Julius Caesar, King Lear,* and *The Tempest.* The aim of the course, according to Dr. Russell Potter, director of the institute, is to utilize applied science to gain a "more sympathetic comprehension" of some of Shakespeare's great character studies. Five psychiatrists, all of them Shakespearean scholars, will co-operate with Dr. Maurice Valency, professor of English at Columbia, in conducting the course. Dr. Daniel E. Schneider, one of the psychiatrists, emphasizes that the course does not seek to psycho-analyse any particular character in the play. "Rather," he says, "we will try to judge the relationship of one character to another to achieve an understanding of the entire outline of the play." It is his opinion that much of modern psycho-analysis derives some of its roots from the great poets and dramatists of the past. "Shakespeare was the greatest analyst of them all," he believes.

CARDIOLOGICAL CASE FINDING BY MEANS OF MASS MINIATURE RADIOGRAPHY

BY

PETER O. LEGGAT, M.B., M.R.C.P.

Medical Director, Mass Radiography Unit, Liverpool Regional Hospital Board

The main object of mass miniature radiography surveys is to identify patients with minimal asymptomatic pulmonary tuberculosis. In carrying out such a survey many non-tuberculous lesions are met with, and these include a fair number of cardiac examples. The following is a description of the methods used in such a survey, and a discussion of the results obtained.

Method

Survey 1 was carried out in an industrial town in the North of England, and Survey 2 in a hospital for mental defectives closely adjoining this town. In the former the material consisted of 11,929 subjects, of whom 3,931 were females and 7,998 were males, with ages varying between 14 and 75 years. The great bulk of the group consisted of 10,306 industrial workers in factories. In the same group there were 1,255 school-children, all 14–15 years old; they were particularly chosen for *x*-ray examination as they were at the age when their school careers terminated. The remaining small group of 368 subjects consisted of those other than factory workers who volunteered for mass miniature radiography. In the mental hospital group of 244 subjects all were women, their ages ranging from 18 to 66 years.

The apparatus used was the standard type as supplied by the Ministry of Health for mass radiography surveys. This has a camera attachment so that the *x*-ray picture is photographed on to a 35-mm. film; after development the miniatures are projected through a Pullin projector on to a specially prepared white screen, the distance of the projector from the screen being so arranged that an enlargement of the miniature to 6½ in. (16.7 cm.) square can be satisfactorily carried out. If the enlargement is increased to greater than these dimensions there is a larger area for the eyes to cover and the strain of reading numerous miniature films is thereby increased.

Any patients who showed evidence of cardiac abnormalities were recalled for a routine history and physical examination, followed by screening and a barium swallow if thought necessary. At the same time large films were taken in the standard postero-anterior and oblique positions.

In making the diagnosis of cardiac abnormality by means of a miniature film, the following criteria were adopted: enlargement of the cardiac shadow; undue prominence of the pulmonary artery; changes in the contour of the aortic arch and cardiac shadow; changes in the lung fields. There are certain difficulties in using miniature films which are not found in large films, quite apart from the reduced size of the negatives. In the taking of miniatures the *x*-ray tube is situated 36 in. (91.4 cm.) from the fluorescent screen, so that there is bound to be some distortion of the cardiac shadow, which will appear larger than normal. Adiposity also causes broadening of the cardiac shadow, by consequent elevation of the diaphragm. I have found that all subjects with a maximum postero-anterior diameter of the chest of over 10½ in. (26.7 cm.) have a diaphragm that is higher than one would normally expect, so that the heart

outline is broadened. A considerable number of such persons were recalled for clinical examination, but were found to be perfectly normal.

An abnormally prominent pulmonary artery was of considerable value as a signpost to cardiac pathology. It was of less importance in young adults, in many of whom a prominent pulmonary artery was a normal feature of their cardiac outline (Parkinson, 1949). Many young adults showing this feature were recalled for clinical examination without any evidence of abnormality being found clinically, and on screening the heart was normal except for a slight to moderate prominence of the pulmonary artery. A very similar picture was produced if the patient was slightly rotated, or if a moderate degree of thoracic scoliosis was present; both of these abnormalities are usually evident on inspection of the miniature, and do not give rise to undue difficulty in diagnosis. Unfolding of the aorta secondary to arteriosclerosis with or without hypertension was particularly difficult to estimate. Considerable variation in the shape of the aortic arch can be brought about by moderate elevation of the diaphragm; thus the same factors are important here as in apparent broadening of the cardiac shadow.

With these many difficulties it is not surprising that a considerable number of those recalled for clinical examination and screening show no evidence of cardiac abnormality. Vascular shadows are much more obvious on the miniature films than they are on large films: evidence of pulmonary congestion if present is usually clearly seen. An additional feature in miniature radiography which tends to obscure the picture is the effect of secondary radiation; it is especially troublesome in obese people, and tends to cast a blur over the cardiac shadow and the pulmonary vascular shadows.

Results

In the two surveys 33 cases of rheumatic heart disease were discovered (see Table). There were 22 cases in Survey 1 (Chart 1) and 11 cases in Survey 2. Although

Cases of Rheumatic Heart Disease in Surveys 1 and 2

Type of Lesion	Sex	Average Age (Years)	No. of Cases
Mitral stenosis	Male	30·75	8
	Female	37·28	7
Mitral stenosis with aortic incompetence	Male	34·0	3
	Female	34·5	2
Mitral stenosis with aortic stenosis	Male	30·0	1
	Female	—	0
Aortic incompetence ..	Male	50·0	2
	Female	27·3	3
Mitral incompetence with aortic incompetence	Male	—	0
	Female	14·0	1
Aortic stenosis	Male	50·0	1
	Female	—	0
Mitral incompetence ..	Male	—	0
	Female	38·0	4
Mitral incompetence with aortic stenosis	Male	—	0
	Female	47·0	1
Total ..	—	—	33

in Survey 1 all the 22 cases were identified through the use of mass miniature radiography, 17 of them had already been diagnosed by other means prior to the survey. In Survey 2 only two cases were diagnosed radiologically, though all 11 cases had been previously diagnosed on clinical grounds. There were 14 instances of hypertensive heart disease discovered in Survey 1, none of which had been diagnosed before the mass miniature radiography survey (see Chart 1). The group consisted of nine males with ages ranging from 33 to 61 years, and five females, the youngest of whom was aged 45 and the oldest 51. Those subjects who had a systolic blood pressure at the high level of normal had a diastolic pressure above normal. There were also subjects who had a diastolic pressure situated at a high level of normal but whose systolic pressure was well above normal (Chart 2). The latter group showed a considerable degree of arteriosclerosis, so that an abnormally rigid aorta may well have been the causal factor in a marked raising of the systolic blood pressure.

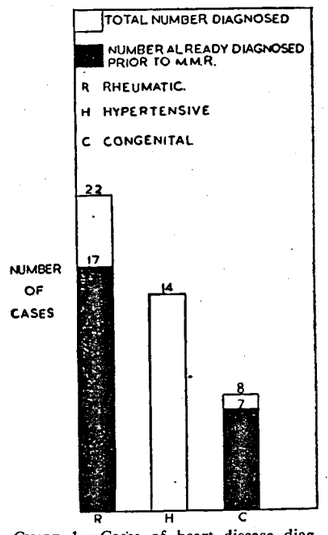

CHART 1.—Cases of heart disease diagnosed in Survey 1.

In regard to Survey 2, four cases of hypertensive heart disease were discovered, of which only one was diagnosed by means of mass miniature radiography—a female aged 62 with a blood pressure of 180/100. The remainder of the group were aged 45, 49, and 66. The lowest systolic blood pressure was 150 mm. Hg and the highest 180 mm.: the diastolic pressure was 100 mm. in all three subjects.

In Survey 1 there were eight cases of congenital heart disease which were diagnosed by means of mass miniature

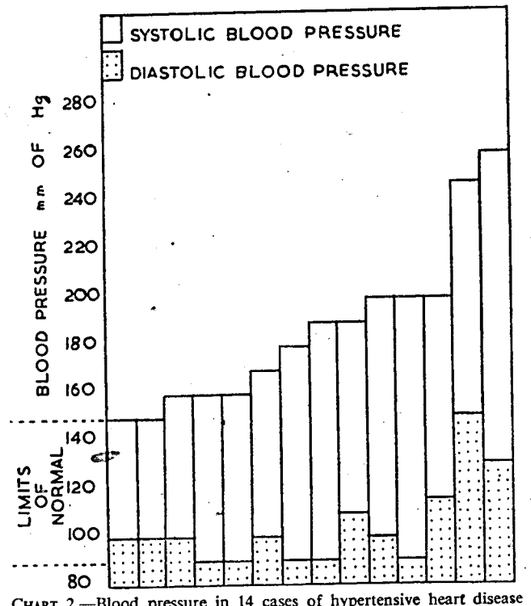

CHART 2.—Blood pressure in 14 cases of hypertensive heart disease occurring in Survey 1.

radiography. Seven of these had been previously diagnosed (Chart 1), usually on a routine school examination, though two had been diagnosed in their pre-school days. All these cases were asymptomatic, and none of them showed any sign of cyanosis or clubbing. The group consisted of two cases of patent interventricular septum (both males, aged 16 and 32) and four cases of patent interauricular septum (all males—two aged 22, one aged 31, and one aged 33). There were also two cases of dextrocardia with situs inversus, both males, aged 42 and 52. Considering the ages of the patients in relation to Campbell's observations that only one in two "blue babies" will survive to the seventh year and less than one in ten will reach the age of 10 years (Campbell, 1948), it is not surprising that cases of congenital heart disease with cyanosis were not present in this particular group.

Discussion

It has been suggested by the earlier pioneers in mass miniature radiography that it might be used for identifying cardiac abnormalities (M.R.C., 1945). No one so far has attempted to assess the potentialities of this method for disclosing the presence of cardiac abnormalities.

In the first survey we were dealing with a population containing an unknown number of cardiac cases, so that it is not possible to estimate how many were missed by the radiological screening. Of those rheumatic cases discovered, over half had already come under the supervision of their doctor on account of symptoms of varying degrees of severity. Subdividing the group into those cases diagnosed prior to mass miniature radiography and those diagnosed primarily by that means, we find that 12 of the former had symptoms, while this was true of only three of the latter.

All the cases in the hypertensive group of Survey 1 were identified from the cardiac enlargement on the miniature film; five had symptoms, and none had been diagnosed previously.

In these two groups the survey was of some value in that it identified 19 cardiac cases not previously diagnosed which would benefit from medical supervision.

None of the cases of congenital heart disease had any symptoms, nor had they any signs of cyanosis or clubbing. With the exception of the two cases of dextrocardia, all would benefit from medical supervision on account of the potential danger of subacute bacterial endocarditis. However, seven of these cases were already known to their medical advisers, so that benefit was brought to only one case by means of mass miniature radiography. There were no cases of congenital heart disease amenable to surgery.

Considering all three groups together, there were 44 cardiac cases in Survey 1, equivalent to 3.68 per 1,000. In the M.R.C. series a total of 21,178 subjects, consisting of office and factory workers in equal proportions, were *x*-rayed. In that survey 32 cardiac cases were discovered, equivalent to 1.51 per 1,000. The considerable difference in the two series is due to the fact that in the latter survey only those young cardiac patients in whom "some benefit was thought to be possible" were recalled for medical interview.

In Survey 2 all the subjects were females. The average age of this group was considerably higher than that of Survey 1; also there were a known number of cardiac cases, as all the patients had been examined on admission to hospital. In the primary radiological survey only three cases were identified by means of mass miniature radiography. Following this, all these known cardiac cases were examined personally and the clinical diagnoses checked. The relevant miniature films were looked at again to see whether any cases had been missed radiologically on the first inspection of the films. Even with the additional knowledge of the clinical condition of these patients, no further cases could be diagnosed radiologically. It appears, therefore, that mass miniature radiography is of some, though limited, value in the diagnosis of cardiac abnormalities, and that by its means some cases of cardiac disease with few or no symptoms may be revealed. It is obvious that in every survey a large number of cardiac cases must be missed, because they have not reached the stage where there are radiological abnormalities, or because the thickness of the chest wall, with or without excessive adiposity, produces such a poor miniature that it is useless for diagnostic purposes.

Summary

In two mass miniature radiography surveys 12,173 subjects were *x*-rayed; 47 cases of cardiac disease were diagnosed radiologically and checked by clinical examination.

Seventeen cases of rheumatic heart disease and seven cases of congenital heart disease had been previously diagnosed in Survey 1 (11,929 cases).

Three cases of cardiac disease were diagnosed out of a known number of 15 occurring among the 244 cases in Survey 2.

The difficulties met with in the reading of miniature films are described.

It is considered that mass miniature radiography is of value in identifying some cases of cardiac disease, though in any survey a large number are bound to be missed for technical reasons and through lack of radiological change.

It gives me pleasure to record my appreciation of the criticism and encouragement given to me by Dr. Robert Coope in the preparation of this paper. In Survey No. 2 I am indebted to Dr. MacKenzie and the staff of Newchurch Hospital for their very willing co-operation.

The Women's Advisory Council on Solid Fuel (18, South Molton Street, London, W.1) took occasion at a conference on November 9 to draw attention to the need for effective safety appliances for kitchen ranges and open coal-fires. The seriousness of the need was pointed out by Mrs. Vera Colebrook, who said that over 100,000 cases of burns and scalds required hospital treatment in England and Wales every year. This represented a financial drain on the National Health Service of over £2m., and 300,000 bed-days could be saved if burns were prevented. Of the cases of burns 70% were caused in the home and 30% in industrial establishments, but while there were safety precautions in industry nothing was done about the domestic fire. Mrs. Colebrook criticized the rule whereby a fireguard when sold separately was not subject to purchase tax, but the tax was chargeable if the guard was incorporated in the heating appliance. Gas and electric fires with fixed guards were being exported to countries like Sweden and Iceland, where the incorporation of the guard with the fire was compulsory, but in this country a tax was imposed on the incorporated device. Two new types of guards were exhibited at the conference. One was for fixing in front of the fire when it was opened in a special type of solid fuel range. The other was an adaptation of the "cage" type of guard for the open fire, having a special door in front so that the guard need not be put aside when more fuel was added, and there was a device for fixing it firmly so that it could not be easily knocked over.

UNUSUAL CASE OF TUBEROUS SCLEROSIS

BY

A. J. N. WARRACK, M.B.E., M.D., D.T.M.&H.
Assistant Director of Pathology, Southern Command; Lieutenant-Colonel, R.A.M.C.

[WITH SPECIAL PLATE]

Tuberous sclerosis is a condition found in the brain as a feature of the syndrome epiloia. Critchley and Earl (1932) described 29 cases of epiloia, and in a review of the literature pointed out the essential features of the disease. Classical cases are characterized by mental deficiency, recognizable in early life, adenoma sebaceum at puberty, and epileptic fits. A psychopathic taint is often a feature of the mental state, and motor restlessness is common. A familial incidence may also be discovered. Other signs recognizable during life may include thickening (shagreen patches) of the skin, flattened dermal fibromata on the back, pedunculated dermal tags, and such stigmata as simian hands, with incurving of the little finger, and misshapen ears.

At post-mortem examination the cerebral convolutions are found to contain numerous sclerotic areas which on microscopy appear to consist of an increase in neuroglial tissue with the addition of giant cells foreign to the central nervous system. Tumours of other organs are common, including cardiac myomata and bizarre renal neoplasms varying from sarcoma to hypernephroma.

Tredgold (1947) described the condition and discussed the features of the mental state. Clinical variants occur, and Stewart (1935) recorded the sudden death in epilepsy of an apparently normal young woman. Typical sclerotic areas were found in the brain, though there was no previous history of mental deficiency or fits, and no evidence of adenoma sebaceum or renal neoplasms.

The purpose of this paper is to describe another of the *formes frustes* of epiloia which occurred in a young soldier.

Case Report

The patient was called up for national service in August, 1949. He was found fit and drafted to a selection unit. His medical documents stated: "Pigmented rash on face. Marked refractive error in both eyes—corrected to 6/6. A history of migrainous headaches." There was no history of fits of any kind. He underwent the usual selection procedure at his unit and was given the intelligence rating "S.G. 3P." This placed him in the top 50% of the Army population and showed him to be above average intelligence. The personnel selection officer made the following comments at a routine interview: "He is a man of above average intelligence and ability and has been on survey work. He is of negative personality."

It should be noted, however, that the man's instructors described him as "slow to learn," while his father later stated that although he was an affectionate boy he was not as quick as his brother. There was no family history of mental disease or of fits.

Soon after his arrival at the selection unit he reported sick with headaches. The presence of adenoma sebaceum on the face was at this time remarked upon and he was kept under observation. Four weeks later his comrades reported, at about 8.30 p.m., that he had complained of drowsiness at about 4.30 p.m., had gone to bed, and could not be roused.

On admission to hospital he was semi-comatose and restless, with alternating pulse and Cheyne–Stokes respiration. The limbs were in the position of decerebrate rigidity; the arms being flexed and legs extended. The tonic state of the limbs was described as striking. The pupils were at first equal and reacted to light, but as his condition deteriorated into deep coma they became fixed and dilated. The tendon reflexes were brisk but the abdominal reflexes were absent.

He died at 10.45 p.m., apparently from a brain-stem lesion, about seven hours after he had first complained of drowsiness.

Post-mortem Examination

External Appearance.—The body was that of a well-nourished young adult male. The pupils were dilated and equal. There was a small pedunculated papilloma close to the left nasal cleft surrounded by several sessile red and brown plaques varying from a pin's head to 2 mm. in size. Similar plaques and a tiny papilloma were visible in the right nasal cleft. A few tiny red spots were visible on the cheeks. The distribution of these plaques was of a butterfly nature and the condition appeared to be one of adenoma sebaceum. There was a small papilloma about 0.5 cm. in diameter in each groin. In the small of the back in the region of the third and fourth lumbar vertebrae there were about a dozen brown sessile plaques varying from 1 mm. to 1 cm. in diameter. A similar collection was present over the sacrum.

Central Nervous System.—The cerebral cortex was studded with firm sclerotic masses about 1 cm. in diameter. These could readily be discerned with the finger-tips, but were extremely difficult to see with the naked eye. There was no evidence of hydrocephalus or haemorrhage. The cerebellum was normal. Examination of the pons and medulla showed surprisingly little change considering the decerebrate and acute nature of the man's death.

Urinary System.—The left kidney was congested. Several white pin-point spots were visible on the surface. On cut section a round circumscribed fibrous mass was found at the upper pole 0.5 cm. below the surface. The right kidney showed a similar mass 1.5 cm. in diameter at the lower pole and another small deposit near the pelvis. No abnormalities were noticed in any other organs.

On histological examination of the central nervous system the sclerotic areas showed an increase in glial tissue, with a bizarre cellular structure. Displacement and disorientation of large nerve cells were characteristic (Plate, Fig. 1). The tumour in the left kidney was epithelial in nature and had an adenocarcinomatous appearance (Fig. 2). The other renal tumours were quite different, and consisted of vascular fibrous tissue (Fig. 3).

This patient thus showed many of the classical lesions of epiloia, including adenoma sebaceum, dermal tags and plaques, tuberous sclerosis, and bizarre renal neoplasms. His normal intelligence and the absence of any history of fits were unusual features.

Summary

Sudden death in a young adult is described in which the typical lesions of epiloia were found with recent evidence of normal intelligence and no evidence of fits.

A similar case described by Stewart (1935) did not exhibit adenoma sebaceum or renal neoplasms.

I am indebted to Lieutenant-Colonel W. D. Hughes, R.A.M.C., officer in charge, Medical Division, Cambridge Hospital, for the clinical details and valuable advice and encouragement, and to Captain T. D. S. Oswald, R.A.M.C., for the previous history and for his interest in the preparation of this report. I also thank the late Dr. K. Paddle, medical superintendent, Botleys Park Mental Colony, Chertsey, and his colleagues for their kindness in demonstrating their cases of typical epiloia; Dr. J. G. Greenfield, of the National Hospital for Nervous Diseases, for his kindness in examining the sections; and Captain J. L. Garson, R.A.M.C., for the photomicrographs.

Medical Memoranda

Pernicious Anaemia and Tumours of the Stomach

The following two cases are considered worthy of record as illustrating the association between pernicious anaemia and gastric tumours.

CASE 1

A 55-year-old man attended the Manchester Royal Infirmary in October, 1946, and was found to be suffering from pernicious anaemia. Fractional gastric analysis showed complete achlorhydria. There was a rapid response to parenteral liver therapy and he was maintained in good health with normal blood count by continued treatment.

In January, 1949, he had a small haematemesis with uneventful recovery, and in June was admitted to hospital under the care of Dr. A. H. Holmes for investigation. He stated that he felt quite well and denied having dyspepsia either before or since the haematemesis. There were no abnormal physical signs, and the results of investigations were as follows: blood count was normal; examination of the faeces for occult blood was positive, and barium-meal examination revealed a smooth mobile filling defect close to the greater curvature of the stomach suggestive of a polyp. This was confirmed gastroscopically by Dr. C. S. D. Don, and a Schoemaker gastrectomy was performed by Professor John Morley. There was no evidence of the presence of other polyps.

Pathological Report.—The portion of the stomach removed contained a tumour situated on the anterior wall close to the greater curvature towards the pylorus. The tumour consisted of two parts, the larger pedunculated and the smaller sessile. Histologically it was an adenomatous gastric polyp with no evidence of malignancy.

CASE 2

A 54-year-old woman had a subtotal thyroidectomy for hyperthyroidism in May, 1946; at that time the blood count was: red cells, 4,900,000 per c.mm.; haemoglobin, 92%; colour index, 0.94; white cells, 7,200 per c.mm. Her health improved after the operation, but in February, 1948, she was readmitted to hospital under the care of Dr. A. H. Holmes complaining of epigastric discomfort, dysphagia at the xiphisternum, and loss of weight, over the last year. The tongue had recently been sore and atrophic glossitis was present. She was wasted and pale. A hard mass was felt in the epigastrium to the left of the midline, and the liver edge was 2 in. (5 cm.) below the right costal margin; it was also thought that the spleen was just palpable.

A blood count showed: red cells, 3,460,000 per c.mm.; haemoglobin, 78%; colour index, 1.13; white cells, 6,700 per c.mm., with normal differential count; the sternal marrow was megaloblastic. Fractional gastric analysis showed absence of free HCl with very low total acid. *X*-ray examination revealed a large filling defect in the fundus and body of the stomach. It was apparent that she had both pernicious anaemia and gastric carcinoma. Intramuscular liver injections resulted in a reticulocyte response reaching 31% on the sixth day, but the haemoglobin did not rise. Laparotomy was carried out by Professor A. M. Boyd, and an inoperable gastric carcinoma with metastases in the liver and peritoneum was discovered. She was discharged from hospital and died soon afterwards.

COMMENT

In the past few years increasing attention has been drawn by American workers to the coexistence of pernicious anaemia and gastric epithelial tumours. Kaplan and Rigler (1945) made a study of 43,021 consecutive necropsies and were able to find 293 cases of pernicious anaemia, 36 of which also had carcinoma of the stomach, an incidence of 12.3%; this was over three times the incidence in the remaining necropsy population of the same age. Concerning benign tumours of the stomach, it is interesting to note that Brown (1934) found 12 gastric polyps (8%) among 151 cases of pernicious anaemia in 18,200 necropsies.

Kaplan and Rigler (1947) also carried out repeated radiological and gastroscopic examinations of patients with pernicious anaemia, and out of 259 such patients 18 (6.9%) were found to have carcinoma of the stomach, and 17 (6.6%) had benign polyps. Bourne (1948) similarly investigated 15 patients with pernicious anaemia over a period of two years and found three symptomless gastric carcinomas, one polyp, and one leiomyoma. Other authors have also reported a high incidence of gastric polyps in pernicious anaemia (Doehring and Eusterman, 1942; Washburn and Rozendaal, 1938). Velde (1938) found six such cases (14%) in a series of 42 patients with pernicious anaemia, as contrasted with an incidence of only 0.7% in a control series of patients with other diseases.

The tendency to the development of gastric polyps displayed by such patients is clearly of great importance when one considers the frequent development of malignant changes in such tumours (Stewart, 1929; Miller *et al.*, 1930; McRoberts, 1933; Lawrence, 1936; Rigler and Erickson, 1936). It is of interest that gastric carcinomas developing in patients with pernicious anaemia are usually of polypoid type and situated in that area of the stomach which Magnus and Ungley (1938) have shown to be atrophic in this disease—namely, the body and fundus.

Wilkinson (1949) stated: "My series produced 28 gastric cancers in 1,532 patients who lived—i.e., 1.83%, or on the basis of total fatal cases (28 gastric cancers in 301 dead pernicious anaemia patients) a frequency of 9.3%—and therefore suggests the necessity for regular and frequent examination of all patients with pernicious anaemia." The most rational explanation of the occurrence together of the two diseases is that both are the result of the same inherent abnormality of the gastric mucosa.

It should be noted that our second case is rather unusual in that the carcinoma and pernicious anaemia apparently arose within a short period of each other, as a blood count performed less than two years before both diagnoses were made was quite normal. As we have pointed out above, in all probability the pernicious anaemia and the carcinoma shared a common "ancestor," whatever that may be; it is conceivable, however, that in our patient the carcinoma actually produced the pernicious anaemia by virtue of its localization in the fundus and body of the stomach.

ADDENDUM: Since our submission of this paper, Mosbech and Videbaek (*British Medical Journal*, 1950, **2**, 390) have recorded 15 cases of gastric carcinoma occurring among 301 patients with pernicious anaemia. These authors considered that the gastric carcinomas of patients with pernicious anaemia had the same anatomical distribution as in normal people.

We wish to thank Dr. A. H. Holmes for his encouragement and advice, and the other physicians and surgeons of the Manchester Royal Infirmary mentioned in the text.

Atresia of the Small Intestine

Congenital atresia of the intestine is not a common condition and it is rarely diagnosed at a stage when surgical treatment holds out a hope of success; yet early diagnosis is relatively simple.

Vomiting always occurs on the first day of life and is persistent and increasing (Ladd and Gross, 1941). It almost invariably contains bile. These two findings distinguish the condition from hypertrophic pyloric stenosis. The stools are usually small, dry, and lighter in colour than normal meconium (Ladd and Gross, 1941; Potts, 1947). Absolute constipation is not the rule. Abdominal distension is variable, depending on the duration of the symptoms and the level of the lesion. When the atresia is in the ileum distension is usually marked and visible peristalsis is often present (Ladd and Gross, 1941; Potts, 1947). Dehydration is pronounced only if the condition has persisted for some days.

A plain radiograph of the abdomen, particularly if taken with the infant held erect, will not only establish the diagnosis of obstruction but will give a clue to its approximate level. The administration of barium in these cases is not only unnecessary but may be dangerous, as an inhalation of vomited barium may give rise to a fatal pneumonia.

Farber's test depends on the fact that normal meconium contains cornified epidermal cells from swallowed liquor amnii. If microscopical examination of a specimen of meconium (taken from the centre of a stool) shows absence of such cells complete obstruction of the intestine may be assumed. As stenosis is not excluded this test would seem to be of more academic than practical value. It should be stressed that repeated vomiting during the first 24 hours of life indicates the urgent need for radiographic investigation.

CASE REPORT

A baby girl, born at 4.30 p.m. on July 31, 1949 (weight, 6 lb. 12 oz.—3.06 kg.), was admitted to hospital at about 1 p.m. the next day with a diagnosis of imperforate anus and a history of repeated vomiting since birth and failure to pass meconium.

On examination the abdomen was distended. Ladder patterns and visible peristalsis were seen over the central and upper abdomen. Her clothes showed evidence of bile-stained vomit. Per rectum there was no difficulty in inserting a finger, and examination was followed at once by the passage of a normal looking tarry meconium. A radiograph of the abdomen (erect position) showed coils of distended small bowel with fluid levels. The radiologist (Dr. J. O. Y. Cole) reported "small-gut obstruction, probably mid-ileum."

A 10E rubber urethral catheter was passed into the stomach, and repeated aspirations were carried out. About 1 oz. (28 ml.) of bile-stained fluid was aspirated. Ringer-lactate solution, 100 ml., was injected subcutaneously.

Operation.—Anaesthesia was induced by ethyl chloride followed by nitrous oxide, oxygen, and ether (Dr. Reid). A right paramedian incision centred opposite the umbilicus and 3 in. (7.5 cm.) in length was made. Grossly distended loops of small intestine presented and were allowed to prolapse freely. The distended bowel ended blindly about midileum, and at this point the gut was almost 2 in. (5 cm.) in diameter and very thin-walled, but not gangrenous. For the next 2 in. there was complete absence of intestine, the mesentery ending in a free edge just distal to the vascular arcades. The distal bowel was extremely small, the diameter being less than ¼ in. (0.6 cm.).

With a fine hypodermic needle some 30 ml. of air was injected into the distal loop, which promptly dilated to about ½ in. (1.25 cm.) diameter and the pelvic colon could be felt distended with air. The proximal loop was aspirated and much gas and a little brown fluid were withdrawn, causing the loop to collapse considerably. The needle puncture was turned in with a purse-string suture of 3/0 chromic catgut.

Using light clamps, a 1½-in. (3.75-cm.) side-to-side anastomosis was made between the two loops by standard technique. As no suitable non-absorbable suture was available 3/0 chromic catgut on an atraumatic needle was used for both layers. No tube was used and anastomosis was not difficult. The gap in the mesentery was closed and the bowel was returned to the abdomen. The abdomen was closed in layers, using 2/0 chromic catgut for the deep layers and fine nylon for the skin.

The gastric catheter was left in place and aspirated hourly. Ringer-lactate solution, 100 ml., was injected subcutaneously at four-hourly intervals for 24 hours. Rectal salines, 4 oz. (114 ml.), were injected four-hourly, partly with a view to increasing fluid intake, but chiefly to distend the distal bowel. Penicillin, 50,000 units three-hourly, was given. The infant was nursed in an incubator with extra oxygen.

On August 2 only a few ounces of bile-stained fluid were aspirated. The bowels opened 12 hours after operation—meconium and a little blood. Next day, with the gastric tube in position, 1 oz. of 5% glucose was fed to the infant from a spoon at hourly intervals and aspirations were continued hourly (midway between feeds). After a few hours it was obvious that the fluid aspirated was much less than the intake. The bowels moved once again. Subcutaneous and rectal fluids were discontinued, the gastric tube was withdrawn, and glucose water was continued and gradually increased.

Three-hourly feeding with a reconstituted food was begun on August 4. From this point the feeding and care of the infant were left entirely to the nursing staff of the maternity unit and the baby was treated as "premature." The successful outcome of the case is due in no small measure to their devotion and skill. The child was discharged on September 17 and, apart from some fat intolerance, was normal. When seen on November 7 she was progressing normally and her weight was 11 lb. 4 oz. (5.1 kg.).

In the not-too-distant future the number of pharmaceutical research scholarships may be substantially increased, Mr. C. W. Maplethorpe, chairman of the Pharmaceutical Society's education committee, stated in the course of an address on the society's education policy. There are already three such scholarships of the annual value of £300 each. A lease of a building, he added, had been taken for the establishment of a well-equipped laboratory for work in connexion with the scientific publications of the society. Because of the new opportunities in pharmacy, more young people were entering the profession. Since January they amounted to 784, and if the number of entries during the remainder of the year was at the same rate as last year they would exceed the entry figures for any year since 1933.

Reviews

SUPERVOLTAGE RADIOTHERAPY

Supervoltage Roentgentherapy. By Franz Buschke, M.D., Simeon T. Cantril, M.D., and Herbert M. Parker, M.Sc. From the Tumour Institute of the Swedish Hospital, Seattle, Washington. (Pp. 297; illustrated. £3 17s. 6d.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1950.

During the last two decades there has been much technical progress in radiotherapy, and one of the principal changes was the application, for therapeutic use, of *x* rays generated at over half a million volts (in the so-called supervoltage range). In this book the authors record their clinical experience with an 800-kV apparatus installed in 1932—in the pioneer stages of supervoltage development—which has continued to provide a satisfactory radiation beam. Physical considerations discussed in the opening chapter include the lay-out of the Villard circuit, protection, and measurements of radiation quality and quantity. The effective wavelength of the beam, 0.0245 Å, is satisfactorily low for a pulsating type of circuit at 800 kVp, but the heavy filtration necessary reduces the dosage rate to about 20 r per minute at one metre focus-skin distance. The *x*-ray beam is projected vertically downwards from an aperture in the ceiling of the treatment room, and spatial angulation has to be made by adjusting the patient's position relative to the fixed beam; this, the authors admit, is an outstanding weakness of the arrangement. The physical advantages claimed for supervoltage therapy are, in addition to the improved depth dose in treating deep-seated lesions, the reduction in skin reaction and the restriction of radiation to the geometric beam, thereby diminishing the constitutional upset of the patient.

Throughout the chapters on the irradiation of malignant disease at various sites the emphasis is on clinical aspects, and many detailed and well-illustrated case histories are included. Statistical analyses are limited, because the authors feel that "at this stage there is more to be gained by a discussion of the particular patient, his disease, and reactions to treatment than can be gained from statistical evaluation." The importance of deep mucosal reactions, and not skin reaction, as the factor limiting permissible dosage in many sites is well brought out in these chapters. Supervoltage therapy, they find, has been used with advantage in advanced carcinomata of the oral cavity and pharynx, especially of the base of the tongue. In carcinoma of the maxillary antrum and larynx they believe the response to depend more on the histological type of the growth than on the dose or energy of the radiation. In oesophageal and bladder growths the results obtained are distinctly encouraging, but breast carcinoma the authors regard pessimistically from a radiotherapeutic viewpoint. In a detailed discussion of the problems presented by carcinoma of the cervix uteri they emphasize the dangers of over-irradiation in the pelvis, where again the limiting factor is the reaction of the intestinal mucosa.

The authors conclude that "supervoltage roentgentherapy has a limited but definite place in an institution which tries to give the cancer patient the benefit of whatever increment has been made in radiation therapy." Their experience has, however, been limited by the lack of flexibility of their apparatus, so that the full benefit of modern supervoltage therapy by multiple beam-directed small fields could not be readily attained. Many radiotherapists now about to use supervoltage therapy for the first time will find in this book a well-produced, fully documented, and clearly illustrated account of the clinical effects of supervoltage radiation on normal and malignant tissues.

ARTHUR JONES.

VENOUS PRESSURE

A Primer of Venous Pressure. By G. E. Burch, M.D. (Pp. 174; illustrated. 28s.) London: Henry Kimpton. 1950.

As stated in the preface, this short monograph is intended for the beginner. It is designed to arouse his interest in the venous pressure and its bearing on clinical problems, so that he may better understand and manage his patient. After reading the 164 pages and studying the 170 diagrams, the novice is unlikely to be a better doctor: he will certainly be unable to estimate the venous pressure at the bedside, unless already taught how to do so elsewhere, and he will be unaware of the chief fallacies in such estimations. This is a pity, especially since the clinical value of measuring and understanding the venous pressure is repeatedly emphasized. The author presents much anatomical and physiological information about the veins in various parts of the body, but it is questionable whether these are the facts the clinician wants to know. His interest might have been captured more securely if his difficulties had been better appreciated and met. For example, at the bedside it is almost impossible to consider the central venous pressure without reference to the venous pulse: but Professor Burch dismisses the jugular pulse in 10 lines He may have had good grounds for doing so, perhaps because he believed it had little to do with his subject: but it is hard to see why. His attitude would excite more sympathy had the title of the book been "A Primer of Peripheral Venous Pressure."

At the bedside the clinician tries to distinguish one cause of raised venous pressure from another, and in doing so he naturally attempts to analyse the venous pulse. In this way he can recognize tricuspid incompetence, tricuspid stenosis, and a group of conditions that give rise to strong right auricular contractions, and so distinguish them from congestive failure. Differences of opinion on the interpretation of the hepato-jugular reflux are not considered, yet there has been and still is much controversy about this elemental phenomenon. The venous pressure is considered in relation to sex, race, age, altitude, and nutrition, but not in relation to bradycardia, pregnancy, menstruation, fever, or anaemia.

Despite such drawbacks much valuable information has been collected and is presented in a manner characteristic of Professor Burch's other works. The book is recommended to those who wish to study the peripheral venous pressure more seriously, and to research workers who are interested in problems relating to the venous pressure But students and clinicians may find it disappointing: much is offered that they may not want to know; much that they may seek is omitted.

PAUL WOOD.

TUBERCULOSIS OF THE HIP

Coxitis tuberkulosa. By Dr. Herbert Gardemin. (Pp. 166; 245 figures. M. 18.) Berlin and Munich: Urban and Schwarzenberg. 1950.

The secondary title of Dr. Herbert Gardemin's book on tuberculosis of the hip is "A Contribution to the Radiological Pathology of Skeletal Tuberculosis." The volume is primarily intended for radiologists, but, as the radiological appearances are related to pathological findings, a wide field is covered, and the book will be of interest to all concerned with the long-term treatment and diagnosis of this disease. The author pays particular attention to the early features of the disease and the detection of the minimal lesion. There is a well-illustrated series of cases showing the main primary sites of infection and their progress. A knowledge of this is of value in forming a prognosis and some assistance in deciding when operative treatment should be carried out.

The author carefully analyses the relationship of the radiological appearances to the healing process. This point is obviously important if minimal immobilization is the goal of treatment. The undesirable influence of pus and caseation in healing is well shown, though its presence does not appear to excite any direct effect on reparative ossification, which starts in the majority of cases from the acetabular area.

In general, the findings emphasize the value of conservative treatment. It is a pity that the space devoted to the discussion of differential diagnosis is disproportionate to the rest of the volume. A diet of rich detail of one aspect raises an appetite for a similar exposition of the imitative lesions.

J. G. BONNIN.

SOMATOGENIC ILLNESSES

Klinische Psychopathologie. By Kurt Schneider. Third edition. (Pp. 179. M. 11.40.) Stuttgart: Georg Thieme. 1950.

The various schools of psychopathology differ in their basic assumptions and the type of clinical data on which they build their systems. This book starts out with a sharp division of psychological disorders into two categories: mental illness, which is due to somatic disease or malformation; and mental abnormality, which is merely an excessive deviation from a normal average. The author claims that this distinction is supported by clinical experience, which revealed to him that transitional conditions between the two categories are exceedingly rare, so that diagnostic difficulties in distinguishing between them hardly ever occur. For example, he has rarely been in doubt whether a patient should be classified as schizophrenic or manic-depressive, or whether he should be regarded merely as an abnormal personality Therefore he concludes that schizophrenia and manic-depressive psychosis are due to an as yet unknown somatic disease—a rather daring conclusion in view of the slender, subjective, and speculative basis on which it rests.

The psychopathology of these two categories of mental disorder are treated in a different manner. Discussing the somatogenic illnesses, the interest of the author is focused on the kind of symptom which can be caused by the underlying somatic disease. In this section of the book he therefore concentrates on a careful and detailed description of the possible symptomatology. He also classifies the symptoms into two groups according to the diagnostic value they have.

When he turns to his second category of mental disorders the author does not limit himself to descriptive analysis and classification The deviations with which he deals in particular are abnormal intellectual endowment, abnormal personality, and abnormal reactions to experience. A delineation of psychopathic and neurotic personality types is attempted, but only limited clinical usefulness is claimed for it. These descriptive formulations are supplemented by dynamic considerations of the interaction between constitutional trends and individual experiences. The views in these chapters approach certain concepts which have been developed by the psycho-analytical school. But the author is critical of these concepts and underlines the difference from them of his point of view. The name of Freud is never mentioned, not even in disagreement. Nor does the term "unconscious" appear in the book; it has to be replaced by such cumbersome circumlocutions as "the basis which is not and cannot be experienced," and "the background of previous experiences which need not be immediately recalled."

DISPLACED REGISTRARS

Since July, 1948, no action of the Minister of Health has caused such disquiet and anxiety as the recent decision summarily to dismiss over 1,000 registrars from the hospital service of this country. The first and most ominous ground for disquiet is this unpleasant reminder of the absolute powers of the Minister. As short a time ago as 11 months the Ministry of Health published a memorandum on the development of consultant services,[1] in which it made this reference to the increase and distribution of consultant staff: "Thus for the first time there is generally available the means of providing additional staff where it is most needed. . . . The deficiency in numbers can be made good only gradually, because the training of consultants is necessarily long." This memorandum, which had been circulated to hospital boards a year previously to guide them in planning consultant services, was generally welcomed as making a constructive approach to the evolution of a consultant service adequate to the needs of the community. In fact, in the first paragraph of the memorandum it was admitted that there are too few consultants to meet the needs of the whole population. This is a matter on which the medical profession and the Ministry of Health are in agreement, and yet what does the Minister do within a year of publishing the memorandum? He cuts the present registrar strength by half and at the same time introduces as a *long-term policy* a proposal which does not yet seem to have aroused enough interest in the profession—namely, that general practitioners should serve as clinical assistants in hospitals in order to meet "staffing difficulties in the senior registrar field." Here is a radical change in policy which has been introduced without agreement by the medical profession. When questioned in the House of Commons Mr. Aneurin Bevan gave a completely false impression when he stated that the proposals relating to registrars had been introduced after consultation with the profession. The falsity lay in the implication that consultation implied agreement. As was made clear in a statement in the *Supplement* to last week's *Journal*, the Joint Committee, representing the Royal Colleges and Corporations and the B.M.A., did not accept the Ministry of Health's proposals. A further statement in this week's *Supplement* makes the position of the Joint Committee unambiguous, and it is urging the Ministry to postpone action on the proposals made and at the same time to reopen discussions on the whole question of registrars in relation to the consultant service of the country. An organization from which Mr. Bevan might have expected some support has, on the contrary, peremptorily demanded "the immediate withdrawal of circular RHB (50) 106." The Socialist Medical Association, which has made this demand, agrees with the Joint Committee when it states that "the circular shows a total failure to understand the importance of the contribution made by registrars to the hospital service. By concentrating on the training they receive it fails to appreciate how much of the essential work on the wards and in the out-patient departments is done by registrars, many of whom are in fact doing consultants' work."

The second disturbing feature of the Minister's recent action is the failure on his part—or perhaps we should say on the part of those who advise him—to appreciate the position of registrars in hospitals and his failure to go ahead with the policy of expanding the consultant services of this country in relation to the needs of the community. Part of the trouble has arisen because of the Minister of Health's apparent habit of regarding registrars merely as trainees. They are of course trainees in the sense that every doctor who practises medicine is undergoing a constant training for his job, if only for the reason that he is always having to learn how to use new methods and new tools. It is absolutely essential that the Minister and his Department should realize that the work of registrars is indispensable to the hospitals of this country and should be related primarily to the needs of the hospital—that is to say, to the needs of the patients in the hospital—and only secondarily to prospective vacancies in the consultant world. It may well be that in some hospitals there are too many registrars, just as in other hospitals there are too few; but the possibility of making arrangements for transfer was envisaged in the Ministry's memorandum on consultant services. No one would pretend that everyone who gets a job as a registrar should be a consultant. This again is one of the unfortunate results of talking about the registrars as being trainees. Before July, 1948, a man was appointed to be a registrar because there was a job of work to be done. At the same time the appointment gave him a chance, and his seniors a chance, to see whether or not he would be likely to make a career as a consultant. But whatever his future, the registrar was under no illusion about his present—and that was that he was an indispensable and hard-working member of the hospital team. Among those factors that decided his future when he came to the end of his time as registrar was the possibility of finding an opening in consulting practice, and this almost invariably depended on obtaining an appointment to a hospital staff. Whether or not there were vacancies available, not all registrars, obviously, had those qualifications which fitted them for a consultant's career, and no one would pretend that all the existing 2,800 senior registrars and registrars should automatically become consultants. It is unfortunate that the idea of their being trainees should have led them to expect this. Nevertheless, we cannot but believe that a good many of the 1,100 who are to be dismissed have the capacity and ability to take up consultant work.

We understand that regional hospital boards and boards of governors would like to create something in the region of 1,000 new consultant posts in the hospital service of the country. Why, therefore, has the Ministry of Health been in such a hurry to get rid of so many potential consultants at a time when they must have been fully aware of the expected demands to be made on them for carrying out the declared Government policy of expanding the consultant service to meet the needs of the community? Mr. Bevan said about the circular on registrar establishments: "It was not prompted by economy—indeed, it provides for alternative appointments if necessary for the work of the hospital." If the pending action is not economic in origin, what is the explanation? It is known that hospitals generally need registrars; the registrars want to do the work; hospitals all over the country are, in fulfilment of the Minister's policy, anxious to make new appointments, in addition of course to filling vacancies created by retirement or death. It may be politically embarrassing for the Minister to admit that the economy of the Health Service as a whole is so overstrained as to call for a standstill in the development of the hospital services. In 1949 Sir Stafford Cripps said in his budget speech that there were to be no supplementary estimates except in special cases. This year he said emphatically that present expenditure on the Health Service must not be exceeded. It is quite plain that the finances of the Health Service have got completely out of hand and that the present decision about registrars is dictated primarily by the need for economy.

The Minister of Health must by now realize that the medical profession as a whole, in the working of its three main services, is in a state of acute dissatisfaction and frustration. It is, we are convinced, anxious to co-operate with the Minister and his Department provided it is able to work with a full sense of co-partnership in an enterprise that should call forth the best out of everyone. It can do this only if, to use a well-worn phrase, the cards are laid face upwards on the table, only if there is frank disclosure of all the facts in a total situation instead of a partial, piecemeal disclosure in an order that seems to be completely illogical. In so far as the present problem is concerned, and its relation to the wider problem of the consultant services of the country, it may well be worth looking into the feasibility of establishing permanent joint consultative machinery for making possible a continuous review of consultant and hospital services by both the Ministry of Health as representing the management, and medical men as representing those who work in the service. This would be something quite other than those standing advisory committees appointed by the Minister. Medical representatives in some such joint consultative mechanism should be appointed by the profession itself. With machinery of this nature, such problems as are worrying the profession now would not arise, and a smoother evolution of the consultant services on constructive lines might well be made possible. If things go on as they are the Health Service will sooner or later become a warning rather than an example to the rest of the world.

TUBERCULOSIS AND THE N.H.S.

Such captions as "Whither Tuberculosis?" "Tuberculosis at the Crossroads," and "Crisis in Tuberculosis," all of which have appeared recently in this *Journal*, themselves express the prevailing dissatisfaction with the development of the tuberculosis services in Britain since July, 1948. Recruitment of doctors to clinic and sanatorium work is already falling short of needs. Behind all the discontent and argument stand the facts that the mortality from tuberculosis is decreasing rapidly, that the number of new cases is increasing, that the average age at the time of first infection with tubercle bacilli is rising, and that the expectancy of life of tuberculous persons is lengthening.

Special reports on what is the most important infectious disease in this country have been published by such bodies as the Joint Tuberculosis Council,[1] the Tuberculosis Group of the Society of Medical Officers of Health,[2] a special joint subcommittee in Scotland,[3] and lastly the Tuberculosis and Diseases of the Chest Group Committee of the British Medical Association. A summary of this last committee's report appears in this issue at page 1382. It describes the present situation as a "national scandal," and later asserts that the Ministry of Health clearly intends "that existing tuberculosis organizations are to be expanded into a branch of medicine dealing with all diseases of the chest." In outlining the organization of the tuberculosis service the Group Committee emphasizes once again the need for well-equipped and well-staffed clinics for diseases of the lung. Those responsible for the administration of the National Health Service must realize that these demands are based

on the carefully considered conclusions of experienced chest physicians who are making a conscientious plea for a service vital to the nation. In discussions on hospital accommodation there is often a tendency to forget that not all tuberculous patients require costly modern treatment, and some readers of this report will be surprised at the statement that "a sanatorium of less than 200 beds is not an economic unit." There is no harm in aiming high, but there is a present shortage of money, materials, and persons. The peak of the incidence of respiratory tuberculosis is moving to the higher age groups, and elderly patients do not necessarily require the same treatment as young adults. In the admirable section on prevention, care, and aftercare—and indeed throughout the whole report—the Group Committee insists that prevention, social welfare, and aftercare of tuberculous families are inseparable from the clinical work of the physician. Reference is also made to the rehabilitation of tuberculous students, and it will probably not be long before practical steps are taken to meet the great need for accommodation where "convalescent" students can continue their studies. In general the Group Committee's report, unlike that of the Scottish subcommittee, does not contain precise suggestions for getting over temporary difficulties until the full proposals can be carried into effect, but it does give a clear picture of the unsatisfactory condition of the existing tuberculosis services.

It would not be fair to attribute to the Ministry of Health all the blame for the deterioration of these services. Before July, 1948, the main criticisms were that they were very uneven in quality, and that the tuberculosis officer was the minion of the medical officer of health, had little or no opportunity for treating patients, and was not recognized as a clinical specialist. Complaints were made that the salaries of tuberculosis officers were too low, that progress was being prevented by the parsimonious attitude of many local authorities, and that the prognosis in individual cases sometimes depended largely on the geographical situation of his home. Many of these justifiable grievances have been met by the National Health Service Act. To-day the slogan is, "Give us beds, and the tuberculosis problem will be solved." But it is to be hoped that this appeal will not be answered by providing only expensively equipped specialized units for thoracic surgery without the smaller, less expensive, convalescent or segregation homes that were of such value in the past. Some of these useful institutions have been recently closed as not being suitable for the treatment of tuberculosis—an action that shows how little some administrators understand the tuberculosis problem. Over 4,000 tuberculosis beds are still empty because of the shortage of nurses, and until they can be filled again very careful thought must be given to the best use of accommodation and also to the possibility of home treatment. The homes of tuberculous patients are often unsatisfactory, and additional proof, if any were needed, of the association between bad housing and tuberculosis has recently been provided by Stein,[4] of Edinburgh. Nevertheless, as Professor F. R. G. Heaf points out in a paper of particular interest to all tuberculosis workers (see page 1353), some patients can be successfully treated by modern methods in their own homes, though not at a small cost. Suitable precautions can reduce to a minimum the risks of home treatment. Heaf suggests that the three essentials for successful home treatment are: full co-operation of the patient and his family; freedom from financial anxiety; and the possibility for the patient to obtain the necessary rest in bed. To this must be added the important proviso that the home as a house is suitable—not an easy condition to secure with the present shortage of houses.

The successful campaign against tuberculosis, as Lloyd[5] emphasized in 1948, cannot be modelled on the "all too common procedure of hospital and out-patient departments." It is no ordinary disease that can be tackled in the general provision for diseases of the chest but a systemic infection that has wide repercussions on the life and work of the nation. Well-equipped clinics, where the whole family can be supervised, are needed to strengthen the measures taken to prevent the spread of infection in homes, factories, or schools. The necessity for a close link with the public health service must never be forgotten. In an article published at page 1380 Dr. G. F. B. Page very rightly reminds us of Sir Robert Philip's conception of a co-ordinated tuberculosis scheme, with the dispensary (Dr. Page prefers that term to "clinic") as the directional centre. The weak spot in the present administrative arrangements is lack of co-ordination. This shows itself in many ways, even in uncertainty about the contracts and salaries of physicians for chest diseases. Page is inclined to think that since the local authorities have had their chance and have not been very successful the whole control of the tuberculosis service should be turned over to the regional hospital boards. Heaf, on the other hand, believes that the problem of tuberculosis cannot be satisfactorily tackled under the National Health Service as it exists at present, and he suggests the creation of a separate tuberculosis administration. In the North of Ireland a tuberculosis authority has been established, but it remains to be seen how effective its work will be. Since the National Health Service Act was passed much has been said and written about the defects in the arrangements for the control of tuberculosis. It is nearly six months since we wrote in these columns, "What is needed now—desperately needed—is not reports but action." The longer the present drift continues the more difficult will become the control of this disease.

CORTISONE AND A.C.T.H. IN BRITAIN

We understand from a newspaper report[1] that the Ministry of Health is to distribute small quantities of "cortisone" and A.C.T.H. to hospitals in various parts of the country. This will be welcomed both by doctors, who are anxious to learn more about these substances, and by the patients with rheumatoid arthritis and other diseases relieved by treatment with them. The necessity for co-ordination in this clinical research is obvious, since the supply of the drugs will be small, though presumably constant, and there may well be an inclination on the part of the selected hospitals to give short courses in order to observe the responses in a wide variety of conditions. The rheumatic diseases are likely to take first place in the use of cortisone and A.C.T.H. Recently the original team[2] from the Mayo Clinic have reported on a second series of cases of rheumatoid arthritis, studied for a much longer period than the first. This report and publications from other American centres and from Copeman and his colleagues[3] in this country all confirm the success of the earlier findings. Many medical men and women in the British Isles have recently had the welcome opportunity of listening to Dr. Philip Hench lecture on these remarkable drugs.[4] Workers at the Mayo Clinic have also contributed to a symposium[5] on cortisone and A.C.T.H. therapy. There is hope that in acute rheumatic fever patients will be protected by these drugs during the course of the disease so that damage to the heart is avoided, but it will be years before this can be proved. Disseminated lupus responds symptomatically,[6] and, though there is evidence that the disease is not arrested, long remissions have been reported after cessation of treatment. Periarteritis nodosa has responded well by reversal of pathological changes in some cases. Bronchial asthma and hay-fever have been relieved more successfully than by desensitizing injections or by the use of antihistamine drugs. In Addison's disease a relatively small dose of cortisone combined with D.C.A. has caused return of strength and the ability to withstand stress. There is some slight evidence that these hormones may prevent the serious protein loss which is such a problem in the treatment of severe burns, and we have recently published two interesting papers on this subject by Canadian workers.[7] Promising results have been obtained in certain diseases of the eye. According to the Mayo Clinic report the intra-ocular operation for the relief of glaucoma of each eye during the course of uveitis was successfully performed under a cortisone "umbrella." Previously the ophthalmic surgeons had not dared to operate on such cases, except in an acute emergency. Surgeons at the Ford Hospital at Detroit[8] have also reported good results in inflammatory eye diseases.

One of the main difficulties with cortisone and A.C.T.H. is maintenance therapy, and effective ways of economizing in these expensive and powerful drugs must be found. Evidently in some cases the gap between the smallest effective dose and overdose is a narrow one, and may indeed vary during the course of treatment. Much more research of the kind recently described in this *Journal* by Goslings and his colleagues[9] will be needed before the most suitable and economic method of administration is settled. It is not yet known whether it is better to prescribe a long period of treatment on the smallest dose which will keep the patient free from pain, or whether shorter courses with intervals between them are preferable. In order to form an opinion on these problems it is obviously necessary to keep suitable cases under treatment and observation for a long period. Though it will be difficult for hospitals to resist the temptation of trying to help a large number of their patients with these drugs, in the long run more will be learned by treating patients whose improvement can be permanently maintained, and this will also be the most humane method of using the drugs. The physician will gain little from observing a short remission which cannot be repeated for lack of supplies, and the effect on the patient is bound to be distressing. Already excellent studies on cortisone or A.C.T.H. have been reported from London,[3] Edinburgh,[10] and Manchester,[11] where with small supplies and grants from the Medical Research Council methods of assessment have been worked out. It is hoped that the experience of the clinicians who have done this work will be enlisted in the wider allocation now contemplated by the Ministry. The selected centres will have a chance to contribute essential information about the best use of these drugs. Failure to obtain this information will result not only in waste of dollars but in waste of opportunity.

MORTALITY FROM APPENDICITIS

When the Medical Research Council published a report on appendicitis by Young and Russell[1] in 1939 it was disturbing to find that the mortality had been increasing at ages under 5 and over 45, but since the case fatality rate recorded by many hospitals in different countries had shown a consistent decline during the same period it was considered reasonable to attribute the increase to a greater incidence of appendicitis. Moloney, Russell, and Wilson[2] have now brought our knowledge of the prevalence of appendicitis up to date with a review of the social factors suspected of playing a part in its aetiology, and of the

recent surgical experience at the Radcliffe Infirmary. According to their estimate 1 in 700 of the population may be expected to get acute appendicitis each year. They are unable to determine whether this represents a continued increase in prevalence or not, but it will at least serve as a basis for comparison in the future. Mortality, it is satisfactory to note, has been decreasing at all ages since 1930, but even in 1945–6 the death rate in patients under 5 and over 65 had not fallen below the level of 1920. Mortality fell during the second world war as in the first, but, unlike the earlier occasion, continued to fall afterwards. In the U.S.A. the deaths from appendicitis in 1948 were a quarter of the 1930 total.[3] The fall during the first world war and the subsequent rise which occurred in the mortality from diabetes, diseases of the gall-bladder, and appendicitis was attributed in this country to the changes in dietary habits induced by wartime conditions. If true, this provided important support for Rendle Short's view that the replacement of cellulose- and fibre-containing foods by meat and processed imported foods was a cause of appendicitis—a view which was also supported by the disproportionately high incidence of appendicitis in the wealthier classes. During the second world war mortality from all three diseases declined, but the decline continued afterwards and was still marked in 1948. The mortality from appendicitis in particular was in that year little more than a third of what it had been 10 years earlier. It must be supposed that even if dietary factors have contributed to a reduction in the disease improvements in therapy have been more important.

In analysing surgical experience Moloney, Russell, and Wilson have taken care to include in their series of cases admitted to the Radcliffe Infirmary in 1945–8 only those in which the diagnosis of acute appendicitis could be firmly substantiated. They were forced, therefore, to discard 499 of the 1,573 cases which had been labelled appendicitis in the hospital records. Many of these must have had a true appendicitis in the past and have come to operation in a quiescent period, but it must be considered whether the safety of appendicectomy has not to some extent hindered clinical judgment, with a consequent wastage of beds, money, and surgical time, quite apart from the inconvenience to the patient. It is to be hoped that these doubtful cases will be followed up and analysed in a further paper. The 1,074 cases which were accepted as being true examples of acute appendicitis have been classified according to Grey Turner's[4] method and the results compared with those reported by Grey Turner for the period up to 1934. In neither series were there any deaths in the group of patients with acute appendicitis without peritonitis, but in the group with diffuse peritonitis the mortality was reduced from 29% to 6%. This is reasonably attributed to the use of sulphonamides and penicillin, though the authors comment that both drugs were probably employed too seldom and in too small a dosage. With the free use of streptomycin or the newer antibiotics it may be supposed that the mortality will be reduced even further. The importance of early admission to hospital is well borne out by this series. Most of the patients (86%) were in hospital within 72 hours of the onset of symptoms. In 12 of the 15 fatal cases the delay in admission was more than 72 hours. General peritonitis was, however, already present in 5% of those cases which were admitted within 24 hours, so that a delay of even a few hours must still be considered dangerous. Sir Cecil Wakeley and Mr. P. Childs, whose report on a series of 217 cases of appendicitis appears in the opening pages of this issue, conclude that early diagnosis and early operation remain the most important factors in reducing mortality. They believe that few people need now die of peritonitis, and they do not see much, if any, need for the expectant treatment of localized peritonitis. Like the Oxford workers, Wakeley and Childs very seldom find it necessary to leave a drainage tube inside the peritoneal cavity, though there are surgeons who still believe in drainage.[3] A point of technical interest is that Moloney and his colleagues found that the use of nylon sutures reduced the incidence of wound sepsis.

STREPTOMYCIN IN GENITO-URINARY TUBERCULOSIS

Patients will have to be observed for many years before a final assessment can be made of the value of new drugs in the treatment of tuberculosis. The Veterans Administration in the U.S.A. is carrying out a long-term investigation into the effects of streptomycin in genito-urinary tuberculosis, and Lattimer, Amberson, and Braham[1] have recently reported the results of treatment of 253 cases followed up for two years. Repeated urine cultures for tubercle bacilli were done in every case, as well as cystoscopies, intravenous and retrograde pyelographies, and renal function tests. Three dose schedules were used. Of 64 patients who received 2 g. of streptomycin daily (in four-hourly doses of 0.3 g.) for 120 days, 83% ceased to pass tubercle bacilli in the urine immediately, while 68% remained free for six months. The corresponding figures for 42 patients who received 1 g. daily (in two doses of 0.5 g.) for 120 days were 60–75% and 46%. The third schedule—1 g. daily for 42 days—was found to be ineffective. As would be expected, the results varied according to the initial severity of the infection. The best results were obtained when there was no pyelographic abnormality, though the urine was T.B.-positive: eight out of ten cases remained negative for two years after beginning treatment, and the remaining two were "probably negative." When demonstrable lesions were present in the kidney the urine became T.B.-negative in only 25% of cases, though in others the progress of the disease was slowed. For large unilateral kidney lesions, and when there is complicating infection of the prostate and epididymis, the authors advocate surgery combined with a short course of streptomycin. Superficial ulceration of the bladder and ureter responded well to streptomycin, but no improvement was obtained in deep-seated lesions. Rinker[2] has reported that old tuberculous lesions of the ureter are apt to contract during treatment, with the formation of a stricture. Negative bacteriological reports may be misleading if this occlusion is not recognized. These results indicate the importance of early diagnosis. If the diagnosis is not made until caseating or ulcerating lesions develop, results with streptomycin will be disappointing, and the bacilli are likely to become resistant to the antibiotic. Better results will probably be obtained by combining *para*-aminosalicylic acid with streptomycin.

PERSONALITY CHANGES AFTER HEAD INJURY

Personality changes associated with head injury were widely studied in this country during the war, with some valuable results. Thus the incidence of personality change in relation to the length of post-traumatic amnesia (and hence to presumptive severity of injury) was defined statistically by Symonds and Ritchie Russell.[1] Kremer[2] drew attention to the important part played by milder grades of personality change in the aetiology of post-traumatic neurosis. Paterson,[3 4] whose studies in this field remain models of their kind, laid stress on the fact that exaggerations of previous temperamental traits are common after head injury, and in severe cases may give rise to a virtual caricature of the original personality. Much work, too, was done on the study and assessment of post-traumatic intellectual defects. Although psychometric methods found their place in such work, all responsible investigators were agreed that the results of mental tests are to be assessed with caution. Further, the relation of intellectual defects to changes in the sphere of personality remains not a little obscure.

In two recent papers Pflugfelder[5] reports detailed studies of 12 cases of severe contusional head injury, and his findings are fully consistent with British wartime experience. He has analysed in some detail the lasting post-traumatic personality changes found in 10 of the patients. The change in four of them was in the direction of expansiveness and lowered self-control, whereas in five it was in the opposite direction of apathy. These changes could be regarded, with some justice, as exaggerations of previous personality traits, thus supporting Paterson's generalization. Intellectual disturbances were present in all cases and were investigated with special care. Although making much use of psychological test methods, Pflugfelder was careful to employ them in a flexible manner and to adapt them where necessary to the specific pattern of disability shown by the individual patient. This approach should be well noted by the clinical psychologist, who has shown himself hitherto only too prone to substitute statistical sophistication for clinical acumen. The precise pattern of post-traumatic intellectual defect exhibited by Pflugfelder's cases varied from patient to patient. In some cases at least these individual differences could be correlated with differences in size and extent of the principal cortical lesions. Although fairly marked defects were shown by all on mental tests, it is interesting that only in six was practical judgment said to be affected. It is also worthy of note that Pflugfelder's follow-up studies strongly suggest that the severity of permanent post-traumatic intellectual loss can be assessed with some accuracy on neuropsychiatric examination six to twelve months after injury. From a practical no less than a scientific standpoint Pflugfelder's careful study deserves close scrutiny.

LUNG ABSCESS AS A COMPLICATION OF E.C.T.

Psychiatrists who are familiar with the use of electro-convulsive therapy would probably rank the incidence of lung abscess fairly low among the complications of this treatment, certainly much less than 1%. The occurrence, therefore, of 25 cases of lung abscess in eight years at one hospital in the U.S.A. among 2,562 patients given E.C.T. deserves attention, particularly since the authors of the report[1] state that the five deaths due to lung abscess constituted well over half the total deaths associated with E.C.T. during this period. In the hospital population as a whole lung abscesses occurred less commonly than among the patients treated by E.C.T. The complication was diagnosed in each case during or shortly after treatment. Lung abscess may, of course, not be recognized as a complication at all if its onset is insidious and the signs become apparent months after the completion of electro-convulsive therapy. Such factors as the position of the patient, the type of mouth gag, or tube feeding could not be related to the occurrence of lung abscess. Nevertheless the authors point out that seven of the patients who developed this complication were being tube-fed as well as having E.C.T., and in the same eight-year period seven tube-fed patients among those not receiving E.C.T. also developed lung abscess. The age of the patient and the severity of the mental disturbance did appear to be related to the incidence of this complication. In 60% of the cases the patients were over 40 years of age, and at least 23 of the 25 patients were severely disturbed. It is a fact that acutely disturbed patients, who are difficult to examine and treat, often have filthy mouths and infected nasal cavities. According to Brock,[2] 40 to 80% of the patients developing lung abscesses in general hospitals have dental abscesses or infections, and he cites evidence that iodized oil injected into the nose while a person is asleep will be aspirated into the lungs, particularly into the right upper lobe. Thirteen of the 25 abscesses among the patients receiving E.C.T. were in the right upper or middle lobe; five in the left lower lobe; four in the left upper lobe; while the site of three could not be determined from the records.

To prevent this complication sedation or light anaesthesia may be necessary before examining the oral and nasal passages in patients with severe psychoses who are to be treated by E.C.T. It is possible that curare may reduce the risk of lung abscess by modifying the vigour of the first inhalations taken by some patients after the apnoea of the fit. The prophylactic use of penicillin in debilitated patients should be considered or in any patient in whom resistance to infection might be lowered. The authors of the American report, besides emphasizing the importance of dental hygiene, suggest the use of atropine to reduce salivation and of suction if secretion is excessive. They advise daily temperature recording while the patient is under treatment, and *x*-ray examination at the first sign of respiratory symptoms after E.C.T. has stopped. Some will see in the possibility of this complication an additional reason for reserving out-patient electro-convulsive therapy for younger, physically fit patients.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

THE MANAGEMENT OF THYROTOXICOSIS

BY

RAYMOND GREENE, M.A., D.M., M.R.C.P.

Physician, Royal Northern, Metropolitan, and Harrow Hospitals; Consulting Physician, New End Hospital and the New End Thyroid Clinic

The diagnosis of thyrotoxicosis and the division of the disorder into its component syndromes lie outside the scope of this paper. Nevertheless, a few introductory words on these subjects are necessary if misunderstanding of what follows is to be avoided.

Pathological Types

It has been customary in the past to lay some stress on the consistence of the thyroid gland, and especially on the presence or absence of nodules. There is little doubt that nodularity is of great pathological significance and academic interest, but until it has been subjected to far more study it is wise to avoid exaggeration of its clinical significance. It should be remembered that almost all diffusely enlarged glands become nodular with the passage of the years. Moreover, it is a common experience that glands considered to be diffusely enlarged before and even during operation are found under the microscope to be in fact nodular. It is therefore justifiable to attach significance to the presence of nodules, but not to their absence.

It is also unwise to be influenced too greatly by the size of the gland, unless severe pressure symptoms occur. Severe thyrotoxicosis may exist in patients whose thyroid glands are impalpable either because of their position or the shape of the neck or because they are in fact not enlarged.

Symptomatology

The sufferer from classical Graves's disease is easy to recognize. He complains of sweating, anxiety, irritability, palpitations of the heart, breathlessness on exertion, excessive activity followed by undue fatigue, loss of weight, and intolerance of warmth, and shows the signs of thyroid enlargement, exophthalmos, upper-lid retraction, vasodilatation, tremor, and tachycardia. Many patients present few of these symptoms and signs, and all too often are stigmatized as malingerers or hysterics, experiencing years of avoidable invalidism. Most often unrecognized are those in whom the brunt of the disease falls upon the heart, in whom no evidence of thyrotoxicosis may be found except tachycardia, fibrillation, and even congestive heart failure, and in whose thyroid glands may be found a nodule too small or too deeply placed to have been obvious even to the patient. There is no more satisfying experience in medicine than the discovery, treatment, and actual cure of patients such as these.

It is important to remember that even when the disorder is fully developed all the symptoms and signs may not be due to thyrotoxicosis. In foretelling the results of treatment, knowledge of the patient's physique and personality before the onset of the disease is of great importance. In many instances thyrotoxicosis attacks the constitutionally inadequate. Indeed, many of us believe that it is sometimes the result of the impact of shocks and strains upon patients ill formed by nature to bear them. In such circumstances we cannot expect to make a silk purse out of a sow's ear. In a few patients the anxiety state or other original inadequacy may remain, expressing itself perhaps by an autonomic or psychological imbalance which both patient and doctor had assumed to be part of the thyrotoxic state. Nevertheless, even these patients are better able after treatment to cope with the difficulties of their lives.

Factors Bearing on Management

Before any definite conclusions can be reached about the ideal management of a case of thyrotoxicosis the disease must be considered historically. The heredity of the patient (for thyrotoxicosis is often familial), his environment before the disease developed (for this may be alterable), the immediate predisposing causes (which may never be repeated), and the nature of the disease itself must be examined.

From the practical point of view a family history of thyroid disease is important because it suggests that the thyroid once having "gone wrong" is likely to go wrong again, should similar circumstances arise. It is one point in favour of the partial removal of the offending organ. The previous environment is important, because careful inquiry may elicit the reasons for the thyroid gland's persistent overactivity—the earlier straws which weakened the camel's back. Such straws may be avoidable, or they may be unavoidable and therefore a continuing risk. The immediate predisposing causes—the last straws which broke the camel's back—are often obvious. Among these are puberty, childbirth, the menopause, severe infection, psychological shock, and the unwise administration of thyroid in the treatment of obesity. Often these are causes against which the patient can be protected, but unfortunately they are frequently interchangeable, and in avoiding one the patient may encounter another. Any last straw will do. Indeed, however successful may be our treatment for the time being, the thyrotoxic patient remains at risk while he retains his thyroid gland, for ever watching the wind to see which way the last straws are blowing. There is much to be said for the dictum of Mr. Charles Donald. At a meeting at the Royal Society of Medicine he criticized the medical treatment of thyrotoxicosis with its claim for remissions lasting several years, and stated his belief that all patients so treated would eventually relapse. Certainly at the New End Thyroid Clinic we have seen scores of middle-aged patients with a typical exacerbation or—a still more serious event—with auricular fibrillation, and sometimes with cardiac failure, who had had thyrotoxicosis in their youth.

Medical Treatment

Despite this proviso, we are still justified in considering the desirability of medical treatment in the individual case, and our justification is likely to remain until we have had an opportunity of examining the after-history of "successfully treated" patients for half a century. Even before the introduction six years ago of the thiouracil derivatives, there were patients who recovered without operation, and some of these have not so far relapsed. My own experience in those days was slight, but it was large enough to leave an impression on my mind clear enough for comparison

with those of older physicians, many of whom formed, with better reason, a similar opinion. In the days when surgery was very risky, physicians often attempted to treat their less severely ill patients by means which are still an essential part of the medical treatment of thyrotoxicosis; means, I would add, which are often unjustifiably neglected by those who are content with the straight choice between thiouracil and thyroidectomy. They attempted to secure for their patients the maximum of physical and mental rest by confinement to bed, sedation, advice on the replanning of their lives, and simple psychotherapy.

My earlier memories suggest that those who responded by a prolonged remission were usually young women with mild thyrotoxicosis and small, diffusely enlarged, or impalpable thyroid glands, with no family history of thyroid disorder, and with an apparently obvious "last straw" from the weight of which they could be easily relieved. My experience in the last six years suggests that this type of patient may have a prolonged remission after treatment with thiouracil derivatives, but whether this remission will prove permanent only time will show. Even when patients are carefully selected and treatment is continued, as it should be, for at least a year, relapse within a year, and usually within six months, is common. Those who relapse can be treated again by the same means, with equally satisfactory results, but, again, relapse is common. In a disorder characterized by undue anxiety it seems unjustifiable thus to play cat-and-mouse with the patient, and it is better to recommend thyroidectomy when the first relapse occurs.

When treatment with thiouracil is chosen, all those general measures which were a part of the older medical treatment should be instituted, though rest in bed is no longer necessary, except in the severest cases. In this country the methyl derivative of thiouracil is generally used, in the United States of America the propyl derivative. The latter is said to be less toxic, but, as serious toxic symptoms are rare with either, more prolonged controlled observations will be needed before a final conclusion can be reached. Methyl thiouracil, 200 mg., is given morning and evening until all signs of thyrotoxicosis have been controlled. During this initial period of a few weeks no reduction can be expected in either the size of the thyroid or the degree of exophthalmos, both of which may indeed be slightly increased. The dose is then gradually reduced to 50 mg. daily, at which level it is kept for at least a year.

Complications of Thiouracil Treatment

It was formerly the custom to perform frequent white cell counts during treatment with thiouracil, as once it was during the administration of the sulphonamide group of drugs. This is now considered neither necessary nor helpful. The dreaded complication of agranulocytosis is very rare, occurring with the modern derivatives of thiouracil and with the small doses now employed in less than 2% of cases. Moreover, agranulocytosis does not usually develop gradually, but strikes suddenly. In one example it occurred only two days after a white cell count of 10,000 had been recorded. Instead of frequent examinations of the blood, a warning is issued to the patient that in the event of his throat becoming sore he should take no more of the drug and report immediately to hospital. Should the white cells then be found to be greatly reduced he is immediately admitted, and massive doses of penicillin and blood transfusions are given.

Other complications of treatment are less serious and rarely enforce discontinuance of the treatment. They include a variety of rashes, such as purpura and urticaria, swelling of the joints, nausea, drug fever, and enlargement of the lymphatic glands. The rashes usually respond to the antihistamine drugs such as promethazine hydrochloride ("phenergan"). The frequency of these complications in two series of 200 patients are as follows:

	Edinburgh*	New End
Agranulocytosis	4	2
Leucopenia	2	2
Purpura	1	0
Urticaria	Not stated	7
Fever and vomiting	5	0
Conjunctivitis	5	2

*Reported by Professor Derek Dunlop.

A different class of complication occurs which should be regarded as evidence of overdosage. It includes obvious increase in the size of the gland or in the degree of exophthalmos, and the appearance of oedema and myxoedema. If these occur treatment should be stopped until the undesirable effects have passed off, when it should be continued in smaller doses.

Contraindications to treatment with methyl thiouracil are the presence of large goitres, causing pressure symptoms, and of retrosternal goitres. In the opinion of the team working at the New End Thyroid Clinic, obvious nodularity is also a contraindication. In our experience, though the signs and symptoms of hyperthyroidism are in such cases easily controlled, relapse invariably occurs. The intelligence of the patient and his willingness to co-operate must be considered seriously, and the slightest deviation from the rules laid down for his safety is an indication for thyroidectomy. But perhaps the most serious contraindication to medical treatment is the fact that it imposes on a patient, already as a rule unduly anxious, a period of prolonged reliance on his doctor, which cannot fail to exaggerate any hypochondriacal traits which may be already present.

Surgical Treatment

The indications for surgical treatment are implicit in what has already been written. After a preliminary enthusiasm for medical treatment on my part, the members of the team at the New End Thyroid Clinic, which has the advantage of treating over 300 patients suffering from thyrotoxicosis per annum, are of the opinion that in most cases thyroidectomy after proper preparation is the ideal method of treatment. In skilled hands (a point referred to below) the risks by either method are too small for comparison. The results of surgery are more certainly and more rapidly achieved. The economic position of the patient is better protected by a method which in most cases rids him within two months of the necessity for further treatment. The cosmetic results, except for the inevitable risk of keloid scars (a risk we shall shortly be able to eliminate), are unexceptionable. Within a month or two the scar in most cases is invisible, or almost invisible, at a normal conversational distance.

The statement that the risks by either method are equal and negligible requires qualification. It implies in the first place a close and friendly collaboration between physician and surgeon, and in the second place a surgical technique of the first order. Even to-day the risk of surgery to the life of the patient and to the integrity of his recurrent laryngeal nerves and of his parathyroid glands is by no means negligible in the hands of one who has been called by Linnell "the occasional thyroid surgeon," however competent he may be to perform the other operations of surgery. In certain areas the general practitioner, dealing with a patient suffering from gastric ulceration, for whom he feels that a partial gastrectomy is the operation of

choice, may decide for similar reasons that his patient had best be dealt with by a gastro-jejunostomy or even by purely medical treatment. I have been forced to make such a choice in circumstances in which the gastric operation would perforce be performed by myself. It is impossible to discuss a question like this except on the assumption that both medical and surgical treatment will be of the highest order.

When, with this assumption granted, it has been decided that the treatment of choice is thyroidectomy, the preparation for operation, important though it may be, is straightforward. Admission to hospital is no longer necessary until a day or two before operation. Patients suffering from mild symptoms and signs of thyrotoxicosis can safely be prepared by means of iodine alone. Lugol's solution in the unnecessarily large dose of 5 minims (0.3 ml.) three times a day is usually given for a period of two to three weeks. The patient is then admitted to hospital and the operation performed almost immediately.

When, however, the degree of toxicity is moderate or severe, it should first be controlled by means of methyl thiouracil. The thiouracil derivatives have the disadvantage of rendering the operation of thyroidectomy more difficult in the occasional case. This disadvantage—a small one in comparison with the enhancement of safety which accompanies it—can usually be overcome by the administration of iodine for two to three weeks before operation. Some physicians prefer to combine the iodine in the pre-operative period with methyl thiouracil; some (as at New End) forgo the thiouracil for the final period and use iodine alone; others overlap the two drugs for various periods, giving at first methyl thiouracil alone, then a combination of methyl thiouracil with iodine, and, finally, iodine alone. Others administer thyroid as well. So far it seems that no advantage is attached to any one of these methods. All are excellent in their results, and it will be many years before any valid comparison can be made between them. Whichever method is adopted, the patient is usually out of bed in four or five days and out of hospital in from nine to twelve days.

There seem to be few contraindications to operation. Certainly auricular fibrillation is not one of them. In from 60 to 80% of cases the fibrillation ceases, almost always in paroxysmal fibrillation, as a result of thyroidectomy alone or of thyroidectomy followed by a short course of quinidine. Even congestive heart failure is no contraindication, though it may call for a longer pre-operative period, perhaps in hospital. The operative death rate in skilled hands is under 1%, the incidence of other complications is negligible, recurrence is of the greatest rarity, and a return to normal life and work almost invariable.

The use of radioactive iodine may well be the method of the future, but no useful purpose would be served in discussing it here. Even in centres in which it is available it is still in the experimental stage. It is not generally available in Great Britain. When it is, it will be beyond the scope of the general practitioner because of the special knowledge and equipment which it requires.

In no other disorder is the judgment of the general practitioner, with his knowledge of the background, character, and economic situation of his patient, of greater value than in thyrotoxicosis. It should be largely his responsibility to decide upon the best method of treatment. On the assumption that an expert thyroid surgeon is at his disposal, he will probably decide on thyroidectomy, after adequate medical preparation, as the best treatment for most of his patients.

A DIFFERENT VIEW OF THE TUBERCULOSIS PROBLEM

BY

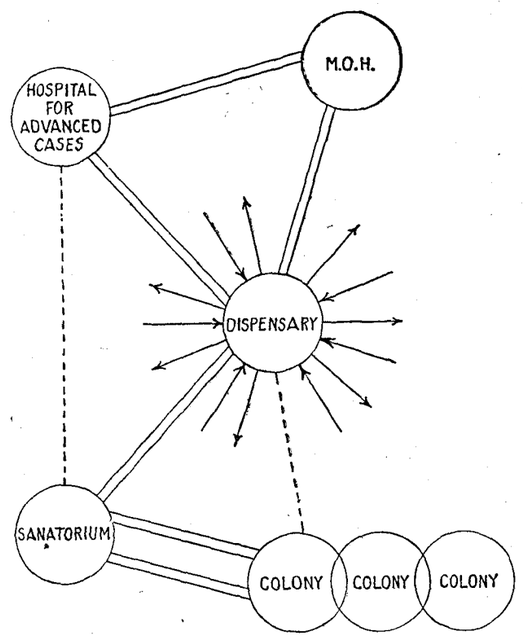
G. F. B. PAGE, M.D., D.P.H.
Late Medical Officer of Health for Exeter

Nearly all those who have written in the lay or medical papers about the tuberculosis problem, as it exists to-day, have emphasized the need for more institutional beds and for more nurses to staff them. While everyone will agree that there is a shortage of beds and staff, and that there are long lists of sick and often infectious persons waiting for admission, it must not be forgotten that the provision of hospital and sanatorium accommodation is but one aspect of the matter in considering any truly comprehensive scheme for the prevention and treatment of tuberculosis.

A few contributors have mentioned what may be called the other end, or perhaps the beginning, of the problem. They have written of the housing situation and particularly of overcrowding. While agreeing with them, most of us on reflection would like to extend the idea to improving the whole environment of the people, whether in the home, school, office, shop, or factory. Many of the early triumphs of preventive medicine were won on the environment front, and there is still plenty to be done there.

Let it be agreed, then, that at one end of the situation we want more functioning beds and at the other end better environmental conditions, especially housing, not overlooking such matters as milk-borne infection.

Sir Robert Philip's Scheme



What is lacking is uniform and purposive control. That kind of control can be produced and maintained only by restoring the tuberculosis dispensary to its proper position in each clinical area as the directional centre of what the late Sir Robert Philip called many years ago a co-ordinated tuberculosis scheme.

It is to be doubted if many of the younger men and women practising medicine to-day, even those working in the tuberculosis field, have any clear conception of what the tuberculosis dispensary should be and should do. It is certain that many members of local health authorities, hospital management committees, and regional hospital boards have only the vaguest ideas about the whole matter, and yet they are the bodies that are supposed to be directing policy. Up to the appointed day there were areas with excellent schemes, and there are still some; but they were never numerous, and many more local authority units were content with poor or indifferent arrangements. In these latter it will be found that the dispensary has become an isolated and degraded out-patient department, falling very far short of the kind of dispensary conceived in Philip's mind as long ago as 1887.

Below is shown how Philip defined the tuberculosis dispensary, and I am able to reproduce from my tuberculosis scrapbook the diagram which accompanied the description. Both pamphlet and diagram were given out to his classes in the University of Edinburgh after the foundation of the chair of tuberculosis.

Under the heading "Co-ordinated Tuberculosis Scheme —Edinburgh Pattern" the tuberculosis dispensary is described as "an institution for the detection of tuberculosis, and for the treatment and guidance of persons and households suffering therefrom. It is a 'reception house' and 'clearing house,' and a centre of information regarding

the prevention and care of tuberculosis." The functions of the sanatorium, the hospital, the colony, the open-air school, the tuberculosis care committee, etc., are then defined. If the diagram is examined it will be seen that the dispensary is the centre of the scheme—in fact, the sun of the tuberculosis solar system. Particular attention should be paid to the arrows pointing into and out of the dispensary. The former represent information, patients, suspects, and contacts coming into the dispensary, and the latter active search by the dispensary staff, including the physicians, for tuberculosis in the population generally by all possible means, together with domiciliary supervision, aftercare arrangements, and preventive measures.

Scheme of anti-tuberculosis measures: Edinburgh plan.

To-day I think we should be content to mark the circle entitled "Hospital for advanced cases" just "Hospital," and probably we should agree to replace the three interlocking circles marked "Colony" by some expression representing organized arrangements under the Ministry of Labour and the Assistance Board, together with voluntary bodies dealing with reablement, in addition to the actual colonies. With these trifling amendments the diagram presents the main idea to-day as well as it did when first drawn.

The Official Outlook

One of the important functions of a dispensary (now called chest clinic, in spite of the fact that tuberculosis affects other systems besides the respiratory) is the selection of cases for treatment. If this is done properly there should be some fairly substantial saving in institutional patient-days.

A recent Ministry of Health circular (RHB (50) 64) addressed to regional hospital boards makes the following statement.

"*Chest Clinics.*—Attention should be given to ways in which chest clinics can help to relieve pressure on institutional beds. A high standard of clinical judgment is necessary to avoid recommendation of treatment for cases in which it is not essential and for which domiciliary care would suffice."

The circular goes on to emphasize the importance of avoiding the use of special treatment "when consequential complications may only protract the stay in the institution." It would be interesting to know how far institutional beds are occupied by and blocked by unfortunate patients who are the victims of ill-considered special therapy. It must be common knowledge that the readily acquired techniques of collapse therapy in its various forms have not always been accompanied by the judgment and wisdom which physicians (and surgeons) are expected to show.

The paragraph ends with a laudable exhortation to chest physicians not to neglect their duties in the spheres of prevention and aftercare. It runs, "Chest physicians will recognize that it is important to concern themselves *no less* with prevention and aftercare than with their clinical work; and that it is necessary to give *sedulous attention* to case-finding and the supervision of the tuberculous family, *including visitation in the home.*" The italics are mine. A chest physician who runs a dispensary as a second-rate and isolated out-patient department is clearly not doing these things, even if some semblance of the work is carried out by clinic nurses.

Speaking at a meeting of the Tuberculosis Society on January 21, 1918, Sir Robert Philip is reported (*British Medical Journal*, 1918, **1**, 150) as saying: "Many cases of tuberculosis do not require residential treatment. Skilled surveillance at home or at the tuberculosis dispensary was sufficient." He goes on to define the cases likely to benefit from hospital and sanatorium treatment, including the rather special type of case suitable for colony treatment rather than prolonged "unnecessary and uneconomic" residence in a sanatorium.

Although 28 years separate these two quotations from authoritative sources, there runs through them the same emphasis on careful and skilful selection at the dispensary, chest clinic, or whatever we choose to call it. Once again it is from this central point, and this point only, that a properly co-ordinated scheme for the prevention and treatment of tuberculosis can be directed. To the layman and to many members of the medical profession a diagnosis of tuberculosis means automatic admission to the waiting-list for residential treatment. In fact, if this is not done, patients, their relatives, and the family doctor are apt sometimes to become resentful and distrustful. It is not surprising that local authority and hospital management committees think only in terms of institutional beds whenever tuberculosis is mentioned. It is someone's job to teach these bodies to revise their ideas and review the matter as a whole.

Unified Control

Two things follow. The tuberculosis dispensary must be restored to its proper position as the centre controlling a properly planned scheme in each area, and the direction must be under a medical officer of consultant status with real administrative ability. As has been stated already, there are still good and well-run schemes in Britain, but a large number of the men and women in charge of dispensaries lack administrative sense and good clinical judgment founded on mature experience. They need guidance, and, while capable of making a useful contribution, should not be left to drift along as many are doing at present. If this is not done, the exhortation quoted from the Ministry's circular can never bear fruit.

Finally, we arrive at the difficulty of dual control—in fact, King Charles's head again. The tuberculosis physician, as

I prefer to call him, is usually an officer of the regional hospital board. So long as he is working at diagnosis and treatment he is doing the board's work. When he is working at prevention, care, and aftercare he is doing duty for the local health authority under section 28 of the National Health Service Act, 1946. This matter was debated with much eloquence and enthusiasm at the Commonwealth and Empire Congress of the National Association for the Prevention of Tuberculosis in July, 1949. No definite decision was reached, but at the end of the meeting the impression remained that those with real knowledge of and deep sympathy with tuberculosis work strongly deprecated this dichotomy, and, moreover, foresaw that it would lead to disaster.

It will in the end have to be admitted even by the most obstinate administrative Civil Servant that the present arrangement, if such a term is admissible, or, to be frank, the present muddle, cannot be permitted to continue. There may be a difference of opinion concerning what body shall control the dispensary, but there surely must be agreement that we cannot continue to have two people at the ship's wheel, each wanting to go his own way, or possibly not caring which way he goes. No amount of talk about co-operation, co-ordination, and liaison—those sugary placebos of the Civil Service—can solve this problem. Above all, do not let us have any more joint committees. The works of the entire Health Service are cluttered up with committees.

Control must be in the hands of the regional hospital boards *or* the local health authorities, unless someone is rash enough to invent a new body altogether, which heaven forbid !

Many will feel that the local health authorities, as county councils and county borough councils, have had their chance, and on the whole have not done the job very well. Moreover, a dispensary (cannot we drop the misleading expression "chest clinic"?) must be attached to a hospital administratively if not physically. This being the case, let the regional hospital boards take control and come to terms with the local health authorities as best they may. This might need new legislation. It would certainly mean revision by the Ministry of paragraph 37 of Circular 118/47, which laid certain duties upon local health authorities.

Conclusion

Section 1(1) of the National Health Service Act, 1946, defines the duty of the Minister. "It shall be the duty of the Minister of Health to promote the establishment in England and Wales of a comprehensive health service . . . and for that purpose to secure the effective provision of services." The tuberculosis service is neither comprehensive nor effective, nor can it be so long as the present imperfect machinery is employed.

To sum up: (1) The tuberculosis dispensary must be restored to its proper position and function in each clinical area. (2) It must be adequately staffed and under the general direction of an officer of consultant status. (3) There must be unified control, preferably by the appropriate regional hospital board.

In his annual report for 1949 to the Kent County Council, Dr. A. Elliott, county medical officer, states that according to his estimate some 180 health centres would eventually be required in the county, but that the realization of such a programme at a possible capital cost of £18m. lies so far in the future as to make no real contribution to the work of the executive council.

TUBERCULOSIS AND THE NATIONAL HEALTH SERVICE

REPORT OF B.M.A. GROUP COMMITTEE

"The inadequacy of the present provision for the diagnosis, treatment, and aftercare of tuberculosis in this country is a national scandal which can no longer be viewed with complacency." So starts the comprehensive report prepared by the Tuberculosis and Diseases of the Chest Group Committee, which was recently approved unanimously by the Council of the British Medical Association. The Group Committee of 12 members, under the chairmanship of Dr. Peter Edwards, includes several medical superintendents of sanatoria and chest physicians in large centres, a thoracic surgeon, and a county medical officer of health.

The report, in discussing the problem of tuberculosis in relation to the National Health Service, draws attention to the 11,000 tuberculous patients awaiting admission to the 23,000 beds provided for the treatment of this disease. The development of a comprehensive plan is the more difficult because of the absence of any official figures on the optimum number of beds, nurses, and doctors, but the report outlines a policy and makes recommendations on the organization of the service, on the staffing of chest clinics and sanatoria, and on measures for the prevention of tuberculosis and the welfare of tuberculous patients.

The Problem Stated

Little detailed consideration is given to the tuberculosis service in the National Health Service Act, but certain general advice on the subject has been given to regional hospital boards by the Ministry of Health, and it is clearly intended that existing tuberculosis organizations are to be expanded into a branch of medicine dealing with all diseases of the chest. It is considered by the Group Committee, however, that tuberculosis will continue to be the main problem in the field of chest diseases for many years to come. In the past, as a problem of public health, it has been too much segregated from general hospital services. Many tuberculosis dispensaries have no *x*-ray equipment and no access to the basic services of a general hospital, and are inadequately used. The chest clinic, which will displace the tuberculosis dispensary, will be the centre from which the attack on tuberculosis is organized, but it must be linked to the general hospital, and it must also have the opportunity of applying to all forms of chest disease the principles of social medicine.

The prevention of tuberculosis and the social welfare and aftercare of the tuberculous patient and his family are the responsibility of local authorities under Section 28 of the Act, but they are inseparable from the clinical work of the chest physician, who must maintain the closest liaison with the medical officer of health, to whom he should act as consultant.

Organization of Clinics for Diseases of the Chest

Four principles are laid down for the development of future clinics for diseases of the chest:

(1) The provision of a complete service comprising all aspects of chest and tuberculosis work.

(2) Association wherever possible with general hospitals; occasionally such clinics may be sited within sanatoria, particularly in rural areas.

(3) Provision of an efficient follow-up service and maintenance of close liaison with local general practitioners.

(4) Provision for the education of medical students, practitioners, nurses, and social workers at suitable centres.

A large full-time clinic for chest diseases established in a general hospital will require its own permanent and specially trained auxiliary staff. In the smaller hospitals a part-time clinic, if adequately housed and equipped, may serve to upgrade the hospital and allow it to provide other specialist services previously available only at a larger hospital at a distance.

It is considered that each hospital region should be subdivided into smaller areas served by appropriately placed clinics. The optimum population served by a clinic would probably be about 200,000 in an urban area and less than this in a rural area. In compact urban areas with good public transport it would be better to have a single well-equipped clinic than a large number of minor centres. It is acknowledged that in rural areas the development of comprehensive clinics for chest diseases may be difficult, especially if there are no general or cottage hospitals. A system of mobile clinics as suggested in the *British Journal of Tuberculosis* (1949, **43**, 36) may be advisable in some areas.

The X-ray Equipment of a Clinic for Chest Diseases

It is estimated that at a clinic serving a population of 200,000 it may be necessary to take 5,000 radiographs a year. This would call for an *x*-ray department within the clinic to deal with chest work only. A rotating anode tube, with a generator capable of producing 200–400 milliamperes at 90–95 kVp, and with provision for tomography, is regarded as essential if the necessary quality and comparability of chest radiographs are to be maintained.

In each consulting- and treatment-room in the clinic there should be equipment for chest fluoroscopy distinct from the main *x*-ray plant and available for the personal use of the chest physician. Small clinics holding only two or three sessions a week may use the general *x*-ray department of the hospital, but it is emphasized that the same high standard of technique and equipment must obtain. In a general hospital these *x*-ray facilities will be the ultimate responsibility of the hospital's radiologist.

A working arrangement between the hospital radiologist and the chest physician to cover such matters as control of quality, reporting on serial radiographs, filing and record-keeping, and appointments for *x*-ray examination will be necessary. In general it is felt that the volume of chest radiography is such that the radiologist should be willing to leave routine reporting to the chest physician, but frequent and mutual consultation upon abnormal findings and other matters of interest is essential.

The provision of a comprehensive dental service in the hospital for all patients attending the clinic for diseases of the chest is also recommended.

Health Visitors and Almoners

In the struggle against a disease in which home conditions count for so much, for both the patient and the other members of his household, the health visitor is a key person. The Committee recommends the appointment of full-time specially trained tuberculosis visitors in urban areas, and wherever possible in rural areas, and that the medical officer of health should delegate the supervision of the work of these visitors to the physician for chest diseases. In the large whole-time clinics something is to be said for the employment of a proportion of clinic nurses who will be engaged solely in out-patient work. In part-time clinics the tuberculosis visitor should always attend the clinic at the same time as the physician and should act as clinic nurse. A system whereby the tuberculosis visitor would divide her time between domiciliary and clinic work is favoured.

It is realized that the work of the health visitor may overlap to some extent that of the almoner; nevertheless, a fully qualified almoner—or, if this is not possible, a trained social worker—is considered an essential part of every large clinic. The general hospital almoner may find it possible to cover this duty in the case of a part-time clinic. So far as possible the same almoner should work in both the chest clinic and the sanatorium, because the social problems of the patient are the same in both. Domiciliary visiting should normally be done by the tuberculosis visitor, not by the almoner. Domiciliary treatment is increasing, and the help of general practitioners may be required if chemotherapeutic and antibiotic drugs have to be administered. The home nursing service may also be called on to provide assistance.

Clerical staff is another necessity in a clinic for chest diseases, to save both the physician and the nurse from much routine labour. A system of reporting to general practitioners is regarded as essential.

Hospital Accommodation

The minimum number of beds needed for the treatment of pulmonary tuberculosis is estimated at one bed for each thousand of the population. At present only about half this number of beds are available. A sanatorium of less than 200 beds is not an economic unit if, as is desirable, every sanatorium is to have *x*-ray equipment of the same standard as that for clinics for chest diseases, adequate laboratories, and the services of consultants and specialists. Diversional and occupational therapy should be designed at the hospitals to effect a process of rehabilitation continuous with and preceding that provided through the clinic.

While the present acute shortage of beds continues it is agreed that some central control of admissions may be necessary, but reference should always be made to the clinic physicians in the area. It is thought that cases of non-respiratory tuberculosis should be treated in appropriate special hospitals, all of which should be regularly visited by a consultant chest physician. A special problem is presented by patients who require treatment for combined respiratory and non-respiratory tuberculosis. In each region at least one central sanatorium block should be provided for such cases. Cases of active respiratory tuberculosis requiring short-stay investigation or treatment for non-respiratory conditions, such as urogenital tuberculosis, should, however, be admitted to general hospitals under the care of the appropriate specialist.

Staff Structure

The Committee next turns to the question of staff. It points out that at present many chest-disease physicians work exclusively either in clinics or in sanatoria. In some cases the clinic physician also acts as medical superintendent of a small sanatorium; in others the medical superintendent of a large sanatorium acts as consultant for the surrounding district. A satisfactory relation between the clinic physician and the sanatorium physician is not always easy to achieve. Probably there is no single solution, and local conditions will often determine the pattern irrespective of any ideal arrangement.

The following recommendations are made:

(1) In the larger sanatoria the sanatorium physician should accept final responsibility for the course of treatment given to any patient in the sanatorium. The programme of treatment for each patient should clearly be decided by mutual consultation between the sanatorium physician and the clinic physician, who should visit the sanatorium regularly.

(2) Regular consultative sessions between sanatorium physicians, physicians concerned with clinic work, and other interested persons (especially thoracic surgeons) should become routine practice both in clinics and in sanatoria.

(3) Small institutions situated within or close to the areas they serve would usually be staffed jointly or work in collaboration with clinics in their areas.

A few remarks are added about co-ordination with other specialties. The development of clinics for chest diseases within general hospitals should assist collaboration between the chest-disease physician and his other specialist colleagues, so that the facilities of other departments would be available to the clinic. Thoracic surgical units which are concerned with both tuberculous and non-tuberculous cases should be established according to geographical needs. The relationship between the physician and the thoracic surgeon should be particularly close. It is suggested also that in addition to any wards allocated for the treatment of tuberculosis each physician should control a number of beds in the general hospital, where diagnosis and assessment could be undertaken, these beds to be associated, wherever possible, with the thoracic surgery unit.

A chest clinic serving, as recommended, a population of 200,000 would need an establishment of one consultant, two assistant physicians, and an appropriate staff of registrar grade. The lay staff would comprise one almoner, five health visitors and clinic nurses, and five clerks. With regard to the intermediate grade of assistant physician for chest diseases—a grade between senior registrar and consultant—it is considered that there is a place in the service for such officers, provided they are recruited solely from the ranks of registrars. This grade

should comprise only practitioners in senior posts acting as assistants to consultants, but not normally trusted with full responsibility.

In sanatoria it is recommended that there should be, on an average, one medical officer to fifty patients. Establishments with fewer than 100 beds should be run by clinic physicians; those between 100 and 150 should have one consultant, one assistant physician, and one medical officer; those between 150 and 200, two consultants, one assistant physician, and two medical officers, and those between 200 and 300, two consultants, two assistant physicians, one senior registrar, and two medical officers. It is added that the staff, especially in sanatoria, may have to be increased during the summer to allow for holidays, and that when locumtenents have to be employed the possibilities for rehabilitation of doctors who themselves have had tuberculosis should be borne in mind.

Mass Radiography

The Group Committee holds the view that mass radiography can be extended far beyond its present scope. The mass radiography unit should be under the direction of the physician for chest diseases, who would work in collaboration with appropriate officers such as medical officers of health. The work of the unit should be limited to the detection of abnormalities. When an abnormality is discovered, its further investigation, with the consent of the patient's general practitioner, should be carried out at the clinic for chest diseases.

It is considered that no medical officer should remain in mass radiography for less than one year or more than two. Where a junior physician accepts such a post in the service he should have the assurance of returning to general chest-disease work without loss of status. The idea of part-time service for the medical officer of a mass radiography unit, the rest of his time being spent in the clinic, is thought to be impracticable, at least in a unit covering a large area with perhaps some 30,000 or 40,000 examinations a year. The medical officer's time-table would be likely to be so irregular as to prevent him from fitting into a clinic time-table. If he had a background of sanatorium and clinic work it is thought that he would lose nothing from full-time work with the unit, and experience in such a unit should be regarded as a desirable part of the training of a physician for chest diseases.

Training of Physicians for Chest Diseases

It is acknowledged that in the past tuberculosis work, as a subordinate part of the public health service, has failed to attract physicians of the highest calibre. The best standards of work in the new chest service will be attained only if the opportunities for promotion are as good as those in any other specialty. The terms of service for chest physicians must therefore be the same as for other consultants. Specialization should begin at the registrar level after the practitioner has held house appointments in general medicine and general surgery and preferably a special post giving experience in general chest diseases. A minimum period of three years should be spent in sanatoria and chest clinics, during which time the practitioner should gain experience of environmental medicine, including attendance at the health department of a local authority. (No reference is made in the report to postgraduate diplomas.)

The Nursing Problem

The nursing problem is specially acute in tuberculosis. Fear of infection is real but is not the only reason for failure in recruitment. This report mentions general dissatisfaction over salary scales. Living conditions for nurses are not always of the highest order, and the charges for board and lodging present many anomalies. Again, the responsibility for the complete rehabilitation of the nurse who develops tuberculosis has not in the past been accepted by all hospital authorities.

It is considered that for the adequate staffing of sanatoria and hospitals it is highly undesirable to work to an arbitrary ratio of nurses to in-patient beds. In convalescent and ambulatory wards the ratio might be 1 to 6, but in tuberculosis hospitals and sanatoria engaged in active treatment, including the practice of major and minor thoracic surgery, with or without out-patient clinics, a ratio of 1 to 2.5 might be necessary, and in theatre units with recovery wards attached it might be 1 to 1. The nursing of tuberculous patients demands a high ratio of trained staff, and the demand cannot be met by the employment of untrained staff in the category of ward orderlies. Part-time nurses are more useful in clinics than in sanatoria, although at present their services to in-patients must be accepted. It is pointed out, however, that two half-time nurses, non-resident, do not add up to one full-time resident nurse.

A real contribution to the solution of some of the difficulties would be met by the inclusion of tuberculosis in the general nursing curriculum and the regular secondment for three months of all student nurses from general hospitals to hospitals specializing in chest diseases. Voluntary secondment of trained staff for six or twelve months would also be most useful. Specialized training in tuberculosis nursing should particularly attract groups of men and women who seek postgraduate qualifications or desire a satisfying vocation other than general nursing. As for the fear which lurks in the tuberculosis hospital, the obligation of routine methods of hygiene in the wards, the use of tests for susceptibility, and the vaccination of susceptibles reduce the risk of illness to below that of the general public.

The following recommendations are made:

(1) Vigorous and well-planned propaganda to stress the urgency of tuberculosis as a national problem.

(2) Education of the nursing profession in the achievements of thoracic surgery and modern chemotherapy.

(3) Inclusion of tuberculosis nursing in approved hospitals or sanatoria in the training of student nurses.

(4) Nurses in general training who present minimal lesions to be advised to accept temporary secondment to sanatorium nursing.

(5) Extension of rehabilitation of trained and untrained nurses suffering from tuberculosis.

(6) Service allowance payable to nurses in tuberculosis service to be paid in two instalments, after six and twelve months' service.

(7) Living conditions and amenities for resident staff to be of the highest order.

(8) Some form of effective representation of sanatorium nurses on the General Nursing Council.

Prevention

In the second part of the report, which deals with prevention, the existing provisions are set out and some of them underlined. Under Section 28 of the National Health Service Act local authorities are given power to carry out functions in relation to prevention, care, and aftercare, and the Minister in his Circular 118 in 1947 directed that such arrangements should be made in relation to tuberculosis. One of the major tasks is to encourage the discovery of pulmonary tuberculosis in the preclinical stage, so that the number of uncontrolled sources of infection may be gradually reduced. "True prevention, apart from the control of infection, must deal primarily with the creation of positive health by the improvement of standards of life, morale, food, housing, and hygiene of the whole population, with particular emphasis on children and adolescents."

A list of the principal preventive measures available to the local health authority is given:

(1) *Supervision of Notifications.*—Close co-ordination is necessary between all engaged in tuberculosis work to ensure that as much as possible is done to follow up the notifications with the object of tracing the sources of infection.

(2) *Health Education of the Population.*—It should be made clear that it is the unsuspected open case that is the public danger.

(3) *Assisted Housing Schemes.*—Housing authorities should give high priority to the rehousing of tuberculous families. Some form of assistance towards higher rate charges should be given in cases of needy families, either through the Assistance Board or by the provision of preferential rents.

(4) *Liaison with Regional Tuberculosis Service.*—The medical officer of a health authority must be given full and up-to-date information regarding new patients and their movements and changes of classification. "Accurate records form the basis of efficient action."

(5) *Mass Radiography.*—This is the responsibility of regional boards, but medical officers of health should participate actively in the planning of the service.

(6) *Control of Milk Supplies.*—Application of laboratory tests should be on a liberal scale, and publicity concerning milk supplies infected with tubercle bacilli is desirable. The Milk (Special Designations) Act, 1949, will go far towards solving the difficulties of bovine infection.

(7) *B.C.G. Vaccination.*—Its adoption in this country for certain susceptible groups is welcomed.

(8) *Examination of Contacts.*—Contact examination is extremely important and is comparable to mass radiography in that it discovers tuberculosis in persons who do not admit to being ill. The local health authority should assist through health visitors in encouraging contacts to be examined.

Care and Aftercare

The object of care work is to prevent deterioration in the living standards of the patient and his family. Sources from which assistance can be obtained are (1) the National Assistance Board, which has wide powers for assisting tuberculous families; (2) the welfare committee of the local health authority, which may provide a wide range of help in kind; (3) the voluntary care committee, giving help from charitable funds; and (4) private charitable trusts existing in a few areas for the benefit of local residents.

The provision of home helps is in many cases essential, and every effort should be made to further this service.

It is stressed that in all schemes the health visitor and the almoner are the vital link between the home and the source of assistance.

Rehabilitation

The restoration of the patient to employment is, as the report points out, again a matter for co-operation. It depends upon the employers, the chest physician, the officers of the Ministry of Labour, the medical officer of health, and not least the patient himself. The object of rehabilitation is to make the patient as useful a member of the community as his disability permits. Rehabilitation is both mental and physical. The majority of non-infectious patients are able to find work on their own account; the problem is almost confined to tuberculous patients who remain infectious. Special measures on their behalf take the form of village settlements, employment under the Disabled Persons (Employment) Act, and local authority employment schemes assisted by the Ministry of Labour.

Village settlements, numbering about half a dozen, have done valuable pioneer work, which should be continued, but it is thought that there is no case for each local authority setting up its own settlement. Accommodation in night sanatoria and hostels for people in ordinary industry should be provided. Under the Disabled Persons (Employment) Act, employers are required to have a quota of 5% of registered disabled in their employment; persons substantially disabled by tuberculosis should be encouraged to register. A final recommendation is for the extension of "Remploy" factories by the establishment of local workshops. "Remploy" factories are built by the Disabled Persons' Employment Corporation specially for tuberculous persons. There is also the special problem of rehabilitation of students suffering from tuberculosis. The development of some scheme to enable the student to continue with his studies while still under medical supervision would be of great value. Sanatoria for this purpose have been established in France and Switzerland.

This comprehensive and forward-looking report should receive the attention it deserves from the appropriate Ministries, the regional hospital boards, and the local authorities. In its proposals for the organization of the chest service and the staffing of chest clinics and sanatoria it lays down lines along which regional and local schemes may effectively proceed.

Half a century has passed since the first distribution of the Nobel Prizes. During this time a total of 242 scientists, authors, and peace champions from twenty-three different nations have been awarded prizes totalling Kr. 28,000,000 (£1,900,000). In order to commemorate the jubilee the Nobel Foundation in Stockholm has issued two almost identical volumes, one in Swedish and one in English, in which a number of representative writers review Alfred Nobel and his life's work as well as the Nobel laureates and their achievements. (*Nobel—The Man and his Prizes*, pp. 620, edited by the Nobel Foundation and published by Sohlmans Förlag, Stockholm, Kr. 30.)

EXPERIMENTS ON THE NERVOUS SYSTEM

PROFESSOR ADRIAN'S LECTURE

The nineteenth Stephen Paget Memorial Lecture, given under the auspices of the Research Defence Society, was delivered by Professor E. D. Adrian, O.M., on November 22. Sir Henry Dale, O.M., was in the chair.

Professor Adrian took as his subject "Experiments on the Nervous System." In discussing the role of animal experiment in this connexion he said that it was true that the bodies of different living creatures were not all alike, and experiments on animals could never completely show what happened in bodies like our own. The work on sulphonamides and on the antibiotics had been based on long-drawn-out animal experiment, but the final experiment was on man. Between man and animals there were some differences in their reactions to drugs and considerable differences in the nature of the infections from which they suffered. But the testing of new remedies on animals before they were used on man had saved an immense amount of sickness and death. If it had been necessary to make all preliminary experiments on man, it would have taken many years to reach anything like the present control over bacterial disease.

Advances in chemotherapy had depended on a knowledge of the general defensive mechanisms of the body, and these were much the same in man and in animals. With most of the special organs the differences were not so important as to prevent a great deal from being learned about the human organ from a study of the corresponding organ in animals. Operations now made on the human heart could be planned by experiments on dogs before they were carried out on babies with congenital heart disease. The nervous system, however, was in a special category, at least as regards its highest level, the brain.

The hearts of different mammals varied in size and shape, but the variations were not much greater than those between one make of motor-cycle and another. One heart was built for speed and another for reliability, but both were blood pumps and worked with the same cycle of operations and the same kind of valve. The differences between the brain of a man and of a rabbit, however, were of quite another order. They were best realized by considering the kind of life that man lived as compared with the rabbit. The human brain, like the elephant's trunk or the giraffe's neck, was an organ developed to a special degree in one species and responsible for behaviour peculiar to that species. Man's dominant position in the animal world had depended on the evolution of the human brain, which had made human behaviour far more intelligent than that of any other animal. Man could control his environment in a manner which no other kind of animal attempted. That was why so much reliance had to be placed on observations and experiments on man if mental disorders were to be understood and treated. Animal experiments were necessary also, but the knowledge to be gained from them came at a much earlier stage. They showed the general plan of the central nervous system, but they could not be expected to cover all the ground.

Investigation of Mental Disorders

Another difficulty arose from the fact that in most mental diseases it was impossible to find what material change had taken place, what had gone wrong with the organization of nerve cells and fibres on which mental processes depended. The abnormal working of the brain could be apprehended from the patient's abnormal behaviour, but often enough no brain lesion could be detected with any certainty. There were a few conditions in which the pathology was known, such as general paralysis of the insane and the alcoholic psychoses, but with the rest they were faced only with symptoms. Many people had been seriously concerned when they read of treatments in mental hospitals in which the human brain was subjected to violent disturbance or permanent mutilation. These critics could now be wise after the event, but the history of these new methods of treating mental disorders was instructive, for it showed how much medical men were handicapped when they

moved outside the field within which animal experiment could give a direct answer.

Professor Adrian then discussed the place of insulin and electric convulsion therapy and leucotomy in the treatment of mental disorders.

Fortunately there was now another source of information about the human brain, deriving from the great advances which had been made in neurosurgery. The exposure of the brain was a much less formidable undertaking than it was when Victor Horsley began to remove cerebral tumours. It was possible to explore the brain surface by electrical methods, and maps could be constructed, comparing with more complete maps made from the brains of the larger apes. The human brain could be stimulated electrically with the patient fully conscious. The procedure was not painful, and the patient could say what he felt or what came into his mind. Thus the work of Penfield and his colleagues in Montreal had afforded new information about the brain which could not be derived from studies on animals, although it could not have been looked for had not studies on animals prepared the way for it.

The Place of Animal Experiment

So far he had dealt only with disorders at the highest level of the central nervous system. High-level activities were developed in man, and accurate information about them could not be expected from animal brains. Advances must come mostly from what could be found out from patients. Experiments on patients were justifiable up to a point when the subject was willing and there was little risk of permanent injury. When the subject was insane and the risk appreciable, the only kind of experiment which could be made was one which, if successful, would give direct benefit to the patient himself. Animal experiments, therefore, had played little part in deciding the present trend in psychiatric treatment. Most of the data had had to be obtained by observation or experiment on man; therefore progress was bound to be slow. On the other hand, many disorders affected the lower part of the nervous system, and here there was quite enough likeness between the human nervous system and that of animals to throw light on the general plan and way of working of the nervous machinery. An essential step in the understanding of these disorders was the accurate mapping of the nervous system and a knowledge of the function of the different pathways. Here the lecturer described the work of Sherrington and other investigators, and touched on some of the achievements of modern neurology in war and peace.

In conclusion he said that he might seem to have assumed that if experiments were made on animals there must be some proportion between the pain inflicted and the benefit gained. That rule was just, but it was a rule which, fortunately, needed to be applied very rarely indeed. The days were long past when operations on animals, as on man, had to be made without anaesthetics, and in the great majority of experiments on the nervous system the animal was anaesthetized and never regained consciousness. If the animal survived there might be paralysis or loss of sensation, but severe pain—the kind of pain which was experienced when the skin was cut—was quite inadmissible, even on the most utilitarian ground, because it would almost inevitably make the experiment valueless.

Pain was an experience of the mind rather than of the body. In unconsciousness one did not feel pain, and yet the sensitive nerve endings and nervous pathways might be sending up urgent signals which would evoke severe pain if the brain were able to receive them. On their way to the brain these signals might give rise to many of the bodily reactions which accompanied pain, such as rise of blood pressure, deeper breathing, widening of pupil, and tension of muscles. These could be studied in completely unconscious animals, because they occur in the decerebrate preparation in which the whole of the forebrain has been destroyed under anaesthesia.

Traditional beliefs died hard, and there was still a tradition that experiments on animals must be painful, and it was natural and right that people should be concerned with this, and those who carried out experiments had the responsibility of making sure that their concern was needless. In the days before anaesthetics experiments on animals were undoubtedly painful, but whether one approved of them or not it must be remembered that very many people had profited by them. Anaesthetics were introduced a hundred years ago, and the experiments of Magendie in 1822, from which he showed the complete separation of motor and sensory functions, and which shocked our forefathers and quickened the anti-vivisection movement, could now be made quite painlessly.

Reports of Societies

TREATMENT OF BELL'S PALSY

A meeting of the Section of Otology of the Royal Society of Medicine was held on December 1, at which Mr. TERENCE CAWTHORNE read a paper on the pathology and surgical treatment of Bell's palsy. Mr. D. F. A. NEILSON was in the chair.

The researches of Sir Charles Bell into the function and diseases of the facial nerve, or "respiratory nerve of the face," to use his own nomenclature, had led in the first half of the nineteenth century to his name being attached to all forms of facial paralysis, no matter what the underlying cause might be. In 1893 Gowers was able to distinguish such obvious causes as injury, infection, and new growth from the true Bell's palsies, those due "to a neuritis within the Fallopian canal."

Mr. CAWTHORNE stated that in a series of 270 cases of facial paralysis under his care he had found that Bell's palsy was responsible for 157 (58%). The disease affected chiefly those between the ages of 20 and 60 years, and men were slightly more prone to the condition than women.

Because the disease did not cause death, histological material was rarely available, and the pathology had not been established; but from his operative findings he was able to state that the lesion lay in the trunk of the facial nerve at or near the stylo-mastoid foramen. Swelling of the nerve was probably the result of ischaemia, and this might be the result of exposure to cold. The consequent compression of the nerve trunk in the bony Fallopian canal would impair the transmission of neural impulses. Mr. Cawthorne described the appearance of the nerve as seen through the binocular operating microscope, and said that the nerve appeared to be unduly constricted at the point where it left the stylo-mastoid foramen and fine haemorrhagic streaks were to be seen running up the length of the nerve for a few millimetres. Above the constriction the nerve was swollen. In three cases of long-standing paralysis the trunk was found to be a shrunken fibrous strand.

Of 151 cases of severe Bell's palsy, within two months 75 (50%) had completely recovered, 19 (12%) had made a partial recovery, and 57 (38%) showed no signs of improvement. The worst prognosis for spontaneous recovery was found in those in whom the facial paralysis was complete and the faradic responses were absent.

Ballance and Duel in 1932 had treated severe cases by exposure and "decompression" of the nerve at the stylo-mastoid foramen and in the lower part of the Fallopian canal.

The speaker said that where the paralysis had remained complete for a month the likelihood of spontaneous and complete recovery was remote, and if in addition the responses to faradic stimulation had been lost he advocated decompression of the nerve. In this direction lay the best chance of good recovery. He stressed that, valuable as were electrical stimulation and splintage of the paralysed side of the face, they contributed nothing to the treatment or relief of the lesion responsible for the palsy. The operation was best done in the second month of the disease. The nerve was exposed through a post-aural incision, and, after the trunk had been identified, as much of the mastoid cortex was removed as would allow of free access to the lower part of the nerve. Slitting up of the sheath and manipulation of the nerve demanded the utmost gentleness and was best done under the binocular operating microscope by an experienced surgeon.

Probably 75% of all cases of Bell's palsy which had lasted a month would show some spontaneous improvement, but frequently there was residual paralysis or spasm of the facial muscles. Of 37 cases recently treated by decompression, 31 had shown considerable improvement, while 6 had not benefited appreciably. Of these last, in 3 the nerve had been found reduced to a thin fibrous cord, and these cases might have done better if this had been excised and a nerve graft inserted.

Air Commodore E. D. D. DICKSON read a short paper on the results of conservative treatment of 37 cases of facial paralysis by means of physiotherapy and splinting the facial muscles by a plastic hook attached to the upper teeth. Treatment lasted from between one and six months. Thirty-three cases recovered completely, three are still improving, and one had failed to improve at all. He was in favour of non-operative measures in dealing with Bell's palsy, at least in the first few months.

Miss D. J. COLLIER was of the same opinion, and she challenged Mr. Cawthorne's views on the pathology of the condition, and his rationale of treatment. If Bell's palsy was due to exposure to cold, why was it not more common in cold climates or in the winter months? Why did it occur in small epidemics? These suggested a virus infection.

She asked whether Mr. Cawthorne recommended decompression to prevent degeneration of the nerve or to promote regeneration. Electromyography had shown that physiological block could persist as long as six weeks. The cases of rapid recovery claimed for decompression might belong to this group. When degeneration of the nerve had occurred recovery could only be by regeneration. The rate of regeneration might vary, but clinical evidence of re-innervation could not be expected earlier than three months and might not be apparent until much later. A single negative faradic response did not preclude the possibility of spontaneous recovery. Serial observations of the electrical reactions and by electromyography were needed for prognosis. The latter might give evidence of impending recovery two to three months before facial movements could be seen.

Operations in traumatic cases of facial paralysis showed that the nerve completely filled the canal during life, and nerve bundles always bulged out when the nerve sheath was opened. If the primary lesion in Bell's palsy was held to be a constriction at the stylo-mastoid foramen it was curious that the nerve should be pathologically constricted just where the Fallopian canal was widest.

Miss R. BOWDEN demonstrated by a series of graphs the importance of serial electrical examinations of both nerve trunk and muscular response in arriving at a reliable estimate of the prognosis. The technique should be a standardized one, using for choice a stimulator in which the current could be measured accurately.

Mr. I. A. TUMARKIN stated that permanent paralysis was caused by herpes of the geniculate ganglion. He doubted the efficacy of an operation which decompressed the lower end of the facial nerve and left its upper reaches unexplored.

Mr. CAWTHORNE, in reply, agreed that the aetiology of Bell's palsy was still in doubt, but felt that the demonstration of constriction and swelling of the nerve at the lower end of the Fallopian canal was so well proved at operation as to pinpoint the site of the lesion accurately. Should the swelling spread up the canal so as to implicate the chorda tympani and give rise to homolateral loss of taste, the prognosis was not necessarily worsened. He agreed with Miss Collier and Miss Bowden on the value of serial electromyography in watching the course of the disease.

MANCHESTER MEDICAL SOCIETY

The Dangers of Giving Fluids

In a paper on "Some Hazards of Fluid Therapy," read on November 1 before the Section of Medicine, Dr. D. A. K. BLACK warned members of some of the dangers of indiscriminate treatment with intravenous fluids. Although the value of suitable treatment with saline or glucose solutions was well established, their use might also give rise to harmful effects which were the more dangerous as they might develop insidiously.

The normal composition and distribution of body fluids were reviewed, and the essential differences between a predominantly salt depletion and a predominantly water depletion were discussed. In spite of Marriott's work on the subject, saline fluid was still given when a non-saline fluid would be more appropriate, and vice versa. Clinically, a complaint of thirst should suggest predominantly water depletion, and signs of peripheral circulatory failure predominantly salt depletion. The estimation of serum sodium was the most direct biochemical method of distinguishing between salt and water depletion. The test for urinary chloride might be misleading in the presence of acidosis or alkalosis, or of renal or suprarenal disease.

In addition to giving the wrong type of fluid, it was possible to give excessive amounts of the correct type of fluid. This was well appreciated with salines, but the dangers of an excessive intake of non-saline fluid were less well known. In anuria, it was essential to restrict the intake of water as well as of salt; and there was also a risk of water intoxication in the period following surgical operations, in which Coller and his associates had shown that the elimination of water was seriously impaired.

There was a danger of producing a significant acidosis when large amounts of normal saline were given to correct salt depletion; it was better in severe salt depletion to give a fifth of the required sodium as lactate. The use of ammonium chloride in the treatment of alkalosis was discussed. When alkalosis was caused by excessive alkali administration, ammonium chloride could safely be given; but, when alkalosis was due to vomiting, it was associated with salt depletion, and normal saline was more suitable than ammonium chloride. It was important to remember that a low alkali reserve might be due to a respiratory alkalosis, and not to a metabolic acidosis; for example, in salicylate poisoning the low alkali reserve was a sign of respiratory alkalosis, and sodium bicarbonate might not be the best treatment. Caution was very necessary in the intravenous use of potassium. Potassium infusions should be given very slowly, to avoid cardiac arrest, and the oral route was much to be preferred, whenever and as soon as practicable.

In conclusion, Dr. Black disclaimed any wish to set up a new specialty of applied electrolytology, but suggested that those undertaking fluid therapy should ask themselves three questions, which could often be answered clinically:

(1) Do we need to give fluid at all?
(2) Should we give saline or non-saline fluid?
(3) Have we given enough, or too much, fluid?

Healthy kidneys were a great help in correcting mistakes in fluid administration, and, after all, most of the patients survived.

A lively discussion followed.

Mice and Lymphocytic Chorio-meningitis

On November 8 Dr. J. O'H. TOBIN read a paper on "The Laboratory Diagnosis of Lymphocytic Chorio-meningitis" before the Section of Pathology. Dr. Tobin said that one of the many types of lymphocytic meningitis was caused by the virus isolated originally by Armstrong. This virus caused true lymphocytic chorio-meningitis, and was pathogenic to man, mice, guinea-pigs, and other animals. In man the virus could give rise to three different clinical pictures, besides an unapparent infection—namely, a simple upper respiratory infection, an influenza-like syndrome followed in one or two weeks by meningitis, or an encephalo-meningitis. In the laboratory the diagnosis was made by the isolation of the causal agent and confirmed by serological methods, or solely by serological methods. Virus could be isolated from C.S.F., throat washings, or blood by inoculating mice or guinea-pigs with fresh material. There was a specific complement-fixation test in which infected guinea-pig spleen was used as the antigen; neutralizing antibodies could also be demonstrated in convalescents.

The disease was associated with house mice, which carried the virus, and eradication of mice in the vicinity of the patient's home should be attempted. In Manchester two such foci were present, and all the cases except one seen in the city had come from these two localized areas. From the routine point of view serological diagnosis was the method of choice, as attempts at virus isolation from human material were a waste of time unless a virus laboratory was in the immediate vicinity.

Correspondence

Displaced Registrars

SIR,—The parlous position of so many registrars is not a matter that should be allowed to be fought out by them alone: we do, although it is sometimes not very obvious, form a profession, in which we owe duties to one another. The seniors must help their junior colleagues to get a fair deal.

It is, of course, obvious that far too many registrar posts have been created, and that when the present holders of these redundant posts have been settled elsewhere they should be allowed to lapse. In this way a recurrence of the present muddle due to incompetent planning would be impossible. Even so, we are faced with the question, "What shall the present registrars do to make a living and to make use of their skill and knowledge?" May I make a few proposals which if put into effect would increase the number of consultant appointments, with only a small increase of expense?

There are many part-time consultants who do nine paid sessions a week, but who remain on the staff of a hospital at which as honoraries they do other unpaid sessions, sometimes because they have a sentimental attachment to an institution at which they have worked for many years, sometimes because there are pay-beds, and for a variety of other reasons. If such unpaid sessions were abolished, there would be vacancies, which could be filled by up-grading senior registrars. Perhaps the number of sessions would be small, but it would give these people a chance to get their feet on to the consultant ladder.

Secondly, in order to reduce the competition for consultant posts I should suggest that nobody who is now a consultant and who is over the age of 50 (or perhaps even 45) should be eligible for appointment to any new post, except of course university ones. (It may prevent rude letters if I say frankly that I am over 50.)

Thirdly, again in order to decrease competition for posts it might well be agreed that no part-time specialist of consultant status who is doing seven or more sessions should be eligible for further sessions.

If these three suggestions were carried into effect the problem would not be completely solved, but at least some of the (about-to-be) displaced registrars would have a chance of climbing upwards.

There is one difficulty which at the moment seems to be insuperable: that is, the unsuitability of men who have been registrars for some years to become competent general practitioners. Could they not be given financial assistance during a period of training? And should we not take steps to see that this absurd position never recurs by doing away with the mobs of registrars who mill round the out-patient and casualty departments, replacing them by old-fashioned casualty or receiving-room officers—a group of residents who made the finest and most promising general practitioners?—I am, etc.,

London, W.1. A. PINEY.

SIR,—We suggest immediate collective action by all registrars for the amendment of the Ministry of Health edict RHB (50) 106, if only to avert our financial ruin, irrespective of the wider questions of increasing the number of consultant posts available and maintaining adequate hospital staffs. We suggest two basic demands to achieve this: security of tenure of non-teaching hospital appointments above the rank of senior houseman, such as existed in the municipal hospital services; constructive proposals for those leaving the hospital service, to replace the impracticable suggestions about the armed Services and the Colonies contained in paragraph 12. This security of tenure will mean that such hospitals will not be robbed of a vital segment of their medical staffs, for a cut is bound to be at their expense, as it appears unlikely that registrar appointments in teaching hospitals will be cut by half; and that individuals not advancing to consultant status will drop out (as, indeed, they always did) at their own convenience, and consultants will be produced by competition, experience, and qualifications instead of by any rigid and uniform time-table system. Artificially recurring crises of superfluous registrars would not then arise. At present the situation can be compared to a factory where the foremen not reaching the board of directors in two years are automatically thrown out of the industry.

The constructive proposals for those leaving the hospital service might include facilitated entry into general practice and training courses without loss of pay—essential for those who have spent years in a specialty—preference for practices where part-time work in the specialty would be available, and no sudden termination of contracts now.

We urge the most vigorous action of all registrars by personal interviews with M.P.s, through their own group of the B.M.A., and, if possible, by deputation to the Minister of Health.—We are, etc.,

J. MURRAY DALE. P. W. GRANT.
H. BOURNE. N. B. JETMALANI.
J. A. IRWIN. J. F. HUDSON.
J. B. JEFFRIES. J. I. HALLINAN.
Coulsdon, Surrey. N. C. CONNELL.

SIR,—The Minister of Health in the House of Commons on November 3 said that "this circular [referring to RHB (50) 106] was issued after full consultation with the profession's representatives." There is no evidence that these representatives would be any other than the Joint Committee. Yet in the *British Medical Journal*, December 2, *Supplement*, p. 205, there is a denial of any agreement with the Minister. The Minister seems cautious enough not to mention agreement, but only consultation. The statements, however, are sufficiently at variance to require further information urgently. The committee can vindicate themselves only by issuing a full and complete statement of what transpired at these consultations, and how far they were committed in this infamy.—We are, etc.,

Central Middlesex Hospital, London, N.W.10. THE REGISTRAR GROUP.

*** See the Joint Committee's statement in this week's *Supplement*, p. 245.—ED., *B.M.J.*

Cost of Academic Clinical Office

SIR,—Who can now blame Oxford for living in a world apart? Academicus (December 2, p. 1275) paints a picture so remote from the grim but exciting world of 1950 as to suggest a fantasy. £250 for professional entertaining? £670 *annually* for a car, £160 for travel, £90 for a telephone? This is surely Wall Street, not the quiet path of academic life. What would an Oxford don, with his gross income of perhaps £1,200 (and that twice the income of many a schoolmaster), think of these figures?

However much individual experience induces a personal smart, the truth is that the twentieth century is one of social revolution. Privileges no longer go by divine right but are subject to scrutiny. The economics of medicine, especially in its specialist branches, still appear to the less fortunate as highly favourable (witness the huge entry to the medical schools). It is not "appeasement" but common sense to recognize this fact. To put it on its lowest plane, we may as well make a virtue of necessity in acknowledging the essential justice of the social change. Nor is there the slightest prospect of a general rise in the standard of living, but rather of increased "austerity" as the demands of depressed millions all over the world are met, either by agreement or conflict.

This is not to deny the essentially sound argument in Academicus's letter—i.e., the distinction made by the Ministry of Health in allowances and by the Inland Revenue in expenses between whole-time specialists and those in private practice. It is this distinction, rather than the distinction of teaching and research, which is anomalous. The choice of an academic career has always been recognized, *ceteris paribus*, as implying a financial sacrifice. And there is one anomaly which affects all intellectual workers—the refusal of the Inland Revenue to allow expenditure on books and journals as a professional expense; this constitutes a tax on thought and efficiency.—I am, etc.,

Bickley, Kent. DUNCAN LEYS.

SIR,—It is unfortunate that the plea of Academicus (December 2, p. 1275) for more adequate remuneration should be based on a collection of extravagant figures and illogical comparisons, since these are more likely to lose than gain the sympathy of his colleagues. From the size of his petrol bill and telephone account, one is tempted to deduce that a considerable number of his claimed 70 hours of work in the week is taken up by motoring and using the telephone. The former, at least, is much higher than one would associate with the essential motor travel imposed by a full-time university appointment.

If the above comments seem uncharitable, may I atone by offering Academicus some advice? Since his £1,400 car is costing him some £250 per annum in tax, insurance, garage, and repairs, might he not be advised either to drive more carefully or to try a different garage or, perhaps, get rid of his present car? I cover 14,000 miles annually in my 30-h.p. car for about £200 (which figure includes petrol, full maintenance, overheads, and garaging at city rates). As regards his figure for his net income, it all depends on what you mean by "net."

Finally, I feel that Academicus rather oversteps the mark when he imagines that most academic clinicians are endowed with substantial wealth from other sources. This appears to me a very rash assumption.

The trend of my remarks may allow me to assume the pseudonym of

REALIST.

SIR,—Academicus (December 2, p. 1275) must have a peculiar interpretation of the necessary expenses of his occupation. I would suggest that he cannot unduly complain when he can run a £1,400 car and spend £250 + £198 + £160 = £608 on what is, after all, personal enjoyment.—I am, etc.,

Barnsley. H. A. CROWTHER.

SIR,—An academic scientist, with a gross income small compared with that of Academicus (December 2, p. 1275), may perhaps sympathize in general with the position of the academic clinician. Yet, in all honesty, he must wonder at a man who, while claiming an effective income of £3 7s. 6d. per week, can apparently write off a £1,400 car completely after only four years. Is the Minister of Health alone responsible for medical extravagance?—I am, etc.,

Hull. J. J. KIPLING.

Protection of Laboratory Animals

SIR,—The time has come to thank you cordially for permitting a correspondence about my draft (see *Journal*, September 23, p. 724, and October 14, p. 888) and to thank likewise those who have contributed comments, whether favourable or unfavourable.

I do not acknowledge the sentiments and aims which Dr. Lane-Petter and Dr. Dyer (November 11, p. 1114) have imputed to me. It would be tedious to rebut all these imputations, but if any reader believes I have sinister intentions I would crave an opportunity of sending him gratis a pamphlet, *How to Befriend Laboratory Animals*, which has been well received by the scientific press and has been distributed in America by the National Society for Medical Research, Chicago. The vivisection controversy has induced strong feelings which are unfavourable to mutual understanding and dispassionate judgment, but I still believe that a good deal of common ground can be found if we patiently analyse it out. The need remains for an agreed scheme which can be offered to foreign humanitarians who seek advice. My draft was got out precipitately with the August conference at the Hague in view, but now that it has missed that boat the revise can be tried on a few selected dogs before being submitted to general discussion. The form of an Act of Parliament was adopted in the hope that concrete proposals would keep discussion to the point, but it aroused so much prejudice that the redraft will have to be in narrative form.

No suggestion of altering the British statute has arisen, of course, though the latter is unsuitable for export because it would lose its virtue if divorced from the administrative tradition that has been built up on it. But surprisingly many people believe that in this country experimental biology consists in cutting animals up alive without anaesthetics; the reports of the Home Office are not widely read, and the Research Defence Society deals mainly with the utility of research. What would reassure the public more than anything else would be to know that research scientists as a class were disposed, in a generous and large-minded spirit, to help a genuine if imperfect attempt to better the lot of laboratory animals abroad. U.F.A.W. has incurred bitter hostility and deliberately sacrificed much support by having licence-holders among its officers and recognizing that experimenters are as humane as anybody else. Is it not rather ungenerous, therefore, on the part of some medical men to adopt a purely negative, hostile, *nitouche* attitude, especially when criticisms have been asked for and welcomed? Happily *non sic omnes*; one director of research is kindly collecting comments for me from all his staff.—I am, etc.,

Universities Federation for Animal Welfare, London, N.3. C. W. HUME.

Reconsideration of B.M.A. Policy

SIR,—It appears that many people outside the profession are asking whether it is sufficient to plan a neat and orderly Health Service (though experience has demonstrated beyond doubt that it is neither) unless the planners ensure that those who are asked to work it are satisfied that the terms and conditions of service are satisfactory to them and to the patients alike; and whether we, as doctors, are taking a broad enough view. Unfortunately, and with some justification, it appears to them that we are boggling over money details when, as you so rightly say (*Journal*, December 2, p. 1262), we should be concerning ourselves with the principles and the "failure [of the Ministry] to define what should be the terms of fulfilment of the Spens recommendations."

If we are able to persuade the Ministry to give such a definition, so much the better; but surely, Sir, we as a profession have many other and more important principles on which we require decision. If our grounds of complaint are adequately marshalled, they will present a damning indictment of the Service and will present us with adequate reasons for withdrawal unless they are rectified. This matter is not one which concerns the G.P. only; it is of vital importance to the consultants as well as to the M.O.H. group; it concerns every branch of the profession, and it concerns the public.

As Dr. Ireland and Dr. Pridham have already said in Council, what is urgently required is a reconsideration of B.M.A. policy to fit the new set of circumstances with which we are faced.

After two and a half years' working of the National Health Service, is such a review not imperative? If this suggestion is acceptable, we should then ask the Government to meet us and invite them to reconsider, in an entirely different atmosphere from that which has prevailed in the past between us, the whole Act and its regulations.

There have been mistakes on both sides. How could it have been otherwise in so vast and complicated an experiment? Is this not the time for recriminations to cease and for broader and wider counsels to prevail?

It behoves us to set our own house in order first, by setting out quite clearly in one document, covering all branches of the profession, the main considerations which lead us to condemn the Service in part, and put forward constructive proposals. If we can persuade the public, as we undoubtedly can in such a document, that our interests and theirs are irretrievably integrated, we shall have their support and good will, and no Government, whatever its complexion, can afford to ignore this.—I am, etc.,

Tunbridge Wells, Kent. R. PROSPER LISTON.

Dead Bodies in Water

SIR,—An admittedly limited experience lends small support to Dr. Hugh Willoughby's suggestion (December 2, p. 1277) that drowned men taken from the Thames invariably float face downwards. I have seen at least one body which did not, and an ageing Thames waterman and certain members of the Metropolitan and River Police will bear me out. Fifteen years ago, perhaps more, I was crossing Waterloo Bridge when I noticed

a waterman standing knee-deep in the sludge off the Surrey shore attempting to lasso a floating body. It was that of an elderly man. He was lying on his back as if resting in a hammock, his knees and hips partly flexed, the head and shoulders bent slightly forward, while his arms and hands, at full extension, grasped the edges of a faded Prince Albert coat as if to draw its skirts protectively about his thighs. While the waterman secured the body a young constable signalled a police launch, which towed the remains towards Westminster Pier. Did he fall or was he pushed? This question naturally arises, for the manner of death may influence in some degree the way a body floats. Its discussion must be left to those with more knowledge of these matters than myself.—I am, etc.,

Bognor Regis. H. D. LIVINGSTONE-SPENCE.

SIR,—I agree with Dr. Hugh Willoughby (December 2, p. 1227) that female adult corpses float face upwards and male corpses float face downwards in fresh water. I have seen them in rivers as far apart as the Yangtze (China) and the rivers and ponds of India and England. It is sometimes difficult for students and busy doctors to keep these facts in mind clearly, but it is helpful if one remembers that in death from drowning the two sexes float in a position complementary to each other.

I am sorry that I have no experience of salt water in these cases.—I am, etc.,

Appleby Magna, Staffs. J. R. SALMOND.

Peanut from Bronchus by Percussion

SIR,—The following case report might be of interest.

The patient, a Chinese boy aged 10 years, was admitted to the Chuanchow General Hospital, Tsinkiang, Fukien, on August 10. His mother stated that, four days before, while eating peanuts he had had an alarming paroxysm of coughing during which he became blue in the face and unable to speak. He was still reluctant to talk. Since the accident he had had some evening fever, and frequent attacks of cough during which he became breathless and cyanosed, but he had not been able to cough up anything. He was somewhat breathless between attacks. At home he had been inverted and his back beaten soundly, but without result.

The child was obviously quiet and anxious, but walked into the consulting-room himself, though he avoided any exertion or sudden movement. He was small for his age, but in good condition. On examination of his chest the right side appeared somewhat collapsed, and respiratory movements and breath sounds were reduced on this side. Temperature on admission was 100° F. (37.8° C.). No other abnormal signs were elicited. A radiograph showed that the mediastinum was shifted towards the right side, but the right lung was still well aerated. A diagnosis of a peanut partially obstructing the right main bronchus was made.

As our hospital is not provided with a bronchoscope the problem of how to remove it was a difficult one, though probably not unique. Our child's size oesophagoscope was obviously too big to pass the cords. Chevalier Jackson states that only 2% of foreign bodies are spontaneously evacuated from the bronchi, and then not usually until the patient is seriously ill.

We remembered that, in some cases of post-operative collapse of the lung, plugs of mucus can be shaken out of the bronchi by the use of postural percussion—i.e., laying the patient with the affected side uppermost, and the head low, then percussing with the closed fist over the other hand placed over the lateral aspect of the ribs. We decided to try to dislodge the peanut in this fashion.

Peanuts and other vegetable foreign bodies cause intense inflammatory reaction in the respiratory passages around the nut, holding it more firmly; also after four days there would be secondary infection increasing the inflammatory swelling. So first we gave penicillin (15,000 units three-hourly for 24 hours) and steam inhalations of tinct. benzoin. co., hoping thereby to reduce this swelling a little. At the end of this time 0.5 ml. of liq. adrenalin. was injected, to reduce the congestion and swelling of the mucosa further and relax any spasm of the bronchus. About five to ten minutes later the patient was taken by the legs and inverted to about 60°. Owing to his struggles it was necessary to have further assistance to hold his chest with the affected side uppermost. The right side of his chest was vigorously pounded as described above. After the third attempt the patient cried out that he could feel the nut in his throat; no doubt his struggles assisted in dislodging it. Sure enough a tap could be felt on the anterior surface of the trachea, occurring with each cough or respiration. This was no doubt due to the nut moving in the current of air, and impinging on the tracheal wall or the cords. It is a well-known sign of a foreign body in the trachea and was, I think, well described by our intern as being like a ball valve in action.

The mother refused permission for further interference in the meantime in the hope that he could cough it out. This seemed to us unlikely, but the child was left lying with his head low and making voluntary efforts to cough it out. The next day the nut was still there, and the mother gave consent for operation.

The patient had not been well behaved or co-operative, and so was given 1/12 gr. (5 mg.) morphine pre-operatively, and this enabled us to perform tracheotomy under local analgesia. The isthmus of the thyroid was divided, and a wider opening than usual made into the trachea. The nut was seen at the first expiration lodged in the lower end of the wound in the trachea. It was removed with a spoon and forceps. It was found to measure 1.75 by 1.00 by 0.75 cm. It is surprising to think that such a large body should be able to pass the cords at all. Some swelling would no doubt have taken place during the time that it was in such a damp situation, but the nut had been cooked in oil, and still showed a practically undamaged glossy surface, and so it is unlikely that it had absorbed very much fluid.

A tracheotomy tube was left in for 24 hours and penicillin continued for four days, when the patient was afebrile and active. He was discharged well with the wound practically healed at the end of seven days from the operation.

We feel that this cannot be a unique situation. We found it worrying, and though we, no doubt, were fortunate we feel that this experience might be of use to others.

It is a pleasure to acknowledge the help of my colleague, Mr. D. W. Short, in the treatment of this case and in reporting it.

—I am, etc.,

Tsinkiang, S. Fukien. N. TUNNELL.

The Meaning of Heart Failure

SIR,—Dr. L. Carp (*Journal*, November 25, p. 1201) reviews a series of 100 post-operative deaths in old people coming to necropsy. He states that 27 of these cases died from heart failure, next to bronchopneumonia the largest single cause of death in his surgical patients. Heart failure as a cause of death looms large in most post-operative mortality figures.

The purpose of this letter is to inquire what exactly we mean by "heart failure" following operation. Do we imply by this term that the patient's death is due to decompensation of one or both ventricles with the attendant clinical picture of systemic or pulmonary congestion, or do we, as I believe, imply that the cause of death is due to collapse of the peripheral circulation? One would like to know on what clinical or pathological grounds Dr. Carp assumes that the heart was at fault in these cases. Does he base his conclusions on the finding of "varying degrees and types of cardiac pathology" though the rest of his series showed similar lesions? These cases may have shown pulmonary oedema at necropsy, but to my mind this finding does not warrant the diagnosis of heart failure, as one would expect the same condition in vascular collapse with loss of tone in the pulmonary vessels.

Despite some experience in dealing with the problems arising during the post-operative period I cannot definitely state that I have seen one single case die primarily from heart failure. I have, however, seen many patients die from peripheral vascular collapse, particularly those cases which have been subjected to extensive surgical procedures involving considerable trauma and exposure of tissues. I feel that many, if not the majority, of deaths following operation and certified as having been due to heart failure are in reality due to peripheral vascular collapse. The fault is not in the heart but rather in the vital centres, and in particular the vasomotor centre, which is unable to cope with the stress of the operation. If the heart does fail to maintain the circulation it is only because it receives an inadequate return of blood from the systemic vessels.

Apart from the academic question of nomenclature, it is surely of great importance from the point of view of treatment that we should be clearly aware of the problems these cases present. The treatment of heart failure requires digitalis, mercurial diuretics, oxygen, and even venesection. The treatment of peripheral vascular failure requires the minimum amount of trauma and exposure at operation, the avoidance of heat loss, the maintenance of fluid and electrolyte balance, and the use of stimulants. One is the treatment of the failing heart, the other the treatment of surgical shock.

As long as the term "heart failure" is used to describe what is in actual fact peripheral vascular failure, so long shall we continue to watch the heart and ignore the essential problem, in these cases, the peripheral circulation.—I am, etc.,

Dublin. RISTEARD MULCAHY.

Indwelling Tube for Haematemesis

SIR,—I would like to endorse the remarks of Mr. V. J. Kinsella (November 18, p. 1174) concerning the use of a Ryle's tube in the treatment of haematemesis. It would seem, in my experience, that, while its value is fully appreciated by a great many surgeons, it is not so appreciated by the physicians under whose care these cases are first admitted to hospital.

There is no doubt that half-hourly aspirations will show instantly whether bleeding is controlled or not, and this is of inestimable value where surgery may be necessary for recurrent haematemesis. For, whereas a patient will always vomit after the first bout of bleeding, no further vomiting may take place at all, or at least until a considerable quantity of blood is present in the stomach and small bowel, as the shock and the reflex dilatation of the stomach present in these cases depress the vomiting reflex; further, the body having compensated for the shock caused by the initial haemorrhage, it is keyed up to compensate quickly for any further bleeding, and consequently it may be some time before blood pressure and pulse indicate a recurrence of the bleeding.

The value from the operative point of view of having a Ryle's tube passed early in the treatment was well illustrated to me in two cases of haematemesis on which I operated on successive days. The first was admitted to a surgical ward and had a tube passed immediately. Aspiration showed a recurrence of the bleeding 14 hours after admission and transfusion, and I was able to operate in good time, on a somewhat hypotonic stomach, it is true, but not one full of blood, despite the fact that the artery spattered my forehead when the stomach had been opened and the ulcer localized. The second case had had no tube passed since attempts to pass one pre-operatively failed because of the distress of the patient. Here the stomach was found full of clot and considerably more distended and flabby than in the previous case. Incidentally, this patient never vomited during his second haemorrhage, which occurred three days after his first, and from the amount of blood in the stomach it must have been proceeding for some time before it was appreciated clinically.

I feel certain, therefore, that a Ryle's tube is an essential in the treatment of haematemesis and that its advantages far outweigh the theoretical disadvantage of the tube itself causing the ulcer to bleed, a likelihood which I believe is negligible.

Finally, in regard to the operative treatment of haematemesis, may I make a plea for simple suture of the bleeding point? In the expert hands of gastric surgeons like Tanner, Ogilvie, and others, gastrectomy may be quick and safe, but in the hands of the average surgeon I feel strongly that obliteration of the bleeding point (with subsequent gastrectomy), a long procedure though it may sometimes be, is a wiser procedure and one with much less risk to the patient.—I am, etc.,

Tunbridge Wells. I. LANGDALE GREGORY.

Teething

SIR,—Perhaps I may illustrate the value of routine examinations and the keeping of height and weight charts during the first five years of life by replying to Dr. H. M. Tietze's letter on teething (December 2, p. 1281). Like Dr. Tietze, I was taught that teething was a physiological process and so should not be looked upon as the cause of infantile ailments. In my early days in child-welfare work I tried to impress this fact on the mothers, often to be told by the owner of a copious family that it was time I had some children myself.

After more than 25 years of child-welfare work with the additional experience of bearing and rearing two children of my own, I would say that the answer in "Any Questions?" of October 28 (p. 1013) is well-reasoned and substantially correct.

Poor colour, lack of appetite, loss of muscle tone, frequency of respiratory infections, and recurrence of the fat intolerance of early infancy (often the cause of vomiting and diarrhoea: careful questioning brings to light the occurrence of loose, offensive, putty-coloured stools following an attack of vomiting and preceded by loss of appetite) occur again and again during the eruption of the first molar and canine teeth. There is a return to normal health for a period until the second molars begin to erupt, when the infections and the offensive stools reappear.

It is a simple matter to mark the period of tooth eruption on the weight chart and to note that all too often the child's weight is at a standstill during this period and that he rapidly puts on weight during a lull in tooth eruption. Few indeed are the children who do not show some signs of distress at this time, and I have long been convinced that it is the loss of muscle tone then which is the cause of so many of the knock-knees so prevalent to-day.

I have heard school teachers say that absenteeism, inattention, and other erratic behaviour occurs more frequently among the age group with the toothless gaps and the imminent eruption of permanent teeth. Children of this age show a recurrence of the bronchial attacks they used to have when cutting teeth as a baby.

From all this I would say that the pain of teething is the cause of lowered resistance to infection, or to a temporary diminution of gastric or intestinal secretions. I would strongly deprecate the dismissal of such ailments as paltry and "only due to teething." Much catarrhal deafness and many deformed chests are the results of respiratory infections untreated because of this belief.

More and more we find the advice of the child-welfare medical officer is sought by mothers who are ex-teachers, university lecturers, or ex-nurses, and even by the wives of medical practitioners. Surely we child-welfare officers have still something to contribute to the future of child health, although I freely admit that we have lost much by not being given the opportunity of keeping in closer touch with the clinical work in hospitals and the curative work in general practice.—I am, etc.,

Manchester. MABEL LINDSEY.

Inoculation and Injection Paralysis

SIR,—The paper by Professor A. Bradford Hill and Dr. J. Knowelden (July 1, p. 1) and your annotation (p. 28) throw light on what is known here among the African natives as "injection paralysis." This condition is seen from time to time in the out-patient department of this hospital, and the story is very similar in each case. The baby had a fever; he was taken to a dispensary, where an injection of quinine was given into a buttock, "since when the baby's leg has been paralysed." It always seems to be the leg which was injected. However, careful questioning of the mother usually makes it clear that the paralysis did not appear until two or three weeks after the injection, and there has never been any evidence of suppuration of the injection site. Clinically, the condition is poliomyelitis; the condition is seen among older children who have not had an injection. It is flaccid and there are no sensory disturbances. Most native dressers are taught carefully how to avoid injections into the region of the sciatic nerve.

It appears, then, that "injection paralysis" has scientific grounds for its existence, and that indeed the localization in the affected limb is a direct effect of the injection, as Congo mothers have so long asserted to sceptical doctors.—I am, etc.,

Sona Bata, Belgian Congo. E. W. PRICE.

Slide Test for P.A.S. Sensitivity

SIR,—I have read with interest the report (November 11, p. 1073) by the M.R.C. on the treatment of pulmonary tuberculosis with streptomycin and *para*-amino salicylic acid (P.A.S.). With regard to testing P.A.S. resistance the view is expressed that the methods used did not prove very reliable. Swedish workers have used Pryce's slide culture method in the P.A.S. test *after* isolation of tubercle bacilli on standard culture media. For the past three months I have been testing P.A.S. sensitivity with the modified slide culture method which I described in the *Lancet*, 1943, **1**, 615, adapting it for the purpose by adding P.A.S. to make concentration from 1 mg.% to 0.006 mg.% and also penicillin (10 units/ml. of culture medium) to counteract secondary contamination. This makes it possible to assess sensitivity on the original material, thereby shortening the time-factor as well as enabling us to study the morphological changes of the bacillus. The assessment is easy and, as judged by limited experience, fairly accurate, as one can use direct microscopical examination of the growth either by low- or high-power magnification.

In 20 cases, so far supplied by Dr. Thompson-Evans, the chest physician, the method has been used and found reliable. It is hoped to report on our results at a later date.—I am, etc.,

Shoreham-by-Sea, Sussex. K. S. RODAN.

Volvulus of the Small Intestine

SIR,—The following cases of volvulus of the small intestine are reported as being unusual: the first was a high intestinal obstruction due to volvulus of the afferent loop of jejunum following partial gastrectomy, and the second obstruction from a volvulus at the terminal part of the ileum.

Case 1.—The patient, aged 69, was admitted to hospital on July 27, at midnight, as a suspected case of perforated peptic ulcer. He stated that ten hours previously he was suddenly seized with severe upper abdominal pain, had vomited small quantities of gastric contents twice, had had his bowels opened before the onset of pain, but had not passed flatus afterwards. The pain had increased in severity and was now situated just above the umbilicus; he also complained of severe backache. He passed urine normally after admission.

He had previously had two operations (the second two years ago) for gastric ulcer, but did not know what exact procedure had taken place. He had enjoyed good health since.

He was obviously in great pain and could not lie still in bed. He did not appear unduly shocked (pulse 86, blood pressure 110/70 mm. Hg). Right abdominal paramedian and mid-line laparotomy incisions were both soundly healed. A palpable, fixed tumour was noted about the level of the umbilicus, tender to touch and fixed posteriorly. The abdominal muscles were rigid except in the lower sectors. Bilateral reducible inguinal herniae were present. Peristaltic sounds were audible. Rectal examination was negative, and no abnormal signs were detected in the chest. A pre-operative diagnosis was made of herniation of a loop of small intestine into the lesser sac, or an acute pancreatitis, with the former the more likely.

After passing a Ryle's tube and establishing an intravenous drip transfusion, laparotomy was undertaken under general anaesthetic. On opening the abdomen, the mass previously palpated was seen to be a very distended duodenum with surrounding retro-peritoneal exudation. Under the left costal margin a loop of jejunum was observed lying below the left part of the transverse colon. It was then ascertained that the patient had previously had a partial gastrectomy with retrocolic isoperistaltic gastro-jejunal anastomosis. The opening in the mesocolon had been fixed on the gastric side of the anastomosis. The distended loop of jejunum was easily displayed and proved to be a volvulus of the afferent loop which was unduly long, approximately 8 in. (20 cm.). Rotation had occurred through 360° in a clockwise direction, the fixed points being the duodeno-jejunal junction and the gastro-jejunal junction. Two obstructions, therefore, were present, one in the duodenum, from the closed duodenal stump to the duodenal-jejunal flexure, and the other in the twisted afferent jejunal loop. The obstruction was relieved by rotating the latter through 360° in an anti-clockwise direction; the intestine was quite viable, but showed intense congestion. Consideration was then given to the best method of preventing a recurrence. To undo and reconstitute the gastro-jejunal anastomosis using a shorter afferent jejunal loop was impracticable owing to the congested state of the jejunum, and consequently the mesentery of the afferent jejunum was fixed to the mesocolon by three or four interrupted catgut sutures, and the abdomen was closed in layers.

The patient's condition at the end of operation and for some hours afterwards was apparently satisfactory. 1,000 ml. of normal saline and 560 ml. "casydrol" had been administered. Seven hours after operation signs of acute cardiac failure developed, with fatal termination. A post-mortem examination showed extremely friable myocardial muscle with coronary narrowing. The duodenum was removed *en bloc*, and the surface of the pancreas was seen to be covered by a sanguineous exudate, as was also the area around the coeliac axis.

Case 2.—This woman, aged 46, was admitted on January 31. She stated that six days prior to admission she developed colicky abdominal pain situated below the umbilicus, mostly in the mid-line. Vomiting occurred on the following day, and constipation had been absolute throughout. She had had an enema on each day prior to admission, without result. The pain had been absent for the past 24 hours; the vomiting had become progressively worse and was now offensive, dark, and copious. There was nothing relevant in her past history.

She presented the typical appearance of advanced intestinal obstruction, with sunken eyes, dry tongue, cold extremities, rapid thready pulse, and anxious expression. The abdomen was grossly distended; no mass could be palpated; there was general slight tenderness. Rectal examination was negative and the hernial orifices clear. No peristaltic sounds were audible. Pulse 126, blood pressure 110/70 mm. Hg. A duodenal tube was passed on admission and continuous aspiration started. Intravenous 5% dextrose in saline was also given, and operation deferred for some hours.

Later, under general anaesthetic, the abdomen was opened through a right lower paramedian incision. The caecum was found to be collapsed, and on locating and tracing a loop of lower ileum it was seen that the obstruction was due to a volvulus of the terminal 10 in. (25 cm.) of ileum. At this site there was complete absence of mesentery for 10 in., and the small intestine was free to twist between the fixed ileocaecal junction and the point where the mesentery ended. The volvulus was undone by rotating the bowel through three complete circles, and the mesenteric defect quickly repaired. The abdomen was closed in layers. An intravenous transfusion of normal saline was maintained and 200,000 units penicillin with "sulphamezathine" 1 g. given four-hourly. Gastric suction continued to produce copious amounts of offensive intestinal contents, and the distension was completely relieved ten hours after operation. The pulse rate, however, continued to rise, and the temperature rose to 105° F. (40.6° C.). Twelve hours after operation the patient was *in extremis*, the peripheral circulation was failing, and she died in hyperthermia.

A routine post-mortem examination failed to reveal any abnormality in chest, brain, or renal systems. The entire small intestine was normal in appearance, except for congestion of the mucosa with small haemorrhagic areas: there was no distension. Death was presumed to be due to toxic absorption from the small intestine.

I wish to express my thanks to Mr. J. Philp, F.R.C.S., consultant surgeon to the hospital, under whose care these patients were admitted, for permission to publish the foregoing.

—I am, etc.,

Warrington. BRENDAN MCCARTHY.

Refusal to Appear in Court

SIR,—Mr. A. A. Walford's letter (November 18, p. 1176) ventilates a state of affairs which is proving a source of difficulty to other members of the legal profession. His impression is quite correct about the value of blood tests in some cases of disputed paternity, and Lord Merthyr's Bill, which was unfortunately shelved in 1939 owing to the outbreak of war, was drafted with a view to clarifying the position. At the same time it is only proper that the legal profession should appreciate that these tests do present difficulties to the pathologist. The examination has to be carried out by a person of experience and necessitates access to the proper sera. After completing the test the pathologist has still to be prepared to face cross-examination after, in many cases, waiting at a court for what may be a considerable period. Finally, he may find that the magistrates have reached conclusions completely in conflict with his findings. Under such circumstances it is not difficult to understand the lack of volunteers, and, although a solution can be found to the problem and is, in fact, being devised, nevertheless it would be greatly simplified if Lord Merthyr's Bill were again to be introduced.—I am, etc.,

London, W.1. FRANCIS CAMPS.

Penicillin in Typhoid

SIR,—The sweeping assertion in the leading article "Antibiotic Synergism and Antagonism" (November 18, p. 1160) that penicillin alone is useless in typhoid is not proved. Effective dosage has never been tried. Penicillin resistance is relative. *In vitro* concentrations of 15–20 units of penicillin per ml., and less, inhibit *Bact. typhosum*. This requires an *in vivo* dosage of not less than 20–40 mega units daily, in divided three- to four-hourly amounts, which has never been tried, except for interrupted daily treatment in the carrier state. "Chloromycetin" has also failed in carriers.

The euphoria produced by this dosage, unrelated to any alleviation of toxaemia, together with the subcutaneous injection technique (Garrod, L. P., August 19, p. 453), lessens the needle phobia, apart from which there are no systemic ill-effects. A subcutaneous injection of 2–3 mega units may leave a pea-sized nodule, which takes at least eight months and more to disappear, a fact previously unrecorded. Large doses diminish the rate of renal excretion and raise the blood level correspondingly (*Subacute Bacterial Endocarditis*, by E. Libman and C. K. Friedberg. Oxford University Press, 1948, 2nd ed., p. 364).—I am, etc.,

Dublin. A. D. MCDWYER.

Diagnosis of Placenta Praevia

SIR,—I have read Dr. J. M. Thomson's interesting letter (November 25, p. 1226) on the report of the discussion on placenta praevia (November 4, p. 1055), and I would like to add a few words in support of vaginal examination through the fornices as a diagnostic method. It is usually mentioned only superficially and rather slightingly in obstetrics textbooks. There is some analogy with *x*-ray examination by cystography. Both methods can give positive results only when the head is presenting, and both reveal the space between the vaginal or bladder structure and the contour of the skull. But palpation is more efficient, because we are able to determine the presence of the placenta praevia by its characteristic consistence and to exclude tumours or other causes of high position of the foetal head. It is even possible to distinguish the accumulation of clots from placental tissue if one has sufficient experience in such examinations. The examination gives positive results in marginal placenta and complete placenta (2nd, 3rd, and 4th degree) but is rather negative when only a small part of the placenta dips in the lower uterine segment. Doubtful results are obtained in cases of placenta praevia membranacea, but this is true of *x*-ray examination.

I believe that, in cases with antepartum haemorrhage characteristic of placenta praevia, a positive result in a vaginal examination through the fornices is from a clinical and practical point of view quite sufficient for diagnosis. There is no doubt that feeling the placenta directly after passing the finger through the cervical canal is more positive, but the examination through the fornices has several advantages which cannot be disregarded—namely, it is usually not necessary to pass the whole hand into the vagina unless the head is very high, and so a general anaesthetic can be avoided; there is less danger of inducing bleeding; it can be used in cases where the cervix is completely closed; and it is possible to determine on which side the placenta is situated and where its margin may be found. This is of the utmost importance not only for the prognosis but also for the treatment. For instance, if there is some contraindication to caesarean section in a case of complete placenta praevia with the margin near the internal os, and thus the vaginal route with Willet's forceps, or podalic version, must be adopted, we have the advantage of knowing in what direction we should seek the placental margin after passing the finger through the cervical canal to rupture the membranes. Thus we avoid going in a false direction and making an unnecessary separation of the placenta which induces haemorrhage and impairs the prognosis for the mother and the foetus. If the result from vaginal examination is negative we can expect that it is a case of accidental haemorrhage or lateral placenta praevia (1st degree) and therefore we can adopt an expectant treatment with very little risk.

From the above it can be seen there are sufficient reasons to use this examination more often, and in any case it should always precede the examination through the cervix. In all this there is, of course, nothing to lessen the value of *x*-ray examination, especially by the method of soft-tissue radiography, developed by Dr. Reid, which is of great assistance in clinical examination.—I am, etc.,

London, W.3. C. UHMA.

Two Public Health Problems

SIR,—I am struck by the contrast between, say, two people who want to live in an old bus but are refused permission on the ground that it is insanitary, and the fact that 30 or more people are crowded into a similar space (perhaps without any heating) for hours on end, with all windows tightly closed—e.g., football excursions. Railway coaches are a little better. After the experience gained during the war in air-raid shelters surely it should be possible to fit automatic hypochlorite sprays in at least new buses, and compel their maintenance and use, at least during the winter months. This problem appears to me greater than that of any notifiable fever.

Examination of at least one well-known brand of flat (folded) toilet paper advertised as being safe because it is impregnated with an antiseptic shows that there are four small perforations near the fold (presumably from the folding machine). The risk of hand infection must be appreciably increased by this.—I am, etc.,

Stockport, Lancs. JOHN HEGINBOTHAM.

POINTS FROM LETTERS

Spontaneous Amputation

Dr. J. BROWNRIGG-GLEESON (Dublin) writes: Spontaneous amputation in arteriosclerotic gangrene seems nowadays to be an unusual rarity. . . . Some months ago while in the country I was called to see a patient, whose relatives described her rather euphemistically as suffering from a "sore foot." I found an emaciated, apathetic, cachectic old woman aged 90, who was obviously in an advanced state of senile degeneration, and who had been confined to bed for some time . . . . Coldness of the toes combined with pain, tingling, and numbness, alternating with pain in the calf muscles, had started five months previously. Her pains were accentuated when in a recumbent position but alleviated by dangling her leg over the side of the bed or chair. Her right big toe first showed signs of gangrene, gradually proceeding to a lifeless white colour and eventually presenting a dark shrivelled appearance. . . . The right foot was now in an advanced stage of gangrene, extending from the great toe to about ½ in. (1.3 cm.) proximal to the ankle-joint. There was no line of demarcation present, and the process seemed to be spreading rapidly. Pulsation was felt in the femoral and to a lesser extent in the popliteal arteries, but not lower down. . . . Conservative measures were adopted in view of the patient's advanced age. The gangrene subsequently ascended to midway between the ankle and knee-joints, where a well-defined line of demarcation appeared, above which the tissues seemed healthy. The fore part of the foot was by now exuding a fetid discharge and was anatomically unrecognizable. In the course of a short time separation ensued and was complete within ten days, the parts merely being held together by a few skin tags; there was no bleeding. The tags were severed, and the stump presented a clean healthy appearance. The patient, who was in a moribund state up to this, seemed to show some signs of a slight improvement and became almost rational. But presently the ominous signs of gangrene became apparent in her other foot, and she died from hypostatic pneumonia about three weeks after the amputation. The whole process, from the onset of gangrene to spontaneous amputation, took approximately five months.

Mass Inoculation Technique

Dr. A. BARLOVATZ (Stanleyville, Belgian Congo) writes: Some of your readers might be interested in a method ensuring sterility during mass inoculations of typhoid and other vaccines. For injecting 1–2 ml. doses to each person I use a series of 20-ml. syringes and two dozen hypodermic needles. After boiling and cooling the syringes, the needles are kept boiling in a rather flat container placed on a table within easy reach of the physician's right hand all the time the inoculation is going on. They are fished out of the boiling water one by one, as needed, with a crossed surgical forceps, fastened on to the syringe's nozzle, and after the patient's inoculation replaced into the boiling water, and the next needle in the row lifted out of the water, and so on. The first needle used remains in the boiling water until one has reached the 24th, and is then employed again, having had ample time to lose all living microbes likely to be transmitted from one patient to another. In order to save time, the forceps remain in the physician's hand, held by two fingers, without ever being dropped, and the needles are never handled with the fingers. Thus it is unnecessary to allow any time for the needle to cool: the base does not touch either the physician's or the patient's skin, and the shaft, if it is of small bore (not more than 0.5 mm. external diameter), cools automatically almost instantaneously. With a little practice it is quite easy to inject while holding syringe and forceps in the same hand. If properly aided, a physician may thus inoculate about 200 persons per hour, provided they are guided right up to him so that he loses no time walking to and fro, and under practically satisfactory conditions of syringe and needle sterility, and with a limited amount of material—viz., a few large syringes, about two dozen hypodermic needles, one crossed forceps, one flat metallic container, and one electric or petrol burner.

Indwelling Tube for Gastric Haemorrhage

Dr. IVOR LEWIS (Liverpool) writes: I am in total agreement with the views expressed by Mr. V. J. Kinsella (November 18, p. 1174) regarding the importance of the use of an indwelling Ryle's tube with frequent aspirations in cases of severe haematemesis and melaena. I have recently seen two cases of peripheral circulatory failure terminating in death on the third day following gastrectomy for severe haematemesis and melaena. . . . Death was due to peripheral circulatory failure caused, in my opinion, by secondary shock following the absorption of altered blood in the intestines. . . . Unlike Mr. Kinsella, I fail to see how the blood vessels can contract in a stomach that is dilated and paralysed.

Obituary

Sir JOHN STRATHEARN, C.B.E., M.D.

Dr. W. E. Thompson writes from Winnipeg: It is only in the last few days that I have heard of the death of my old colleague and friend, Sir John Strathearn (whose obituary notice appeared in the *Journal* of September 2). My association with him became close when in 1924 I worked under him as registrar at the Ophthalmic Hospital of the Order of St. John of Jerusalem. This was a time of rather exceptional activity, since the Ophthalmic Hospital was being improved, new departments added, and the scope of work increased in special ways. Strathearn's tireless devotion to each and every patient was evident in many ways, and everyone wondered when the annual reports were issued how it was possible to do so much on the expenditure. His motto was, "The greatest good for the greatest number." Each patient, however humble, was a guest of the hospital, whether as an in-patient, out-patient, or visitor, and the same courtesy was extended to them whether they were penniless or could pay liberally. All treatment was free and given without any distinction of class, creed, or colour, and anything contributed was voluntary. A hard morning's work, when upward of 200 new cases and over 400 old cases were seen, was bound to fatigue the staff, but Strathearn conserved his energy amazingly well, though it never could have been possible without the watchful care of his wife. Many instances could be related of his prowess and unique methods of professional work, but he could not be persuaded to publish his methods and results. His aim was simplicity in everything—preparation, operation, and after-treatment. There was always a willingness to carry out new procedures after due consideration of their merit, and ophthalmic surgeons from many parts of the world felt humble in his presence. He was known as one of the ten best eye surgeons in the world. There was nothing spectacular about him or "playing to the gallery." He could not be flustered. Finesse was the rule in all his operations. He had an uncanny intuition whether an eye was good for intra-ocular interference or not. Those doctors and nurses who were fortunate enough to train under him will always remember his gentleness, personal interest, enthusiasm, and desire to help the unfortunate ones. His love of music, quiet humour, and "pawky" remarks made him delightful in company, though he was of a retiring nature and hated fuss. Even when he was persuaded to accept his knighthood there was a reticence and desire that friends should forget about it. It was an honour fully merited and gave the greatest pleasure to his many admirers, who knew that it was his sheer merit which won him that recognition. I am certain that those who were intimate with him bless the day they met him, knowing that his character lives on in the lives of so many, professional and lay, who were fortunate to have him as a friend.

Sir ERNEST GRAHAM-LITTLE, M.D., F.R.C.P.

Dame Louise McIlroy and Mr. G. F. Goodchild write: We would like to thank you for the fine and sympathetic obituary notice (October 21, p. 952) you gave of Sir Ernest Graham-Little, one of our most distinguished physicians and an upholder of the highest ethical standards of medical practice. May we, however, be allowed to amend the statement that he won his last parliamentary election by "a very few votes"? A graduate of the University of London had to pay a fee to become a registered member of Convocation, and thus only would he qualify for the vote. Therefore the actual electorate was small in number compared to the graduates represented, and in his last published election address Sir Ernest wrote of having won all "successive elections" since 1924 by "progressively increasing majorities. My majority in my last election was 13 times as large as in my first." In the parliamentary election to which you refer occurred one of the biggest landslides for the Conservative Party and independents known to history, when a wave of Labour supporters and fellow travellers had swept over our universities. Indeed, Sir Ernest's opponent, Mrs. Stocks, was reported in the public press to have boasted that "she hopes to unite the Left . . . from the Liberals to the Communists." The poll in 1945 was particularly small—a mere 15,000-odd—owing to the large numbers of graduates abroad and in the fighting Forces and to other results of the war. However, despite all this, Sir Ernest had a majority which can hardly be described as "a very few votes" when we consider that the present Labour Party came into power by an overall majority one-twenty-fifth of the number by which Sir Ernest Graham-Little won and retained his seat until the university franchise was abolished in the early part of this year.

MAX LOWENBERG, M.D.

Dr. R. T. Brain writes: Dr. Max Lowenberg, who died on November 22, was an eminent refugee dermatologist from Düsseldorf. He had been assistant in the clinic for internal diseases in Frankfurt-am-Main under Professor von Noorden and in the clinic for surgical diseases under Professor Bockenheimer. After specializing, he became chief assistant to Professor Hern in the clinic for skin and venereal diseases of the medical academy in Düsseldorf. Early in the war he came to this country as a refugee, and because of his excellent credentials he was welcomed by Professor R. A. Webb and his colleagues in the pathological department at the Royal Free Hospital. Unfortunately, until he was registered a few years ago, the only work he could be offered was that of a technician, and he settled down very contentedly to the simple tasks of cutting sections. It was a revelation to see so eminent a physician working happily and enthusiastically in this humble role. Dr. Lowenberg was quite deaf, and although he could lip-read spoken German and, astonishingly, learnt to speak good English, our communications with him had to be written. His wide knowledge of dermatology and histopathology was soon appreciated. It is probable that there was no greater authority on the histopathology of the skin in this country, and as soon as his registration could be effected after the war he was appointed senior clinical assistant to the skin department of the Royal Free Hospital, where his help with difficult cases was invaluable. The few of us at the Royal Free Hospital who knew him well regarded our association with him as an outstanding philosophical experience. He had the charm of the old-time gentleman, and his natural modesty and humility merely enhanced his intellectual brilliance. He had a severe attack of angina about a year ago, but he returned to his laboratory with all his old vigour, and none could persuade him to devote less time to the hospital. For some months before his death he seemed to know that it was imminent, but he always hoped that he would die in the laboratory that had afforded him so much interest and hospitality and in which he had made admiring friends of all. His wish was granted.

ADOLF LICHTENSTEIN, M.D.

Professor Adolf Lichtenstein, who was born in Stockholm on November 1, 1884, was on his way to the International Congress in Paediatrics at Zurich last summer when he was taken ill. Two days after his return to Stockholm on July 21 he died of a cerebral thrombosis. He was undoubtedly the outstanding figure in the Scandinavian world of paediatrics at the time of his death. This was so largely because of his tireless energy and enterprise in countless directions within his specialty: during the last three years of his professional life he published some 50 studies either alone or in association with his colleagues. His first important work appeared in 1917 and was concerned with haematological studies of prematurely born infants during the first years of life. In a series of 10 different publications he discussed the subject of scarlatina, its aetiology, prophylaxis, and treatment, and he was among the first to show that the so-called relapses from this disease may be due to reinfections with haemolytic streptococci from recent cases of scarlatina admitted to the same hospital. Applying this hypothesis in practice, he succeeded in reducing the incidence of such cases by individual isolation. Another field in which he was a pioneer was in the treatment of diabetic children, whose strict dieting used to cause much distress. The comparatively free diet he introduced was, in spite of insulin, accompanied by the risk of coma and hypoglycaemia, and it needed all his powers of persuasion and his large series of successfully treated patients to convince his colleagues of the soundness of his, at that time, unorthodox views. In conjunction with Professor Frölich, of Oslo, and Professor Monrad, of Copenhagen, Lichtenstein was the author of the standard textbook on paediatrics for students in the Scandinavian countries. He was also editor of *Acta Pediatrica* since 1946. On his retirement from the chair of paediatrics in Stockholm, this publication appeared as a 687-page Festskrift to which colleagues from the U.S.A., Holland, Switzerland, and Italy, as well as the Scandinavian countries, had contributed.

J. H. VINCENT, M.D.

Professor J. H. Vincent, the eminent French bacteriologist, died in Paris on November 23 at the age of 87.

Jean Hyacinthe Vincent was born at Bordeaux on December 22, 1862, and was educated there and at Paris. He joined the staff of the Val de Grâce Military Hospital in 1896, becoming professor of epidemiology there in 1912. In 1925 he was appointed a professor of the Collège de France, where he worked as director of the laboratory of epidemiology and infectious diseases. He was elected a member of the Académie de Médecine in 1907, and in 1940 was president of the Académie des Sciences, of which he became a member in 1922. Vincent introduced a new method of preparing typhoid-paratyphoid vaccine, which proved its value during the first world war, and his work on antibacterial sera was also fruitful. In 1894 he isolated *Nocardia madurae* (*Actinomyces madurae*), one of the organisms causing Madura foot, and two years later he first described *Borrelia vincentii* and *Fusobacterium plauti-vincenti*, which he found associated with "hospital gangrene." Later he demonstrated these two organisms in ulcero-membranous stomatitis ("Vincent's angina"). He also made important contributions to the knowledge of the aetiology and pathogenesis of tetanus. In clinical medicine Vincent published papers on occipital neuralgia, the relation between thyroid disorders and rheumatism, Graves's disease, scleroderma, and meningitis. He was a foreign honorary fellow of the Royal Society of Medicine.

Dr. H. D. A. UTIDJIAN, who was in practice in Wembley for 21 years, died suddenly at the age of 59 at his home in Kenton, Middlesex, on November 12. He had been forced for the past year by failing health to modify his unsparing services to his patients. Born in Nicosia, Cyprus, of distinguished Armenian parentage, he was educated at the University of Beirut, where he graduated in the equivalent degrees of B.A. and B.Com. He worked with the American Red Cross in 1917–18, and held the posts of medical officer at the Brumana Hospital, Lebanon, and first assistant at the Lebanon Hospital for Mental and Nervous Diseases. He proceeded to the French State Diploma of Doctor of Medicine in 1920 and in the same year came to England, where he studied at University College Hospital, taking the Conjoint qualification in 1922. He practised, always arduously, in the East End and in Kilburn before coming to Wembley. He was an honorary member of the staff of Wembley Hospital throughout his practising years and was made a life member of the British Red Cross Society for his war services as medical officer to a Middlesex detachment. He was a greatly respected member of the Armenian community in England and was prominently identified with the affairs of the Armenian Church. He was chosen to go as the English delegate to the world conference in Soviet Armenia in 1945 for the election of the Catholicos of all Armenians. He was justly proud that his mission, primarily ecclesiastical, yet semi-political, was sponsored at high level by the Foreign Office while England was still at war. He was fluent in many languages and had an expert knowledge of Levantine history, of which he had a comprehensive library. He is survived by a widow, two sons who are medical students, and a daughter who may also follow his calling. The Armenian community in England, and indeed abroad, have suffered a great loss. His Wembley patients will mourn the death of a kindly, sympathetic, and truly devoted family doctor and friend.—R. E. D.

Dr. JOHN RANKIN died at Southport on November 16 at the age of 77. Born near Londonderry, he graduated M.B. at Glasgow University in 1895, and after a short period of practice in Newtownstewart he moved to Drogheda, where in 1908 he found time to take his F.R.C.S.I. He went to Southport in 1909, and worked for 37 years in the Churchtown district of that town, retiring in 1946. He suffered for many years from severe rheumatoid arthritis, and there was a touch of true greatness in the way he rose above this handicap and carried on. He was the ideal general practitioner, accurate in diagnosis, skilled in treatment, and always a personal friend of his patient. He usually had a joke or new story to tell, and his visits alone were a tonic. It was a great privilege as well as a great benefit to work with him.—H. G. M.

Dr. ALEXANDER JOHNSTONE, medical officer of health for Greenock, died suddenly at his home on November 17 at the age of 58. He was born in Aberdeen, and was educated at Aberdeen Grammar School and Aberdeen University, graduating M.A. in 1913, and M.B., Ch.B. in 1915. He proceeded M.D. in 1928. After a short period as house-surgeon in Aberdeen Royal Infirmary, he served from 1916 to 1919 with the R.A.M.C. in Mesopotamia and India, and was awarded the Military Cross. On his return to civilian life he took the D.P.H. in 1920, and was then appointed assistant medical officer of health for the county of Angus—a post which he held for two years. From 1922 to 1927 he was assistant medical officer for the county of Dunbarton. In November, 1927, he was appointed medical officer of health for the burgh of Greenock—a post which he filled with distinction until his death. He held many local appointments, being a member of the local medical committee and the Greenock hospital board and secretary of the Greenock and District Faculty of Medicine. He was also an examiner for the Royal Sanitary Association of Scotland.

H. F. K. writes: It is no easy task to write of Alexander Johnstone. As a friend during the past 23 years of his stay in Greenock I came to appreciate his qualities year by year. He was a typical Aberdonian—friendly, cautious, and energetic. He started his appointment a young man in his prime, and

he soon revealed qualities which made him respected by all who came in contact with him. His many duties included medical officer of the V.D. Clinic and police surgeon of the burgh of Greenock. His one desire was to seek co-operation with the medical practitioners of the town. During the war years he had the task of organizing the first-aid services of the burgh. In this capacity he became known intimately to thousands of the population. Many of the former civil defence workers will remember his nightly visits to their posts from 1939 to 1945, for he always had a cheery and encouraging word for everyone. There is no doubt that these years left their mark on him physically, and Greenock owes him a great debt of gratitude. He was also a prime mover in getting the new Rankin Maternity Hospital built, and this will be a lasting reminder of his efficiency. His many other achievements towards improving the health of the community included the extension of the maternity services, the organization of local arrangements for diphtheria immunization, and the provision of day nurseries. He was always anxious to consult the general practitioners before introducing anything new, and this co-operation with us was a feature of his tenure of office. His staff were devoted to him, and they appreciated his loyalty towards them. We feel his loss greatly as a medical officer of health, a friend, and secretary of the Faculty. We respected his integrity, admired his industry, and loved him as a man. He is survived by his wife, who shared with him the appreciation of all who came in contact with them.

Dr. HENRY JOHN MACEVOY, who practised for many years in North London, died in Sticklepath, Devon, on November 17, aged 87. The earliest years of his long life were spent in France —his spiritual home. He went to school there as a young boy, but he was eventually sent to England to attend an English school. Much of his wide knowledge and logical mentality sprang from his French sympathies, and he was deeply versed in French history and literature. Before taking up the study of medicine at St. Thomas's Hospital he obtained the B.Sc.(London) with honours in 1883. He qualified in 1886 and graduated M.B. with honours in medicine in 1888. A year later he proceeded M.D. At St. Thomas's Macevoy was house-physician to Dr. Ord just at the time when Ord was working out the aetiology of myxoedema and establishing it as an entity, the honour for which he shared with Sir William Gull. Macevoy also distinguished himself at athletics, winning the inter-hospital 100 yards on at least two occasions. He continued his post-graduate studies in Paris, where he attended the lectures of Dr. G. Dieulafoy and Professor Charcot, whose theatrical displays with hysterical patients and hypnotic demonstrations he witnessed. Later he settled down in practice in Brondesbury. For many years he took an active part in the affairs of the B.M.A., having been an ex-chairman of the Willesden and Hampstead Divisions and an ex-vice-president of the Metropolitan Counties Branch.

J. L. M. writes: Macevoy was an original member of a most flourishing and friendly little medical club, the Priory Medical Society, to which I was admitted in 1895. About 15 of us met every fortnight at one another's houses, and the cases we were able to show were drawn from every class, rich and poor. Macevoy was a remarkably wise, able, and experienced doctor, not without strong opinions and prejudices. His consultations with the physicians and surgeons of his time were sometimes more controversial than usual, since when he did not agree he said so, and I think some famous specialists were careful "to pull up their socks" when going to meet Macevoy again after a first encounter. His opinion on mental cases was particularly valuable. He was always interested in myxoedema, and if he saw an obvious case of this disease in the street or in a shop he could not refrain from engaging the woman in conversation, and if her condition had been until then unrecognized and untreated he would find out the name of her doctor and give him a kindly hint about the nature of her trouble. As an obstetrician he had the complete confidence of his medical neighbours, who often sought his help with difficult confinements. Besides his professional work he had many other interests. His botanical knowledge was great, and he loved wild flowers. This was one of the great interests of his old age after he went to live in Devonshire: he was a familiar figure as he stood gazing into the hedgerows. His mental activity and power seemed quite unimpaired to the end of his life, and except when he was listening to music his mind seemed always to be actively at work. With his wide background of experience and knowledge he was an ornament to his profession.

C. H. H. writes: It cannot be the good fortune of many practitioners to be able to boast of a friendship lasting between two of them for 50 years. My friendship with H. J. Macevoy began in a meeting of medical men in one of the suburbs of London. He was typically a Frenchman, and, be it said, a non-believer in the Englishman's traditional superiority. "He is too lazy," was one of his favourite sayings. Macevoy was always keen to show his deep knowledge of French clinical medicine to a few of his friends. "Creative evolution" was his answer to many of the problems of thought; the absolute that many would lightly suggest found little favour with him. An independent thinker upon most things, he was a most careful seeker after the truth. His friendship was something to be treasured.

Dr. G. A. JONES, who was for many years anaesthetist to the Samaritan Free Hospital for Women and to the Grosvenor Hospital for Women and Children, died at Beaconsfield on November 21. He was the son of an Essex clergyman, and his younger brother was the late Lawrence Jones, F.R.C.S., who died in July, 1949. George Arthur Jones was educated at St. Paul's School, Oxford University, and St. George's Hospital. He took an arts degree at Oxford before studying medicine. He qualified L.S.A. in 1902, and after holding house appointments at St. George's Hospital he took up anaesthetics as a specialty. Like his brother, with whom he lived for many years, he was of an essentially modest and unassuming disposition; this endeared him to very many friends.—H. R.

By the death of Dr. JOHN BROADLEY on November 24 at the age of 76 Sheffield has lost a well-known member of the medical profession. He was born at Keighley and educated at the local grammar school. He entered the medical school at Leeds in 1891 and obtained the M.B. degree of the University of London in 1897 as an external student. After holding a resident appointment as house-surgeon in the Leeds General Infirmary, he decided to widen his experience by acting as a locumtenent in the district, and for a time he was an assistant to a general practitioner in Wakefield. In 1900, having developed a liking for surgery, he became a house-surgeon in the ear, nose, and throat department of the Leeds General Infirmary, and in 1901 came to the Royal Infirmary, Sheffield, as a house-surgeon. Later he held the post of resident surgical officer for a year. In 1902 he obtained the diploma of F.R.C.S. (Edinburgh) and in 1903 the degree of B.S. of the University of London. He began general practice in Sheffield in 1903, and when the University of Leeds in 1905 obtained its charter to grant its own medical degrees he immediately graduated M.B., Ch.B. at that university. While in practice as a general practitioner he did most of the operations required by his patients, and in 1909 he was appointed an honorary surgeon to the Children's Hospital in Sheffield. He retained this post until 1935, when he retired, having reached the age limit. He was also for many years honorary medical officer of the x-ray and electrical department. At the outbreak of the first world war he joined the R.A.M.C. and served on the staff of the 3rd Northern General Hospital. In 1917 he went to France, being attached to the 59th General Hospital at St. Omer. He was awarded the King Albert Medal for his work there.

E. F. writes: John Broadley was an outstanding example of a type of practitioner who is rapidly disappearing—the competent, efficient, and well-read general-practitioner surgeon. Under the National Health Service this type will soon be a thing of the past, but it should be understood that these men played a very important part in the evolution of modern surgery. They probably practised more pure medicine than operative surgery, and it was this which gave them such a wide outlook. They knew full well their limitations and were never too proud to ask for help from others with more experience in particular surgical procedures. Broadley was appointed to the surgical staff of the Sheffield Children's Hospital at a crucial time in its development, and the position it holds to-day in the paediatric world is due in no small degree to his self-sacrificing work there. During the first world war he did much for the wounded and sick, both before and after the period of his service abroad. The men had, like his own patients, the greatest confidence in his skill as a surgeon, and this was supplemented by his kindliness and humane attitude in treating their disabilities. In all his dealings with colleagues and patients he had the same, perhaps sometimes blunt, but always straightforward method of approach which he had inherited from his Yorkshire forebears. This was very noticeable in his treatment of injured miners and colliery workers whom he examined for the Yorkshire Coal Owners' Federation. Many owe much to his sympathetic but firm handling of their case. He will be missed by them as he will be by his former patients, friends, and colleagues, who sympathize with his widow and two daughters in their loss.

Dr. JAMES LESLIE BARFORD died suddenly on November 29, after a brief illness, in Redhill County Hospital, at the age of 67. The fourth son of Dr. James Gale Barford, who was the first medical officer to Wellington College, he was educated at Epsom College and King's College Hospital, where he was house-surgeon to the late Mr. Barrow. He qualified M.R.C.S., L.R.C.P. in 1905, and almost immediately entered the Royal Navy, in which he served till 1919, becoming the youngest surgeon-commander in the Service at the end of the first world war. He then transferred to the Merchant Navy, serving for many years, mainly with the P. and O. line, and travelling to most parts of the world. Later he became interested in mental health, and worked as a locumtenent at mental hospitals in Lincoln and Ipswich. In 1938 he became assistant medical officer at the Royal Earlswood Institution, and, a year later, at the comparatively late age of 56, he took the D.P.M. During the second world war he was medical officer to the Surrey County Council civil defence organization, to which he devoted characteristic enthusiasm and ingenuity in planning and in the teaching of first aid. In 1946 he spent nine months in the Antarctic with the first post-war whaling expedition to leave this country, as medical officer to s.s. *Southern Venturer*, and he carried out much research into the collection and large-scale manufacture of various glandular products. On his return his desire for adventure soon reasserted itself and he joined the Post Office telegraph department as medical officer on H.M. Telegraph Ship *Alert* and later on H.M.T.S. *Monarch*. Barlow remained a bachelor, and during his varied career he made great numbers of friends in all countries and walks of life. He had a special delight in the company of youth, on whom he was an unfailing influence for good. Often whimsical, with a constant sense of humour and possessed of a certain literary gift, he made several original and refreshing contributions to the pages of this *Journal*.—F. J. C.

Professor EMIL ABDERHALDEN, known throughout the world for his physiological research, died in Zurich on August 5 aged 74 after a cerebral haemorrhage. He was born on March 9, 1877, the son of a Swiss schoolmaster. He studied medicine in Basle, and, after receiving his doctorate in 1902, he went to Berlin to work with Professor Emil Fischer on protein chemistry. His earliest important publication appeared in 1904 and was a complete scientific bibliography on alcohol and alcoholism. He himself was an ardent worker for temperance. His book on physiological chemistry proved extremely popular, running through 26 editions in 42 years. He worked on protein chemistry, digestion, and enzymes from 1902 to 1908. He became a professor in 1908 and followed Munk at the Veterinary University in Berlin. In 1909 he started editing the immense *Handbuch der biologischen Arbeitsmethoden*. He was appointed to the chair of physiology in Halle in 1911, and won the Helmholtz Prize in 1913. From this time dates his interest in mental hygiene and social problems. He founded a children's hospital in 1915, and interested himself in the smallholding movement. He was also active in sending undernourished German children to Switzerland after the 1914–18 war. In 1921 the Swedish Medical Association gave him the Berzelius Medal. He founded two journals, one on enzyme research and one on ethics. In the autumn of 1945 he and his family were obliged to leave Halle and return to Switzerland, where he became emeritus professor in Zurich. He was a modest and deeply religious person, a clear thinker, and a born teacher. He is said to have dictated his entire *Textbook of Physiological Chemistry*, together with the references, from memory.

Medical Notes in Parliament

Kingston Dispute

On December 7 Mr. J. BOYD-CARPENTER asked Mr. Bevan whether he had considered the proposal of the British Medical Association that a public inquiry be held in connexion with the dispute over the future use of the Kingston Victoria Hospital; and what action he proposed to take.

Mr. A. BEVAN said the future of this hospital had been fully and carefully reviewed, both by the regional board and by his own Department, and had been the subject of a debate in the House. He certainly did not think that the proposed inquiry would either be appropriate or add to their knowledge, and he saw no reason to intervene.

Mr. BOYD-CARPENTER pointed out that no opportunity had been given for local opinion to express itself directly to those responsible.

Mr. BEVAN said he did not believe that any better court of inquiry existed in Great Britain than the House of Commons on a matter of this kind.

Mr. SOMERVILLE HASTINGS asked whether Mr. Bevan agreed that in hospital management the opinion of experts was more important than local opinion.

Mr. BEVAN said that was the view which had been taken by the management committee and the regional hospital board with all the facts before them. If this matter had not been sufficiently ventilated he would be happy to recount these facts again.

Colonel M. STODDART-SCOTT asked whether it was true that Mr. Bevan, during the passage of the National Health Service Bill, had again and again advocated the establishment of general-practitioner hospitals, but that ever since the passage of the Act he had closed one general-practitioner hospital after another.

Mr. BEVAN said this statement was as prejudiced and inaccurate as most of Colonel Stoddart-Scott's statements.

Mr. BOYD-CARPENTER gave notice that he would raise the matter again.

River Pollution

Mr. ANEURIN BEVAN, on November 27, moved the second reading of the Rivers (Prevention of Pollution) Bill founded on the agreed report of the expert Central Water Advisory Committee. Their main object was to make a survey of the rivers and to lay down standards, and the river boards would be advised by technical bodies on the degree of purification which they could reasonably demand for particular effluents. The technical knowledge of how to control industrial effluents was in its infancy, and protection of rivers and streams would have to be done gradually over the years.

Mr. WALTER ELLIOT said the Bill really attempted to define under what conditions rivers could be polluted.

After some debate on individual rivers Mr. JOHN MORRISON said that, with some of the modern spraying chemicals, pollution from farm drainage might in future be important.

Sir HUGH LUCAS-TOOTH asked what the Government intended to do about pollution by cottagers in rural neighbourhoods who simply upset their sewage into the river.

Mr. A. BLENKINSOP said that the Ministry expected that a series of standards would be laid down for the different reaches of the rivers, and in each case there would be a gradual improvement. Under the Bill it would be possible to apply the

definition of a stream to the tidal reaches of a river without having to establish a connexion between public health and the amount of polluting matter in the water.

The Bill was read a second time without a division.

Domiciliary Physiotherapy

Mr. KENNETH THOMPSON on December 4 raised the need for domiciliary physiotherapy services. Some people for whom the treatment was prescribed, such as sufferers from cardiac complications, heart disease, old age, and advancing infirmity, could not attend hospitals and clinics where the regional hospital boards provided physiotherapy. Several regions had contractual arrangements with district nursing associations and private practitioners to take the service to such patients. All these regions now appeared to have received instructions to terminate the contracts, and had been told that

The shortage of adequate trained personnel, which will continue for an indefinite period, makes it imperative to concentrate them in hospital departments.

He had found no clear statement of whether this was to secure the fullest use of skill in short supply, or to ensure that the patient received adequate treatment, or on the grounds of economy. Physiotherapists would in all probability continue in the service of the nursing associations and would be used less rather than more after the instruction was put into operation. The Ministry of Health had declared that the system of contracting with other agencies had proved to be expensive, but Mr. Thompson said that in Liverpool it cost the board not more than 9s. a treatment. In another part of the country the cost to the board was 11s., and in a third 14s. He asked if the Minister wanted the House to believe that any system he could establish would provide treatment at a lower cost than that. The cost of transport of a patient to hospital in an ambulance was about 20s. a trip. The regions should be entitled to decide a matter like this themselves, and, where they could arrange an efficient and inexpensive service, should not be subject to this kind of blanket instruction.

Mr. A. BLENKINSOP, replying for the Ministry, said their chief concern was with the welfare of the patient. Those who on medical grounds required physiotherapy in their homes would continue to receive it, but he had to insist that physiotherapy provided in the home was a poor second-best to that provided in the medical surroundings of a hospital or clinic properly fitted out for the purpose. With old people the important question was to give active treatment, and not to let it be regarded as a natural part of the life of the patient. That was the great danger with treatment at home, which few old people needed. It was obvious that the amount of equipment which could be provided with a domiciliary team was limited compared with provision in hospital. It was not economical that trained staff should wander about the country giving individual treatment instead of providing treatment for several patients together in a clinic. The experience of the Ministry had been that when contracts of the sort under discussion had been made, whether with an organization or with individual physiotherapists, there was a danger of a gradual growth of demand which could not properly be regarded as medical. The Ministry was concerned not merely with sifting out those who could be regarded in the initial stages as medical cases, but also with ensuring that it had a reasonable control over how long the treatment continued. The difficulty with domiciliary treatment was that it tended to become permanent, instead of being a method of ensuring that patients could later go to a hospital for treatment, which would be much better for them. Discussions were going on with the regional boards to work out ways in which the problem could be overcome, either by use of existing hospital staff or by appointments of part-time or full-time physiotherapists. If that should prove impossible, the Ministry would look into the matter again, to ensure that the service was provided for those who really needed it.

Pneumoconiosis

At the close of a debate on Welsh affairs in the House of Commons on December 5, Mr. NESS EDWARDS said that 6,000 sufferers had gone back to the pits, and they complained that if they became worse they could not get increased compensation. He was authorized to say that Dr. Edith Summerskill had consulted the Industrial Injuries Advisory Council and was willing to make regulations to enable these men to get Industrial Injuries benefit.

Mr. EMRYS ROBERTS asked whether this would apply to slate quarries.

Mr. NESS EDWARDS said that if the concession came under the general Industrial Injuries Regulations he imagined it would, but a question should be put on the subject to Dr. Summerskill. He believed that under the auspices of the Ministry of Fuel and Power a new method of extracting the dust had been devised, and they hoped the quarries would introduce these new methods and conquer the fear of pneumoconiosis among slate-quarry workers.

Among 32,000 unemployed in South Wales 10,000 were disabled workers, and one-third of these were pneumoconiosis cases. In the last five years 15,000 men had left the mines with pneumoconiosis, and, in spite of all the efforts to get these men into employment, more were getting on to the unemployment register.

Central Buying for Hospitals

Mr. A. BEVAN, in reply to a question on December 7, stated that central contracts were placed for *x*-ray equipment and films, laboratory and blood transfusion apparatus, spectacles, rubber goods, and certain scarce and costly drugs. Hearing-aids were purchased under contract by the Post Office, surgical and orthopaedic appliances by the Ministry of Pensions, and occupational therapy equipment and invalid tricycles by the Ministry of Works. He added that he intended, as soon as practicable, to extend these arrangements to cleaning materials and hardware, bedding, cotton and woollen textiles, drugs and dressings, and other common-user goods. Net savings could not be precisely calculated, but were not less than £2½m. to £3m.

Registrars

Mr. A. BEVAN on December 7 said that he had suggested to hospital boards a transfer system whereby registrars of non-teaching hospitals would spend a portion of their training period at teaching hospitals and vice versa.

Mr. NIGEL DAVIES pointed out on December 7 that, whereas Mr. Bevan had proposed that the number of hospital registrars and senior registrars in England and Wales should be cut from 2,800 to 1,700, it was proposed that the cut in the North-east Metropolitan Region should be from approximately 300 to 134.

Mr. BEVAN replied that the reduced number represented the share of the total which he thought appropriate to that region, taking into account its population, the number of consultants, the available training facilities, and the number of beds there compared with the country as a whole. In the South-west Metropolitan Region there were about 320 senior registrars and 320 hospital registrars (including teaching hospitals), and the new establishments were to be 83 and 151 respectively.

The Capitation Fee

In reply to a question on December 7 Mr. A. BEVAN replied that he had always preferred the idea of a graduated system, with a higher capitation rate for the first 1,000 or so patients on the doctor's list. This would discourage the accumulation of over-large lists and encourage the better-balanced practices. It was not always easy to translate idea into fact; he wanted to go into it very thoroughly with the profession.

Smallpox.—Figures in the Registrar-General's Weekly Returns relate to original notifications, though the disease may afterwards be shown not to be smallpox. Figures in the Registrar-General's other publications relate to corrected notifications.

Diphtheria.—The numbers of original notifications of diphtheria in 1947, 1948, and 1949 were 10,465, 8,035, and 4,982 respectively; after correction they were 5,592, 3,560, and 1,881.

Gifts to Hospitals.—Where the benefit of a gratuitous covenant in favour of a named hospital has been transferred under the National Health Service Act, 1946, to the Hospital Endowments Fund the distribution of money is regulated by statute and the Minister of Health has no power to vary it by a direction. Hospital management committees should have regard to the original intention of the gift in the use made of their shares.

Clean Food.—The Minister of Food announced that up to November 17 he had confirmed model by-laws governing cleanliness in the handling, wrapping, and delivery of food for 973 authorities, and was shortly to do likewise for a further 260; but 211 authorities were still outstanding.

Exemption from National Service.—Men exempt on medical grounds (excluding men not examined, because blind, etc.) in 1946 numbered 39,964; in 1947, 24,648; in 1948, 24,711; in 1949, 33,818; in 1950 (to September 28), 34,506.

Housing.—In Liverpool 27,328 houses are classified by the Liverpool medical officer of health as unfit for human habitation.

Medico-Legal

DEATH DUE TO A SWAB

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

In spite of the strict precautions taken in all operating theatres, now and again a swab still eludes the vigilance of the team. In a recent case the victim was a girl aged 2 who was brought into the Warwick Hospital for an emergency operation to relieve torsion of a dermoid cyst in the region of the left ovary. She made a good recovery and was sent back in due course to the sanatorium from which she had been admitted, where she was under treatment for advanced tuberculosis of the lungs. About 11 weeks afterwards she was readmitted for abdominal pain and vomiting. A tumour was palpable in the mid-abdominal region, but radiography gave no assistance in diagnosis. There was no evidence of obstruction. She settled down very rapidly, and, in view of the tuberculosis and the finding at the operation of enlarged mesenteric glands, the surgeon thought that her symptoms might be due to a plastic tuberculous peritonitis with further enlargement of the glands. He therefore decided to observe her and treat her conservatively. She continued to improve up to the fourth day after admission, when she suddenly collapsed and died. At necropsy the palpable mass in the abdomen was found to be a swab which had become encysted and adherent to a loop of small bowel.

The case was therefore reported to the coroner, who held an inquest on August 29. The surgical registrar who performed the operation said that great care was always taken over the counting of swabs both before use and after the closing of the abdominal cavity. He might, on account of the child's small size, have used a "large six" swab as a pack instead of an ordinary pack, but even so it should have been counted with the other swabs. He maintained that, when the child was brought in for the second time, there had been no evidence of obstruction, and the diagnosis of the condition as a result of her tuberculosis was clinically right. The theatre sister explained in evidence that large swabs ("big sixes") were counted before and after an operation; small swabs were not counted but were always used on a holder. The night, however, had been hot, and the surgeon might have had to have his brow wiped. If this were done with an unsterilized swab it might have been picked up and included in the count. The theatre technician, whose task had been to check the swabs, described how an operation was usually begun with 24 "big sixes" and two abdominal packs, which were all checked. During the operation it was his custom to collect all the used swabs and lay them in a special rack until six were used; those were then taken out of the rack, placed in a bucket, and marked off on the graph which he used for keeping the count. If extra swabs were taken into use they also were marked on the graph. He was certain that the routine had been observed on that occasion. It was his duty to wipe the surgeon's brow, which he did with an unsterile swab which he would put into his pocket.

The jury found that the little girl had died from intestinal obstruction by a surgical swab inadvertently left in the abdomen during the operation. They added two riders: (1) that thought should be given by the hospital authorities to devising a scheme by which swabs used for packing could be recorded and recovered, and (2) that a record should be kept by the hospital of all the persons engaged in an operation.

In a letter to the senior officer of the Birmingham Regional Board the acting deputy coroner, Mr. L. D. Overell, suggested that in their first rider the jury might have been referring to the possible use of a "big six" as a pack, and have considered it desirable for any material used for packing to be quite distinct from ordinary dressings. The second rider referred to an uncertainty in regard to the identity of the assistant to the theatre sister, which had caused an adjournment. The surgeon, he added, had immediately given instructions that in future some quite different material, which could not be mistaken for a dressing, should always be used for wiping the surgeon's brow. The coroner went on to say that all the usual routine drill to prevent a mishap of this kind appeared to be in operation at the Warwick Hospital; but he expressed the personal opinion that, as quite well educated persons were frequently faulty in arithmetic, such an accident could easily be due to a failure by a harassed theatre sister to add correctly the numbers of the used and the unused swabs. Whether this or the use of a swab for the surgeon's brow is the true explanation, this case has pointed to another possible source of what is fortunately an extremely rare mishap.

Universities and Colleges

UNIVERSITY OF OXFORD

The Weldon Memorial Prize for 1950 has been awarded to Lionel Sharples Penrose, M.D., Galton Professor of Eugenics, University College, London.

UNIVERSITY OF CAMBRIDGE

In Congregation on December 2 the following degrees were conferred:

M.A.—Oswald Lloyd, M.D., F.R.C.S., M.R.C.O.G., Associate Lecturer in the Faculty of Medicine.

M.D.—P. Sainsbury, G. M. Fleming, W. L. Calnan, H. Butler.

M.B., B.CHIR.—*Ion-Dan Edeleanu.

A Grace recommending the conferment of the degree of M.A. upon Janet E. Bottomley, M.D., F.R.C.S., M.R.C.O.G., Associate Lecturer in the Faculty of Medicine, passed the Senate on December 2.

*By proxy.

UNIVERSITY OF GLASGOW

On December 1 the degree of Ph.D. was confirmed *in absentia* by diploma upon C. Mukherjee, M.B., Ch.B.

UNIVERSITY OF LONDON

The following candidates have been approved at the examination indicated:

THIRD M.B., B.S.—[1 3]D. Burman, [1 6]M. W. Cemlyn-Jones, [1 2]P. J. Chapman, [1 2 5]S. S. Epstein, [1 5]D. I. Fryer, [1 7]L. G. Goodwin, [1 5]P. E. B. Holmes, [1 4]C. B. Ingor-Willey, [1 5]R. P. V. Jayewardene, [1 5]R. S. Jelliffe, [1 2 4 6 7]D. J. Jenden (*University Medal*), [1 4]N. MacDonald, [1 5]F. W. O'Grady, [1 2]T. H. Roffe, [1 6]M. K. Sawday, [1 6]G. Walker, R. G. Adams, D. G. E. Alldridge, J. D. B. Andrews, B. Bass, D. A. Begg, Marion Berry, C. N. Best, Margaret E. Beynon, N. P. Bhandari, Irene F. A. Blakeney, A. G. Blyth, Elizabeth M. Bough, J. Ll. Bowen, Betty B. UNIVERSITY OF BIRMINGHAM

In the *Journal* of December 2 (p. 1286) we announced the appointment of Mr. Alexander Innes as University Lecturer in Minor Operative Surgery. The announcement should have read that Mr. Innes has *resigned* from the post.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

At the annual meeting of the College held on November 30, with the President, Sir David K. Henderson, in the chair, the following were elected to the Council: Dr. W. A. Alexander, Dr. D. J. A. Kerr, Dr. D. N. Nicholson, Dr. R. M. Murray-Lyon, Dr. J. G. M. Hamilton, Dr. T. Anderson.

Sir David Henderson was re-elected President for the ensuing year and Dr. Alexander was re-elected Vice-president.

At a meeting of Council held on December 5, the following were elected office-bearers for the ensuing year: *Trustees*, The Treasurer, Dr. A. Fergus Hewat, Dr. W. D. D. Small, Professor Thomas Ferguson, Mr. I. Simson Hall; *Treasurer*, Dr. J. Alastair Bruce; *Secretary and Registrar*, Dr. J. Halliday Croom; *Honorary Librarian*, Professor D. M. Lyon.

CONJOINT BOARD OF IRELAND

The following candidates were duly admitted licentiates in medicine and midwifery on December 1, having passed the final examination in medicine, surgery, and midwifery of the Conjoint Board of Ireland: Eleanor A. Bolger, Alice Boushel, J. P. Cahill, James Connolly, Dorothy J. Davis, M. J. Foley, Carmel P. Gibson, V. J. Haslan, Mabel Jackson, Sheila Moriarty, Mary J. McCann, Helena M. McManus, M. P. McPartlin, Maureen B. O'Gorman, A. P. O'Kelly, M. P. O'Reilly, Sheelah K. O'Shea, R. A. Power, S. J. Raverty, A. Rudnick, W. E. Rutherford, Dympna E. Sharkey, W. S. Snow, C. M. Watson, Avril M. Webb, J. R. White, J. E. Whyte, C. E. Wilson.

The Services

The *London Gazette* has announced the appointment as M.B.E. (Military Division) to Temporary Surgeon Lieutenant-Commander D. S. Macphail, R.N.V.R., for courage, skill, and determination when he was dropped by parachute into Yugoslavia in May, 1944, and, in spite of the very primitive conditions and the scarcity of medical supplies, established a hospital for the Partisans.

Medical News

Plan for New Medical Centre

London University has just acquired property in Bloomsbury at the corner of Guilford Street and Millman Street almost opposite London House, the hostel for postgraduate students from the Dominions, and hopes to build there, as soon as circumstances permit, a headquarters for the British Postgraduate Medical Federation. This new centre will be within easy reach of the Institutes of Neurology in Queen Square, of Child Health in Great Ormond Street, of Ophthalmology in Judd Street, and of Laryngology and Otology in Gray's Inn Road, and will probably contain a refectory and common-rooms and be a social as well as an administrative centre.

A Medical Christmas Present

The last 50 years have seen astounding developments in medicine and surgery, in public health, and in medical administration. In a well-designed book of 330 pages, in an attractive dust-jacket and beautifully bound in red cloth boards with gold lettering on the spine, the articles on "Fifty Years of Medicine" which appeared originally in the special issue of the *British Medical Journal* for January 7, 1950, have now been reprinted. There are over 300 text pages, a 16-page index, and 32 pages of illustrations on art paper, and the price is 15s. through booksellers, or post free from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Chelsea Clinical Society

The second meeting of the session was held on November 14, at the South Kensington Hotel, with the president, Mr. Geoffrey Parker, in the chair, when Mr. Dickson Wright, M.S., F.R.C.S., showed a series of films from the B.M.A. library: "Radioactive Isotopes in Cancer of the Thyroid," "Thrombosis and Embolism," "Infections of the Hands," and "Total Retro-Pleural Sympathectomy for Relief of Hypertension."

Medical Films for Pathologists

In 1946 the Scientific Film Association issued a *Catalogue of Medical Films*, which has now long been sold out. While a new edition is in preparation, the association is issuing up-to-date interim lists of films on special subjects. A list of films for nurses is on the way, and a list of *Films of Interest to Pathologists* (publication 60) is now available, price 2s. 6d., from 4, Great Russell Street, London, W.C.1, or 16–17, Woodside Terrace, Glasgow, C.3.

Cortisone Summary

Some 90 papers on cortisone and A.C.T.H., mostly published this year in British or American journals, have been summarized conveniently in a 48-page booklet just issued by the Empire Rheumatism Council from Tavistock House, Tavistock Square, London, W.C.1, price 5s.

Centenary of Bernhard Baron

December 5 was the hundredth anniversary of the birth of Bernhard Baron, and also marked the end of the distribution of the funds of the two charitable trusts he founded, in accordance with his order that all money must be given away within 20 years of foundation. In addition to orphanages, homes for cripples and old people, and institutions for the blind, many hospitals have benefited from large gifts, including the Middlesex (£61,000), which has a wing named after him, Queen Charlotte's (£75,000), and the Hospital for Sick Children (£14,000). The Royal College of Obstetricians and Gynaecologists received £10,000 for a travelling scholarship and the Royal College of Surgeons £70,000 to establish research laboratories and a professorship. In all £1,625,922 has been distributed to many hundreds of institutions not supported by the State or local rates. A maximum of one-quarter of one fund, and one-fifth of the other, have been devoted to Jewish charities, as the donor laid down. At his death in 1929 Baron's estate was worth nearly £5m., while during his life he had given away about £2m. in charity. This wealth came primarily from the manufacture and sale of cigarettes, in particular from his firm, Carreras Ltd.

Baron was born in Russia of Jewish parents, and moved as a boy to the United States where he got work in a New York tobacco factory just at the time when cigarettes were first devised. After various early misfortunes, including the loss of his savings in a bank failure in 1874, he began to prosper with a cigar factory in Baltimore, and from 1890 to 1895 was managing director of the National Cigarette Tobacco Company of New York. During this time he invented a cigarette-making machine, and when he came to England in 1895 he formed his own company to exploit its use. To sell his cigarettes in competition with the Imperial Tobacco Company, he bought the small London tobacco business of J. J. Carreras in 1903, and built it up to its present large and wealthy form.

Jordan Medical Journal

This first medical periodical to be published in the Hashimite Kingdom of the Jordan will include papers in English and Arabic, and will appear six times a year. The editor is Dr. Wasif Kana'an, P.O. Box 256, Amman, Jordan.

In Brief

Professor R. E. Lane, M.D., F.R.C.P. (Nuffield professor of occupational health in the University of Manchester), Professor J. M. Mackintosh, M.D., F.R.C.P. (professor of public health, University of London), and Sir Hugh E. Griffiths, C.B.E., F.R.C.S. (a consulting surgeon), are the medical members of the Industrial Injuries Advisory Council.

Professor Ange Catacuzinos, director of the neuro-psychiatry unit at the Evangelismos and Pammakaristos Hospitals in Athens, is in Britain, December 3–19, and is lecturing at the National Hospital, Queen Square, London, W.C.1.

The Secretary of State for Scotland has appointed Mr. James South, senior partner of an Inverness firm of solicitors, to be chairman of the Northern Regional Hospital Board.

Dr. H. Gardiner Hill has been elected president and Dr. J. G. H. McNabb captain for the 1951 season of the Medical Golfing Society.

Wills

Dr. George Taylor, of Coldingham, Berwickshire, late of Edinburgh, left £21,132; Dr. James Lyons, late police surgeon in Lincoln, left £23,835; Mr. Howard Stevenson, of Belfast, a former member of the Northern Ireland Parliament, left estate in Great Britain and personal estate in Northern Ireland valued at £9,266; Mr. M. T. Williams, of Aberystwyth, £34,372; Dr. H. G. Stacey, of Harrogate, formerly in practice in Leeds, £19,184; Dr. E. C. Carter, of Enfield, £69,801.

COMING EVENTS

Franco-Anglo-American Medical Society

A business meeting will be held on Tuesday, December 19, at 2.30 p.m., at 11, Chandos Street, Cavendish Square, London, W.1.

Association of Clinical Pathologists

The winter meeting of the Association of Clinical Pathologists will be held at Westminster Hospital, London, S.W., on January 25, 26, and 27, 1951.

International Congress of Clinical Pathology

This will be held in London, July 16–20, 1951, under the presidency of Sir Lionel Whitby. The scientific meetings, which will be held in English and French, are to be grouped under the headings of microbiology, haematology, morbid anatomy, and chemical pathology. Travel and hotel arrangements are in the hands of Messrs. Thos. Cook and Son, Ltd., and for all other matters the secretary is Dr. W. H. McMenemey, Maida Vale Hospital for Nervous Diseases, London, W.9.

American Academy of Forensic Sciences

The second annual meeting of the American Academy of Forensic Sciences will take place in Chicago on March 1–3, 1951. Further particulars of this meeting can be obtained from Dr. R. B. H. Gradwohl, 3514, Lucas Avenue, St. Louis 3, Mo., U.S.A.

German Society for Internal Medicine

The 57th meeting of the Deutschen Gesellschaft für Innere Medizin will be held at Wiesbaden, April 2–5, 1951, under the chairmanship of Professor M. Bürger, of Leipzig. The chief topics are the relation between hypophysis and adrenal; changes in the clinical picture of thyroid disease, lung cancer and its treatment, physical and biological basis of ultrasonic treatment, endocrine aspects of the relation between diabetes and tuberculosis. Those proposing to read papers must submit a summary before January 15. Further information can be obtained from Professor Fr. Kauffmann, (16) Wiesbaden, Städt. Krankenanstalten.

Italian Tuberculosis Congress

The 10th Italian Congress of Pulmonary Tuberculosis will take place at Naples on April 3–8, 1951. Further particulars of the Congress may be obtained from the Secretary of the Congress at the Istituto "Principi di Piemonte," Naples.

International Gynaecological Congress, 1951

The Congrès International Jubilaire de la Société Française de Gynécologie will be held in Paris on June 23–29, 1951. Further particulars may be obtained from Dr. Maurice Fabre, 1, rue Jules-Lefebvre, Paris 9e, and information regarding the exhibition at the congress from M. André Pecker, 74, boulevard Haussmann, Paris 8e.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday

●INSTITUTE OF NEUROLOGY, National Hospital, Queen Square, London, W.C.—December 18, 5 p.m., *"Aphasia in Children,"* by Dr. Macdonald Critchley.

INSTITUTE OF OPHTHALMOLOGY, Judd Street, London, W.C.—December 18, 5.30 p.m., *"Visual Pigments,"* by Dr. H. J. Dartnall.

●ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.—December 18, 3.45 p.m., *"Analgesic Drugs,"* by Dr. C. A. Keele.

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—December 18, 4 p.m., *"Optics"* (Revision), by Mr. H. N. Reed.

●ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—December 18, 5.30 p.m., *"Anatomy of the Eye and Orbit,"* by Professor T. Nicol.

Tuesday

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C., December 19, 5.30 p.m., *"Respiratory Chemistry of the Blood,"* by Professor F. J. W. Roughton, Ph.D., F.R.S.

EUGENICS SOCIETY.—At Royal Society, Burlington House, Piccadilly, London, W., December 19, 5.30 p.m., *"The Ideal of an Elite,"* by Mr. Paul Bloomfield.

INSTITUTE OF OPHTHALMOLOGY, Judd Street, London, W.C.—December 19, 5.30 p.m., *"Ocular Tuberculosis,"* by Mr. P. McG. Moffatt.

INSTITUTE OF UROLOGY (UNIVERSITY OF LONDON).—At St. Paul's Hospital, Endell Street, London, W.C., December 19, 5 p.m., *"Stress Incontinence in the Female,"* by Mr. Harland Rees.

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—December 19, 5 p.m., *"Science and Art of Refraction,"* by Dr. T. H. Whittington.

Wednesday

INSTITUTE OF UROLOGY (UNIVERSITY OF LONDON).—At St. Paul's Hospital, Endell Street, London, W.C., December 20, (1) 3.30 p.m., demonstration of museum specimens by Mr. H. G. Hanley; (2) 5 p.m., *"Incontinence in the Male, Atony of the Bladder, and Enuresis,"* by Mr. D. I. Williams.

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—December 20, 4 p.m., *"Clinical Ophthalmology"* (Revision), by Mr. R. A. Burn and Mr. R. P. Crick.

Thursday

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.; December 21, 5.30 p.m., "*Respiratory Chemistry of the Blood*," by Professor F. J. W. Roughton, Ph.D., F.R.S.

INSTITUTE OF UROLOGY (UNIVERSITY OF LONDON).—At St. Paul's Hospital, Endell Street, London, W.C., December 21, 5 p.m., "*Infertility in the Male*," by Mr. A. R. C. Higham.

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—December 21, 5 p.m., "*Methods of Examination*," by Mr. C. M. Shafto.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, Hyde Park Corner, London, S.W.—December 21, 4.30 p.m., lecture-demonstration on psychiatry by Dr. M. A. Partridge.

APPOINTMENTS

CROYDON GROUP HOSPITAL MANAGEMENT COMMITTEE.—The following appointments at the hospitals indicated in parentheses are announced: *Consultant Venereologist*, Joan Halstead, M.B., Ch.B. (General Hospital); *Resident Anaesthetist*, T. R. Bomonji, M.R.C.S., L.R.C.P. (General Hospital); *Casualty Officer*, W. E. O'Hara, M.D. (General Hospital); *Junior Obstetrical Registrar*, D. J. Cassidy, M.B., B.S. (Mayday Hospital); *Obstetrical House Officer*, A. K. Doust, M.R.C.S., L.R.C.P. (Mayday Hospital); *Assistant Medical Officer (Surgical)*, D. O'Keeffe, M.B., B.Ch. (Mayday Hospital); *Anaesthetist Registrar*, Mary Connolly, M.B., B.Ch. (Mayday Hospital); *Casualty Officer*, D. W. Heustis, M.D. (Mayday Hospital); *Consultant Radiologist*, D. W. Seth-Smith, M.R.C.S., L.R.C.P., D.M.R. (Croydon Group).

DUIGNAN, JAMES, M.B., B.Ch., D.P.H., Assistant County Medical Officer of Health, County Mayo, Eire.

MILLER, R. G., M.B., M.R.C.P., Resident Medical Officer, Manchester Royal Infirmary.

SMYTH, MICHAEL J., M.Ch., F.R.C.S., Consulting Surgeon to the Jockey Club; Consulting Surgeon to the National Hunt.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Beaton.—On November 13, 1950, to Betty (formerly Dr. Elizabeth S. Bayne), wife of Donald Beaton, M.B., Ch.B., D.A., 92, Bonnymuir Place, Aberdeen, a daughter.

Davidson.—*On November 3, 1950*, at Nicosia General Hospital, to Helen Audrey Davidson, M.B., B.Ch., B.A.O. (formerly Lynas), wife of Mr. Malcolm Norman Davidson, Colonial Administrative Service, Cyprus, a daughter.

Hingston.—On November 9, 1950, at Leeds, to Dr. Etheline (formerly Brady), wife of Dr. James Hingston, 19, Bainbrigge Road, Headingley, Leeds, a daughter.

Sloan.—*On December 7, 1950*, to Mairi, wife of Dr. J. Burnley Sloan, High Corner, Ardnave Crescent, Bassett, Southampton, a son—Gordon Burnley.

MARRIAGES

Pearce—Thompson.—On December 2, 1950, at Llanishen, Cardiff, Douglas John Pearce, M.B., B.S., to Margaret Patricia Thompson, S.R.N.

Sidebotham—Jefferies.—On December 2, 1950, at Wilmslow Parish Church, Robert Noël Sidebotham, M.B., B.S., to Patricia Mary Jefferies, M.C.S.P.

DEATHS

Barford.—On November 29, 1950, in hospital, James Leslie Barford, M.R.C.S., L.R.C.P., D.P.M., of 2, Earlswood Road, Redhill, Surrey.

Benton.—On December 5, 1950, at Broughton Corner, Thornton Road, Thornton Heath, Surrey, *William Benton*, M.R.C.S., L.R.C.P., D.P.H., J.P., also of 35, Robson Road, Worthing, Sussex, aged 82.

Caldwell.—On December 3, 1950, at St. Albans, *Alfred George Caldwell*, M.D., D.P.H.

Evans.—On November 26, 1950, at Crowell, Oxford, Jessie Downie Granger Evans, M.D.

Howat.—On November 26, 1950, at Westminster Hospital, William Howat, M.B., Ch.B., of Leyton, London, E.

Hutchinson.—On December 2, 1950, at Highbury, Walmersley, Bury, Gladys Hilda Hutchinson, M.B., Ch.B.

Purdon.—On December 1, 1950, at his home, Kensington, London, William Brooke Purdon, D.S.O., O.B.E., M.C., M.B., B.Ch., D.P.H., Major-General, A.M.S., retired, aged 68.

Rankin.—On November 16, 1950, at Southport, Lancs, John Rankin, M.B., F.R.C.S.I., aged 77.

Russell.—On November 27, 1950, Henry Bret Russell, M.D., M.R.C.P., aged 55.

Walcot.—On November 24, 1950, at a North Finchley nursing-home, Thomas Walcot, M.D., aged 87.

EPIDEMIOLOGICAL NOTES

Poliomyelitis

Notifications of poliomyelitis in the week ending December 2 were: paralytic, 90 (111); non-paralytic, 38 (19); total, 128 (130). The figures for the previous week, compared with which there was a total decrease of 2, are in parentheses.

Uncorrected notifications for the corresponding week in 1947 and 1949 totalled 106 and 157 respectively. Total uncorrected notifications for 1950 up to and including the week under review are 8,379. The corresponding figures for 1947, 1948, and 1949 are 8,927, 2,272, and 6,483 respectively.

County areas with the most numerous notifications were Devon 6, Gloucester 10, Lancs 12, Southampton 6, Surrey 10, and West Riding 10. The decrease in the week ending December 2 is insignificant and disappointing in view of the large fall in the previous week.

Discussion of Table

In *England and Wales* a further increase was reported in the very high incidence of measles 1,211, whooping-cough 204, and dysentery 152. A rise of 97 occurred in the number of notifications of scarlet fever, but, in relation to the incidence in former years, this disease is at a low level. A fall in incidence was recorded for acute pneumonia 68, acute poliomyelitis 19, and diphtheria 15.

The largest rises in the number of notifications of measles were Lancashire 512, Middlesex 215, Essex 101, while the chief exception to the rising trend was a decrease of 107 in Surrey. A small rise in the incidence of whooping-cough was general throughout the country; the outstanding exception to the increasing trend was a fall of 106 in Yorkshire West Riding. The increase in the incidence of scarlet fever was due to a small rise in most sections of the country. The chief variations in the returns for diphtheria were falls in Yorkshire West Riding 9, Lancashire 8, Glamorganshire 5, and a rise of 4 in London.

The largest rises in the number of notifications of dysentery were Lancashire 63, Leicestershire 36, and Wales 26. The largest returns for dysentery during the week were Lancashire 129 (Manchester C.B. 22, Southport C.B. 16, Prestwich M.B. 15, Great Harwood U.D. 14, Middleton M.B. 10, Urmston U.D. 8); Leicestershire 76 (Leicester C.B. 63); Yorkshire West Riding 52 (Dewsbury C.B. 14, Saddleworth U.D. 14); Durham 39 (Darlington C.B. 13, South Shields C.B. 13); Monmouthshire 29 (Abercorn U.D. 17, Newport C.B. 9); London 28; Cheshire 28; Surrey 23 (Surbiton M.B. 18); Essex 23 (Romford M.B. 17); Shropshire 21 (Whitchurch U.D. 11); Northumberland 20 (Newcastle-upon-Tyne C.B. 11); Nottinghamshire 16 (Mansfield M.B. 12); Northamptonshire 15 (Kettering M.B. 14); Middlesex 12; Gloucestershire 12 (Thornbury R.D. 7); Cumberland 12; Caernarvonshire 12 (Bangor M.B. 8); Carmarthenshire 10 (Llandovery M.B. 8).

The largest returns of acute poliomyelitis were Surrey 9, Lancashire 9, Devonshire 8, Gloucestershire 8 (Bristol C.B. 8), Yorkshire West Riding 8.

In *Scotland* infectious diseases were more prevalent during the week, and increases occurred in the number of notifications of whooping-cough 110, measles 79, diphtheria 16, and dysentery 11. The largest increases in diphtheria were Glasgow 7 and Lanark county 5. The number of notifications of dysentery in Glasgow fell from 103 to 64, and rises were recorded in Edinburgh from 9 to 36, and in Dundee from 4 to 14. The other important centre of dysentery was Lanark county 17.

In *Eire* rises occurred in the number of notifications of measles 60, whooping-cough 14, diarrhoea and enteritis 12, and a fall of 34 was recorded for scarlet fever. A decline in the incidence of scarlet fever occurred in the country generally with the exception of Dublin C.B.

In *Northern Ireland* a rise of 85 in the notifications of measles and of 15 for scarlet fever were the chief features of the returns. The largest rise for measles was 32 in Armagh county.

Week Ending December 2

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,434, whooping-cough 4,458, diphtheria 45, measles 12,323, acute pneumonia 497, acute poliomyelitis 128, dysentery 856, paratyphoid fever 8, and typhoid fever 1.

Quarterly Returns for Northern Ireland

The birth rate during the March quarter of this year was equivalent to an annual rate of 21.3 per 1,000, and was 1.2 below the average of the five preceding first quarters. The infant mortality was 44 per 1,000 registered births, and was 21 below the average of the corresponding quarter for the five preceding years. The general death rate was 13.3 per 1,000, and was 2.0 below the five-year average. Deaths from pulmonary tuberculosis numbered 152, and 36 from other forms of tuberculosis. These were 45 and 2 below the number registered in the first quarter of 1949. Of the 113 deaths attributed to the principal epidemic diseases, 75 were due to influenza, 21 to diarrhoea and enteritis, and 11 to whooping-cough.

No. 47

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended November 25.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Measles is not notifiable in Scotland, and the returns are therefore an approximation only.

† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

‖ Includes puerperal fever for England and Wales and Eire.

¶ Primary pneumonia no longer notifiable in Eire.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Hypersensitivity after B.C.G.

Q.—*I am a final-year student and persistently Mantoux negative. I have been offered B.C.G. vaccination and would be glad to avail myself of the opportunity. However, I am due to do a tuberculosis course at a sanatorium in four months' time. If I have my inoculation in the next few weeks, will I be hypersensitive to tuberculous infection when I do my course?*

A.—An individual who is given B.C.G. vaccine while incubating a virulent tuberculous infection, or who is exposed to such an infection during the pre-allergic phase following vaccination, appears to run no greater risk of serious disease than if he had not been vaccinated. Nor is there evidence of any hypersusceptible phase following Mantoux-conversion due to B.C.G. vaccination. The purpose of separating a vaccinated person from a known infective case is to preserve the reputation of B.C.G. vaccination rather than the subject. When carried out, segregation is usually from six weeks before vaccination until six to twelve weeks after, so that the physician can know both that the individual was tuberculin-negative sufficiently long after the contact had been broken to have escaped natural infection therefrom, and that he has become tuberculin-positive (from B.C.G.) before he resumed contact. By these tokens the questioner, if vaccinated successfully in the next few weeks, will have had his tuberculin-conversion demonstrated before starting his sanatorium course, and will thereafter have some degree of protection.

Small Temperature Swings in Spinal Tuberculosis

Q.—*What is the significance of a small but persistent daily temperature swing (97.2 to 98.8° F.—36.2 to 37.1° C.) in a patient suffering from spinal tuberculosis? A lumbar abscess complicated by a sinus has subsided, and the sinus has ceased to discharge. The blood sedimentation rate is within normal limits, and the radiological appearance of the diseased vertebrae is satisfactory. I may add that the patient has had this temperature swing for the last two years, while undergoing immobilization on a plaster bed to which he is still confined.*

A.—The disease in this patient is in all probability quiescent. But it is wise in such a case to continue immobilization on the plaster bed for three months after first obtaining a satisfactory sedimentation rate and radiograph. If the sedimentation rate and radiological appearances remain satisfactory and the sinus keeps dry, the small temperature swing mentioned may be disregarded.

Causes of Kerato-conjunctivitis

Q.—*What is the aetiology of non-specific kerato-conjunctivitis? Is there any association with tuberculosis?*

A.—The causes of kerato-conjunctivitis are many; some are known, and about others we are at present ignorant. Often there are several aetiological factors. Kerato-conjunctivitis is sometimes associated with systemic disorders of endogenous origin and with a number of skin diseases such as acne rosacea, seborrhoeic dermatitis, pemphigus, and others. Superficial punctate keratitis occurs in epidemic form in India and Malaya, and indeed it did so in London in 1930–1; it is then associated with an acute but transitory infection of the upper air passages, and is thought to be due to a filter-passing virus. Some cases of kerato-conjunctivitis are bacterial in origin and some are due to neurotrophic causes, as when the Gasserian ganglion is diseased. The disease may also appear during the acute exanthemata and influenza. It may result from exposure of the cornea due to absence of blinking in severe illness and unconsciousness or to failure of the upper lid to cover the cornea.

The condition may also arise from such industrial hazards as electric short-circuit flashes; exposure of the unprotected eyes in acetylene welding and to ultra-violet-light lamps; the irritation of chemical fumes and dust; and in the manufacture of artificial silk. Kerato-conjunctivitis is evident in so-called "snow-blindness," when the injurious agent is thought to be ultra-violet rays reflected by snow fields at high altitudes. Some people are very sensitive to aniline dyes, and in such paraphenylene diamine, which is used in certain eyelash cosmetics, may cause a very severe kerato-conjunctivitis. A number of articles such as jequirity seeds,* used for self-inflicted eye injuries, induce kerato-conjunctivitis, and in war mustard gas causes characteristic lesions of the bulbar conjunctiva and cornea.

Kerato-conjunctivitis may also occur in arsenical poisoning associated with exfoliative dermatitis, and when chrysarobin is administered for skin diseases.

Phlyctenular kerato-conjunctivitis is a tuberculo-allergic manifestation which may be associated with a healed tuberculous lesion, and occurs in children and young adults with a family history of tuberculosis. Those affected by this disease are often living in poor hygienic conditions; they are often in a low state of health, indulge in a diet with carbohydrate excess, and have lymphoid hyperplasia of their tonsils and adenoids and some upper respiratory infection.

Blindness and Heredity

Q.—*What are the hereditary causes of blindness, and at what ages does hereditary blindness usually occur? What are the chances of transmitting these diseases?*

A.—There are a large number of hereditary diseases that lead to blindness. Some produce gross visual defect or total blindness from congenital anomalies, others are abiotrophic in character—i.e., the eye is normal at birth and for some years subsequently, when degenerative changes set in and progress, leading to blindness in early life or very much later, the time depending on the affection. Microphthalmos is typical of the first group and retinitis pigmentosa of the second. Whether a particular form of hereditary disease is transmitted or not depends on the mode of inheritance. In recessive affections transmission of the disease occurs only under exceptional conditions; with a regular dominant mode of inheritance 50% of the offspring are likely to be affected; in recessive sex-linked affections the children of an affected man will not be affected, but 50% of his daughters' sons will be affected. Further information on this subject will be found in *Genetics in Ophthalmology* (Butterworth, London), by Professor Arnold Sorsby.

Ultra-violet Light and Children

Q.—*Will regular ultra-violet-light baths help normal healthy children, from 1 to 4 years old, to resist the common cold and other infections? Are there any contraindications? Can you suggest dosage for these ages?*

A.—The only extensive controlled survey of the value of ultra-violet light in the prevention of colds was that carried out by Dora Colebrook under the auspices of the Medical Research Council (*Industrial Health Research Board Report*, No. 89, H.M.S.O.). The work applied to adults only and showed that as a prophylactic ultra-violet light had no demonstrable value. There seems to have been no corresponding survey in children, but there is no reason to believe that a "normal healthy child" will react differently from an adult. On the other hand many clinicians believe that under-developed children with poor appetites and a tendency to respiratory infections are less liable to develop colds if given regular courses of ultra-violet light. This is a clinical impression only. Ultra-violet light sometimes aggravates an already existing cold and should temporarily be discontinued if a cold develops during the course of treatment, otherwise there are no obvious contraindications to its use in *healthy* children. The dosage for a child between the ages of 1 to 4 is half the normal adult dose recommended by the makers of the lamp.

*Jequirity, or the poisonous seeds of *Abrus precatorius*, contains an active principle called abrin, which is a toxalbumin similar to ricin and to snake venom. This has no action by mouth if the mucous membrane is intact, but when injected into the skin or applied to the surface of a wound urgent symptoms of collapse occur. These are accompanied by local inflammation and oedema, and capillary thrombosis and haemorrhage, and are often followed by death.

Leucoderma

Q.—*Has there been any recent advance in the treatment of leucoderma? Does pregnancy affect the condition?*

A.—There is as yet no effective treatment for leucoderma. Pregnancy may affect the condition for better or worse. It is an expression of disturbance of pigmentary function which appears in the majority of cases to be due to emotional, nervous, or endocrine influences, not of a gross nature nor, unfortunately, amenable to treatment. Recovery may occur spontaneously.

Meat and Chicken Soups

Q.—*What nutritive value have meat and chicken soups?*

A.—The composition of a meat or chicken soup will naturally depend on the relative amounts of water and of meat or chicken which have been used in its preparation. Even the most concentrated soups, however, contain little in the way of nutrients. One plateful (one-third of a pint or about 200 ml.) might contain, as a maximum, about 5 g. protein, 1 g. fat, and 3 g. carbohydrate, which together would yield about 40 calories. It may also contain a little vitamin B_1, riboflavin, and nicotinic acid, but not more than one-tenth of the daily requirements of these. The chief components that give the flavour are the soluble salts and extractives. The former are too small in quantity to contribute appreciably to the needs of the body. The extractives include very little urea, but appreciable amounts of creatine and creatinine, each of which may amount to 1 g. in a portion.

If we are interpreting nutritive value rather more widely, we should mention two further points. First, soups, taken as they are in the early part of the meal, stimulate appetite, and may thus indirectly improve the dietary. Secondly, when a meat or chicken soup is used as a base for a thick soup made with, say, pulses or potatoes, and to which has perhaps been added small pieces of meat or chicken, it is clearly possible to obtain a dish of quite high nutritive value.

Inheritance of Epilepsy

Q.—*A married woman, whose aunt suffers from epilepsy, wishes to have children. What risk is there that a child would be affected?*

A.—The risk is not appreciably greater than that for a woman with no family history of epilepsy.

NOTES AND COMMENTS

Carbon Dioxide and Asthma.—Dr. S. F. GILBERT (Manchester) writes: May I add my comments to your answer to this question ("Any Questions?" November 25, p. 1236)? While being in full agreement that such inhalations can be most harmful in some cases, and of no benefit in others, when given by uncontrolled methods, I have yet to see in my own practice any but beneficial effects. . . . At a later date I intend to submit full details of my method and results for publication.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology, Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

LONDON SATURDAY DECEMBER 23 1950

HARVEY AND THE SCIENTIFIC METHOD*

BY

Sir HENRY COHEN, M.D., LL.D., F.R.C.P.

Corresponding Member of the Harveian Society of London

No compliment could be more acceptable to a physician than an invitation to deliver a lecture adorned by the name of Harvey. Yet the task and responsibility which the honour conveys are less enviable, and increase in difficulty as the years advance. Two hundred and thirty Harveian orators at the Royal College of Physicians and nearly a hundred Harveian lecturers of this distinguished society have probed deeply and well-nigh exhausted all that might be said of Harvey, his life and times, his contemporaries and forebears, his philosophy, and his contributions to medicine and science. So little would seem to remain that some orators and lecturers, having faced their difficulties, have solved them by avoiding them and have unashamedly deleted Harvey from the theme of their discourses, whilst not a few have sought refuge in the reflection of the French writer that "everything has been said before, but since nobody seems to listen we can say it all over again." As my tale unfolds you may well believe that I am not wholly guiltless of this exprobation.

Yet new facts concerning Harvey are still being revealed, and in the past year Harveian literature has been splendidly enriched by Mr. Geoffrey Keynes in his Linacre and Thomas Vicary Lectures dealing with the personality and portraiture of Harvey. The physician must feel deeply the passing of the initiative in this field of medical scholarship to the surgeon; if he is wise he will not be addulced by Mr. Keynes's assertion that "as a surgeon I belong to the less learned half of the medical profession"; rather will he sense that this is a meretricious concession not to the superior learning of the physician but to his overweening conceit.

But there is an aspect of history more significant than the study of persons and portraits, a study which is too apt to reflect the personality, not of the subject, but of the biographer and the artist. As Sir Arthur Helps has written:

> "To us, my friend, the times that are gone by
> Are a mysterious book, sealed with seven seals:
> That which you call the spirit of ages past
> Is but, in truth, the spirit of some few authors
> In which those ages are beheld reflected,
> With what distortion strange heaven only knows.
> History!
> Facts dramatized say rather—action—plot—
> Sentiment, everything the writer's own,
> As it best fits the web-work of his story,
> With here and there a solitary fact
> Of consequence."

*The Harveian Lecture delivered before the Harveian Society of London on March 22.

We can, however, study the mind of the man and its working in his writings. It is this which conveys to us a due sense of his greatness; it is this which helps us to assess his contribution to that irrepressible insurgence of the human spirit which reveals itself in the advancing frontiers of knowledge. It explains why we place Harvey amongst the greatest physicians of all times, not because he *discovered* that the blood circulates but because he *demonstrated* beyond all reasonable doubt that the blood circulates. It is with the Harveian method that I propose to concern myself in this lecture, and with why after he had demonstrated "the passage of the blood from the veins into the arteries and of the manner in which it is transmitted and distributed by the action of the heart" he was constrained to write: "But what remains to be said upon the quantity and source of the blood which thus passes, is of a character so novel and unheard-of that I not only fear injury to myself from the envy of a few, but I tremble lest I have mankind at large for my enemies, so much doth wont and custom become a second nature. Doctrine once sown strikes deep its root, and respect for antiquity influences all men. Still the die is cast, and my trust is in my love of truth, and the candour of cultivated minds."

In this passage Harvey hints at the bases, the reasons for human beliefs. Translated into modern terminology these resolve themselves into four groups—the methods of tenacity, authority, intuition, and science or reflective inquiry.

Method of Tenacity

Tenacity, obstinacy, perseveration, call it what you will, is the spring of many of the doctrines we hold to be true. The pain of a new idea, said Walter Bagehot, is one of the greatest pains to human nature. "It is as people say, so upsetting; it makes you think that after all your favourite notions may be wrong, your firmest beliefs ill founded; it is certain that till now there was no place allotted in your mind to the new and startling inhabitant; and now that it has conquered an entrance, you do not at once see which of your old ideas it will not turn out, with which of them it can be reconciled, and with which it is at essential enmity."

And Wilfred Trotter (1932), in his "Commemoration of Great Men"—and I commend not merely this but all that he wrote to your attention—said: "The mind delights in a static environment, and if there is any change to be itself the source of it. Change from without, interfering as it must with the sovereignty of the individual, seems in its very essence to be repulsive and an object

of fear. A little self-examination tells us pretty easily how deeply rooted in the mind is the fear of the new, and how simple it is when fear is afoot to block the path of the new idea by unbelief and call it scepticism, and by misunderstanding and call it suspended judgment."

A glance at our medical textbooks establishes that habit or inertia makes it easier for us to continue to believe a proposition simply because we have always believed it. Fables about the value of drugs and other forms of therapy, and of such diagnostic measures as percussion, persist because we close our minds to all contradictory evidence. History may not repeat itself but the writers of textbooks do, and their reiteration, be it true or false, strengthens our beliefs. Moreover, the interests of ourselves, our country, our religion, our business or profession—all these and a host of others—will determine how far we insulate ourselves from contrary views and opinions. And since we have different interests we shall cling to different beliefs. Thus the method of tenacity is incapable of deciding between conflicting views.

Method of Authority

Secondly, as a basis of belief there is the method of authority, the appeal to an accepted source which in the highest degree is regarded as infallible. Two forms of appeal to authority must be clearly distinguished. One is both reasonable and inevitable. In the practice of medicine, for example, no one man can have the time, even if he had the ability, to find out all knowledge for himself. He accepts the carbohydrate values of certain foodstuffs given by competent authorities; he does not question that specific patterns in an electrocardiogram indicate a posterior cardiac infarction, or that herpes zoster is a virus infection. But he retains the right to question the authorities if his own experiences cause him to doubt their dicta; there are other authorities to whom he can appeal; and, indeed, if he is prepared to do so he can acquire the competence and experience himself with which to test the validity of the pronouncements of authority.

The second form of appeal to authority is fundamentally different. It "invokes an external source, which it invests with infallibility and finality to give sanction to beliefs." This is the basis of many of our religious beliefs and our political affinities even to-day, and in the history of science it has played a sinister and obstructive part. Even Vesalius in 1543 was content to teach the Galenic doctrine of the ebb and flow of blood, which, as I shall later describe, demanded a perforated ventricular septum. He wrote: "The septum of the ventricle, composed as I have said of the thickest substance of the heart, abounds on both sides with little pits impressed in it. Of these pits, none, so far at least as can be perceived by the senses, penetrate through from the right into the left ventricle, so that we are driven to wonder at the handiwork of the Almighty, by means of which the blood sweats from the right into the left ventricle through passages which escape human vision."

You will observe that he permits himself to express not doubt at the teaching of Galen but wonder at the handiwork of the Almighty, who could create a ventricular septum which allowed the passage of blood though no perforations are visible; but perhaps his true belief is hinted at in a later writing, when he confessed that he "accommodated his statements to the dogmas of Galen not because he thought that these were in all consonant with truth but because in such a new great work he hesitated to lay down his own opinions, and did not dare to swerve a nail's breadth from the doctrines of the Prince of Medicine."

The influence of authority is perhaps most strikingly exemplified in the sentence of the Inquisition on Galileo in 1633 for maintaining that the earth goes round the sun. Recollect that this was five years after Harvey had published *De Motu Cordis* and you will better appreciate the courage and magnitude of Harvey's contribution. For in his time the methods of tenacity and authority dominated anatomy and medicine. The anatomist saw only what his mind had been attuned to see by the prior dicta of his teachers; he selected, perhaps unconsciously, what confirmed accepted doctrine. The purpose of dissection in Harvey's time was not to ascertain new facts but to demonstrate the truth of Galenic teaching; the assistant dissected the body, and the lecturer, seated apart, recited the appropriate passages from the works of Galen.

There were a few anatomists, however, prepared to dispute the authority of Galen. Of these, Matheus Realdus Columbus, a man of dubious integrity, who succeeded Vesalius at Padua in 1544, was the most outspoken, for in his *De Re Anatomica Libri XV*, published in 1559 after his death (a fact which might explain his frankness), occurs this indictment of his fellow anatomists: "But for these it is enough that Galen said so. What? To think that some folk in our time swear to the dogmas of Galen about anatomy so that they dare to assert that Galen ought to be taken as gospel, and that there is nothing in his writings which is not true! It is wonderful how men are carried away by this doctrine; and the princes of the anatomy offer it to the rabble. Yet no one sees how much this is to be blamed. Who indeed is there who never offends? But of this enough and more than enough."

Any chapter in the history of human thought will reveal that there can be no uniformity or stability of belief for *Homo sapiens*—the species with the inquiring, the inquisitive mind—which is based on authority, for authorities differ.

Method of Intuition

Is there a better guarantee of stable beliefs than those we have thus far discussed? Some have chosen and urged the method of intuition, the acceptance of truths which when uttered are seen to be and are accepted as self-evident, and they point in support to the utterances of the prophets and poets. But intuitions must be tested by experience, for intuitions are only self-evident within an accepted framework.

It was at one time "self-evident" that the earth was flat, and that the sun moved round the earth; to some it is self-evident that polygamy is a sin; and most people would accept such intuitions as that every effect must have a cause, and that the axioms of Euclidian geometry are true. For most propositions self-evidence has been claimed, yet it is not difficult to establish that early training, inherent desires, and current knowledge play a large part in the formulation of our intuitions, and the certainty and authority with which we utter them is no guarantee of their validity.

Method of Science or Reflective Inquiry

It is the fourth method of arriving at truth, the method of science or reflective inquiry, which is the essence of my theme. Scientific method has been so often described that it may seem unnecessary to elaborate its content and its form, but there are certain aspects of it which in

relation to Harvey's work need elaboration if his contribution to the stream of human thought is to be properly assessed. It is customary to describe three main stages in arriving at a scientific truth. First, there is the observation of significant facts; secondly, a hypothesis is formulated which, if true, would account for the facts; and thirdly, from the hypothesis are deduced consequences, whose validity can be tested by observation or experiment.

This is, I suggest, an over-simplification. The first stage of most discoveries is the chance observation, which in not a few instances has been associated with the false assumption. From the time that King Hiero asked Archimedes to test his suspicion that his artificers were alloying gold with silver in his crown, and Archimedes, by chance, noticed that in his bath he displaced water equal to the volume of his body and realized at once that, weight for weight, the lighter alloy would displace more water than the heavier gold, to Fleming's observation on *Penicillium notatum*, the path of the history of science is strewn with the fruits of accidental observations.

But we must not forget with Pasteur that "chance only visits the mind that is prepared." The chance observation lights the spark only in the mind of the receptive, and he responds by a tentative, a very tentative, hypothesis or hypotheses which lead him to seek *significant* facts, by observation or experiment. The operative word is "significant." There must be critical discrimination in the selection of apposite data; there must be lack of bias, and face value must not mislead. It is a mark of scientific ability to be able to distinguish the significant facts and to know where and how they may be found. In other words, "observation of significant facts" is not uncontrolled observation, but observation with a purpose. Meandering aimlessly and unguided in the realm of nature is rarely a profitable pursuit. When the significant facts are assembled possible explanations are formulated; an attempt is made to produce order out of chaos; for science is interested in systems and classes, in generalizations.

It is here that formal logic plays its part. But formal logic is not scientific method. It is an instrument which demonstrates to us that if certain propositions are true others also are true, but logic does not establish the truth of our initial premises. Formal logic aids us in devising ways of formulating hypotheses explicitly and accurately. If alternative hypotheses are available logic helps us in the next stage of our scientific method; it helps us to develop the consequences of these alternative hypotheses so that when compared with other observable phenomena we can test which hypothesis is in harmony with the observed facts.

To summarize, the stages in the method of science as exemplified by its history are: (i) the chance observation; (ii) the immediate reactive hypothesis; (iii) the search for significant facts which confirm or refute the initial hypothesis or (iv) lead to further hypotheses (induction), which can (v) be tested by observation and experiment (deduction).

It is perhaps necessary to re-emphasize, for those who hold the Baconian view that the mere orderly arrangement of data would make the right hypothesis obvious, that at each stage of scientific inquiry ability (it may be intuition) often amounting to genius is indispensable. As Butterfield (1949) has observed: "Of all forms of mental activity the most difficult to induce, even in the minds of the young who may be presumed not to have lost their flexibility, is the art of handling the same bundle of data as before, but placing them in a new system of relations with one another, by giving them a different framework, all of which virtually means putting on a different kind of thinking-cap for the moment." But any logically trained mind, once the sequence is pointed out, must of necessity accept the conclusion or question the accuracy of the observations or the validity of the logical processes which led to the hypothesis.

The Galenic Doctrine

Let us within this scheme of belief consider the contribution which Harvey made to the knowledge of the heart and blood vessels. Until his day, and indeed for many years after in places where the methods of tenacity and authority held sway, the universal teaching was the Galenic doctrine. This regarded the heart as a source of heat, an innate God-given property persisting from the beginning to the end of life. Food particles passed from the gut by the portal vein to the liver, where a crude blood of base nutritive quality (said to be endowed with "natural spirit") was manufactured and, passing to the right side of the heart, was sent by flow and ebb to irrigate the tissues and organs. Diastole of heart and veins occurred at the same time. The "natural spirit" flowed (*a*) through the venae cavae to all the tissues and (*b*) through the artery-like vein (what we now call the pulmonary artery) to the lungs, for their nutrition; and (*c*) through invisible pores of the ventricular septum to the left side of the heart. The left heart received also air direct from the trachea and bronchi and through skin and tissues, which not only cooled the innate heat of the heart but by mixing with the blood seeping through from the right heart gave rise to the "vital spirit" which was conveyed again by ebb and flow, with synchronous diastole of heart and arteries, to the tissues, endowing them with their "vital" functions.

In the process of forming "vital spirit," attributed to a fermentative activity, fuliginous vapours arose which were carried to the lungs and tissues for excretion. The brain had its special function: from the arterial blood which is received it distilled off the "animal spirit" (the breath of the soul), which was carried along nerves for movement and sensation.

Galen's Critics

The Galenic view had its critics even before Harvey's day. That air passed direct from lungs to heart had been doubted by Leonardo da Vinci, who found it impossible to pump air into the heart through the trachea and bronchi. Vesalius, as we earlier saw, had been unable to demonstrate the septal pores. Michael Servetus had published in 1553 an earlier written work, *Restitutio Christianismi*, in which he inferred that the passage of blood from right ventricle to left "does not, as is generally believed, take place through the median wall septum of the heart, but by a signal artifice the subtle blood is driven by a long passage through the lungs." He then repeats the Galenic view that "it is mixed with the inspired air, and by expiration is cleansed from its fumes. And so at length it is drawn in a complete mixture, by the left ventricle through the diastole, stuff fit to become the vital spirit." His reasons for accepting the lesser or pulmonary circulation merit recall. He writes: "This view is confirmed by the conspicuous size of the artery-like vein which would not have been made so large and so stout, and would not discharge from the heart itself such a power of very pure blood into the lungs, for the mere purpose of nourishing these organs. Nor would the heart serve the lungs in this manner, especially since at an earlier date in the embryo on account of

the little membranes of the heart, the lungs themselves are up to the hour of birth nourished from other sources, as Galen teaches."

Columbus, too, had in 1559, in the work to which I earlier referred, rejected the view that blood passed from right to left ventricle through the septum, and he enunciated the pulmonary circuit. But he was a proved plagiarist in that he falsely claimed to have discovered the stapes which from Fallopius we know to have been earlier described by John Phillip Ingrassias, of Palermo; and he may well have seen a copy of the *Restitutio* of Servetus and claimed the discovery as his own.

It was Andreas Caesalpinus, professor of medicine at Pisa, great both as scholar and as disputant, who came closest to Harveian views in his opposition to Galen, and he incorporated his conclusions in two books. In the first, *Quaestiones Peripateticae,* published in 1571, he states, from a study of the valves of the heart and their directional opening and closing, that the heart in systole propels blood into the aorta and pulmonary artery, and in diastole receives blood from the venae cavae and pulmonary vein. And again, in his *Quaestiones Medicae* in 1593, he appears to have recognized that blood flows from arteries to veins, and along the veins to the heart. He noted also that veins when ligated swell on the far side—"a fact well known by experience to those who let blood"—and he recognized that this was in opposition to Galenic teaching. But, though Caesalpinus clearly formulated the pulmonary circulation and groped after a systemic circulation, he was making assertions unsupported by careful observation or experiment; and his views did not influence the teachings of his contemporaries.

Harvey in Padua

Whatever contributions da Vinci, Vesalius, Servetus, Columbus, Caesalpinus, and even Fabricius may have made to the idea of the circulation of the blood, they are insignificant when compared with Harvey's. He stands alone by virtue of his *methods* rather than by his *discovery,* great as were to be the repercussions of that discovery on the growth of scientific medicine.

But, given that he was a man of genius, how was his mind prepared for the rich harvest it was later to yield? The field was ploughed and the seeds first sown in the University of Padua, which as late as 1670 was described as "the Imperial University for Physic of all others in the world." It played an impressive part in freeing Harvey's mind, for of all European universities it was the least shackled in the fetters of authoritarianism. It had fallen under the rule of Venice in 1404, and Venice was at that time and for long after the most anticlerical State in Europe. Experimental and quantitative methods of investigation were there early introduced into the physical and biological sciences, and it is not surprising that in a university so highly secularized as Padua doubts were early harboured about the part which final causes play in natural philosophy. The question "How?" assumed greater importance than "Why?"; and the answer to "How?" in a university which sheltered Copernicus and Galileo at important periods of their lives had naturally a large mechanical bias. Thus it was that Harvey, in contrast to his predecessors and indeed contemporaries, professed both to learn and to teach anatomy, not from "books but from dissections; not from the positions of philosophers but from the fabric of nature"; and for him the heart "is in a piece of machinery in which, though one wheel gives movement to another, yet all the wheels seem to move simultaneously."

That Harvey should turn to the heart for his major interest can occasion no surprise. The pulse and breathing were problems of movement in living organisms suggested by the kinetics of matter which he had heard discussed at Padua. Moreover, with Aristotle, he regarded (as he writes in his introduction to *De Motu Cordis*) "the heart of animals as the foundation of their life, the sovereign of everything within them, the sun of their microcosm, that upon which all growth depends, from which all power proceeds." I suspect that this panegyric was influenced, however, by the need for an appropriate analogy with which to dedicate his work to his patient and monarch, that "most illustrious and indomitable prince, Charles, King of Great Britain, France, and Ireland, Defender of the Faith."

Whilst Harvey was in residence in Padua, Fabricius, his master and friend, was perfecting his knowledge of the valves of the veins which he was to record in 1603 in the small treatise *De Venarum Ostiolis.* This must have excited Harvey's interest, though there is nothing to show that he appreciated at that time the significance of the direction of the orifices of these valves or that he rejected Fabricius's interpretation of their function on the basis of Galenic doctrine—namely, that they were there to slow the flow and check the accumulation of large quantities of blood at the periphery.

Harvey's predecessors had known that when veins were cut or ligated blood flowed out of them in the direction of the heart, but so attached were they to Galenic doctrine that they explained it as "blood behaving irregularly when tortured by such experiments, rushing off in the wrong direction like a fluttering, frightened hen." Osler quotes Boyle as saying that in the only conversation he ever had with him Harvey acknowledged that a study of the valves of the veins had led him to the discovery of the circulation of the blood. Yet I suspect that a chance observation was the spark which set alight the conflagration which consumed Galenic doctrine, an observation to which no author seems hitherto to have drawn attention.

In order to demonstrate that the arteries were filled with blood and not air, as Erasistratus had maintained in naming them, Galen had carried out a simple experiment. "If you include a portion of the artery between two ligatures," he wrote, "and slit it open lengthways, you will find nothing but blood"; and, as Harvey comments, "thus he proves that the arteries contain blood only." But Harvey went further: "We too may be permitted to proceed by a like train of reasoning: if we find the same blood in the arteries as in the veins, after having tied them in the same way, as I have myself repeatedly ascertained, both in the dead body and in living animals, we may fairly conclude that the arteries contain the *same blood as the veins, and nothing but the same blood.*"

Is it not likely that this observation started a train of reasoning in Harvey's mind? He had been tutored in the Galenic teaching that the veins are filled with a crude blood containing "natural spirit" and the arteries with a lighter blood replete with "vital spirit"; yet Harvey believed that the blood he saw in the arteries and veins was the *same*—an inaccurate observation when critically assessed, but surely the most probable source of the inference that, since the blood is the same, there must be continuity or communication between arteries and veins. With this in mind Harvey then sought for significant facts, but before so doing he disposed of certain hypotheses by revealing their inconsistencies with known facts; indeed, the introduction to *De Motu Cordis* is a model critical review of past work. There is no doubt that in Harvey's mind the

idea of the circulation was formulated early, for in his notes to his Lumleian Lectures at the College of Physicians in April, 1616, he writes of it in a curious mixture of Latin and English:

"constat per fabricam cordis sanguinem per pulmones in Aortam perpetuo transferri, as by two clacks of a water bellows to rayse water constat per ligaturam transitum sanguinis ab arteriis ad venas unde perpetuum sanguinis motum in circulo fieri pulsu cordis." ("It is proved through the structure of the heart that blood is constantly transferred through the lungs into the aorta, as by two clacks of a water bellows to raise water. It is proved by ligatures that blood passes from arteries to veins whereby the heart's beat produces a perpetual motion of blood in a circle.")

Mechanics of the Heart

With the bare idea of a circulation in his mind he sought for significant facts, but he sought them in relation to a significant question, which merely to ask, let alone to answer, was a remarkable innovation, for in the true spirit of science he isolated from a mass of irrelevant considerations the one which was amenable to scientific treatment—namely, the mechanics of the heart. His predecessors had asked, "Why?" about the heart and concerned themselves with "heat, spirit, and perfection," which, as Harvey rightly said, must be "decided upon other grounds." Harvey asked, "How?" and only occasionally did he deviate from this question.

The first task of the scientist is to find how he may make his most significant observations, and what material is best suited for his task—a point illustrated in recent years, for example, by the use of the giant axon of the squid in experiments on nerve conduction, and by T. H. Morgan in selecting the fruit-fly, *Drosophila,* for his genetic studies because of its rapid reproduction and its clearly defined chromosomes. Now, Harvey writes:

"When I first gave my mind to vivisections, as a means to discovering the motions and uses of the heart, and sought to discover these from actual inspection, and not from the writings of others, I found the task so truly arduous, so full of difficulties, that I was almost tempted to think, with Fracastorius, that the motion of the heart was only to be comprehended by God. *For I could neither rightly perceive at first when the systole and when the diastole took place, nor when and where dilatation and contraction occurred, by reason of the rapidity of the motion, which in many animals is accomplished in the twinkling of an eye, coming and going like a flash of lightning;* so that the systole presented itself to me now from this point, now from that; the diastole the same; and then everything was reversed, the motions occurring, as it seemed, variously and confusedly together. My mind was therefore greatly unsettled, nor did I know what I should myself conclude, nor what believe from others. I was not surprised that Andreas Laurentius should have written that the motion of the heart was as perplexing as the flux and reflux of Euripus had appeared to Aristotle."

But Harvey was not defeated, and he found his suitable material in cold-blooded animals with slowly beating hearts and in the dying warm-blooded animal when the heart begins to flag.

Harvey's Test of his Views

Between the crude formulation of his hypothesis and the publication of his *De Motu Cordis* Harvey was engaged in collecting data from human anatomy (for he held that design indicated function), from comparative anatomy, from embryology, from animal experiments, and from clinical observations which would test his views. Only a few examples can be quoted, but especially significant are his observations on the structure of the valves of the veins and on the arrangement of the circular and longitudinal fibres of the heart; on his condemnation of those who "confine their researches to the human body alone, and that when it is dead," and who "upon the ground of one particular proposition should proceed to draw general conclusions." So he turned to comparative anatomy and embryology, and thus he argues from the fishes with a single ventricle and no lungs, through amphibians with lungs and a single ventricle, and the human foetus with its unidirectional foramen ovale and ductus arteriosus, leading to the probability that in warm-blooded animals the passage from vena cava to aorta is accomplished through the substance of the lungs.

His experiments included the application of ligatures in the living animal, perfusions, and experimental observations on man, including those illustrated in *De Motu Cordis* which revealed with certainty the centripetal one-way flow of blood in the veins and the absolute bar afforded by the valves to a peripheral venous reflux. His clinical observations were accurate (for example, he knew of the insensitivity of the heart muscle to pricking and pinching), and they were apposite to his thesis. He denied that the arterial wall itself originated the pulse, because false aneurysms pulsated though they had no arterial covering, and because blood spurts in regular jets out of even the calcified artery, whose rigid wall prevents pulsation. He calls in evidence of the circulation the general spread in the body of "contagions, poisons from wounds, bites of serpents and rabid animals, lues venerea, and the like" even though "the part first infected remains sound." Indeed, so clear are his observations and so cogent his reasoning that I would insist on every medical student having *De Motu Cordis* as a set book for his preclinical studies.

Quantitative Considerations

But there is yet another form of argument which Harvey introduces, as Singer (1928) emphasizes, for the first time in biological literature; that is, the *quantitative* considerations which would be expected to flow from the Galenical theory.

"Let us assume," writes Harvey, "whether arbitrarily or from experiment, the quantity of blood which the left ventricle of the heart will contain when distended to be, say, two ounces, three ounces, or one ounce and a half—in the dead body I have found it to hold upwards of two ounces. Let us assume further, how much less the heart will hold in the contracted than in the dilated state; and how much blood it will project into the aorta upon each contraction—and all the world allows that with the systole something is always projected, a necessary consequence demonstrated in the third chapter, and obvious from the structure of the valves; and let us suppose as approaching the truth that the fourth, or fifth, or sixth, or even the eighth part of its charge is thrown into the artery at each contraction; this would give either half an ounce, or three drachms, or one drachm of blood as propelled by the heart at each pulse into the aorta; which quantity, by reason of the valves at the root of the vessel, can by no means return into the ventricle. Now in the course of half an hour, the heart will have made more than one thousand beats, in some as many as two, three, and even four thousand. Multiplying the number of drachms propelled by the number of pulses, we shall have either one thousand half ounces, or one thousand times three drachms, or a like proportional quantity of blood, according to the amount which we assume as propelled with each stroke of the heart, sent from this organ into the artery; *a larger quantity in every case than is contained in the whole body!* In the same way, in the sheep or dog, say that but a single scruple of blood passes with each stroke of the heart, in one half-hour we should have one thousand scruples, or about three pounds and a half of blood injected into the aorta; but the body of neither animal contains above four pounds of blood, a fact which I have myself ascertained in the case of the sheep.

"Upon this supposition, therefore, assumed merely as a ground for reasoning, we see the whole mass of blood passing

through the heart, from the veins to the arteries, and in like manner through the lungs.

"But let it be said that this does not take place in half an hour, but in an hour, or even in a day; any way it is still manifest that *more blood passes through the heart in consequence of its action, than can either be supplied by the whole of the ingesta, or than can be contained in the veins at the same moment.*"

And so by advocacy, cogent and unassailable, we too must conclude with Harvey that:

"Since all things, both argument and ocular demonstration, show that the blood passes through the lungs and heart by the force of the ventricles, and is sent for distribution to all parts of the body, where it makes its way into the veins and porosities of the flesh, and then flows by the veins from the circumference on every side to the centre, from the lesser to the greater veins, and is by them finally discharged into the vena cava and right auricle of the heart, and this in such a quantity or in such a flux and reflux thither by the arteries, hither by the veins, as cannot possibly be supplied by the ingesta, and is much greater than can be required for mere purposes of nutrition; it is absolutely necessary to conclude that the blood in the animal body is impelled in a circle, and is in a state of ceaseless motion; that this is the act or function which the heart performs by means of its pulse; and that it is the sole and only end of the motion and contraction of the heart."

Passages from Arteries to Veins

Yet there was a missing link in Harvey's demonstration—the channels of communication between arteries and veins, which were to be revealed by Malpighi in 1661. With the aid of his microscope he was to see the capillaries of the frog's lung. But in retrospect it seems strange to us that *Harvey did not himself perform a simple yet crucial perfusion experiment to show that the passages from arteries to veins are direct and continuous.* He was not unacquainted with the technique of perfusion, and had used it to demonstrate that water injected into the pulmonary artery passes into the left ventricle. In a letter to Paul Marquand Slegel, dated "London, this 26th of March, 1651," Harvey, then over 70 and racked with gout, relates yet another experiment devised to demonstrate the pulmonary circulation.

"Having tied the pulmonary artery, the pulmonary veins, and the aorta, in the body of a man who had been hanged, and then opened the left ventricle of the heart, we passed a tube through the vena cava into the right ventricle of the heart, and having at the same time attached an ox's bladder to the tube, in the same way as a clyster-bag is usually made, we filled it nearly full of warm water and forcibly injected the fluid into the heart, so that the greater part of a pound of water was thrown into the right auricle and ventricle. The result was that the right ventricle and auricle were enormously distended, but not a drop of water or of blood made its escape through the orifice in the left ventricle. The ligatures having been undone, the same tube was passed into the pulmonary artery and, a tight ligature having been put round it to prevent any reflux into the right ventricle, the water in the bladder was now pushed towards the lungs, upon which a torrent of the fluid, mixed with a quantity of blood, immediately gushed forth from the perforation in the left ventricle; so that a quantity of water, equal to that which was pressed from the bladder into the lungs at each effort, instantly escaped by the perforation mentioned. You may try this experiment as often as you please: the result you will still find to be as I have stated it."

The last sentence makes it clear that Harvey was well aware that consistent uniform results must ensue if the experiment is valid for scientific induction.

There are errors, many errors, in both observation and interpretation in *De Motu Cordis*, and as a speculator on ultimate causes Harvey was not far removed from his physiological predecessors for two thousand years (see Curtis, 1915). These do not detract from Michael Foster's (1901) appraisement of this work. "His wonderful book," wrote Foster in his *History of Physiology*, "or rather tract, for it is little more, is one sustained and condensed argument, but an argument founded not on general principles and analogies but on the results of repeated 'frequent appeals to vivisection' and ocular inspection. He makes good one position, and having done that advances on to another, and so marches victoriously from position to position until the whole truth is put clearly before the reader, and all that remains is to drive the truth home by further striking illustrations."

But I would suggest that Harvey's book did more than achieve its *scientific* purpose. It attacked and laid bare the shallowness of the conventional mind; it pressed for the acceptance of rational truth even if the apparent foundations of revelation and authority be undermined in the process. If man is a reasoning being, it taught, he must pursue his findings wheresoever they lead him in order, as Harvey himself avowed, that "what is true may be confirmed, and what is false set right by dissection, multiplied experience and accurate observation." If I am to describe the mind of Harvey I can do no better than borrow the words of one of Harvey's patients, Francis Bacon, of whom Harvey had cynically remarked that "he wrote philosophy like a Lord Chancellor," and who, in his *Proemium*, thus flatteringly describes himself—"A mind nimble and versatile enough to catch the resemblance of things, which is the chief point, and at the same time, steady enough to fix and distinguish their subtle differences; . . . endowed by nature with the desire to seek, the patience to doubt, fondness to meditate, slowness to assert, readiness to reconsider, carefulness to dispose and set in order; and neither affecting what is new nor admiring what is old, and hating every kind of imposture."

Conclusion

In the turmoil in which we who spend most of our days and nights in practising and teaching medicine and in trying to fashion its future there is a great need for the refreshing, calming, and cultural diversion of the literature and scholarship of our calling. The time which we can devote to reading, research, and meditation becomes less as the complexity of our lives increases. Yet there is nothing, even in the demands of our many-sided vocation, that compels us to abate our interest in our ancient masters, and especially in the workings of their minds. I have taken advantage of the opportunity which this occasion offers to express opinions and formulate judgments upon a historical and philosophical theme. I pray my critics will in justice remember, what I shall certainly not forget, that these are necessarily the work not of an expert but of an amateur

MILD CUSHING'S SYNDROME DUE TO ASPIRIN

BY

J. B. COCHRAN, M.B., B.Sc., F.R.F.P.S., M.R.C.P.

R. D. WATSON, B.Sc.

AND

J. REID, M.D., M.R.C.P.

(From the Clinical Chemotherapeutic Research Unit of the Medical Research Council in the Gardiner Institute of Medicine, University of Glasgow)

Since Hench, Kendall, Slocumb, and Polley (1949) first reported the results of treating rheumatoid arthritis with 17-hydroxy-11-dehydrocorticosterone ("compound E," or cortisone) disturbing side-effects have been observed following prolonged treatment which suggest the development of a mild Cushing's syndrome. The effects which have been recorded are rounding of the facial contours, hirsutism, acne, dorsal fat pad, glycosuria and diminished glucose tolerance, sodium retention leading to oedema, alkalosis, hypertension, and alteration of psyche. Hench and his colleagues (1950) state that there is no characteristic pattern for the development of side-effects. In their series of 23 rheumatoid patients treated with cortisone or A.C.T.H. the commonest side-effects were mild and occurred in eight patients. The effects noted in these cases were "mild acne, mild hirsutism, rounding of the face, and mild irritability." According to Baehr and Soffer (1950) side-effects occur more often during the treatment of acute conditions such as disseminated lupus erythematosus than in rheumatoid arthritis.

The metabolic effects of cortisone as summarized by Carlisle (1950) are retention of sodium and water early in the course of treatment, especially on high dosage, followed by spontaneous diuresis on continued administration of the hormone or after its discontinuation. High dosage has caused increased excretion of potassium with metabolic alkalosis in some cases, and the continued administration of large doses usually produces a negative nitrogen balance. Carlisle, in describing the clinical effects of cortisone in acute rheumatic fever, states that, in addition to the beneficial effects on arthritis, pyrexia is abolished in one to four and a half days, tachycardia in three and a half to five days, and in some cases a bradycardia follows; the E.S.R. becomes normal within 12 to 18 days; haemoglobin value increases by as much as 2.4 g. within three weeks in patients in whom the pretreatment levels are low; and in almost every instance cortisone causes a slight increase in the values for serum albumin and a reduction in the values for serum globulin.

The following report is of a patient suffering from a third attack of acute rheumatic fever who under treatment with aspirin developed signs of a mild Cushing's syndrome, which disappeared as the acute attack subsided and aspirin dosage was reduced. The clinical and metabolic effects observed during aspirin therapy resemble closely those attributed to cortisone.

Case Report

A girl aged 13 was admitted to hospital on September 29, 1950, suffering from an acute attack of rheumatic fever of one week's duration. This was her third attack, and the clinical findings on admission included severe general prostration, pyrexia (104° F.—40° C.), tachycardia (120 a minute), rapid respiratory rate (44 a minute), a dry coated tongue, and a dry warm skin. The heart was grossly enlarged, the apex beat being distinctly palpable on the anterior axillary line. Apical systolic and diastolic murmurs were present and the veins of the neck were overfilled, though there was no peripheral oedema or hepatic enlargement. The lower lobe of the left lung was collapsed. An electrocardiogram suggested pericarditis, and a portable *x*-ray film of the chest showed the cardiac outline of mitral valvular disease. The collapse of the left lower lobe was probably due to pericardial effusion and cardiac dilatation. The other clinical features were acute arthritis of the joints of the second and third fingers of both hands, both wrists, and the right elbow.

The patient was given a standard diet, and on September 30 administration of a dihydroxybenzoate in doses of 1 g. daily was started, and was continued for four days. This substance is at present under test, and will be reported on later. The acute arthritis disappeared within 24 hours, the temperature and rapid respiratory rates began to fall, but there was only a slight drop in the pulse rate. Improvement was thought to be too slow, so it was decided to change to aspirin treatment on October 4. Aspirin was given in doses of 1 g. five times daily, and the temperature, pulse, and respiratory rates continued to fall.

On the second day of aspirin treatment the face appeared to have become rounded and it looked "puffy," although there was no pitting on pressure. During the next 10 days the pulse and respiratory rates slowly settled and the temperature remained about 98–99° F. (36.7–37.2° C.). On October 17, 13 days after the start of aspirin treatment, acne was observed on the front of the chest and along the hair margin of the forehead. It later spread to the shoulders and back. A specimen of urine was found at this time to reduce Benedict's solution, producing a yellowish deposit. On account of a possible salicylate fallacy, a fermentation test with controls was set up; this showed the abnormality to be a reducing sugar. It was noticed that for some days the patient had been extremely morose, would not respond to questions, and never smiled, and this demeanour seemed to be out of proportion to the malaise of her illness. She continued to improve under aspirin therapy, and on October 19 the dosage was reduced to 1 g. thrice daily. Next day the face looked a little less "puffy," and from this point cheek measurements, using special callipers, were recorded. By November 2 each cheek had shown a reduction in thickness of 1.5 mm. Aspirin dosage was further reduced to 1 g. twice daily on October 23, and to 1 g. daily on October 28 for a further four days. The rounding of the facial contours and acne gradually disappeared and she lost her surly demeanour.

A glucose tolerance test was carried out on the day after a reducing sugar was found in the urine. The blood sugar (Folin and Wu) showed a high fasting level (163 mg. per 100 ml.), rising during the following two hours well above the normal renal threshold, and the urine contained glucose. A sudden fall to levels below 130 mg. occurred at two and a half and three hours. The next day the fasting level was 147 mg. Further tests showed that glucose tolerance returned to normal as aspirin dosage was reduced (Fig. 1).

The effects of treatment on the E.S.R. (Westergren), haemoglobin level, temperature, pulse, and respiratory rates are shown in Fig. 2. The temperature reached normal limits within two days of beginning aspirin therapy, but the pulse rate fell more slowly and reached normal on the twelfth day. A few days later the patient developed a bradycardia, which lasted six days. The E.S.R. fell from an initial level of 82 mm. to 12 mm. an hour within three weeks of beginning aspirin treatment. Increase in haemoglobin value by 2.8 g. occurred within four weeks.

The results of fluid, chloride, and nitrogen balance studies are shown in Fig. 3. During the first 10 days of aspirin treatment water and chloride were retained and the output of nitrogen greatly exceeded intake. During the next 15 days the volume of urine relative to the fluid intake progressively increased, and this was accompanied by an increased output of chloride and a steady diminution in nitrogen output.

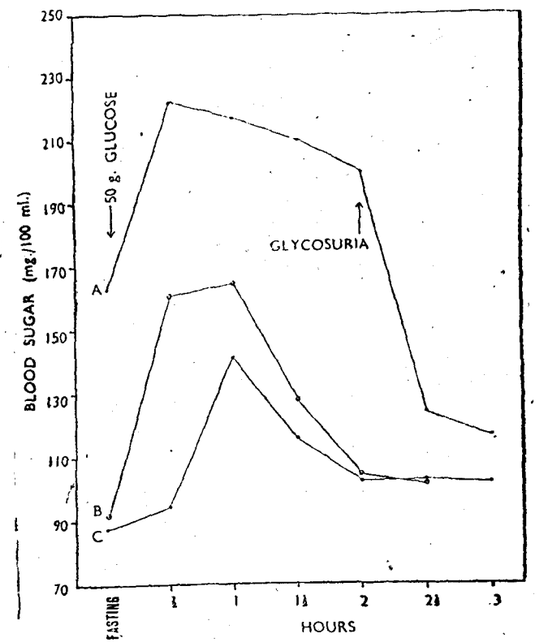

FIG. 1.—Glucose-tolerance curves after the ingestion of 50 g. of glucose following a 12-hour fast. Curve A was obtained at the height of aspirin therapy; curves B and C were obtained later, when aspirin was withdrawn.

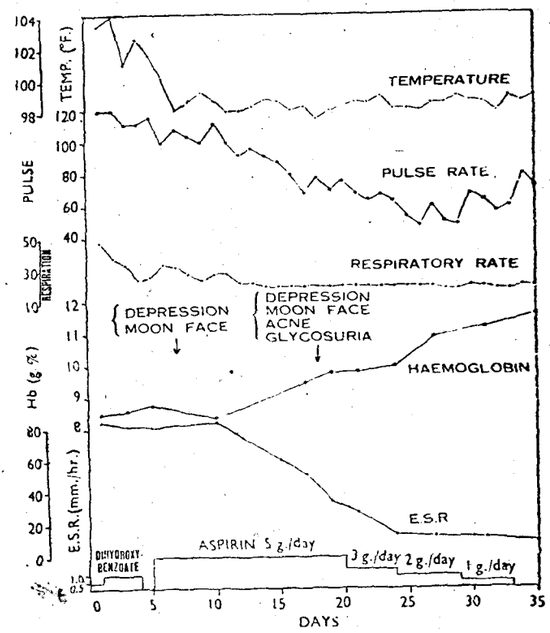

FIG. 2.—Effect of therapy on haemoglobin, E.S.R., temperature, pulse, and respiratory rates. The times of appearance of the side-effects suggesting Cushing's syndrome are indicated.

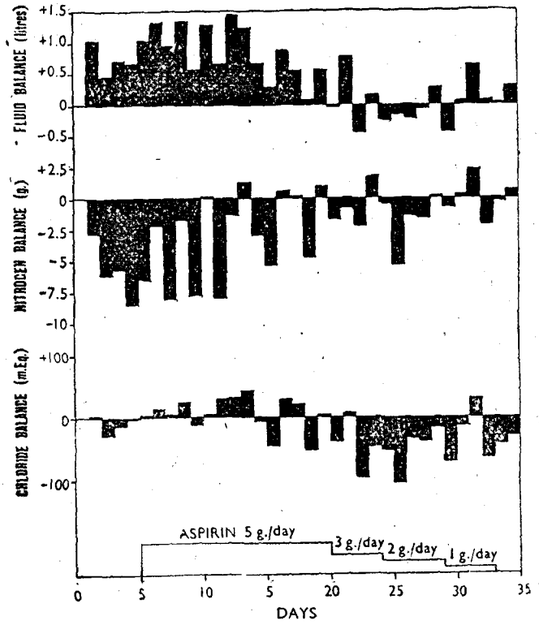

FIG. 3.—Effect of therapy on fluid, chloride, and nitrogen balance

During the course of treatment the albumin–globulin ratio fell to normal from its original reversed state. Serum albumin rose by 2.3 g. and globulin fell by 1.7 g. Plasma fibrinogen fell from its original high level of 0.77 g.% to 0.42 g.%.

Ketosteroid excretion (Tompsett and Oastler, 1946) was estimated daily from October 17 to 30 and showed no significant alteration. The daily output varied between 5.4 and 8.8 mg

Discussion

The clinical and metabolic effects of aspirin in this patient are identical with those previously reported (Reid, Watson, and Sproull, 1950). The effect of aspirin on pyrexia, tachycardia, E.S.R., and haemoglobin level compares favourably with that reported for cortisone. The two substances have the same effect on fluid, chloride, and nitrogen balance and on plasma protein. The similarity is further strengthened by the development under aspirin therapy of side-effects suggesting mild Cushing's syndrome.

If aspirin and cortisone have a similar action certain important considerations arise. Aspirin may stimulate the adrenal cortex to produce cortisone or may act in this way via the pituitary and the secretion of A.C.T.H.; or the two substances may have an identical peripheral action Aspirin and cortisone appear to differ in one respect. The former produces a respiratory alkalosis, while the latter causes a fixed base alkalosis. This discrepancy may be explained by the great difference in therapeutic dosage of the two substances. The comparatively large doses of salicylate lead to accumulation of the drug in the plasma. displacement of equivalent amounts of bicarbonate, and a raised plasma *p*H (Reid, Watson, and Sproull, 1950). As plasma *p*H depends on the ratio $H_2CO_3 : NaHCO_3$, any reduction in bicarbonate must be accompanied by an equivalent reduction in the concentrations of plasma H_2CO_3. This may be achieved by increasing alveolar volume, which lowers alveolar CO_2 concentration and

therefore plasma H_2CO_3. The clinical counterpart of this physiological adjustment is the slow deep breathing on salicylate administration.

It is realized that a single case has been cited as evidence of a possible common action of aspirin and cortisone, but on examination of our records of previous cases of acute rheumatism treated with sodium salicylate we find that frequent reference is made to puffiness of the face and acne-like lesions on the face, front of chest, and back. In fact, puffiness of the face may be observed in almost every patient receiving full therapeutic doses of salicylate, and it tends to be most pronounced in children. Most of these patients also had a reducing substance in the urine which was assumed to be a salicylate fallacy. However, addition of salicylic acid, sodium salicylate, and aspirin to normal urine in concentrations greater than we have ever encountered in the urine of patients under treatment failed to show any reduction of Benedict's solution. This does not exclude the presence of reducing substances other than glucose, but it may well be that the reductions previously observed were partly if not wholly due to glucose. These retrospective observations suggest that the development of mild Cushing's syndrome during intensive salicylate treatment is not uncommon, but there are many points requiring further investigation before any final conclusion may be drawn. Nevertheless, it is thought that this initial report is justified in view of the significance of the findings.

Summary

The clinical and metabolic effects of aspirin in the treatment of acute rheumatism resemble closely those attributed to cortisone.

A case is presented, and others referred to, in which the similarity in action of the two substances is further strengthened by the development under aspirin treatment of side-effects suggesting a mild Cushing's syndrome.

The effects observed were rounding of the facial contours, acne, diminished glucose tolerance, glycosuria, and alteration of the mental state.

Some important considerations arising out of this conception are discussed.

We thank Professor J. W. McNee for his advice and generous help in providing facilities for this work. We are also indebted to Mr. S. L. Rae for the ketosteroid estimations.

The British Standards Institution has issued a British Standard for one-mark bulb pipettes. *Sixteen sizes of pipette from 1 ml.* to 100 ml. capacity are specified, being those most in demand for general laboratory use. Full dimensions are given, but, in accordance with current practice in British Standards for laboratory glassware, only the essential ones are listed as mandatory, the remainder being given for the guidance of manufacturers. Standard methods are included for the determination of capacity and delivery time, and tolerances listed for both. An appendix gives the sizes of glass tubing recommended for the manufacture of these pipettes. Copies of this standard may be obtained from the British Standards Institution, Sales Department, 24, Victoria Street, London, S.W.1 (2s. post free). The Institution has also issued standards for hospital beds and other hospital equipment, and for paper boxes for pills, creams, powders, pastes, etc.

EVALUATION OF TREATMENT IN INTERMITTENT CLAUDICATION*

BY

J. T. SHEPHERD, M.B., M.Ch.

Lecturer in Physiology, Queen's University of Belfast

Arteriosclerosis is by far the commonest cause of intermittent claudication, and numerous drugs and operations have been advocated for the treatment of this condition. Any effective treatment must increase the distance a patient can walk, either by increasing the blood flow to the affected muscles or by reducing the pain which occurs on exercise.

Direct measurement of the distance a patient can walk is the common method of assessing treatment. This has two disadvantages. First, if improvement does occur it is impossible to say whether this is due to an increased blood flow to the muscles or to a pain-relieving action of the drug. Secondly, it does not allow the limbs to be tested separately. Often both legs are affected by the disease, but the earlier onset of pain in the more severely affected one may stop the patient walking before pain is felt on the other side.

An alternative method for evaluating treatment is described which does not suffer from these disadvantages.

Methods

The method employs an ergograph to determine the amount of work a patient can perform and a venous occlusion plethysmograph to enable the blood flow through the calf to be measured after the exercise.

The ergograph has already been briefly described (Shepherd, 1950). The patient, by depressing a footboard on plantar flexion, raises a weight. The footboard is so arranged that the axis of its movement passes through the ankle-joint (Goetz, 1942) and, as the leg is kept horizontal, with the knee flexed through an angle of about 60 degrees, the posterior calf muscles perform most of the work.

On the return stroke, as the ankle is dorsiflexed, the speed of the falling weight is controlled by a brake (Fig. 1). Alternate contraction and relaxation of the muscles is therefore possible, the posterior calf muscles being relaxed on dorsiflexion instead of having to resist the descent of the weight. This is important, because it leads to a large difference between the amount of work that can be done by the normal and the arteriosclerotic subject. The normal adult male of whatever build can make 500 contractions at a rate of 24 a minute and show no sign of fatigue or pain at the end. The number of contractions that can be made by arteriosclerotics with symptoms of claudication varies according to the severity of the disease, but even mild cases are generally forced to stop by pain and fatigue in the affected muscles before they have completed 200 contractions. The ergograph could also be adapted for testing the extensor muscles of the leg so that work is performed on dorsiflexion only. In practice this has never been done, as in all our patients pain on exercise was limited to the posterior calf muscles. The movement of the foot-board is transmitted to an indicator. A mark is placed on a scale behind the indicator, and by pushing to this mark the foot-board moves through an angle of 33 degrees and the subject lifts a 5.5-kg. weight a distance of 26 cm. By arranging

*This work was carried out during tenure of a British Medical Association scholarship.

the pointer of a metronome to move parallel to this indicator the subject, guided by the metronome, works at a constant rate. This allows accurate comparisons to be made.

Blood flows are recorded through the calf of the leg after exercise by means of a light celluloid plethysmograph (Shepherd, 1950) applied to the leg before exercise. Grant (1938) pointed out that any material departure from the resting forearm blood flow after local exercise can be attributed to a change in muscle circulation. It is probable that the same is true of the calf, and that recordings made after exercise represent mainly muscle blood flow. With the technique described, the first recording can be started within a second of the cessation of exercise

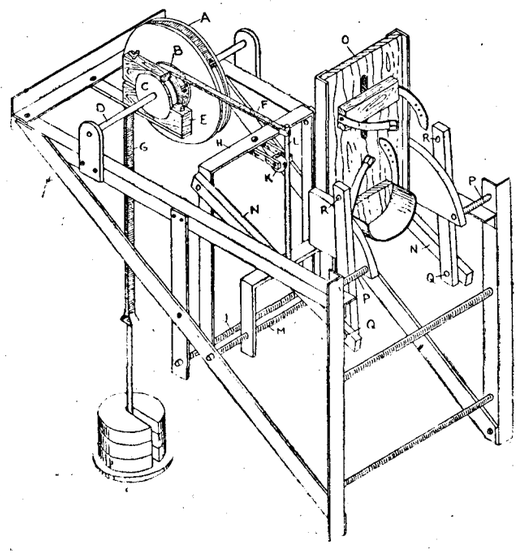

FIG. 1.—The ergograph. Framework made from light angle-iron and attached to the end of a couch so that the machine overhangs one end. Pulleys A, B, and C are mounted on axle D. Pulleys B and C are connected through a free-wheel device free from back-lash; A and B are permanently fastened together. A wooden block E encircles pulley C and the frictional force can be adjusted by means of two wing nuts. The brake-block is shown cut away to enable pulleys to be seen. The foot is strapped to the footplate O; the plate swings about the axles P. The footplate and attachments are counterbalanced by a weight not shown.

As the foot is plantar-flexed the connecting rods N move towards the right and pull lever H, which can swing about axle J, also towards the right. Roller K, attached to lever H, pushes to right a second lever L, swinging about axle M. A leather belt F, one end attached to lever L, passes round and is fastened to pulley B. As lever L moves to right the belt causes pulley B to rotate, and with it pulley A. Pulley C is kept stationary by means of the brake-block. A second belt G, one end attached to pulley A, carries a hanger on which the 5.5-kg. weight is placed. The rotation of A causes the weight to be raised.

On the return stroke, as the foot moves backwards and the weight falls, all three pulleys move together, the speed of the falling weight being controlled by the brake. This enables the foot to return to the dorsiflexed position without any force being exerted on it by the falling weight, since levers H and L can move independently

Results

Observation of the number of contractions that a subject can make on the ergograph, working at a rate of 24 contractions a minute, with the limb circulation both free and occluded, combined with a study of the calf blood flow after exercise, enables the deficiency of the circulation to the muscles to be assessed

In the occasional case in which the cause of the pain is in doubt this procedure may enable vascular deficiency to be ruled out. The following case is an example.

A man aged 49 complained of having had attacks of cramp in the left calf for two and a half years. He was able to make 500 contractions without pain or fatigue. The plethysmographic record showed normal pulsations. The immediate post-exercise flow was 23.2 ml. per 100 ml. calf a minute, and this was followed by a return to the resting level in two minutes. In addition, when exercise was carried out with the circulation occluded by a thigh cuff inflated to 200 mm. Hg. which was released just before the first post-exercise recording, the immediate flow was 33.4 ml., indicating that a considerable potential reserve was available (Fig. 2). This is a normal response to these tests.

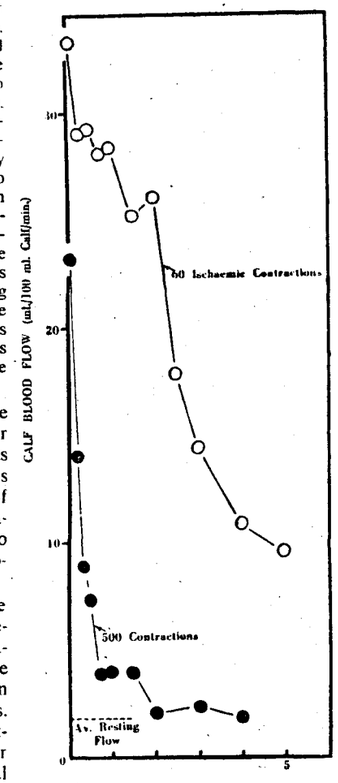

FIG. 2.—Patient aged 49. Normal pattern for the calf circulation. Normal pulsations on plethysmogram. 500 contractions of left calf without symptoms. Initial high flow with a rapid recovery to resting level. With 60 ischaemic contractions of left calf the immediate post-exercise flow is higher than with 500 normal contractions, indicating the potential reserve available.

The pattern of the calf blood flows after exercise in patients with arteriosclerosis and symptoms of intermittent claudication falls into two main groups (Shepherd, 1950).

Group A.—The plethysmographic record shows pulsations, but they are usually smaller than in normal subjects. The immediate post-exercise flow is lower than in the normal individual, and the flow subsequently declines very slowly to the resting level (Fig. 3). Ischaemic exercise carried on to claudication does not increase the post-exercise flow.

Group B.—The plethysmographic record shows either very small pulsations or none at all. The immediate post-exercise flow is much lower than in the normal subject, but instead of declining slowly to the resting level it gradually increases to a maximum some time after the cessation of the exercise and then declines to the resting level. The maximum level reached in these cases is invariably much less than the immediate post-exercise flow in normal individuals (Fig. 4). This pattern and the initial flow are unchanged if the exercise is carried out with the circulation arrested in the leg

Treatment of Intermittent Claudication with "Padutin"

Werle and Multhaupt (1937) found that the injection of padutin, an insulin-free pancreatic extract, caused an

increase in the skin temperature of the fingers. On the other hand, Abramson *et al.* (1941) found no change in the resting blood flow to the hand, leg, or forearm after the intramuscular injection of four biological units. Allen *et al.* (1946) state that the exact mechanism of relief of the pain of claudication by tissue extracts is not well understood, but that the extract seems to prevent in some way the chemical changes which produce pain in exercised ischaemic muscles.

In the present experiments the effect of padutin has been tested on eight male patients with arteriosclerosis whose ages ranged from 44 to 57 years, average 52. The primary complaint in all cases was intermittent claudication. None were diabetic, and the skin in all cases was healthy. The calf blood flow after exercise showed a Group A pattern in four, and a Group B pattern in four. Treatment lasted from 12 to 21 weeks, average 16.

The general routine was as follows. The patient made five visits before any treatment was started. On the first visit he practised on the ergograph in order to become familiar with the exercise, but no observations were made. At each of the following four visits the claudication index and the calf blood flow after exercise were measured. By claudication index is meant the number of contractions the patient could make before pain and fatigue in the affected muscles forced him to stop. Owing to the dependence of the claudication index on the determination of the subject, it was thought desirable to have four baseline observations.

The drug was given by weekly intramuscular injection: usually 1 ml. (three biological units) weekly for the first two weeks, then 2 ml. weekly until the last four weeks, when the dose was usually increased to 3 ml. In addition, the patient took the drug by mouth (10 biological units per ml.): 10 drops three times a day for the first two weeks, then 20 drops increased to 30 drops in the last four weeks. The claudication index and post-exercise calf blood flows were usually determined at weekly or occasionally fortnightly intervals throughout the period of treatment. Recordings were made about 15 minutes after the injection, but in some cases were also made before the injection was given, in order to rule out the possibility of the injection itself reducing the claudication index. No undesirable symptoms were reported.

In neither group was there any evidence that the drug relieved the claudication or increased the calf blood flow after exercise. Fig. 3 shows the post-exercise calf blood flow before and at the end of treatment in a patient with a Group A pattern. The pattern and the extent of the blood-flow response were unchanged and the average of the four determinations of the claudication index before treatment was not materially different from that at the end of treatment. Fig. 4 shows the post-exercise calf blood flow in a patient with a Group B pattern before and after treatment. The results of all the tests on this patient are shown in Fig. 5. It will be noted that there is no marked change in the calf blood flow or claudication index during the treatment.

It was often difficult to reconcile the patient's own assessment of changes in his condition with the objective measurements in the laboratory. Some patients thought they were improved about the middle of treatment, and two said that they could walk a mile whereas formerly they could walk only 200 yards. All, however, at the end of treatment felt there was no substantial improvement. Even during the time of alleged improvement the laboratory measurements showed no increase in claudication index or post-exercise blood flow.

All the patients smoked from 8 to 35 cigarettes a day, the average consumption being 20. Four ceased smoking for almost two months during treatment, with no important difference in their claudication index or their calf blood flow after exercise. Four patients, at one of their tests, smoked a cigarette and inhaled the smoke during exercise, with no change in the calf blood flow or the number of contractions carried out. In seven of these eight cases treated with padutin the circulation through the other calf was tested. Four showed a normal response, two a Group A response, and one a Group B response (Fig. 6).

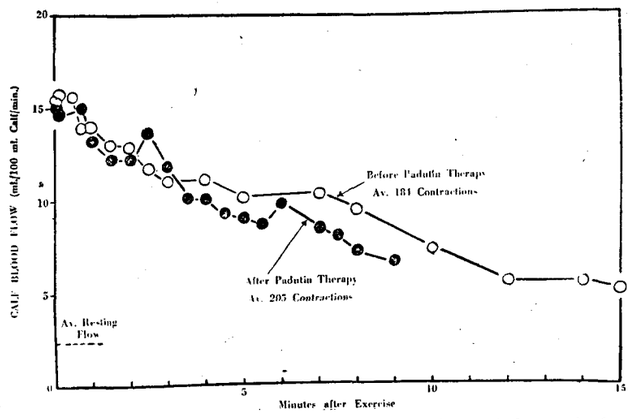

FIG. 3.—Group A pattern. Post exercise calf blood flow before and after 14 weeks' treatment with padutin in a patient aged 44. No change in blood flow and little alteration in number of contractions that can be made on the ergograph.

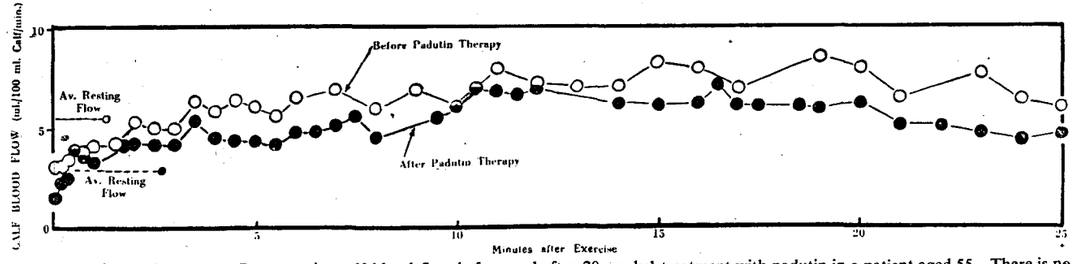

FIG. 4.—Group B pattern. Post-exercise calf blood flow before and after 20 weeks' treatment with padutin in a patient aged 55. There is no increase in blood flow as a result of treatment. Note that in this case the immediate post-exercise flows are lower than the average resting flows.

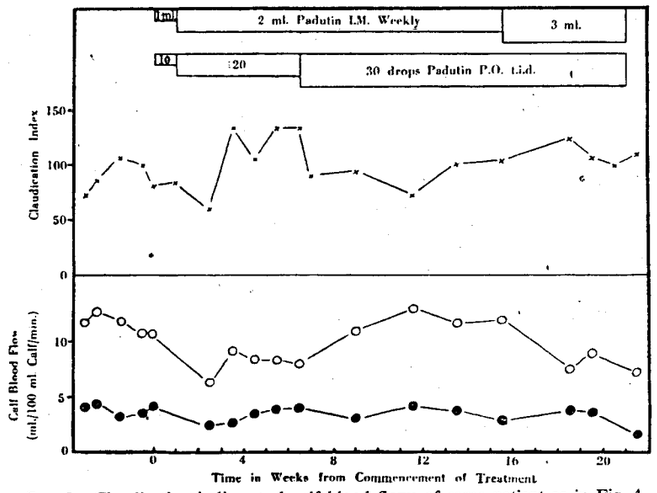

FIG. 5.—Claudication indices and calf blood flows of same patient as in Fig. 4. Black circles represent immediate flow after the exercise, and the open circles the maximum flow attained. The amount of padutin given is shown at the top of the figure. / This patient received the maximum dose for a longer period than the average.

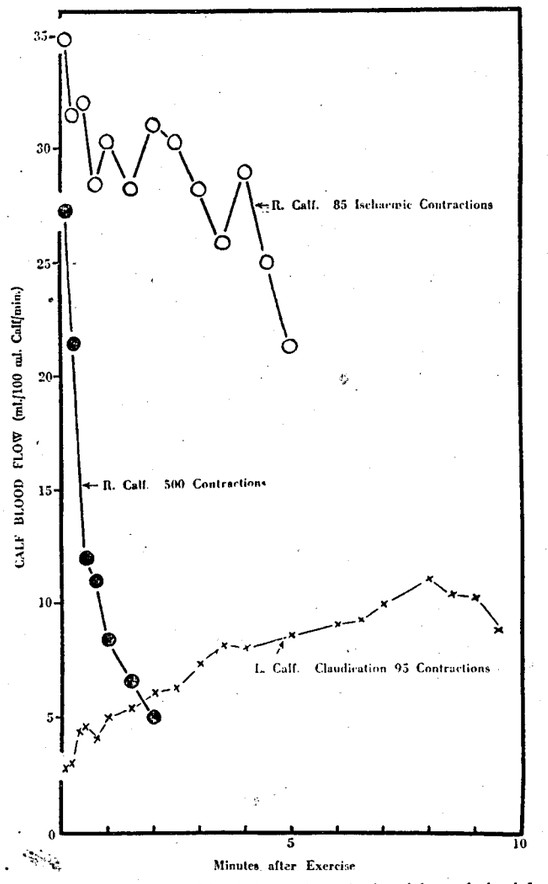

FIG. 6.—Post-exercise blood flows through the right and the left calf of same patient as in Figs. 4 and 5. Right calf shows a normal response, left calf a Group B response.

Prediction of the Effects of Sympathetic Neurectomy

In a series of 10 cases of arteriosclerosis with a healthy skin, whose primary complaint was claudication, an attempt was made to determine the effect of acute release of sympathetic control on the calf blood flow after exercise. Five of these cases had a Group A response to exercise, and five a Group B. Two methods were used. In the first the claudication index and the post-exercise calf blood flow were measured before and after heating the subject by wrapping him in blankets and immersing one arm in stirred water at 43° C. (Gibbon and Landis, 1932). Heating lasted one hour, unless the resting calf blood flow reached a steady maximum sooner. In the second method the claudication index and the calf blood flow after the exercise were first determined, and, after allowing one hour for recovery, the subject was asked to make the same number of contractions, during the last 18–24 of which 500 mg. of tetraethylammonium bromide (T.E.A.B.) (Acheson and Moe, 1945, 1946) was injected intravenously The calf blood flow was again determined immediately after the exercise. This procedure was used because of the brief action of T.E.A.B.

In four patients both these methods were used on separate occasions, in three T.E.A.B. only, and in three indirect heating only. In no case did either method increase the calf blood flow after the exercise, nor did indirect heating increase the claudication index.

Effects of Lumbar Sympathectomy

Eight cases have been examined before lumbar sympathectomy, including three from the series just described Four of these were in Group A and four in Group B. These patients also were non-diabetic and had healthy skins ; their primary complaint was of intermittent claudication. Five had one cold foot, but the skin temperature of the toes of this foot rose to 31.5–34.5° C. in response to indirect heating (Gibbon and Landis, 1932). The other three also showed a similar rise on the more affected side.

After lumbar sympathectomy there was in no case any conclusive evidence of improvement either in calf blood flow after exercise or in the claudication index. Fig. 7 shows, for example, the blood flow before and eight weeks after sympathectomy in a patient with a Group A response The blood flow was also determined at 5, 14, and 19 weeks after the operation, with similar results. The claudication index averaged 77 before and 79 after operation. A typical patient who showed a Group B response made 173, 120, 150, and 150 contractions 7, 8, 8½, and 9 weeks after the operation respectively, whereas his previous best was 140 contractions. There was no improvement in his calf blood flows in any post-operative test (Fig. 8). All these patients said that their exercise tolerance had not been improved by the operation.

Discussion

In order to assess any treatment of intermittent claudication it is desirable to study both the claudication index and the calf blood flow during exercise. The latter may bear no relation to the resting calf blood flow, so that the demonstration of an increase in resting calf flow is of no significance. The flow immediately after exercise is probably similar to that during the relaxation periods in exercise

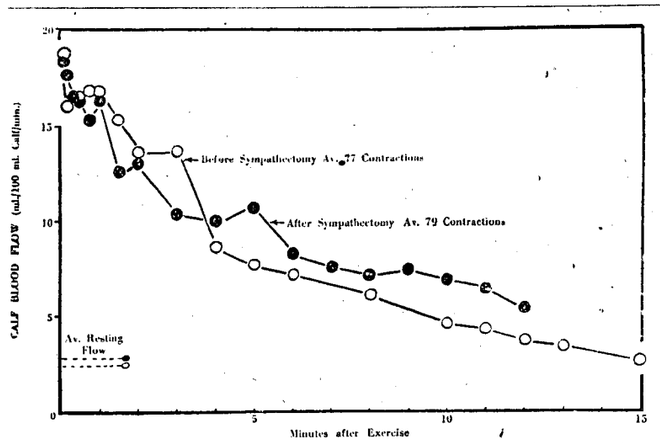

FIG. 7.—Group A pattern. Post-exercise calf blood flow before and eight weeks after removal of the first, second, and third lumbar ganglia in a patient aged 50. Similar flows were obtained 5, 14, and 19 weeks after operation. Skin temperature and skin resistance of foot after sympathectomy showed no change in response to indirect heating carried out by immersing the hand, forearm, and as much of the arm as possible in a stirred water-bath at 44° C. In view, however, of the findings of Boyd and Monro (1949) it is unlikely that all the vessels in the leg were completely denervated.

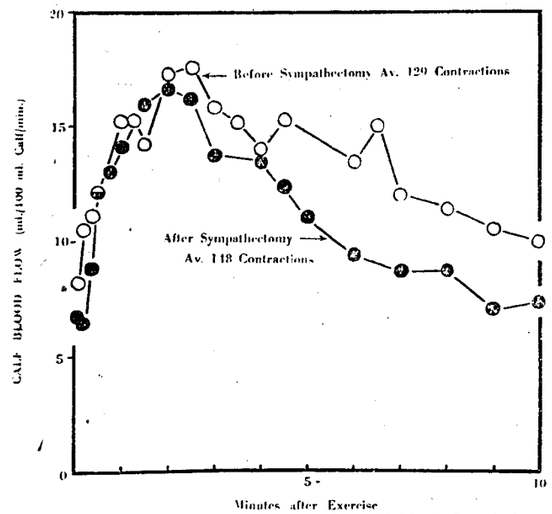

FIG. 8.—Group B pattern. Post-exercise calf blood flow before and eight weeks after sympathectomy in a patient aged 47. Similar flows were obtained seven and nine weeks after operation.

It is a much better, though still indirect, index of the blood flow during exercise than is the resting blood flow. It can also be determined simply and with precision. For these reasons its use is recommended, and it has been employed in this work. The ergograph does not, of course, exactly reproduce normal walking conditions, but it allows the blood flow to be measured after standardized exercise. To do this after walking involves some delay.

The values obtained for the claudication index were not constant for any one patient but varied somewhat on different occasions. In order to reduce these differences as much as possible it is essential for the subject to have a preliminary practice on the ergograph. After becoming familiar with the exercise his claudication index should be determined on at least four separate occasions. It is important to tell him to carry on until compelled to stop. The knee must be kept at the same angle throughout the series, because when it is more extended the subject is often able to perform many more contractions.

On pooling all results, 95% of the claudication indices and immediate post-exercise calf blood flows before treatment lay between 38% and 17% respectively above and below the mean for each individual. Any increase that was less than these values after treatment cannot be considered significant. The stage of the disease did not seem to affect the range of variation, in the same individual on different occasions, of either the claudication index or the immediate post-exercise blood flow. There was no evidence in any of the patients tested in the present series that padutin or lumbar sympathectomy caused a significant change in the claudication index or the immediate post-exercise calf blood flows.

The patients' own statements during treatment are occasionally misleading. They may, in an attempt to convince themselves that they are getting better, go further by walking more slowly, or overestimate the distance walked, or drive themselves further in spite of pain. For instance, four of the patients in the middle of their course of treatment with padutin said that their walking distance was increased, but their claudication index was found to be unchanged.

Since the condition may be progressive, the fact that the claudication index and the calf blood flow after exercise remained more or less unchanged during padutin treatment might indicate that this drug prevented a deterioration in the patient's condition. Before beginning treatment two of the patients were examined for four and six months respectively, during which time there was no deterioration in the calf blood flow after exercise. However, to obtain definite evidence on this point it would require two large groups, one acting as a control.

If during treatment there had been any definite evidence of improvement in the claudication index in these patients without a change in the calf blood flow following the exercise, it would have been necessary to control the results by treatment with a placebo in order to rule out the possibility of psychological improvement. As no improvement was found, this was not thought to be necessary.

The tests described with indirect heating and T.E.A.B may be useful in assessing whether sympathectomy can be expected to cause at least a temporary (Barcroft and Walker, 1949 ; Lynn and Barcroft, 1950) increase in the calf blood flow immediately after exercise. Three patients who had no increase of their post-exercise calf blood flow during heating or after T.E.A.B. also had no increase after sympathetic neurectomy.

Finally, these results deal only with claudication and the calf blood flow, not with the effect of padutin or sympathectomy on the temperature or circulation of the foot. All but one of the sympathectomized patients had a warm foot after the operation; and five of them felt that this made it worth while.

Summary

A method is described in which an ergograph and a light celluloid plethysmograph were used to measure the claudication index and the post-exercise blood flow through the calf.

The use of this method in the evaluation of treatment in intermittent claudication is discussed.

In eight cases of arteriosclerosis in which the primary complaint was intermittent claudication, padutin, administered both by mouth and by intramuscular injection over periods of 14–21 weeks, had no effect on the claudication index or the post-exercise blood flow through the calf.

Eight cases of arteriosclerosis with claudication examined before and at varying times after sympathetic neurectomy showed no evidence of improvement in the claudication index or the post-exercise blood flow through the calf.

I would like to thank Mr. E. J. Finnan, M.Sc., of the Department of Civil Engineering, Queen's University of Belfast, who designed and constructed the ergograph; also the patients, who willingly co-operated. I would also like to thank Messrs. Bayer Products, Ltd., for their co-operation and for the supplies of padutin.

INTRAMUSCULAR HEPARIN

BY

D. GORDON ABRAHAMS, M.A., M.D., M.R.C.P.
Senior Registrar, Institute of Cardiology, National Heart Hospital

It is generally considered that heparin is the most efficient and the safest anticoagulant in common clinical use. However, satisfactory therapy with this drug has hitherto necessitated frequent intravenous injections, which are irksome to both patient and doctor. Since heparin cannot be given by mouth, a method of administration which avoids the intravenous route and decreases the frequency of injections would have obvious advantages. Attempts to achieve this have been made in the past with various preparations of "depot" heparin, incorporated in Pitkin menstruum or other media. These have not proved completely successful.

A concentrated aqueous solution of heparin, 25,000 units per ml., for intramuscular injection has recently come on the market. This paper describes trials with this preparation carried out on 20 cases at the Institute of Cardiology.

Methods

All clotting times were determined by the method of Dale and Laidlaw (1911–12). Objections have been raised to this test, since it employs capillary blood. However, most authorities agree that all methods of estimating clotting time are unsatisfactory, and that techniques employing capillary blood are no more inaccurate than those in which venous blood is used. Moreover, the Dale and Laidlaw method is easy to carry out, gives an excellent end-point, and avoids the necessity for repeated venepuncture on the same patient. It was therefore admirably suited to the present type of study. The normal clotting time determined with this technique is two and a half to three minutes.

It was necessary to establish a criterion for adequate anticoagulation when using this method. This was done by injecting a standard dose of heparin intravenously into normal subjects and measuring by Dale and Laidlaw's method the extra time before clotting occurred.

Fig. 1 shows the average delay of clotting at ten-minute intervals in 16 normal subjects following the intravenous injection of a standard dose of heparin. The dose used was 100 units per kilogram body weight, and in a subject of average weight this amount approximates to a therapeutic dose. The shape of the curve in Fig. 1 should be particularly noted. The sharp rise following injection and the abrupt descent show that the drug is eliminated rapidly from the blood stream when given intravenously. After one hour the delay of clotting was two minutes. It was felt that a satisfactory blood level of heparin should exist for one hour after the intravenous injection of a therapeutic dose, and accordingly this was the criterion for adequate anticoagulation adopted in this work.

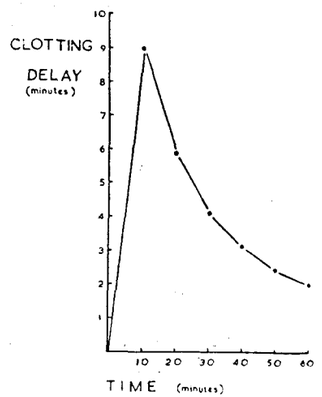

FIG. 1.—Average curve obtained in 16 normal subjects after an intravenous injection of 100 units of heparin per kg. body weight. Delay of clotting = actual clotting time minus control clotting time.

Results

The usual dose of heparin when given intravenously is about 30,000 units a day. It was reasonable to suppose that intramuscular injection would demand higher dosage, and trial and error showed that a single dose of 35,000 to 40,000 units given intramuscularly would delay clotting satisfactorily for twelve hours. The results obtained were extremely uniform, with only minor variations from patient to patient.

Fig. 2 shows the curves from two patients. After a single intramuscular injection of 37,500 units of heparin (1.5 ml. of solution) the delay of clotting has been plotted for twelve hours. Both these curves differ markedly from that obtained following intravenous injection (Fig. 1). With intramuscular injection, clotting is never considerably prolonged even in the initial stages, and the anticoagulant effect is very well maintained. This would seem to show that the drug is absorbed from muscle at a constant

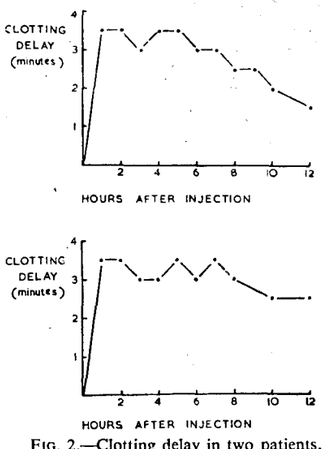

FIG. 2.—Clotting delay in two patients, followed for twelve hours after an intramuscular injection of 37,500 units of heparin.

rate. Even after twelve hours the delay of clotting is still adequate when judged by the criterion previously stated.

The problem of long-term anticoagulant therapy with intramuscular heparin was also studied in the same way.

Fig. 3 shows the dosage of heparin and the delay in clotting times in one patient over a period of four days. An initial dose of 37,500 units of heparin was given intramuscularly, followed by injections of 25,000 units (1 ml. of solution) twelve-hourly. The delay of clotting was satisfactory throughout and there was some indication that the dosage of heparin could be decreased after the initial stages. This was shown by the increase in the delay of clotting after the first two or three days. It therefore seems probable that either the dosage of heparin may be decreased after this time or the time interval between injections may be increased.

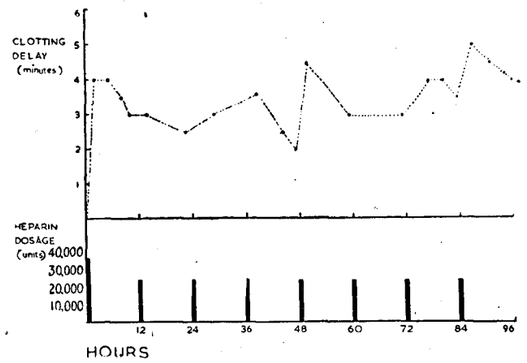

FIG. 3.—Long-term anticoagulant therapy with intramuscular heparin.

Discussion

There are some disadvantages to the intramuscular injection of heparin. It was at first found that the injection was attended in some patients by local pain. This, however, was satisfactorily overcome by the simultaneous injection of procaine : 1–1.5 ml. of a 1% solution of procaine should be given in the same syringe as the heparin. This has no effect on the action of the drug and considerably diminishes the pain.

The discomfort of the injection may also be ameliorated by injecting into the vastus lateralis muscle, and not into the buttock upon which the patient has to lie.

Very occasionally a haematoma may develop at the site of injection. This is not a common complication, and was encountered only twice during the course of this work. Bauer *et al.* (1950) reported five significant haematomata in a series of 41 patients treated with intramuscular heparin. These workers used large needles for the injection, presumably because of the consistence of their heparin solution. The heparin solution used in the present work was aqueous, and so this disadvantage was overcome. Indeed, a fine needle, 18–20 gauge, should be used, and not the ordinary intramuscular needle. In this way the possibility of trauma is reduced to a minimum, and haematomata can usually be avoided. Elaborate precautions are unnecessary when making the injection, but care should always be exercised.

Hitherto, treatment with anticoagulant drugs has almost invariably demanded admission of the patient to an institution. This has been rendered necessary by the numerous intravenous injections required for heparin therapy, and by the frequent laboratory tests which must always be done to control dicoumarol dosage. Neither of these factors need be considered when heparin is given intramuscularly. The clotting time is never grossly prolonged, and the risk of haemorrhage is extremely slight. The results obtained in this investigation indicate that the treatment may be conveniently and safely carried out in the home. If this conclusion is confirmed by subsequent work, the use of an anticoagulant in domiciliary practice would constitute a significant advance for both patient and doctor.

Summary and Conclusions

The possibility of giving heparin by intramuscular injection has been studied in 20 patients. A concentrated aqueous solution of heparin of strength 25,000 units per ml. was used. Results indicate that this is a satisfactory method for short-term or long-term anticoagulant therapy.

An initial dose of 1.5 ml. of this solution followed by 1 ml. twice daily is recommended as a scheme of dosage.

Local pain and occasional haematomata which may result are discussed, and the way in which these disadvantages may be prevented or minimized is indicated.

I wish to thank Dr. Paul Wood, Director of the Institute of Cardiology, for his advice and encouragement, and the physicians of the National Heart Hospital for permission to carry out this work on patients in their care.

'ANAESTHESIA IN THE NEWBORN*

BY

G. JACKSON REES, M.B., Ch.B., D.A.
Demonstrator in Anaesthetics, University of Liverpool

The newborn infant differs so greatly from the adult in his anatomy and physiology that the approach to anaesthesia in the two groups must be quite different. In the past there has been a tendency to adapt to infants those methods of anaesthesia which have proved to be of value in adults. The time has come to consider the problem of anaesthetizing the newborn in relation to their peculiar physiology.

During early life the ribs of an infant are disposed almost horizontally when the infant is in the erect position. Movements of the ribs can therefore produce only insignificant effects on the capacity of the thoracic cage, and costal respiration is practically impossible.

The Neonatal Lung

In addition to the relatively poor mechanism for its ventilation, the neonatal lung itself is a comparatively rudimentary structure. The area available for respiratory exchange is small in comparison with that of the adult lung: the amount per cubic centimetre of lung volume is half that of adult lung tissue, and the respiratory surface of the lungs per kilogram of body weight is about one-third that of the adult (Engel, 1947). To compensate for these deficiencies, as well as for the high oxygen consumption per kilogram of body weight, the infant has a rapid respiratory rate.

The infantile tracheo-bronchial tree is to some extent adapted to function in these circumstances, and the area of

*Read to the Section of Anaesthetics at the Annual Meeting of the British Medical Association, Liverpool, 1950.

the cross-section of the trachea of the newborn infant per unit of lung volume is twice that at 12 months. The sagittal diameter of the trachea of the neonatal infant is variously quoted as 3.6 to 5.7 mm. and of the adult as 15 to 20 mm. The diameter of the adult trachea is four to five times greater than that of the infant. If the forces governing the rate of flow of gases through the trachea follow Poiseuille's law, it would follow that an increase in the rate of flow in the child's trachea would produce an effect on the resistance to respiration 4^4 times greater than the increase in resistance produced by the same increase in the rate of flow through the adult trachea. In other words, if an increase in the rate of flow through an adult trachea increases the resistance to respiration by, say, x, the same increase in the flow rate through an infant's trachea would increase the resistance by $256x$.

On theoretical grounds, then, it is desirable that any technique employed for anaesthetizing young babies should not tend to increase the respiratory volume per minute, and should, if possible, reduce the amount of mechanical energy required for pulmonary respiration.

In addition to these mechanical differences between adult and neonatal respiratory systems, there seem to be certain differences in the sensitivity of the respiratory centre. The experiments in which Snyder and Rosenfeld (1937) observed the activity of the respiratory centres of post-mature foetal rabbits showed that smaller reductions in blood carbon-dioxide levels were required to produce acapnia in the young animals than in the maternal animals.

The immature state of the neuromuscular system in the newborn eliminates some of the problems which are met with in adult anaesthesia. The adult type of reaction to the irritation of an endotracheal tube under light anaesthesia is not seen in infants. The so-called "bucking" is impossible in children under 3 months of age, because until this time the cervical muscles are not capable of raising the head from the pillow. The only sign of irritation of the trachea under light levels of anaesthesia is a disturbance in the rhythm of respiration.

Similarly, deep levels of anaesthesia or heavy curarization are not necessary to produce muscular relaxation, because muscle tone is virtually non-existent in the newborn. During abdominal operations on young infants, intrusion of the abdominal contents into the operative field is sometimes very troublesome, but factors other than muscle tone appear to be mainly responsible for this. The infant at birth has an abdomen adapted to accommodate an alimentary tract which is devoid of gas, and thereafter the intestines acquire their gaseous content. It would seem inevitable that this, combined with the purely diaphragmatic type of respiration, would produce protrusion of the gut through the wound on opening the child's abdomen soon after birth.

The relative absence of muscle tone in infants can easily be demonstrated by artificial ventilation of the lungs under light anaesthesia; in small babies it is possible to inflate the lungs by the application of surprisingly low pressures, in sharp contrast with the resistance to inflation which the adult patient exhibits under similar conditions.

This ease with which the neonatal lungs can be inflated, combined with the small reduction in blood CO_2 required to produce acapnia, permits easy control of the respiration in young infants. In this respect the behaviour of the lightly anaesthetized infant bears a striking resemblance to the curarized and anaesthetized adult. Control of the respiration is extremely desirable in infants because it relieves the respiratory muscles of their whole load, and in abdominal surgery does much to prevent the pushing out of the abdominal contents. There is one theoretical objection to this procedure—there must be a shift of the oxygen dissociation curve of the blood to the left, thus reducing the peripheral oxygen tension. Barcroft (1946), however, showed that in newborn mammals the arterial oxygen saturation is only 75%, because the permeability of the pulmonary alveolar walls to oxygen is lowered, and that high oxygen atmospheres are able to raise the saturation level. In neonatal anaesthetic practice, then, a high oxygen atmosphere would more than compensate for the shift in the dissociation curve produced by artificial hyperventilation.

Use of Muscle Relaxants

In the light of these observations it is necessary to consider the use of muscle relaxants in the newborn. In anaesthetic practice generally these drugs can be used to reduce the dose of anaesthetic agent required for the production of good operating conditions because: (1) they reduce respiratory movements and enable adequate ventilation of the lungs to be carried out by the intermittent application of positive intrapulmonary pressures, without the use of excessive pressures; (2) they produce muscular relaxation in the surgical field; and (3) they reduce the effects of irritation by endotracheal tubes.

In the newborn, as has already been shown, control of the respiration is easily obtained at light levels of anaesthesia without the use of relaxants: muscle relaxation does not appear to be of major importance in the production of good operating conditions, and the usual untoward effects of endotracheal-tube induction are not seen. On these grounds it can be said that the use of relaxant drugs in anaesthesia is contraindicated in the newborn patient, and I have abandoned these drugs in such cases.

In view of the desirability of keeping the patient's respiratory activity at minimal levels and the relative absence of muscle tone, cyclopropane would seem to be an ideal anaesthetic drug for neonatal patients. The type of respiration which it produces would minimize the pushing out of the abdominal contents by the movements of the diaphragm, and the lack of muscle-relaxing properties would not be disadvantageous. There are, however, certain other effects which, I feel, render it undesirable. During surgical operations there is undoubtedly a greater loss of blood from those patients who are anaesthetized with cyclopropane, and this becomes a point of major importance in choosing an anaesthetic agent for a patient whose total blood volume is 300–400 ml. Prolonged administration of this drug to very small infants seems to produce in the early post-operative period a shock picture comparable to that often seen after its use in adults. For these reasons I consider that cyclopropane has little value in anaesthesia for the newborn, and that diethyl ether is the principal anaesthetic agent of choice, provided that the respiratory effect is reduced by controlled respiration produced by hyperventilation.

Operative Risk

The operative risk in newborn infants at term is slight, but it increases rapidly during the first week of life. This is in part due to the fact that the continuance of the abnormal state which the operation is designed to rectify increases the risk in some cases, but there is evidence to show that the resistance of all newborn mammals to physiological abuse becomes reduced during early extrauterine life. Glass *et al.* (1944), in a series of experiments on rabbits, estimated their survival time when they were subjected to

complete anoxia at term and at various days after term, and found that if the survival time in minutes was plotted graphically against the age of the animal the curve showed a regular decline from 30 minutes at term to 2 minutes at 20 days.

In those cases in which there is obstruction at some level of the alimentary tract the impairment of respiratory function by the aspiration of regurgitated fluid increases with time, and reflects on the operative risk; but this can be minimized by continuous aspiration of the pharynx in the pre-operative period.

In general, it can be said that the optimum time to operate is during the first 24 hours of life, or at the earliest period at which the blood urea and the urinary chlorides can be brought to normal levels.

Premedication

Some authorities have recently recommended that premedication of very young infants with morphine should be done. Leigh and Belton (1948) suggest a dose of 1/400 gr. (0.16 mg.) of morphine for 7-lb. (3.2-kg.) babies. This treatment appears to facilitate the smooth maintenance of anaesthesia, and would seem desirable if respiration is not to be aided or controlled. It does, however, make the induction of anaesthesia by inhalation agents—a tedious process at best—a very prolonged procedure.

Atropine should be given in all cases, and a dose which can be used on all newborn cases is 1/200 gr. (0.32 mg.).

Endotracheal Intubation

There are certain anatomical differences between the largest of newborn infants and adults that produce greater technical difficulties in the former. The infant larynx occupies a higher position in the neck in relation to the vertebrae, and the axis of its lumen tends to pass forwards as well as downwards. With the descent of the larynx which takes place in later life the forward angulation disappears (Tucker, 1932).

The complication of endotracheal intubation in young children that is most to be feared is subglottic oedema, the danger of which following instrumentation was first pointed out by Chevalier Jackson. Gillespie (1939) says that this oedema is the result of streptococcal invasion of abrasions produced by trauma during laryngoscopy, and that if care is taken during inhalation the risk is negligible. In his own published series of 70 cases of children under 18 months he does not report one instance of this complication. I have not met any case of respiratory stridor, nor have I seen any evidence of laryngeal oedema at post-mortem examination, following endotracheal intubation of neonatal infants. On the other hand, necropsy has revealed varying degrees of tracheitis, including one case in which there was on the anterior wall of the trachea a small circular ulcer similar to those reported recently by Dwyer *et al.* (1949). These lesions do not seem to have contributed towards the fatal outcome in these cases.

The advantages to be derived from intubation are very great, in that the tube ensures a reliable airway and enables the lungs to be readily inflated, and is an invaluable insurance against the dangers of gastric regurgitation, which is very common in the obstructive group of cases.

Apparatus

If CO_2-absorption apparatus is used on the newborn the only suitable standard equipment is the ¼-lb. (114-g.) Waters type of absorber described by Cope (1947). This has certain inherent disadvantages which greatly impair its value. Despite the fact that it is designed to reduce dead space, those parts of the apparatus which lie between the patient's respiratory tract and the soda lime have a considerable internal capacity. When the absorber is connected to an endotracheal tube its positioning is difficult if a considerable length of tubing is not used between the endotracheal tube and the absorber.

During the operation the Ayre's T-piece is very much easier to handle than the Cope absorber, and the internal capacity between the gas inlet and the patient is very small, so that with adequate flows of gas rebreathing is minimal. Artificial ventilation may be carried out by attaching a double-ended bag (B.L.B. type) to the exhaust tube, the open end of which is fitted with a vulcanite tap. This tap can be adjusted so that the intermittent pressure applied to the bag expels the amount of gas required to maintain the equilibrium of the system.

Thoracic and Abdominal Operations

I have now adopted a routine technique based on the views set out in this paper for anaesthetizing newborn infants for thoracic and abdominal operations.

The child is brought to the theatre dressed in a gamgee jacket and bonnet, and with the limbs bound in cotton-wool. An intravenous drip is run into one leg, and in cases in which there is alimentary obstruction a tube is passed into the stomach or, when there is oesophageal atresia, to the site of the obstruction. The thoracic cases that are cyanosed are brought up in an oxygen tent, and are transferred to the operating table only when the induction of anaesthesia is about to begin. The child lies on an electric pad on the table.

Induction of anaesthesia is effected by leading gases from a continuous-flow machine to beneath a Schimmelbusch mask covered by a thick layer of gauze, and separated from the patient's face by a thick layer of gamgee tissue.

Initially the gas flow is at the rate of 2 litres of oxygen a minute, maintained for one minute. At the end of this time 100 ml. of CO_2 a minute is added, and, finally, ether vapour to the limit of the patient's tolerance.

When the child breathes the full vapour concentration of ether regularly, the largest possible endotracheal tube is inserted, and this is connected by the shortest possible length of rubber tubing to an Ayre's T-piece.

The gas flow is adjusted to give a 50% O_2 and N_2O mixture flowing at a total rate of 3–4 litres a minute, and the ether vapour is turned off until the child shows movement of the limbs. In the meantime the mouth is packed with sterile ribbon gauze and the endotracheal tube is fixed. Ether is added to the mixture in concentrations just high enough to prevent movement.

The patient is now placed in the correct position for the operation, and a double-ended bag is fitted to the exhaust limb of the Ayre's T-piece. When the incision is made the respiration is brought under control by intermittent positive pressure applied by squeezing the bag, and the child is kept from spontaneous breathing throughout the operation.

Anaesthesia is maintained at the lightest possible level, and in view of the difficulty of eliciting and interpreting the signs of anaesthesia in these cases the ether vapour is turned off at intervals of 20 minutes for a period long enough to allow a return of some movements of the limbs. In this way rapid recovery after operation is ensured.

The method has proved to be extremely satisfactory, and the babies appear to be in much better condition post-operatively than those in whom spontaneous respiration was allowed to continue throughout the operation, or in

whom deeper levels of anaesthesia were attained. There seems to be rather less bleeding, and the surgeon is unhampered by respiratory activity.

OBSTETRIC ANALGESIA AND PLACENTAL INSUFFICIENCY

BY

E. H. SEWARD, M.A., B.M., D.A., D.Obst.R.C.O.G.
Research Assistant, Nuffield Department of Anaesthetics, Radcliffe Infirmary, Oxford

For the relief of pain in labour the combination of general medication and intermittent inhalation analgesia can be very effective and is suitable for all types of labour. Relief from pain is effectively obtained by careful antenatal preparation, by careful supervision during labour, by the judicious use of analgesic drugs such as pethidine, and by inhalation of a mixture that provides analgesia within 15 seconds. Success depends largely on the quality of the psychological management. The mother will be satisfied only if she appreciates the rationale of the method—that she will be aware of uterine contractions and will feel the baby delivered, but will not feel pain.

I closely supervised pain relief in a series of 200 labours, including 141 primiparae, selected at random but with every prospect of normal delivery. The patients had received no antenatal preparation for analgesia. Supervision and reassurance during labour were therefore exacting, but 89% admitted that analgesia was adequate. Subsequent experience has emphasized the well-known fact that antenatal preparation makes supervision in labour easier and more effective. Failure to obtain adequate analgesia has been due to lack of co-operation (or inadequate preparation for labour), to continuous backache at the end of the first stage of labour (needing higher dosage of analgesic drug), and to labour being well advanced on arrival in hospital.

In the 200 cases the inhaled mixture was either 0.5% trichlorethylene in air or 75% nitrous oxide with 25% oxygen, in both of which mixtures the oxygen content is at least as great as that of air. The commonly used 50% nitrous oxide with air provides only 10% oxygen: inhalation of such a mixture lowers the arterial oxygen tension to below 50 mm. Hg (McQuiston, Cullen, and Cook, 1943). This fall in tension is rapid. Examination with an oximeter (G. af. Geijerstam, 1949—personal communication) has shown that when a woman in labour inhales 4 litres of pure nitrous oxide in about 10 seconds the percentage saturation of her blood with oxygen falls from the normal 96% to 69% within 20 seconds, that is, to an oxygen tension of about 40 mm. Hg. The particular value of intermittent inhalation is to provide pain relief with negligible respiratory depression in the baby. It is important that the analgesic should not contribute to oxygen lack, which is a potent and insidious depressant of nervous function. The following considerations suggest that even intermittent inhalation of an oxygen-deficient mixture may contribute to intrauterine asphyxia when placental function is impaired.

Oxygen Transfer to Foetus

It is generally agreed that the passage of oxygen from mother to foetus is a matter of diffusion across the placenta, and that there is an oxygen-tension gradient towards the baby. Eastman (1930) has calculated that the probable oxygen tension in the placenta available to umbilical-vein blood during labour is 40–50 mm. Hg, compared with the 90 mm. Hg of maternal arterial blood. Whatever the actual figures may be, transfer is facilitated by devices such as an arrangement of vessels in the placenta whereby the streams of maternal and foetal blood run parallel but in opposite directions, so that umbilical-vein blood has maximum exposure to maternal arterial blood (Spanner, 1935); by the large numbers of foetal blood cells for oxygen transport (Windle, 1941); and by a difference in the oxygen dissociation curves of the two bloods which promotes the passage of oxygen across the tissue barrier. With a maternal arterial oxygen tension of 50 mm. Hg or less, the oxygen-tension gradient across the placenta is considerably reduced and possibly abolished.

There is little doubt, too, that a progressive decline in the saturation of the blood reaching the foetus takes place towards the end of gestation, and the point at which labour occurs is variable. Windle (1945) points out that, so long as normal healthy conditions prevail in the placenta, a reservoir of oxygen in combination with haemoglobin is present to provide for the needs of the foetus. This constitutes a factor of safety equivalent to at least 40 ml. of oxygen in the human at term, and enables the foetus to survive severe oxygen lack in the mother for short periods of time. The safety margin may be reduced by ageing of the placenta, by partial separation of the placenta, and by conditions in the placenta involving deposition of fibrin and ischaemic necrosis of villi.

Intrauterine Asphyxia

It is commonly accepted that changes in the foetal heart rate afford evidence of intrauterine asphyxia. This change in rate is similar to that seen in asphyxia in the adult where there is a preliminary acceleration followed by bradycardia The cardiac acceleration is thought to be due to reduced vagal restraint together with increased sympathetic drive The acceleration is later converted to positive vagal slowing, due either to a rise in arterial blood pressure acting via the carotid and aortic nerves or to a central discharge (McDowall, 1938).

A similar effect is seen in asphyxia neonatorum: when a baby takes occasional gasps with a long pause between, the pulse becomes progressively slower between gasps, but rises to the normal rate within a few seconds after a gasp which introduces oxygen into the lungs. When regular respiration is established the rate remains at 120–140 a minute. This implies that the vascular reflexes concerned in asphyxia of the adult are well developed in the foetus at the end of pregnancy, though the tachycardia mechanism may not operate. Barcroft (1946) wrote that there is a good chance of there being some vagus control before birth in man, but that it is not necessarily always present. It has been demonstrated experimentally in the goat that clamping the umbilical cord causes foetal bradycardia (Helliwell and Hutton, 1950).

Uterine Contractions and Oxygen Transfer

The weak pre-labour contractions of the uterus can lower the oxygen content of maternal placental blood (Windle and Steele, 1938). It is thought that the changes in foetal heart rate in relation to uterine contraction in labour are mainly asphyxial in origin owing to impairment of placental circulation and hence of oxygen transfer (Schultze, 1871). These changes are not invariable. In some labours there is no change in foetal heart rate during a contraction. In many there is a bradycardia during the contraction followed by a return to resting level as the contraction passes off. Waters and Harris (1931) described how the bradycardia may often be prevented by the mother's inhaling of oxygen.

Perhaps when the foetal heart rate does not vary during contractions either the reflexes are not fully developed or the placental reserve compensates for the impairment of placental circulation; or perhaps the slowing is due to pressure on the foetal head, for this often occurs when the head is subjected to pressure, such as when it is passing through the pelvic brim in a trial of labour, when the stretched cervix is sliding over it at the time of full dilatation, or when traction is applied with the obstetric forceps. The cause of the bradycardia in these circumstances is almost certainly a local asphyxia due to slowed circulation through the brain as a result of cerebral compression. Another factor which may operate was suggested by Leff (1932)—that uterine contraction squeezes blood from the placenta into the foetus, raises the pressure in the foetal circulation, and slows the heart according to Marey's law.

It is reasonable to regard foetal bradycardia during labour as being caused by local asphyxia in the medulla of the foetal brain, due either to pressure on the foetal head or to a general asphyxia of the foetus.

Placental Insufficiency

Asphyxia of the foetus may be enhanced by maternal oxygen deficiency. Under normal healthy conditions there is enough placental reserve to tide over temporary crises. When placental function is not normal it is clearly dangerous to lower the maternal arterial oxygen tension even during uterine contractions.

In a maternity department handling abnormal cases the foetal heart rate has from time to time been observed to give rise to anxiety while the mother inhales 50% nitrous oxide and air, whereas pure oxygen or 75% nitrous oxide with 25% oxygen seems to improve the foetal condition. Thus placental reserve is not always sufficient to withstand the impact of a uterine contraction and a low maternal arterial oxygen tension. A fall in the foetal heart rate of 10 beats a minute during uterine contraction is within normal limits. If the fall is greater than this, especially if the membranes are intact, then nitrous oxide and air should not be used for pain relief. Sometimes foetal bradycardia during a contraction for which the mother inhales nitrous oxide and air may not develop if she inhales nitrous oxide and oxygen. Waters and Harris described how foetal distress often follows in a labour in which there is foetal bradycardia during uterine contraction.

Thus the effect of a uterine contraction on the foetal heart rate can afford an indication of the placental reserve, though of course placental insufficiency is not the only cause of foetal distress in labour. The point is illustrated by a case described recently by Ewart Williams (1949—personal communication).

Pregnancy in a multipara with hypertension, oedema, and albuminuria was allowed to continue with some misgivings until 36 weeks, when labour began spontaneously. With the weak contractions of early labour there was a marked foetal bradycardia during the contraction and arrhythmia between contractions. Inhalation of oxygen by the mother restored the foetal heart rate to a steady rhythm, and contractions caused only slight bradycardia. The baby was delivered by caesarean section. The placenta was small, grossly infarcted, and degenerate on naked-eye examination. The placental reserve was so small that the impact of even weak uterine contractions was enough to cause obvious foetal distress.

If placental function is suspect, or if labour shows the reserve to be small, then maternal arterial-oxygen tension should be maintained and nitrous oxide and air avoided. Maternal oxygenation should also be maintained during labour lasting more than 24 hours. In a series of prolonged labours, with normal labours as controls, there was a significant increase in nucleated red corpuscles of cord blood, suggesting possible foetal oxygen lack. Again, if general anaesthesia is used for forceps delivery for foetal distress, induction of anaesthesia with pure nitrous oxide may be convenient for the anaesthetist but endanger a foetus already in distress.

Conclusion

Intermittent inhalation analgesia can play a valuable part in relief of pain in labour. Nitrous oxide and air has been used in countless thousands of labours without harm: in normal labour there is a reserve which more than compensates for any oxygen deficiency it may cause. Nitrous oxide and oxygen mixtures can, however, provide better relief of pain by virtue of the higher nitrous oxide content that can be used. At the same time they maintain the maternal arterial–oxygen tension, the importance of which has been emphasized by Greenhill (1947). Under certain conditions a fall in the maternal arterial-oxygen tension during labour is dangerous for the baby. Such conditions are when the placental reserve is suspect, as in pre-eclamptic toxaemia and premature separation of the placenta; when uterine contractions reveal a small placental reserve by their effect on the foetal heart rate; when labour is prolonged; and when labour occurs in the presence of erythroblastosis foetalis. In these circumstances intermittent inhalation of a nitrous oxide and oxygen mixture is advisable, as it is also when the mother is embarrassed by cardiac disease, pulmonary disease, or anaemia.

A mixture of 75% nitrous oxide with 25% oxygen has already been reported as giving good results (Seward, 1949a). This mixture maintains normal oxygenation while providing a high proportion of nitrous oxide for pain relief. In more than two years' use it has proved satisfactory for self-administration under the supervision of midwives trained in the use of nitrous oxide and air. Suitable apparatus should provide intermittent flow of the constant mixture at not less than 25 litres a minute; should include a reservoir bag of 6–7 litres capacity; and should incorporate a device whereby the nitrous oxide is automatically cut off when the oxygen supply fails. The apparatus designed by Warming and reported elsewhere (Seward, 1949b) has proved satisfactory in use. A refinement can be added so that the mother may inhale pure oxygen between contractions and nitrous oxide and oxygen during contractions when the foetus is distressed. Such apparatus is necessarily cumbersome because of the necessary cylinders, which restrict its convenient use to institutions.

I acknowledge with thanks the facilities afforded by the Nuffield Department of Obstetrics and Gynaecology, and the Area Department

of Obstetrics and Gynaecology, Oxford. The labour ward sisters and nursing staff have at all times been most helpful and co-operauve. Mr. D. J. Finney, of the Lectureship in Design and Analysis of Scientific Experiment, University of Oxford, kindly provided assistance with some statistical problems.

Medical Memoranda

Vulvovaginitis in a Child due to Shigella flexneri

It has been pointed out by various writers that organisms other than the gonococcus may give rise to vulvovaginitis in children. Haemolytic streptococci, staphylococci, and possibly Petit's bacillus have been found to be responsible for the condition (Topley and Wilson, 1946—referring to Hardy, 1941, and Osmond, 1944), and it is generally held that diagnosis of gonorrhoeal infection in children should never be made unless the gonococcus is demonstrated by cultural methods. The following case affords further evidence in support of this view.

CLINICAL HISTORY

A girl aged 7 was brought to hospital by her mother, who was worried because the child had a copious vaginal discharge for 24 hours. She was normally under the care of an African nursemaid.

Examination revealed a very heavy vaginal discharge of thick creamy pus. There was a moderate inflammatory reaction in the vulvar region. Vaginal swabs and smears were obtained, and, in view of the severity of the condition and the presence of Gram-negative diplococci in the stained direct smear, intensive treatment with penicillin was instituted. After 72 hours' treatment there seemed to be no marked improvement. Further laboratory investigations (see below) indicated a more specific line of treatment, and sulphaguanidine was given orally and sulphaguanidine powder by vaginal insufflation. The discharge ceased within 48 hours from the beginning of this therapy. Up to one month after leaving hospital there was no sign of recurrence of the discharge.

LABORATORY INVESTIGATION

The smear sent to the laboratory was stained by Gram's method and showed very numerous polymorphonuclear cells and some Gram-negative intracellular organisms, coccal in shape, occurring in small groups and arranged in pairs within these groups. As the child had an African nursemaid gonococcal infection was thought to be not unlikely, and cultural examination for the gonococcus was decided upon.

Two swabs were sent for examination, the second because of some delay which occurred between the taking and the arrival at the laboratory of the first. Both swabs were plated on blood agar and incubated at 37° C. in an atmosphere of approximately 10% carbon dioxide. The plates were examined after 24 hours' incubation. The blood agar inoculated with the first swab showed a few colonies of *Staphylococcus albus* and a few greyish, circular, low convex colonies, about 1 mm. in diameter, which were suggestive in appearance of a coliform type of organism. The blood agar inoculated with the second swab gave a heavy growth of the greyish colony in pure culture. Both plates were incubated for a further 24 hours, but no other colonies developed.

Films made of the colonies from both plates showed a Gram-negative cocco-bacillus about 1 μ in length and 0.5 μ in width. One colony from each plate was subcultured on agar slopes and, after incubation at 37° C., inoculated into tubes of lactose, glucose, mannitol, dulcitol, sucrose, and peptone water. In each case acid was formed in glucose and mannitol; there was no change in lactose, dulcitol, or sucrose; indole was not produced and the organism was non-motile.

Slide agglutination tests performed with polyvalent Flexner I and polyvalent Flexner II sera showed agglutination with the former only. Suspensions of the organism were prepared, using mercuric iodide and potassium iodide in buffered formol-saline, and tested for agglutination in tube against polyvalent Flexner I and the individual sera making up polyvalent Flexner I. *Sh. flexneri* V, W, and Z. There was agglutination to a dilution of 1 in 250 with polyvalent Flexner I and *Sh. flexneri* W; *Sh. flexneri* V showed agglutination to 1 in 25, but agglutination was not observed with *Sh. flexneri* Z.

Inquiries elicited that the girl had had diarrhoea some seven days previous to the onset of the vulvovaginitis. No one else in the family or any of the African house-servants admitted to having had diarrhoea or dysentery, so it was decided to examine specimens of faeces and rectal swabs from the child over the next 14 days. The first stool was fluid, but macroscopically no blood was seen, though microscopically red blood cells were observed together with abundant pus cells. Later specimens were more formed, and the pus cells and erythrocytes were considerably reduced in number. The swabs and faeces were inoculated on desoxycholate-citrate agar (Hynes's modification) but *Sh. flexneri* was not isolated.

In view of the findings of the direct examination, however, there was strong presumptive evidence of a bacillary dysentery infection, and the inability to isolate the organism from specimens of faeces might be accounted for by the fact that the patient was being treated with sulphaguanidine.

Herpes Zoster Provoked by Smallpox Vaccination

In view of the correspondence on the subject of herpes zoster since the day that Bókai (1892) first noted the clinical association of the condition with varicella, the following case may be of interest.

CASE REPORT

A Chinese man aged 22, who had previously been vaccinated successfully on two occasions, was again vaccinated on November 12, 1949. This was successful, producing a small reaction in the skin over the right deltoid muscle. On November 22 he complained of pain in the right arm and the right side of the neck. A skin eruption began on the arm on the following day, and he was admitted under my care on the 25th, when he had an obvious and extensive herpes zoster from the root of the neck down the outer aspect of the right arm to the thumb. He also had widespread varicella-like discrete lesions on the trunk and face (herpes generalisatus). The dry crust of his

recent vaccination was still present, and separated normally on November 27. The course of the illness was uneventful, and he was discharged about ten days after admission.

COMMENT

This case may be an example of the activation of a latent virus disease by another virus disease. A similar sequence of events has previously been reported. The Committee on Vaccination in London (1928) suggested that vaccination may precipitate encephalitis in persons harbouring the latter virus. Levaditi and Nicolau (1926) noted that the injection of the rabies virus in rabbits produced death from latent neurovaccinia. Madonick (1946) reported a case of herpes zoster in which vaccination (in a patient twice previously vaccinated) provoked encephalitis. The herpes began on October 26, vaccination was performed on October 30, and encephalitis developed on November 7.

In Singapore herpes zoster seems to be more common and less severe than in the U.K. The above case was the most severe I have seen on the island. Vaccination of the skin served by the fifth sensory root provoked a subsequent severe herpes involving particularly the fifth and sixth roots on the same side. This case seems to be of importance as illustrating that there are dangers attached to smallpox vaccination, and possibly to autovaccination of vesicle fluid, as a therapeutic measure in cases of herpes zoster and herpes simplex.

I wish to thank Brigadier J. T. Collins, D.M.S., F.E.L.F., and Colonel C. P. Chambers, O.C., B.M.H., Singapore, for permission to publish.

Torsion of the Gall-Bladder

Torsion of the gall-bladder is a rare condition, fewer than 80 cases having been reported in the literature. No recorded case has been diagnosed correctly pre-operatively in spite of the well-known and classical paper by Rendle Short and Paul (1934), which describes the symptomatology with great clarity and points out that a pre-operative diagnosis should be possible. The importance of making the diagnosis lies in the facts that the operation for cure is extremely simple and quick; that pre-operative treatment can be reduced to a minimum; that recovery is uneventful; while the mortality rate is directly reciprocal with the delay in operating. In the age group in which most of these cases occur—that is, 60–80—both doctor and particularly patient wish to avoid operation wherever possible, and the delay has usually arisen through giving expectant treatment on a diagnosis of acute cholecystitis.

If, however, the condition is borne in mind, the necessity for operation, together with its ease and rapidity of performance, can be plainly expressed to the patient, and the mortality rate should fall considerably from the 16% estimated by Smith (1936).

CASE REPORT

The patient, a woman aged 77, was admitted to Southmead Hospital, Bristol, on September 27, 1949. Four days previously she had had an attack of acute abdominal pain which was very severe. Retching occurred but there was no vomiting. Her bowels had not been opened for three days, but an enema gave a good result. Her temperature was 97.4° F. (36.3° C.) and a swelling which was tender was felt on the right side below the umbilicus. The next day the abdomen was less distended and an enema produced only flatus + + +. The following day there was no vomiting but the patient still complained of pain in her right side. An enema gave a good result. This state continued throughout the following 24 hours, but the swelling was becoming more tender. She was admitted to hospital four days after the onset of pain.

On admission she was seen to be a very frail old lady in severe pain. Her temperature was 98.4° F. (36.9° C.). Her tongue was dry; heart and lungs N.A.D. There was no jaundice. The abdomen was distended and tympanitic. A hard swelling which was extremely tender but quite mobile was present in the right iliac fossa. The extreme tenderness made full examination difficult. A doubtful provisional diagnosis of twisted ovarian cyst was made, but it was evident that there was some mischief in the abdomen which required laparotomy.

Operation.—Through a paramedian incision the gall-bladder presented itself wrapped in the omentum, black, distended to the size of a pear, and with a few green spots of incipient perforation. It was twisted in a clockwise direction through three complete turns around its oedematous pedicle of cystic duct and artery. Its removal was extremely simple, but the cystic artery was so arteriosclerotic that the first ligature did not occlude it. There were no stones. Convalescence was uneventful.

COMMENT

This case was misleading in that the swelling itself was so low in the abdomen: otherwise the fluctuating course of the illness, and a mobile tender lump in a frail old lady, should have enabled a correct diagnosis to be made.

Since Rendle Short and Paul's paper the balance between clockwise and anticlockwise rotation has been levelled, and to date the ratio is about 50–50. The clockwise rotation is attributed to peristalsis in the stomach (Barber, 1939), while the anticlockwise is due to colonic movements. This is a plausible theory, but does not explain why a gall-bladder lying with a free pedicle and exposed to these movements for upwards of 60 years should suddenly rotate. In my case the cystic artery which entered the pedicle above the cystic duct was a true bill "pipe-stem" artery and acted as a strut around which the pedicle must revolve, as any to-and-fro movement was impeded. The condition of the arteries has not previously been noted, but some arteriosclerotic change could be expected in the general age group, and the position of such an artery in relation to the duct might explain the direction of rotation.

The lower age limit has, however, fallen to 5 years (Cuervo, 1939), but it is easier to understand such congenital anomalies causing trouble in the first decades. In the case quoted by Berry (1939) there was a rough vehicular ride to initiate the process. In Gowland's (1946) case the attacks had been repeated over many years.

I wish to express my thanks to Dr. Phillips, medical superintendent at Southmead Hospital, for permission to publish this case.

Reviews

THE SCIENCE OF GENETICS

The Elements of Genetics. By C. D. Darlington, F.R.S., and K. Mather, F.R.S. (Pp. 446; 88 figures. 25s.) London: George Allen and Unwin. 1949.

There must be many medical men who are wondering where the science of genetics has got to and would like to have a comprehensive but relatively brief account, without, of course, popularization. This is just the book they are waiting for, provided that they are prepared to take some trouble over a subject which must remain difficult, however skilful the presentation. Some medical men are allergic to mathematics, even if they would not go so far as to say, as does one friend, that they feel quite sick if they see a square-root sign. Two of these chapters will defeat them. A much smaller number are baffled by visualizing three dimensions, finding that embryology, for example, is a very difficult subject. It is, however, only the unfortunates, if there are any such, who suffer from both disabilities who should be advised that the book is not for them.

Professor Darlington and Professor Mather have written a very concise textbook of only 374 pages, not counting glossary and index. The principles of the subject are not obscured by detail. Yet it is a very bold attempt at a complete synthesis of knowledge up to the present time. In such a book the gaps must be filled in by intelligent speculation, and this is part of their plan. It is at this point that the book may perhaps be criticized, for often it is not clearly indicated where what is generally accepted ends and the speculation begins. But this is not a serious disadvantage for those in other branches of science who want a conspectus of the subject. Apart from its excellence as a general textbook this volume should appeal especially to those whose main interests lie in the human field: there is much reference to viruses and micro-organisms and to genetics and the cancer problem, as well as a particularly interesting chapter on man himself.

GUIDE-BOOK TO BRITISH MEDICINE

The British Encyclopaedia of Medical Practice. Abdominal Emergencies to Anus Diseases. Under the general editorship of the Rt. Hon. Lord Horder, G.C.V.O., M.D., F.R.C.P. Volume I. Second edition. (Pp. 786; 148 figures. £3.) London: Butterworth. 1950.

The second edition of the *British Encyclopaedia of Medical Practice* needs no introduction. Lord Horder has now assumed the general editorship formerly held by the late Sir Humphry Rolleston, and he contributes a brief foreword, while retaining, as an engaging act of piety, the scholarly introduction written by his predecessor for the first edition. The articles are arranged in alphabetical order, this volume beginning with "abdominal emergencies" and ending with "diseases of the anus." "Medical practice" is used in the widest sense, embracing, in this volume alone, medicine *sensu stricto*, surgery, gynaecology, obstetrics, tropical diseases, dermatology, anaesthesia, and rhinology. The articles are concise, and emphasis is laid on the practical rather than on the academic aspects. The contributors are acknowledged experts in their subjects, and it is perhaps invidious to select particular articles for mention. The excellence of Mr. Zachary Cope's account of "abdominal emergencies" was to be expected; the sections on "aneurysm" and "myocardial infarction," respectively by Dr. Maurice Campbell and Dr. Evan Bedford, are concise and lucid expositions of the subjects; and Mr. Gabriel's description of "diseases of the anus" is a contribution of great practical value.

If the aim of the editor is to provide a handbook to which the general practitioner may turn for illumination and practical guidance this first volume suggests that he has been abundantly successful in achieving it. It is not, nor indeed does it set out to be, a rival to the great systems of medicine, and in this respect its title may be misleading. As an example of book production this volume ranks high, even for one of Messrs. Butterworth's publications. It is superbly printed on fine calendered paper, and the many half-tone blocks are flawlessly reproduced. It is perhaps a little disquieting to note that the publishers found it necessary to employ a firm of printers in Vienna.

R. BODLEY SCOTT.

LECTURES ON ANATOMY

Vorlesungen über Topographische Anatomie. By Professor O. Grosser. (Pp. 354; 313 figures. 46s.) Vienna: Springer. 1950.

This volume consists of the lectures given by Professor Otto Grosser at the German University in Prague. It is a common practice in German universities for the professor to publish such a book for the benefit of the students who have attended his lectures, for it is of the utmost value to them. It is thus not exactly a textbook, for it is in such an abbreviated form as to be unintelligible to anyone not already familiar with the subject. This very brevity, however, is an advantage not only to those for whom it is intended but to those with some familiarity with human anatomy who wish to revise and extend their knowledge.

Unless this is appreciated the first chapter would fill any student with despair, for the author describes the brain and central nervous system in so compressed a form that only an advanced student could possibly understand it. Yet these are obviously the notes of very brilliant lectures from which the expert may gather hints of real value for his own work. With a very moderate knowledge of German he will have no difficulty with the language, for the expression is simple and entirely avoids the complex sentences so dear to the German mind.

There are ample illustrations, mostly reproduced from such famous classics as Toldt and Sobotta, and, although they do not attempt to emulate the superb artistic value of the originals, they are quite serviceable. One original drawing of the brain by Lepier, with the surrounding skull and overlying sutures, is of the highest quality and a real pleasure to study. Many of the diagrams will be useful to lecturers on anatomy, but in some of the illustrations, as so often happens, the artist has buried the essential points in a mass of irrelevant detail.

The book is plainly the result of a profound knowledge of human anatomy and a wide experience of teaching. It will well repay careful study by those engaged in the teaching of a difficult subject.

HENRY SOUTTAR.

TREATMENT WITH QUINIDINE

Quinidine in Disorders of the Heart. By Harry Gold, M.D. (Pp. 115. 16s.) London: Cassell and Co. 1950.

Any book that will help to overcome fear and prejudice concerning quinidine is welcome. In this country, especially, its toxic effects have been long overemphasized and its action and value improperly appreciated. This book offers a much-needed corrective. Though the book is written primarily for general practitioners, the author's belief that students and specialists may also find it helpful is justified. The facts given and the opinions offered are based on pharmacological and clinical research, extensive reading, intimate contact with postgraduate difficulties, and practical experience over 25 years.

The many actions of quinidine are described. The side-effects are shown to be the direct result of some of these actions and, while undesirable under certain circumstances, are not necessarily toxic. Thus, quinidine lowers the blood pressure by reducing the peripheral resistance: such a side-action is undesirable when the drug is given intravenously to stop paroxysmal ventricular tachycardia in a shocked patient, and may cause immediate syncope; but a similar side-action is common to many drugs which prolong the refractory period of heart muscle and depress cardiac excitability—for example, procaine.

Although the author admits that there are patients who are allergic to quinidine and who may react to it by developing urticaria, purpura, or asthma, he has never encountered such a case himself, and does not give a test dose before beginning treatment. His observations on dosage are interesting. He wisely points out that the toxic dose of a drug is that which produces toxic symptoms, and the therapeutic dose is that which has the desired effect. It is no surprise to learn, then, that he has a number of patients who have been taking 30 to 60 gr. (2–4 g.) of quinidine daily for years.

The latter half of the book is on quinidine therapy in particular conditions. This is also helpful and informative.

As a whole, the work is an unpretentious handbook. It is written in a free narrative style, and is not illustrated. There are no references in the text, but a useful bibliography is appended. It provides just the sort of information that students and practitioners need.

PAUL WOOD.

COMMUNITY HEALTH

Personal and Community Hygiene Applied. By Jesse Feiring Williams, M.D., Sc.D., and Gloyd Gage Wetherill, M.A., M.D. (Pp. 610: 147 figures. £1.) Philadelphia and London: W. B. Saunders Company. 1950.

The preface tells us that this book is the natural development of an earlier book—*Personal Hygiene Applied.* It is a development that recognizes the significance of community problems and the social as contrasted with the individual aspects of health and hygiene.

The book is not written for the specialist. It opens with a general survey of the health problems which confront the individual. We are first given a list of 10 headings to embrace all the physical, mental, and emotional facets of health. For full positive health the individual must be adequately provided with each one of the 10 abilities which are listed—for example, ability to engage in mental and physical activity; to recover efficiently from the effects of activity; to resist fatigue in extraordinary situations; to exert strength in certain muscle groups; to act with others in harmonious groups; to experience, express, and control emotions; and so on. Thus the concept of positive health is taken to include adjustment within the social situation in which the individual finds himself.

In following chapters the authors consider more specific aspects of personal health. Thus they give simple straightforward information and advice on care of the skin, posture, fatigue and rest, food and nutrition, and so on. The pattern followed is logical: the data are presented clearly and simply. Though a paragraph heading "A Trip through the Respiratory Passage" may surprise or even shock the medical graduate, to the reasonably intelligent public it probably stimulates the imagination and offers adventure and interest.

If the first half of the book is primarily written for the lay reader, the last seven chapters, which discuss community problems, are appropriate to medical and non-medical reader alike. The study of social medicine and community health is sufficiently new to need greater publicity among the medical profession. But interest in community health, which is defined as "the quality of life in a community that is marked by the effort of people to live at their best and to help others in the community to do likewise," is clearly not the prerogative of doctors. Doctors, engineers, chemists, psychologists, and indeed every citizen—all are directly and intimately concerned. The causes and methods of prevention of disease are discussed in two of these chapters. Besides the obvious aspects with which public health authorities have for a long time been concerned, questions of occupational diseases and accidents are included here.

Some of the subjects mentioned are touched upon too briefly and insufficient evidence is provided to support the claims. Thus, for example, the paragraph on noise is far from adequate. Lighting, heating, and ventilation are all dismissed in short paragraphs. The chapter on the work of the public health authorities can do no more than give the briefest survey, but even this is sufficient to arouse the interest and satisfy some of the curiosity of the reader.

SATURDAY DECEMBER 23 1950

A TOAST TO BACCHUS

Christmas is by some celebrated as a Saturnalia, the eating and drinking festival of the year. Wine and mead and spirits flow into unaccustomed stomachs, and beer, the national drink since 1500, softens our sorrows and spreads an air of tolerance and social warmth. Alcohol is one of the oldest drugs known to all mankind, and for hundreds of centuries has played a role in religious ceremonies and in the art of healing. Modern pharmacology has taught us how much of the teachings of tradition to accept, and what must be discarded. To-day we know that alcohol is no cerebral stimulant, but a gentle anaesthetic which lulls criticism and judgment to sleep; that the warmth of whisky in the stomach, the glow which spreads over the body and out along the limbs to frozen toes and fingers, is no new life-saving heat but a wanton spending of the body's own carefully preserved internal store, a rush of warm blood from the depths as the vessels of the skin are forced to open up. We know, too, that alcohol stimulates gastric secretion—hence the value of a glass of sherry before dinner—and provides energy for work, seven calories for every gramme.[1] Fourteen pints of beer, containing 4.5% alcohol, provide 3,500 calories, a reasonable day's energy ration without other food. Alcohol is one of the few substances absorbed directly from the stomach, and within five or ten minutes of a drink the liver is already beginning to oxidize it to acetaldehyde and acetate, which joins in the cycles of intermediary carbohydrate metabolism.

But beer, like wine, is more than alcohol. It contains vitamins. Though vitamin B_1 is notoriously absent, and many of the chronic alcoholic's symptoms are, like beriberi, traceable to this avitaminosis and not to some toxic property of the drink, beer is rich in riboflavin and nicotinic acid (0.5–1.7 μg. per ml. and 15 μg. per ml. respectively).[2] Thus a daily four pints of beer will satisfy the human requirements of riboflavin. This is of more than academic interest at a time when food supplies are short, and particularly important to peoples who may in natural circumstances enjoy but a very limited diet. Missionaries have sometimes quite properly tried to suppress the evils of drink among their native converts, only to find them falling mysteriously ill: the ban on native beer removes the native's only source of vitamin-B complex. Platt and Webb,[3] in a study of Kaffir beer, which is brewed from maize, point out that, while maize-eaters are notoriously liable to pellagra, this nicotinic-acid-deficiency disease is never seen among maize-beer drinkers because during brewing the fermenting yeast synthesizes nicotinic acid and riboflavin, so that the drink contains more than the grain from which it is made.

But for us in Britain this Christmas drink is a pleasure, not a stern necessity. We shall be less concerned with the balance of our diet than with other kinds of balance. In the great days of drinking, in the eighteenth century, a man might sit down after dinner and drink his way through four bottles of port (containing 20% alcohol by volume). He achieved this by a combination of time and practice. Food in the stomach, particularly if fatty, slows alcohol absorption; with practice the liver comes to oxidize it quicker; and with plenty of time a man may spin out his cups to keep a constant level of optimism and good fellowship.

It is said[4] that a pint of whisky or seven average bottles of beer will produce drunkenness in the average man, but few of us to-day will have the opportunity to test the first part of this statement. By the standards of our ancestors[4] we are an abstemious if not degenerate race. Gone are the days when pale ale was a breakfast drink for ladies and for boys at school, and sherry a mid-morning break. Gone too are the days of cheap gin, a sip of spirits to keep the baby quiet, and a row of infant corpses with cirrhosis of the liver. Yet a nursing mother may safely take her modest glass of stout with the best, for alcohol does not get into her milk.[1]

Talk about drink is apt to raise passions quite as fierce as those let loose by the actual consumption of liquor. The literature is immense, the debate endless. Yet medical opinion has never been against the drinking of wine and ale within reason. Hospital residents have often been served with free beer as part of their emoluments, hospital patients have often had stout prescribed as part of their diet, and textbooks sometimes indicate what wine may be allowed. It may be that the National Health Service will change this too. At least one hospital is in future to provide its residents with free journals instead of free drink, and whisky, in spite of the patient's plea, is not available on an E.C.10. "Dr. A., Please Sir would you kindly leave a prescription for me to get some Benedictine and surgical spirit. Thank you," and: "Dear Dr. B., I am writing on behalf of my sister, and as she has got a very bad cold, and also as I have heard that it is possible to have a prescription for whisky under the National Health Scheme, I hope you will give her son one. . . ." How many of us there are who get appeals of this kind! The modern planned State is the direct inheritor of the Puritan tradition. Yet a little of Merrie England still lingers on in the season from Christmas to New Year, and its symbol is the glass that cheers.

FERTILITY AND INTELLIGENCE

The Royal Commission on Population was set up in 1943 and issued its report[1] in 1949. During the course of its deliberations it considered not only the total decline in the fertility of the people but also the ageing of the population which resulted from this decline, the danger of the continuance of the decline in the next decades, the different rates of decline in fertility in the different sections of the population, and also the possible effects of the continuance of this differential fertility. Since the publication of the report there has been much discussion about the effect which differential fertility might have on the quality, as distinct from the quantity, of a population and in particular upon the national "intelligence." To define intelligence in a way that would be generally accepted has always been a matter of great difficulty. Moreover, there has been, and remains, much disagreement about the value of the various methods of test used in the measurement of this attribute and also about the extent to which it is genetic in origin. Another subject of controversy has been the suggestion that the differential fertility rates which are known to exist are leading to the disproportionate reproduction of the less intelligent sections of the population. The fifth volume[2] of the *Papers of the Royal Commission* contains the data which were presented by certain authorities about the relation between intelligence and fertility. Most of this evidence has appeared in the form of papers or books since 1944, and refers to the final report of a survey carried out in 1947 by a special committee of the Scottish Council for Research in Education,[3] which found a rise in the average intelligence quotient, but some of it is additional.

The evidence which was put before the Commission was derived from a variety of investigations of both selected and unselected groups of children and was concerned with the relation between the I.Q.s of children and the sizes of the families to which they belong. Certain matters are clearly not in dispute. Fertility is different in the different social groups, and it also varies within a given social group. There is some conflict of opinion about which of these differences is the greater. The highly intelligent within the population are less fertile than the average, and those of very low intelligence are even less fertile, but here again there is a disagreement about the extent of the difference. An attribute of a general kind which can be called intelligence is inherited in part, but the relative roles of nature and nurture in its fashioning still remain matters of speculation.

The main points made by the majority of the individual authorities who presented memoranda on this subject were that the negative correlation found between the I.Q.s of children and the sizes of the families to which they belong must necessarily mean that a progressive decline in national intelligence is proceeding; that the magnitude of this decline, estimated either directly or indirectly, is of the order of $1\frac{1}{2}$–3 points per generation; that the differences in the quality called "intelligence" between social classes are far less than are the differences within a particular class; and, finally, that much more evidence of the same kind as that presented to the Commission is needed—and also better methods for the testing of children—before final judgments can be made.

With these views Professor J. B. S. Haldane is not in agreement. He points out that in certain investigations it has been revealed that within a particular social class a positive correlation of parental intelligence with fertility exists. He shows that the data presented are not themselves sufficient to permit any firm conclusions to be based upon them, and suggests that it may well be that, among other influences, natural selection and mutation counteract any decline in national intelligence that might be a possible outcome of differential fertility. In his view it is imperative that an argument of this kind must be based upon knowledge of the genetic basis of this attribute "intelligence," and that before any prediction can be made it is necessary to know to what extent mating occurs between individuals of the same level of intelligence within a population and also what percentage of the extremes, above or below the average, marry and reproduce.

The possibility of a decline in the national intelligence is thus still a matter for argument. It seems unlikely that the additional knowledge that is needed can emerge from a repetition and extension of the investigations that have so far been carried out, and it is improbable that much more can be gained from the study of the I.Q.s of children alone. One complicating feature is that the rating of the child by the tests at present in use does not necessarily have any relation to what is considered intelligence in the adult: the worlds of children and of adults are different, and so are the qualities which make for success in both these worlds. The tests that are used for the measurement of intelligence may be of some value in the educational sphere; they measure an attribute in the child that is of definite importance in conventional schooling. But as yet there is no test which provides a complete assessment

[1] *Report of the Royal Commission on Population*, 1949. London: H.M.S.O. See leading article in the *British Medical Journal*, 1949, 1, 1127.

of the qualities that make for success in the adult world. In fact there is no general agreement about what constitutes success of this kind. This being so, it follows that the intelligence of the future population cannot be assessed from the results obtained from intelligence tests of the children now within it. It is generally agreed that about half or three-quarters of the attribute measured by these intelligence tests is closely associated with the genetic endowment of the individual, but what is not yet known is the relative value to the adult of this portion of the individual's total intelligence, compared with the remaining half or quarter which is an acquisition and therefore subject to the influence of improving standards of living, of education, and of experience generally.

THRUSH IN INFANTS

The general belief that oral thrush is a benign disease of infants which scarcely merits attention is a dangerous illusion. Several publications in recent years have shown that serious complications are relatively common and often prove fatal. Thrush is caused by the fungus *Monilia albicans*, which is saprophytic to man except in conditions specially favourable to it. Such conditions occur in the mouth of the young infant and the vagina of the pregnant woman, for both possess acid secretions with an unusually high *p*H close to the optimal for this organism. This is the principal reason for the high incidence of oral thrush in early infancy and vaginal thrush in pregnancy, though low immunity is also a predisposing factor in the former. Ludlam and Henderson[1] and Anderson and his colleagues[2,3] demonstrated by repeated routine swabbing of the mouth in newborn infants that infection of the mouth with *Monilia albicans* in the neonatal period almost always causes thrush lesions within two to eight days, and they pointed out that the much higher incidence of bacteriological thrush than of recorded clinical thrush at this period of life is due to failure to recognize minor degrees of the latter. After infancy, however, infection of the mouth with this organism seldom if ever causes thrush lesions unless there is pre-existing disease, such as herpetic stomatitis. Todd[3] isolated the thrush fungus from the mouth in 14% of 1,000 healthy adults, none of whom developed thrush.

The characteristic greyish-white adherent colonies and plaques of oral thrush are most often seen on the tongue, but usually affect several parts of the buccal cavity. As a rule the lesions cover only a relatively small part of the mucosa at the height of the disease; there are no symptoms, and the infection gradually subsides. But such a benign course should never be assumed, for the disease may progress and cause fatal lesions in the alimentary tract or elsewhere. There is thus a potential danger in every case of thrush, particularly in premature and debilitated infants. It is impossible to estimate the incidence of extrabuccal thrush lesions, but in post-mortem examinations of infants they have been shown to be quite common. In severe cases of oral thrush the infection is more likely to spread down the alimentary tract than in mild cases and to reach either the pharynx or oesophagus or both. Several series of thrush oesophagitis discovered at necropsy have been reported. In this country Ebbs[4] found the infection in 22 infants under 1 year, and Ludlam and Henderson in 20 newborn infants, while Lederer and Todd[5] discovered 21 cases in a series of 204 post-mortem examinations on infants up to 12 months old. Invasion of the stomach and intestines is very uncommon. Ludlam and Henderson observed gastric lesions in four of their cases of oesophagitis in the newborn; Lederer and Todd reported lesions of the ileum in three infants with thrush oesophagitis and in one with pharyngitis. Lesions in the colon were found in two of Ebbs's cases. Macgregor and Henderson[6] described thrush ileitis in two premature infants, one of whom had oesophagitis and the other no detectable thrush lesions elsewhere. The diagnosis of extrabuccal thrush lesions is a matter of conjecture, and can generally be made with certainty only at necropsy; but the presence of oral thrush, which may require careful search, or the demonstration of *Monilia albicans* in films or cultures made from oral swabs or from the stools, should at least suggest the possibility of this infection in ailing infants in whom no other cause of illness can be found.

Severe thrush causes ulceration of the underlying mucosa, with consequent secondary infection by pyogenic organisms. In oesophageal infections a pseudomembrane may be formed. The lesions then become acutely inflamed, and painful if in the mouth, pharynx, or oesophagus. The infant looks ill, loses appetite, and may have difficulty in swallowing if the pharynx and oesophagus are affected. Regurgitation is another common feature of oesophagitis, and vomiting—sometimes associated with haematemesis—dehydration, and loss of weight may also occur. In such severe infections vomited matter may be aspirated by the weakly infant, with fatal results, either from sudden suffocation by occlusion of the main air passages or more often from aspiration bronchopneumonia. The thrush fungus can usually be found in inhaled foreign matter and inflammatory exudate, but seldom invades the bronchopulmonary tissues. Infection of the middle ear is an occasional complication: Lederer and Todd found the mastoid infected in 5 of 21 infants with oesophagitis. In large thrush lesions there is deep penetration of the mycelial strands with invasion of lymphatics and venules and, rarely, of surrounding structures. Organisms thus gaining access to the blood stream usually perish, but occasionally set up metastatic lesions in distant parts of the body. Several cases of *Monilia albicans* meningitis have been described, and Lederer and Todd reported two instances of metastatic thrush lesions in the kidneys. The same authors also found the hitherto unreported complication of empyema in two infants with thrush oesophagitis, and they showed that there had been a direct spread from the oesophagus by penetration of the mycelium through the oesophageal wall and parietal pleura. Septicaemia and pyaemia caused by secondary pyogenic invaders of thrush lesions, usually *Staphylococcus aureus*, are probably more common than metastatic lesions: Lederer and Todd observed this complication in five cases, one of which also had renal metastatic lesions.

The incidence of thrush is much higher in nurseries, where opportunities for cross-infection usually abound, than in the home. It is also much higher in bottle-fed than in breast-fed infants, because feeding utensils may be contaminated. Ludlam and Henderson found that in a maternity hospital infants with oral thrush excrete viable organisms in the stools and usually have infected hands. They also isolated the organism from pooled breast milk used for feeding premature infants, and from the fingers of nurses engaged in feeding infants. Aerial dissemination of the spores rarely occurs. The slightly higher incidence of oral thrush in the infants of mothers with vaginal thrush may be due to direct inoculation of the mouth at birth, but is more likely to be caused later by indirect infection from the hands of the mother. There is no doubt that cross-infection resulting from faulty nursing technique is the principal reason for the high incidence of thrush in nurseries. Where the danger of cross-infection exists the infants' mouths should be carefully inspected daily, and those who show the earliest sign of thrush, as of any other infection, should be isolated immediately. The application of gentian violet, 1% in aqueous solution twice daily, in the early stage of oral thrush usually checks the spread of the lesions and causes their disappearance within a week.

BACTERIOLOGICAL GRADING OF ICE-CREAM

The Regulations[1] introduced for the processing and heat-treatment of ice-cream "mixes" (and the increasingly effective methods of detection and supervision of excreters of enteric bacilli) have helped to make ice-cream safer. Because no laboratory test can guarantee the absence of pathogens there is a need for a reliable test of general bacterial cleanliness. This has been for some years the concern of a subcommittee of the Public Health Laboratory Service, which has recently issued the last of four reports.[2-5] The evidence submitted by the committee indicates that ice-cream can be examined for bacterial contamination in a simple and practical way by the methylene-blue test, the principles of which are the same as in the test applied to milk. The technique of the test was described in 1949.[3] In order to show latent contamination the reductase tube containing the sample and the dye must be pre-incubated in a water-bath at 20° C. for 17 hours. Provisional gradings are as follows: grade 1 fails to reduce methylene blue in 4 hours; grade 2 reduces in 2½–4 hours; grade 3 in ½–2 hours; and grade 4 in 0 hours—i.e., is decolorized on removal from the 20° C. water-bath.

Some early reports on this test seemed to indicate that it was too severe and did not reflect the degree of cleanliness or contamination. These complaints have been investigated and answered by the committee, the members of which were unable to detect the existence in ice-cream of any non-bacterial substance capable of reducing methylene blue. A complaint was also examined that the presence of aerobic spore-bearing bacteria of no hygienic significance was responsible for the failure of certain makers with good equipment to attain grade 1. It was found that these thermoduric bacteria were in fact responsible, in a small percentage of cases only, for grade 2 results when grade 1 might have been expected. But, as the committee points out, organisms of this type are a potential cause of food-poisoning, and their presence usually indicates imperfect cleansing and sterilization of plant. The committee also discussed the claims of other tests favoured by certain workers. The sampling and experimental errors of the plate count are numerous, and it has special disadvantages as a test for ice-cream, which is difficult to measure accurately because of its physical characters and contains bacterial aggregates unevenly disintegrated by the various methods used for homogenization. It is more costly and time-consuming than the methylene-blue test. The coliform test, which is also subject to large sampling errors, takes count of one group of bacteria only, and the presence of *Bact. coli* Type I (so classified on the basis of the 44° C. MacConkey broth test) does not have the same significance as in water examination, since these organisms in ice-cream classified as grades 1 and 2 were found mostly to be irregular types, presumably not of faecal origin. The methylene-blue test has been criticized because its results could not be related with those of the plate-count and coliform tests, but in view of the variable results given by the latter any close correlation would be surprising.

The conclusion is that the methylene-blue test is a satisfactory method for the bacteriological grading of ice-cream. Samples must be carefully collected, and the hygienic quality of ice-cream from any one producer must be judged on a series and not on a single sample. It is gratifying to learn that a steady increase in cleanliness has been observed during the last three years, for all who are concerned about methods of food handling in general know how much progress has yet to be made. A final point of

practical importance is that the efforts of the producer may be vitiated by the practice common among retailers of keeping the serving-spoon in a jar of water which in warm weather rapidly becomes heavily contaminated with bacteria.

ASPIRIN AND CORTISONE

We mentioned in last week's *Journal* that the Ministry of Health is to distribute small quantities of cortisone and A.C.T.H. to selected hospitals, but this, of course, will not mean any slowing down of the search for substitutes for these substances which might have similar effects in rheumatoid arthritis and other diseases. The great interest shown recently in the use of deoxycortone acetate and ascorbic acid exemplifies this tendency, though, as it turned out, this treatment was ineffective.[1 2] The paper by Drs. J. B. Cochran, R. D. Watson, and J. Reid in this issue suggests a new approach to the problem by pointing out certain similarities between the action of aspirin and of cortisone in acute rheumatic fever. They observed acne, rounding of the face, and a reduction of glucose tolerance in a patient under treatment with aspirin for acute rheumatism, and they suggest that the development of a mild Cushing's syndrome during intensive salicylate treatment is not uncommon. The general similarities between the effects of salicylates and cortisone in the treatment of acute rheumatism are obvious. Both substances bring about a rapid relief from pain, an improvement in the arthritis, a fall in pulse rate and temperature, and a reduction of the erythrocyte sedimentation rate. Both prevent relapse so long as administration is continued. Neither can be said to be curative, though both seem to hold the disease at bay and to give the patient an opportunity to make his own recovery. Indeed, the introduction of salicylate therapy for acute rheumatism in 1875 must have raised many of the questions that have been asked more recently about the advantages and disadvantages of cortisone. The Glasgow workers support their contention that the two substances may have a common action in acute rheumatism by comparing the metabolic effects of salicylate therapy, which were recently reported in detail by Reid, Watson, and Sproull,[3] with those of cortisone. They refer in particular to the changes in sodium, potassium, water, and protein metabolism, though in so far as the last is concerned it is not clear whether the negative nitrogen balance noted by them in acute rheumatism is due to salicylate therapy or whether it may be present in any acute febrile illness. On the other hand, there are arguments against the possible common action of aspirin and cortisone. Among the diseases in which cortisone is of benefit, acute rheumatism alone responds in dramatic fashion to aspirin. It seems possible, though not yet certain, that cortisone may prevent the occurrence of heart lesions in acute rheumatism, while it is doubtful whether salicylates have any such effect. Cochran and his colleagues emphasize that the two substances cause alkalosis by different means, though they consider that this may be explained by differences in the doses commonly used. Possibly the occurrence of features suggesting Cushing's syndrome may be an expression not of aspirin therapy but of a large endogenous production of cortisone and other steroids as a part of the patient's reaction to his disease. As the authors recognize, there are many points requiring investigation before any final conclusions may be reached about their most interesting suggestion. It will be important to compare the metabolic effects of salicylates with those of cortisone in non-rheumatic subjects, and it would be interesting to know more about the metabolic features of acute rheumatism uninfluenced by salicylate therapy, though it is hardly justifiable to withhold such treatment.

ELECTRON MICROSCOPY

As with other new instruments, the successful use of the electron microscope demands knowledge of a practical kind. This is usually the last to be systematized, being inadequately covered both in conventional textbooks and in original publications, which for the most part are concerned with results. However, as instruments multiply, it becomes increasingly desirable that such information should be placed on record and that experience won the hard way should be shared with others. There are also points on which it is well that a wider audience should be informed. Electron microscopy is a technique of research from which the best value is often obtained in conjunction with other methods, as was well demonstrated by Cooper, Rowley, and Dawson[1] when they used it in conjunction with the radioactive tracer method to provide a virtually conclusive proof that the action of penicillin is within the bacterium and not on the cell wall. Such uses can become common only when there is a fairly wide knowledge of both the strength and the limitations of the method: for the contribution it can make will not otherwise be apparent to those with problems to present. There are also other matters—such as the degree of reliance to be placed on magnification figures, and the extent of distortion which is possible within a single picture—on which others concerned with interpretation may be in need of guidance.

For all these reasons the Royal Microscopical Society and the Electron Microscopy Group of the Institute of Physics have earned gratitude by their co-operation in producing a practical treatise which contains references up to 1949 and, through successive processes of editing, has been adequately systematized. Its origin was a meeting of British electron microscopists which was held at Hampstead in 1945. Draft articles were supplied by some 10 authors and edited by Dr. D. G. Drummond into a composite treatise, published in a typescript edition by the Institute in 1948. Further notes were written for a summer school in electron microscopy which was held at Cambridge in the same year, and additional material has been collected from original publications and conferences. The end-result is a treatise—in effect a complete issue of the Society's journal[2]—in which individual contributions, though acknowledged, are no longer recognizable. To obtain full benefit it should be studied as a whole, and it may be hoped that many concerned with the use of electron microscopy may be induced to do so. Chapters on basic techniques and on the calibration of magnification and resolving power are common to all uses. From the latter it may be learnt that the repeat patterns on certain diatoms have proved of value as working standards and that, with further improvements in instruments, the particles of a plant virus may prove still more satisfactory. A serious point to be noted is that the assignment of magnification figures is a matter of difficulty, and that uncertainties of the order of 10% are to be expected. Chapters of specifically medical interest deal with airborne particles, micro-organisms, and biological tissues.

ANAESTHESIA IN THE NEWBORN

With increasing refinements in the surgical treatment of congenital abnormalities more newborn infants are likely to be operated on than a few years ago. To keep pace with surgical advance anaesthetists must readjust their approach to the anaesthesia of these very small patients. Local analgesia is still the choice of many surgeons, but if general anaesthesia can be used with safety to the child and at the same time provide a quieter field for the surgeon it is likely to replace regional infiltration, as it has done in other difficult operations. What the anaesthetist has to try to develop is a technique which overcomes the resistance in the infant's air passages, avoids excessive rebreathing, and maintains light anaesthesia. Respiration in the neonatal period is normally accomplished by the diaphragm and abdominal muscles, with very little thoracic movement. An effect of the infant's relatively large body surface is seen in the comparatively large respiratory minute volume at this time. In the newborn it is 838 ml., compared with 7,100 in the adult. Measured per kilo of body weight, it is 239.5 ml. and 101.5 ml. respectively. The larger value in the infant appears to be the result of rapidity rather than of depth in breathing, since its tidal air volume is about 19 ml. and the vital capacity 170 ml. Anatomically, the infant's tracheobronchial tree is adapted to counteract the comparatively small area available for respiratory exchange, and, as Dr. G. Jackson Rees mentions in his paper published on another page, the area of the cross-section of the trachea in the newborn is twice that at twelve months in proportion to the lung volume. Snyder's work on rabbit foetuses of varying maturity has shown the great sensitivity of the respiratory centre to the lack of carbon dioxide. His experiments indicate that a certain level of carbon dioxide is essential for the maintenance of foetal respiration. However, it still remains to be shown whether or not the chemical regulation of the breathing before birth is the same as that following delivery. Therefore the newborn infant cannot be relied on to react to varying concentrations of carbon dioxide in the same way as the foetus, even if the latter is post-mature.

The moderately asphyxiated newborn infant registers a definite objection to the insertion of an endotracheal tube, but, as Rees states, the infant is unable to exhibit the reflex contractions of the cervical muscles which are seen in the adult. The observable reactions of the infant are an active pharyngeal reflex and a facial appearance of being on the point of crying. But under light anaesthesia the facial sign is absent, and the only sign then present on insertion of an endotracheal tube is a disturbance of respiratory rhythm. *X*-ray photographs of the newborn, taken at intervals from birth to about twenty-four hours after delivery, show increasing quantities of air in the gastro-intestinal tract. The entrance of air inevitably causes crowding of the abdominal cavity. This and the diaphragmatic breathing peculiar to the newborn tend to cause turbulence in the operative field—an added difficulty for the surgeon. Fortunately, natural conditions can be used to ease the anaesthetist's task. Because of the relative absence of muscle tone in infants their lungs can be artificially ventilated with very low pressures, a process impossible in the average adult; and the rapidity with which acapnia occurs allows easy control of respiration.

TREATMENT WITH HEPARIN

The increasing use of anticoagulants brings to the fore the need for an agent that is safe, effective, easy to control, and convenient to administer. No such agent yet exists. Owing to the difficulty in controlling dicoumarol and similar substances, and the grave risks attached to overdosage, attempts have been made to find a more convenient way of administering heparin, which is certainly the safest and most effective anticoagulant. It is, however, still expensive. Up to the present time heparin has usually been given in hospital by intravenous injection; Gunnar Bauer[1] has recently described the results obtained over a nine-year period at the Mariestad Hospital, Sweden. In an article in this issue Dr. D. G. Abrahams describes the effects of intramuscular heparin. He obtained satisfactory prolongation of the clotting time by giving 25,000 units twice a day. Such dosage may be kept up for two or three weeks or even longer. If heparin is to be used in this way in general practice it is necessary that the complications should be fully recognized. Wood[2] has discussed these in his description of heparin therapy. Abrahams says that local pain may be satisfactorily overcome by the simultaneous injection of 1–2 ml. of 1% procaine. It is only fair to point out, however, that, although this prevents immediate pain, marked discomfort may arise an hour or two later. Again, local bleeding is common rather than "very occasional," and may be extensive. Patients should certainly be warned that bruising may occur, and that it need cause no alarm. Over the past few years quite a large number of patients have been treated with intramuscular heparin in their homes, on the whole successfully, and, so far as is known, safely. A satisfactory dose is 15,000–20,000 units intramuscularly with 1–2 ml. of 1–2% procaine; this may be given twice daily to an adult without danger. Clotting times can be estimated occasionally to make sure the dose is adequate, but are unnecessary as a precaution against overdosage (unless larger doses are used). The chief indications for heparin therapy include thrombophlebitis, phlebothrombosis, acute peripheral arterial occlusion, and severe or complicated cardiac infarction. Treatment should be continued for two to three weeks. As a rule general practitioners should seek expert advice before embarking on a course of heparin injections.

We announce with great regret the sudden death of Sir Leonard Parsons, F.R.S., in Birmingham on December 17. He was 71 years old.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

THE TREATMENT OF LUMBAR DISK LESIONS

BY

JAMES CYRIAX, M.D.

Physician to the Department of Physical Medicine, St. Thomas's Hospital

Much confusion exists on this subject. Some years ago the main difficulty was to appear credible when attributing such well-known conditions as lumbago, fibrositis, and sciatica to so recent a discovery as a disk lesion. Now that the diagnosis has become widely accepted, medical men have found themselves in a therapeutic quandary. Traditional measures such as drugs (apart from analgesics), radiant heat, diathermy, massage, exercises, injecting nodules, and "taking the waters" have suddenly lost their last vestige of theoretical justification. Little has so far come forward to replace these abandoned types of "treatment"; and the distress of doctors and patients at the apparent absence of effective conservative measures is heightened when they find out that the only radical treatment is an operation—by no means always successful—warranted only in extreme cases.

This therapeutic nihilism is quite unjustified, for there are a number of simple treatments, none a panacea, each with its due proportion of successes. Few patients prove unrelievable if conservative means are intelligently employed, and it is only for some of these few that surgery need be contemplated at all.

Prophylaxis

Realization that disk protrusion is very common and that maintenance of the lumbar lordosis provides the main safeguard against this phenomenon is proceeding slowly. Aesthetic considerations have held the foreground for a century, and it is difficult now to get gymnasts to realize that a reasonable degree of lordosis in children is a great advantage in later life (see Fig. 1). School medical officers can see to it that exercises towards trunk flexion (see Fig. 2) are carried out sparingly, and that, unless marked kyphosis is present, no effort is made to flatten school-children's lumbar spines. If any individual cannot reach forwards far enough to touch his toes he must not be encouraged to practise this useless range of movement. Adult women's backache often dates from lying in bed in "the nursing mother's position"—that is, many pillows propping the thorax and no proper support at the lumbar spine, which droops into kyphosis all day. No wonder the posterior longitudinal ligament finally stretches and the beginnings of disk protrusion are laid down. All patients, including puerperal women, should lie flat when they have no reason to be sitting up, and as soon as their condition permits they should turn and lie prone for several periods each day

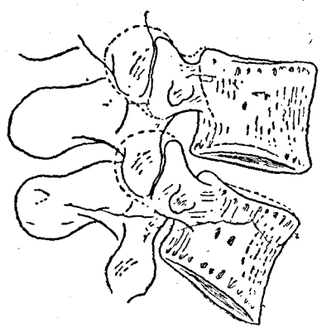

FIG. 1.—Joint space in extension. Tracing of *x*-ray photograph of the four h lumbar intervertebral joint in a normal subject, bending backwards. Note that the front of the joint space is ¼ in. (1·25 cm.) wide, but the back only 3/16 in. (0.5 cm.). In this position backward movement of the intervertebral disk is virtually impossible.

Industrial medical officers can help by arranging that weights are presented to workers at a proper level and by showing them how to lift safely. Since an attack of disk protrusion is clearly an industrial accident, they can also save their firms much money in this way. Builders can put in sinks at a higher level than has hitherto been customary, and so on. The makers of car seats are among the worst offenders; these are so shaped that it is all but impossible to maintain a lordosis while sitting in a front seat.

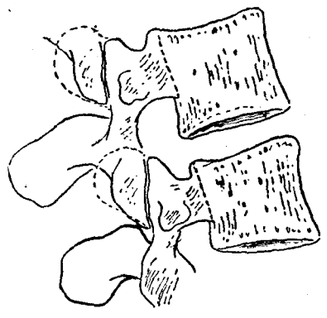

FIG. 2.—Joint space in flexion. The same subject as in Fig. 1, bending forwards. The joint space is now 5/16 in. (0.8 cm.) wide in front, and ¼ in. (0.6 cm.) behind.

Manipulation

Naturally if something is out of place the most obvious treatment is to restore it to its proper position and then maintain it there. Therefore, unless some good reason exists, manipulative reduction should be attempted at once. This measure is universally adopted when a torn meniscus in the knee-joint has moved, but it has been left largely to osteopaths to reduce cartilaginous subluxations at the spinal joints. Without realizing it, they have been doing so for years, to the recurrent discomfiture of doctors. When one considers how unskilled many lay manipulators are and how faulty are their views on the nature of the disorder under treatment; when, too, one remembers for how many years patients with severe disk lesions have been manipulated—often without benefit, it is true, but also without hurt—even under anaesthesia by medical men, it is evident that the present change of front towards emphasizing the dangers of manipulating the lumbar spine represents too great a swing of the pendulum.

The first decision that has to be made is whether the displacement is reducible or irreducible by manipulation. The reason for the two different responses to manipulation is anatomical. Protrusions may consist primarily of a fragment of annulus fibrosus or of nuclear material with an intact annulus. R. H. Young, in an analysis of cases coming to laminectomy, showed that in 56% of his cases the protrusion was cartilaginous, and in 44% pulpy. My impression is that in patients not requiring operation the

proportion is more like two cartilaginous protrusions to one pulpy. Manipulation can, of course, reduce a cartilaginous displacement but cannot affect a pulpy protrusion; this, by contrast, can nearly always be made to ooze back into position by gradual means. Thus the first major decision—whether or not manipulation should be attempted—rests on an evaluation of the symptoms and signs differentiating a nuclear from an annular protrusion. These are set out below.

Differentiation of Cartilaginous from Pulpy Protrusions

The history is often indicative. For example, a patient bends forwards and feels some aching in his back, which gets worse later in the day. Next morning he finds himself unable to get out of bed because of severe lumbago. This history indicates a protrusion that has gradually

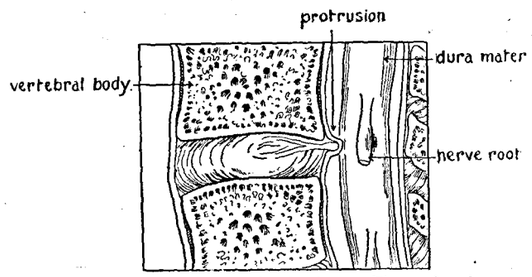

FIG. 3.—Pulpy protrusion causing lumbago. The nucleus has protruded backwards, the annulus remaining intact (after R. H. Young). Manipulation is unlikely to succeed; sustained traction or recumbency is effective.

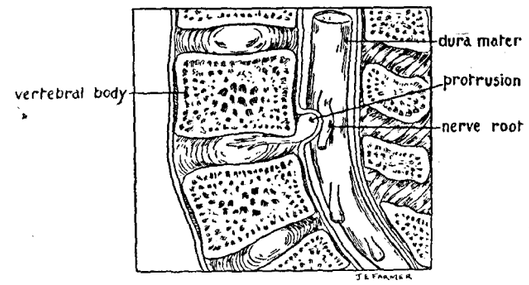

FIG. 4.—Pulpy protrusion causing sciatica. The protrusion has increased in size and has passed postero-laterally. As a result the pressure on the dura mater is released but the nerve root is severely squeezed (after R. H. Young).

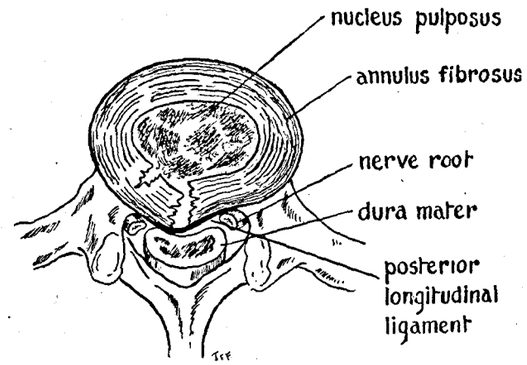

FIG. 5.—Cartilaginous protrusion causing lumbago. The annulus is cracked and hinged. Reduction by manipulation should be simple.

increased in size—that is, one consisting of nuclear material (see Figs. 3 and 4). By contrast, the patient who is subject to attacks initiated by a click in the back followed by agonizing lumbar pain fixing him in flexion has clearly suffered an abrupt cartilaginous displacement (see Fig. 5). Pulpy protrusions are rare in the elderly; hence any protrusion in a patient aged 60 and over, especially if lumbar osteo-arthritis is present, is almost certainly reducible by manipulation, whether causing lumbar, gluteal, or sciatic symptoms.

Primary postero-lateral protrusions causing sciatica are nearly always irreducible by manipulation. This is indicated when a patient with a low lumbar disk lesion states that his pain began in the calf or thigh without previous backache. Naturally a central displacement impinges first against the dura mater, thus causing backache before it sets up sciatica; primary postero-lateral protrusions never touch the dura at all, hence premonitory backache is absent.

Another type of history characterizes the self-reducing disk lesion; in such a case manipulative reduction may well succeed there and then, but brings only a few hours' relief. The patient wakes comfortable, and as the day goes on backache appears and becomes slowly more severe, especially if he stoops or lifts. A night's rest once more abolishes the pain. Naturally, if the posterior bulge at the joint recedes spontaneously as soon as the stress on the joint ends, only to recur when the joint is made to bear weight again, the reduction brought about by manipulation is equally unstable and ephemeral. Manipulation carried out at a time when no displacement is present is, of course, quite pointless.

A similar history characterizes what I have named the "mushroom phenomenon." In an elderly patient, backache accompanied by bilateral sciatica comes on after about 10 minutes' walking or standing and is abolished as soon as he rests. It is often mistaken for intermittent claudication. *X*-ray examination shows that the joint space

FIG. 6.—*Anterior disk protrusion.* All the disk substance has passed forwards and lies enclosed between two large osteophytes. The intervertebral space has disappeared.

at, usually, the fifth lumbar level has disappeared, the disk substance being displaced forwards and lying as a round ball between two large osteophytes (see Fig. 6). Anterior protrusion proceeds silently, causing no symptoms until the disk has been ground to pieces and the compression of weight-bearing causes capsular bulging all the way round the joint. The posterior component then irritates both the dura mater and the nerve roots. This lesion is difficult to treat and seldom responds to manipulation.

Referred rectal, penile, or coccygeal pain, paraesthesiae felt in the scrotum, or a complaint of difficulty in micturition may indicate a protrusion imperilling the lower sacral roots. Since the important danger of manipulation in an unsuitable case is lasting urinary incontinence, I regard this type of referred pain as contraindicating manipulation. Not having attempted it in such a case, I naturally cannot be sure to what extent this apparent danger is real.

Of the physical signs, the appearance of the patient's back is the most informative. Lateral deformity of the lumbar spine when he is viewed standing still, or apparent when he bends forwards, indicates a protrusion that has gradually increased in size until it visibly interferes with joint movement. A cartilaginous displacement does not get larger; a pulpy protrusion can; hence considerable lateral deviation indicates irreducibility. I have also found that reduction by manipulation is difficult, at times impossible, in patients whose most painful movement is side flexion *towards* the painful side.

Marked neurological signs should be taken as an indication of irreducibility, whether the lesion was originally of cartilage or pulp. Displacement of a fragment of annulus may later be followed by extrusion of nuclear material along the line of the fracture. This leads to severe compression of the nerve root and proportionate interference with conduction. Thus, weakness of more than one muscle in the leg, combined with, say, loss of ankle-jerk, cutaneous analgesia, or much gluteal wasting, shows that this secondary effect has supervened.

A disk lesion at the unstable joint resulting from spondylolisthesis is treated in the same way as an ordinary disk lesion.

Technique of Manipulation

Manipulation, then, is carried out unless a contraindication exists. Anaesthesia must be avoided; for the patient stands up after each repetition so that he can judge the effect on his pain and the manipulator can assess any change in the range of movement. The patient lies prone on a firm couch 15 inches (38 cm.) high and various manual pressures are applied at the appropriate lumbar level. If these fail, rotation strains should be tried. If manipulative reduction is attempted in this careful way aggravation can be certainly avoided. However, this treatment may require two or three repetitions and an adequate session may last half an hour, hence it is my practice to delegate almost all this work to physiotherapists trained—as all our students are—in these methods. Few doctors have time, inclination, or a suitable couch for carrying out such manœuvres themselves; moreover, these have in practice been found suited to delegation.

Other Treatments

When manipulative reduction is contraindicated or fails, less satisfactory methods have to be tried.

Sustained Traction

Sustained traction is the method of choice for ambulant patients with pulpy herniations whose symptoms warrant treatment. Distraction at the affected joint has two effects. (1) Increase in the interval between the vertebral bodies, thus enlarging the space into which the protrusion must recede. (2) Tautening of the joint capsule. Naturally, when the slack is taken up, the ligaments joining the vertebral bodies exert centripetal force all round the joint; this tends to squeeze the pulp back into place. Thus, sustained traction merely represents a way of achieving in a very short time the same effect as rest in bed for some weeks.

Bands encircle the patient's mid-thorax and pelvis as he lies on the traction couch (see Fig. 7); they are attached to

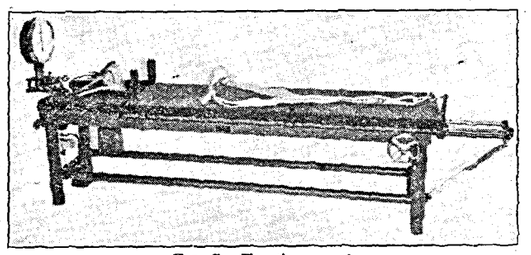

FIG. 7.—Traction couch.

hooks at the head and foot of the couch. The greatest possible traction that he will permit is then applied for as long as is reasonable. In practice, 200–300 lb. (91–136 kg.) is applied for two or three periods of 20 minutes each with, say, five minutes' rest between whiles. The longer the patient can stand the traction, the more effective it becomes. This treatment is carried out daily until he is well; and this takes one to two weeks.

Sustained traction is useless for the reduction of cartilaginous displacements; these have to be clicked back. Manipulation during traction, however, is sometimes called for in difficult cases, but is not often much of an improvement on manipulation alone.

Recurrence after laminectomy is distressingly common and in my experience hardly ever relievable by manipulation. By contrast, sustained traction may be successful.

Epidural Local Analgesia

The injection for epidural analgesia is regarded as difficult and dangerous by some authorities. So far I have used this method on out-patients more than 10,000 times without ill effect and have found it impossible to introduce the needle properly in less than 1% of all cases. There are three main indications:

1. In acute lumbago the cause of the pain is a central posterior protrusion impinging on the dura mater. If this membrane is anaesthetized by 50 ml. of 0.5% procaine, introduced extrathecally via the sacral canal, the protrusion presses on a membrane no longer sensitive and all pain ceases for the duration of the analgesia—that is, one to two hours. During this time a patient can move freely, perform some essential work, or go home to bed. He can be manipulated during local analgesia. Often, as a result of the free active joint movement obtained, he succeeds in himself initiating reduction; hence the infiltration is often followed by a large measure of lasting relief.

2. Persistent lumbar or sciatic aching *after* reduction of a prolapsed disk may prove troublesome; it is apparently due to persistent local bruising of the dura mater. One or two epidural injections usually suffice to stop it.

3. Chronic backache, especially if it is more severe at night than by day, associated with only slight articular signs at the lumbar spine can often be lastingly abolished by one induction of epidural local analgesia.

Recumbency

This is the traditional treatment for both lumbago and sciatica; though tedious and time-consuming, it is regularly effective in the end. It brings about reduction by abolishing the compression factor at the affected joint. The more severe the symptoms—*not* the signs—the more is recumbency both called for and welcomed. In sciatica the pain may not begin to abate for the first two days and the patient may insist on getting out of bed to walk about the room. Though this may bring slight temporary relief, it postpones the initiation of reduction. Hence the patient should receive enough analgesics, usually morphine, to keep him quietly resting for the first day or two. As soon as he can, he must lie supine with a small pillow under his lumbar area and only one under his head. This maintains his lordosis—that is, keeps the front of the joint as open as possible. In this position the articular contents tend to move anteriorly, away from the dura mater or nerve root. Patients with sciatica should be kept in bed until straight-leg raising is painless at full range. No one should be kept in bed until all the neurological signs recede, for these may take months to disappear; indeed, an absent ankle-jerk may never return.

Patients in severe pain, with marked weakness of the muscles controlling the foot coming on in, say, less than a week from the onset of sciatica, should be put to bed at once. The mild discogenic backache that so many people experience is usually unaffected by recumbency; sometimes it makes it worse.

Spontaneous Cure

Backache shows little tendency to spontaneous cure; it may last, or recur, during a patient's whole lifetime. Sciatica, however, nearly always gets well of itself in about 12 months. The two exceptions are: (*a*) after laminectomy this does not happen, and sciatica may then persist for years; and (*b*) after the age of 60 spontaneous cure with the lapse of time is improbable.

Young patients with sciatica are sometimes seen showing clear evidence of a pulpy herniation, at a low lumbar level, of some months' standing. The pain often amounts to only an ache; the patient has a cheerful demeanour and sleeps well. Examination shows a symmetrical lumbar spine when he stands upright, lateral deviation on attempted flexion, 45 degrees limitation of straight-leg raising on one side only, and slight neurological signs. Treatment is not called for, except epidural local analgesia, which sometimes lastingly diminishes the pain, and the patient can safely be advised merely to await spontaneous cure. This takes place by erosion of bone at the posterior aspect of the vertebral body, the displacement becoming accommodated in a situation where it no longer presses on anything sensitive and from which redisplacement is impossible. Hence patients who get well by awaiting erosion appear thereafter no more liable to sciatica than normal people. This is an important point, for the only alternative treatment in these cases is laminectomy, which, however successful it may be, cannot afford the patient comparable security from recurrence.

The tendency to lumbago often ceases spontaneously between the ages of 50 and 60. As age advances, the spinal joints stiffen and osteophytes, both cupping the disk and limiting articular movement, make their welcome appearance.

Laminectomy

This is to be avoided as far as possible, but operation should not be unreasonably withheld. In the best hands the results are far from perfect; immediate cure is not always secured and eventual recurrence is regrettably frequent, even in patients who never go back to heavy work. The three main indications are:

Gross Lumbar Deformity.—A young patient should not be left to recover spontaneously from sciatica or—less often—backache causing marked persistent lumbar deformity. Though he may recover as regards pain, the deformity remains permanent.

Incipient Drop-foot.—A patient who develops increasingly pronounced weakness of the dorsiflexor muscles of the foot must be warned, so that he may choose between laminectomy and a permanent weak foot. In such cases pressure atrophy may cause complete insensitivity of the nerve root; as a result, pain is abolished and straight-leg raising quickly reaches full range; at the same time the palsy becomes complete. The patient, concerned as he has been with his pain, is apt mistakenly to believe himself to be improving; unless his foot is examined, the doctor may be led to share in this error.

Intractable Severe Pain.—Care should be taken to make sure that the physical signs present are in proportion to the symptoms. Instances of laminectomy performed for hysteria are, in my experience, on the increase. On the whole, the worse the symptoms and signs are before the operation, the better the result.

Arthrodesis

Arthrodesis is the operation of choice in spondylolisthesis causing sufficient local capsular pain, or setting up traction on the relevant lumbar nerve roots with consequent bilateral sciatica. It is the only effective treatment for anterior protrusion of the whole disk (mushroom phenomenon), and is well worth carrying out in patients under 60. It is also indicated in recurrence after laminectomy if conservative measures fail.

Prevention of Recurrence

Advice to the Patient

The mechanics of lumbar disk protrusion must be explained to the patient, who often imagines that septic foci, choice of food or underclothing, or damp working conditions affect his back. He must be told that so long as his lumbar spine is held in lordosis the joint tilts so that the front is more widely open than the back; in this position movement backwards of the loose part of the disk is virtually impossible (Fig. 1). He must be shown how to stand, sit, bend, and lift, using his knees rather than his back. Neurosis is prevented by explaining that the disorder is purely mechanical, and not the precursor of a crippling disease capable of spreading to other parts of the body. With some exceptions he can go on doing whatever he did before; it is, merely the way of doing it that has to be changed.

Patients who find that bending forward hurts often practise this movement vigorously, hoping thus to overcome what to them appears stiffness. This movement defeats its own ends by tending to increase the degree of posterior protrusion. Well-meaning friends often urge exercises on patients with backache; these are all at best harmless. In most hospitals only prone-lying trunk-extension exercises are now prescribed; this is a great advance. They do, however, have two disadvantages over the avoidance of active exercises altogether: (1) When the sacrospinalis muscle contracts it first compresses the spinal joints as far as they will go; it is only when this slack has been taken up that the extension movement begins. (2) The greater the mobility at a joint containing a fragmented meniscus, the greater the liability to internal derangement.

Hence exercising the joint towards *full* extension is less satisfactory than maintaining it as still as possible in *slight* extension.

Support

A Plaster Jacket.—This is a method in great vogue at the moment, but I believe it is seldom worth the discomfort it entails. It is usually employed wrongly—that is, in the hope of securing reduction rather than of maintaining it. It is a mistaken policy to put a patient with an annular protrusion into plaster, for I have reduced such displacements by one manipulation after as long as six months' vain immobilization. By contrast, pulpy herniations do sometimes reduce themselves slowly in plaster, but these are the simple ones that do so much more quickly when treated by sustained traction or recumbency. The results of treating sciatica with and without a plaster jacket do not appear significantly different. It is a palliative measure useful for relieving acute symptoms. Moreover, I have found that patients with gall-stones, peptic ulcer, or merely prone to indigestion usually cannot tolerate plaster; neurasthenic patients with disk lesions demand the removal of the cast within a few days. It is thus only in the exceptional case that plaster is required. One untenable reason for immobilization has been expressed: that rest in plaster allows the broken cartilage to unite. Intra-articular cartilage has no blood supply, therefore it cannot heal at a spinal joint any more than at the knee-joint. The real indication for a plaster jacket is—as for a fracture—the maintenance of reduction in cases of marked instability until a bespoke corset is ready. If a good corset cannot be obtained in a few days, and the patient keeps having recurrences, a plaster jacket may be kept on until the corset is ready.

A Corset.—Whereas a plaster jacket cannot be worn for longer than some months, and thus cannot provide lasting protection against recurrence, corsets, renewed each year or two, can be worn indefinitely, thus affording permanent security. If the two steels are accurately moulded to the lumbar curve, lordosis is maintained and the joints steadied. Moreover, if the patient bends too far forwards or sags as he sits, the front of the corset presses unpleasantly against his lower ribs—a salutary reminder.

Repeated crippling attacks of internal derangement in spite of adequate precautions once more raise the question of laminectomy.

Figs. 3 and 4, which appeared originally in the author's book *Osteopathy and Manipulation*, are reproduced by kind permission of the publishers, Messrs. Crosby Lockwood and Sons, Ltd.

The total number of administrations of analgesia given by midwives in the domiciliary midwifery service in London during the first six months of the present year was 4,929, or 66% of all the confinements which the midwives attended. This applies to all classes of midwives, those of the L.C.C. and of the District Nursing Association and the hospital district midwives. It is stated that the opportunity of receiving analgesia is given in all cases. The confinements where it is not recorded as having been administered consist mainly of those attended by doctors (concerning which no information is available of the analgesia or anaesthetic administered), women who do not wish to receive analgesia, women who are medically unfit for its administration, and confinements where labour is precipitate. All the 123 L.C.C. midwives, the 30 midwives employed by district nursing associations, and the 84 employed by hospitals on district work are qualified to administer analgesia. The percentage of confinements in which analgesia is administered has risen steadily. For L.C.C. midwives alone, the percentage of confinements in which analgesia was administered was 34 in 1948, and 68 in the first six months of 1950.

MARS AND AESCULAPIUS

A NEW ZEALAND MEMORIAL ORATION

BY

Sir ARTHUR PORRITT, M.Ch., F.R.C.S.

[*During his recent visit to New Zealand, his native country, Sir Arthur Porritt delivered an oration at the biennial meeting of the New Zealand Branch of the British Medical Association. The oration was the first to be given in memory of members of the New Zealand Medical Corps who lost their lives in the two world wars. We print below an abridged version of an address which must have given special pleasure to its audience.*]

This address must perforce to some extent be personal, but it is my aim to draw from these personal reminiscences deductions which may help to provide such practical and constructive answers to some of our national, professional, and individual problems as one feels would have been endorsed by those whom we are remembering to-day. In the main they were not dramatic heroes, they were not military geniuses, nor were they giants of the medical and scientific world. They were good New Zealanders; good doctors, and our friends, welded together in an inflexible purpose by the furnace of war.

Hence my title—Mars, the god of war, and Aesculapius, the god of medicine. Mars was always represented as a powerful, eager, virile youth (not the helmeted blood-stained brute of modern cartoons), and Aesculapius as an old bearded man, slightly bent, and leaning on a staff around which was entwined a serpent, the emblem of wisdom. The legendary end of Aesculapius is sad and yet prophetic. As a result of a complaint laid by Pluto that mortals were dying too slowly (presumably thanks to the good offices of Aesculapius), and that therefore Hades was being depopulated, Zeus slew him with a thunderbolt. It is comforting to remember, however, that, at the request of Apollo, Zeus subsequently placed Aesculapius amongst the stars for ever and ever, thus symbolizing medicine in perpetuity. . . .

It is from two angles, therefore, that I wish to speak of those of our friends who have gone on—as New Zealanders and as doctors—broadly, though not entirely, in relation to the two cataclysms through which most of us have passed during the last few decades. When one thinks of these last fifty years—Edwardian comfort and complacency, the rude awakening of 1914–18, the spurious artificial prosperity and depression of the inter-war period, the second holocaust, and the years of inevitable reaction, with the stark realities of moral and economic failure lurking just round the corner—is it any wonder that those who have lived five generations in one should feel some measure of instability, should find it difficult to assess their values, should perhaps feel older than their age, and should search consciously or unconsciously for some firm rock of faith to which to cling?

I feel that those we honour to-day had found such a rock. They were New Zealanders. Let us not shut our eyes to the fact that with a short history of little more than one hundred years we have a great tradition. . . . In this young country few of us have got beyond the third generation of New Zealanders, but our grandfathers and fathers were of rugged stock—independent, God-fearing, self-reliant—the real pioneers. Their legacy of virility and stout-hearted adventure has been intensified by the lovely country of our birth. . . . Most of us know far too little of this country of ours—its history, its economic assets, its development, its wealth of beauty in scenery and flowers and birds. It should be impressed on every New Zealand child that so far as his circumstances allow he should aim to know his own country inside out before he travels from its shores.

The New Zealand Soldier

[Sir Arthur Porritt went on to speak of three groups of New Zealanders who had helped to put the country "on the map" during the last 30 or 40 years—the New Zealand Divisions in two world wars, New Zealand athletes and sportsmen, and certain noteworthy individuals, such as Lord Rutherford in science, Sir William Marris in diplomacy, and Sir Harold Gillies and Sir Archibald McIndoe in medicine. Of the New Zealand soldier he said:]

New Zealand had produced some doughty fighters in the Boer war, but it was the 1914–18 war which first really brought them to the fore as a national military entity. Their deeds of derring-do in the Middle East, in Gallipoli, in France, carried out with a dash which would have been almost bravado had they not been accompanied by a steely discipline and precision such as might have been expected more from seasoned regulars than from casual volunteers, their morale, comradeship, and friendship became by-words in the British armies. Their record has proved to be one which even another and greater war and thirty intervening years have not dimmed in perspective.

[Here, before passing to some personal reminiscences of the Second New Zealand Division, Sir Arthur Porritt mentioned that one of the original band who went with the First Expeditionary Force to Samoa in 1914 and ultimately returned to New Zealand in 1919—a doctor and a soldier—was to his great delight present on this occasion: the orator's father (Dr. E. E. Porritt, F.R.C.S., of Wanganui, N.Z.).]

During two years' service with the British Army in the Middle East in 1941–2 I personally saw much of the Second New Zealand Division from a medical angle. The medical officers of that division and its attendant military hospitals were my contemporaries and friends of Otago days. I do not think there was a New Zealand hospital in the Middle East that I did not find excuse to visit at some time during that period.

At work in a British unit and generally unrecognized as a New Zealander, it was a great joy to me to hear the constant and repeated praise of the New Zealand Division, not only as a fighting force but as individuals. . . . It was always a great delight to me to have New Zealand patients in the six to seven hundred—sometimes a thousand—surgical beds of my division, and I like to think that to those patients it was a consolation to find a New Zealander in charge. At one time after Greece and Crete we had well over 500 New Zealanders in at the same time. Nor did the liaison stop there. One of my best surgical specialists was a New Zealander, and so was the British consulting surgeon to the Middle East—a well-known character to most of you—General "Jock" Monro. I feel it is not my province to trace that historical pilgrimage from Alamein to Tripoli, to Sicily, and on to Italy in detail, but I should be lacking in my bounden duty if I did not underline the enormously stimulating effect the New Zealand Division obtained from its quite unique leadership. Here was a New Zealander of New Zealanders, whose inspiring personal example, apart altogether from his military genius, was almost enough by itself to ensure the success of any formation. As a soldier, as a sportsman, as an individual, Sir Bernard Freyberg has certainly done his fair share in putting New Zealand "on the map."

[After referring to the popular welcome of the New Zealand soldier in the home country, Sir Arthur Porritt mentioned the sportsmen and athletes of New Zealand. New Zealand had just had the honour of staging the first post-war and "biggest ever" Empire Games, which had been an unparalleled success.]

Here in the development of a thousand friendships through a common interest in sport lies one strengthened link in the chain of the Empire. Furthermore, to those of us who are doctors these games should embody the ideal of national physical fitness. In New Zealand the standard is already high. Let us strive not only to maintain but to raise it. A life without health is less than a life, a nation without health is at best second-best, an empire without health is on the way out. The future of medicine undoubtedly lies not in curing diseases but in maintaining health.

[In mentioning some New Zealand achievements in sport he spoke of the exploits of Jack Lovelock—"an Aesculapian like ourselves." "I can see him now in that gigantic stadium in Berlin . . . a seeming pygmy among giants, but with superb track sense and an inflexible determination to succeed, run the best eight milers off their feet to register New Zealand's first athletic Olympic victory in record time."]

Expatriate New Zealanders

[Reference to some famous New Zealanders in the world of affairs brought him to one controversial point which should not be glossed over.]

They are all expatriate New Zealanders. How does it come about that their great work has been done elsewhere? In many cases it is sheer force of circumstances; in others the lack of facilities sufficient to allow them adequately to exhibit their skill and ability to the full. In neither of these eventualities need New Zealand accept any blame, for blame there is none, on either side. Nor need she bemoan her loss, for such men do infinitely more to enhance her prestige in the world at large by remaining outside her shores than, with the inevitably limited facilities available, by staying in New Zealand.

Let us admit frankly, however, that this by no means answers the whole question, and it would seem a matter of no small importance in New Zealand's present stage of development to restrict to a very definite minimum this export of brains she badly needs. This is a matter for politicians, educationalists, and industrialists alike. Too many good young New Zealanders in varied fields of activity go or are sent abroad to widen their experience and extend their knowledge, and, having done so, find to their great disappointment that New Zealand makes no attempt to encourage their return, and that if they do come back reasonable opportunities are unobtainable. This state of affairs can and should be remedied. Spending of money—even State money—on worthy objects can often in the long run be an economy, and what more worthy object than a young New Zealander specially trained in his own particular sphere who wishes to devote his talents to his own country?

[He then spoke of New Zealand doctors, nearly all of them, like himself, graduates of Otago University.]

New Zealand graduates in pre-war days were accepted at face value—known to be well-trained, skilful doctors. They still are, but not perhaps to quite the same extent. Reasons for this lie on both sides of the world. Within the limits of the clinical material available a New Zealand graduate can bear comparison with the best, and probably win. Such were the doctors with whom the New Zealand Division was blessed. Add to their professional background the possibilities of a wide experience of travel and of the closer co-operation and opportunities for friendship and understanding which come automatically with military service, and you will appreciate what a chosen band they were.

Under their very eyes, through their own hands, the stimulus of war was being applied to medicine. Mars, with one hand reaping that terrible harvest of human lives, was with the other prodding Aesculapius along to prodigious feats. Just as the first world war established orthopaedic surgery as an entity, so has the second opened up vast possibilities in the surgery of the chest, of the brain, of the blood vessels. Three handmaidens of surgery contributing to this result are the dramatic improvement in anaesthetic methods, the immensely increased use of the life-saving blood transfusion, and the advent of first the sulphonamide drugs and then penicillin and the antibiotics. Many of us came to divide our medical war into three stages—the pre-sulphonamide, the sulphonamide, and the penicillin.

In the first, the stage of the B.E.F. in France in 1939–40, sepsis in war wounds and septicaemia were still rife; in the second, the stage of the Middle East campaigns, the sulphonamides had to a very large extent prevented generalized infections, but every local wound was potentially if not actually septic; in the third, the stage of Normandy, of Italy, of the Far East, penicillin made septic wounds the exception rather than the rule.

[The orator described other wartime advances in medicine—the advent of drugs which had almost abolished dysentery and typhoid in armies fighting in hot climates; the improvement of mechanization whereby surgery was gradually taken right forward to the wounded man in small units; the arrival of the nursing sister in these forward surgical units, bringing with her that human touch essential to preserve the flickering flame of life in severely wounded men.]

The Service Doctor

But it was not only in these direct ways that stimulus and interest came to the Service doctor. More than ever before he became invaluable as a "back-room boy," studying and elucidating problems which had a great if incalculable effect upon many of the major campaigns. By this I mean such problems as the efficient protection of life and limb in tanks and armoured vehicles; the variety of food and clothing to provide the correct level of sustenance and cover in a dozen different climates; the study of remedies to prevent sea-sickness in assault landings; the investigation of effects of variation in atmospheric pressure and speed on pilots and submarine personnel; and many other fascinating problems in which it was found that clinical knowledge, physiological data, and scientific fact were of prime importance.

Just one other point perhaps remains to be considered. In the war we were working in a regimented State-controlled service. Were the results efficient? Were the personnel satisfied and happy in their work? In all fairness the answers must be, by and large, that they were. Why, then, does a civilian State service go so largely against the grain?

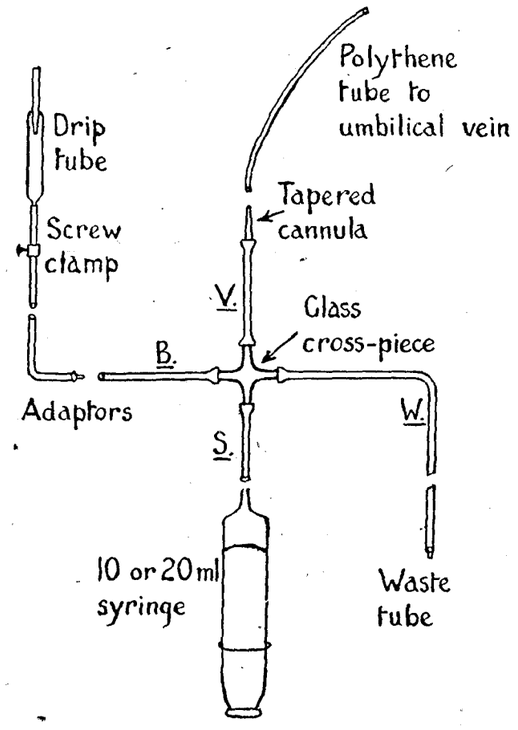
Admittedly the circumstances are different. However much we would like it to be so in these difficult times of peace, we know that the sense of urgency to achieve cohesion of purpose at any personal sacrifice is not of anything like the same potency. Let us remember, too, that in the Services both doctor and patient were being clothed, fed, transported, and generally cared for free of individual cost. Let us not forget that in all medical services it was only when the cast-iron bureaucracy of administration, excellent as it admittedly was, had been made reasonably malleable by the unquenchable clinical flame of those large numbers of our professional colleagues temporarily under arms that a really co-ordinated and efficient service resulted. There were many hard lessons learned on both sides, but it was worth it. No machinery, however good, will run a profession. The economic as well as the efficient administration of any medical service depends upon its ability to encompass the personal idiosyncrasies of both patient and doctor within reasonable limits. Because the profession, being doctors, realized the many difficulties of achieving this end, they would appear to have lost the "kudos" for the conception of a comprehensive medical service for all; but it was a medical idea and ideal long before it became one of the more important planks in a political platform.

What the ideal State medical service should achieve is that no individual is denied the facilities medicine has to offer. By "facilities" I mean institutions—hospitals, sanatoria, health centres—also instruments and drugs. These are the inanimate objects that can be nationalized to the great advantage of all, particularly if good medical advice is taken on how it should be done. It is not the idea of the State schemes which is at fault; it is the precipitate, relatively thoughtless implementation of them that has led to so many unfortunate complications. . . .

I believe strongly that there is a great deal of good in most of these schemes, but such good will be watered down just to the extent to which any particular scheme inhibits the incentive, the initiative, or the independence of either partner—the doctor or the patient. It is not the politician of to-day who will suffer from an ill-conceived scheme, but the patient of the future. Such a possibility we, as medical men, must prevent at all costs. As a profession, from the very nature of our work we are, and have proved ourselves to be, poor hands at producing a united and concerted effort. A man who, night and day, is facing up to the responsibility of dealing with the individual physical and psychological problems of his fellow men is, generally speaking, not adept at formulating overall plans to cope even with a large series of circumstances and conditions, and far less a large series of people.

But at least each of us can take out of the back cupboard his moral values and see to what extent they allow him to support this scheme or part of a scheme or strongly oppose another. I am sure that we all now have to make this individual effort if we are to ensure the best treatment for our present and future patients, safeguard a generation of the profession still unborn, and be as good doctors as God and Otago University may make us. . . .

[Reverting, as he concluded, to his main theme, a tribute to the men of the N.Z.M.C. who lost their lives in war, Sir Arthur Porritt said:]



Time in his comforting and effortless way is steadily deadening that sense of personal and professional loss we felt when these good men departed. He has pushed Mars back—well back, we trust—into the shadows of the past, but he has led out a rejuvenated Aesculapius into the limelight—one might say the floodlight—of to-day and the future.

The second annual report of the Scottish Society of the History of Medicine says that an increasing number of North of England members are being enrolled. Three meetings were held during the year: a discussion on the teaching of the history of medicine; a paper on the history of British dentistry since 1685; and a full day devoted to papers by two distinguished American visitors on the history of Johns Hopkins University and on the life and work of John Morgan, founder of the first medical school in America (Philadelphia, 1765), followed by a pilgrimage to places of medical interest round Edinburgh.

Preparations and Appliances

THE "CAMBRIDGE" EXCHANGE TRANSFUSION OUTFIT

Dr. C. B. V. WALKER, director of the Regional Transfusion Centre, Cambridge, writes: The technique of exchange transfusion via the umbilical vein in cases of haemolytic diseases of the newborn was first developed by Diamond (1947) in the U.S.A., and the apparatus required has been described by Mollison *et al.* (1948) in this country. A modification of this apparatus has been tried clinically with success in the Cambridge Regional Blood Transfusion Centre. The main points of difference are: (1) that the use of three-way stopcocks has been entirely dispensed with, and irritating delays due to the joints

becoming dislodged in the course of the transfusion have been obviated; and (2) a tapered cannula has been incorporated into the outfit, which not only prevents leakages due to a poor fit between the polythene tube and the cannula on account of variations in the internal diameter of the polythene tube, but the operator can select the size of tubing he wishes to use, on clinical considerations, and fit it forthwith to the outfit without previously ascertaining that a tightly fitting cannula is available.

As shown in the diagram, the set comprises a cross-piece made of ¼-in. (0.6-cm.) glass tubing, each arm of which is 1 in. (2.5 cm.) in length, and is corrugated to give a firm purchase for the attachment of a rubber tube. In the following description the letters B, V, W, and S refer to the arms of the cross-piece connected to the blood bottle, umbilical vein, waste, and syringe respectively. Arm B is provided with about 3 in. (7.5 cm.) of rubber tubing mounted with a female Record-fitting adaptor, as used in the distal part of the normal administration set supplied by the National Transfusion Service. This adaptor is designed to receive the corresponding male adaptor of the Transfusion Service outfit. Arm V has 2 in. (5 cm.) of rubber tubing mounted with an Alban Andrews tapered cannula, and is designed to receive polythene tubing of a reputed internal diameter of 1 mm. or 1.5 mm. as desired by the operator. Arm W has a rubber tube about 2 ft. 6 in. (75 cm.) long mounted at the distal end by a male adaptor; this is the tube by which the extracted blood is run to waste. Arm S has 2 in. (5 cm.) of rubber tubing mounted with a metal adaptor to take a 10-ml. or 20-ml. Luer-fitting syringe.

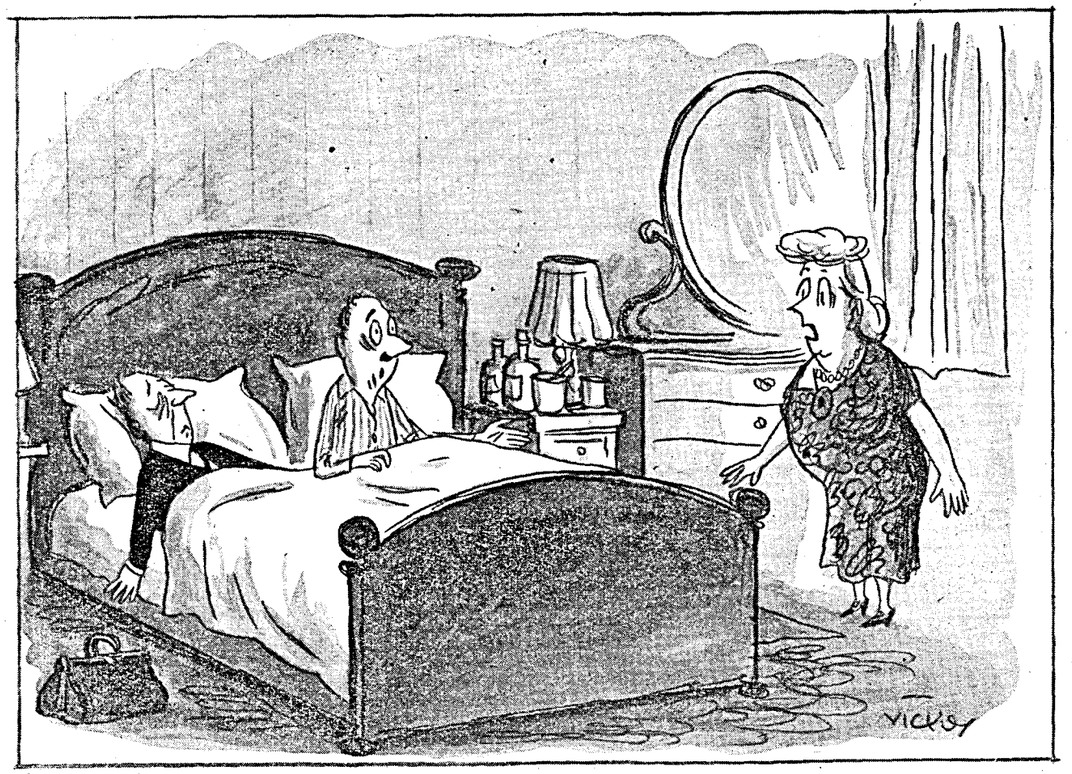
It is desirable that the length of rubber in arms V and S be kept as short as possible, to minimize the amount of "dead space" in the outfit. The exact length of rubber on arm B is unimportant.

If an operator prefers to use a Record type syringe, it is a simple matter for tube S to be fitted with a suitable adaptor when the outfit is being assembled. The only other equipment needed consists of two haemostat forceps.

A bottle of suitable blood is fitted with a standard giving set in the ordinary way, air in the delivery tube is removed, and the screw clamp closed. The set is then connected to arm B of the exchange outfit. Haemostats are clamped on the rubber of arms V and S, and the syringe is attached to arm S. The screw clamp of the standard set is then adjusted to deliver a fast drip through the waste pipe, arm W, and when this has been done the rubber of arm B is at once clamped with the haemostat from arm S. Then a polythene tube of suitable diameter, 1 mm. or 1.5 mm., is introduced into the infant's umbilical vein and connected to the tapered cannula. The clamp on arm V is transferred to arm W (waste), and the syringe is filled with the infant's blood by suction. The clamp is then returned from arm W to arm V and the blood in the syringe is discarded.

The exchange transfusion may now begin. The clamp on tube B is transferred to tube W and the syringe filled from the bottle of blood. The clamp on tube V is transferred to tube B. The syringe is emptied into the umbilical vein and refilled from the vein by suction. The clamp on tube W is transferred to tube V and the syringe emptied through the waste pipe. The clamp on tube B is then transferred again to tube W and the cycle repeated until the whole 500 ml. in the bottle has been used.

The point to note is that once the exchange transfusion has begun the two haemostats circulate between tubes B, W, and V in that order, and the vacant tube is clamped, at the appropriate point in the cycle, by the use of the haemostat from the preceding tube, the above convention being kept in mind.



The outfits, as issued by the Cambridge Centre of the National Transfusion Service, are supplied in a "cellophane" wrapper in a 2×4×11-in. (5×10×27.5-cm.) tin, which also contains a standard giving outfit minus the distal needle unit, and also two 8-in. (20-cm.) lengths of sterile polythene tubing of 1 mm. and 1.5 mm. internal diameter packed separately in straight glass tubes with cotton-wool plugs and cellophane wrappers. The polythene is sterilized by steaming at atmospheric pressure in the autoclave for 30 minutes on three successive days (Tyndall's method). It should be noted that the contents are packed in the tin after sterilization. It follows that the outsides of the cellophane wrappers are not to be regarded as sterile.

A further distinct advantage in this type of outfit consists in the fact that all parts are easy to dismantle, inspect, and clean thoroughly before reassembly, and the design lends itself to multiple production at a Regional Transfusion Centre. It has been found almost impossible to be sure that the metal three-way stopcocks of the original method have been cleansed completely from fragments of residue from previous use.

"The Doctor was *so* tired, Dear."

HAPPY CHRISTMAS!

The Editor and his staff, in sending the usual greetings of the season, are aware that the serried columns of portentous print of the *B.M.J.* keep them impersonally remote from their readers. This, of course, has its advantages. When the man with the burning message finds the chill waters of editorial disapproval poured on it he at least doesn't feel that his best friend has pushed one of his disks out. He can pour out the vials of his wrath on that somewhat monolithic abstraction the Editor. But behind the severe black-and-white of our austere pages there are human chaps at work, back-room boys all, longing at times to burst out into licentious song, but restrained all the time by professional decorum and—believe it or not—a desire to be fair even to the most unfair.

Some readers have begged us to be funny. We must reply in the terms of an article in a contemporary journal: "This type of personality was absent in 10% of their patients." Nice to think you can have an absent personality. The funny things are there if you look for them. We find them, in a quite unbiased way of course, in other journals. At this time of the year this message comes straight from the heart of a leading article: "The part played by heavy meals shortly before bathing deserves critical examination." One can see those heavy meals gallantly playing their part before the severe eye of a dyspeptic critic. And for those who go in for higher thinking comes this reassurance from a reviewer: "A brief section takes the reader as far as he needs to get a proper grasp of the betatron, the synchroton, and the latest form of linear accelerator." This irresistibly called up a picture of Harpo Marx grasping, and quite properly, a linear accelerator. Knowing how easy it is to err, our editorial hearts beat an extrasystole of sympathy when we read this confession from a contemporary: "By an error which we much regret, we last week printed under this heading the review of a different book. The proper review will be published shortly." And from the same and highly esteemed organ of opinion came this startling—the only word to use is—revelation: "Most people seem to think that the vaginal passage runs straight up and down the body—a misapprehension sustained by the usual neat diagrams showing the uterus poised on top of the vagina." Some misapprehension!

Editorial humour being in short supply, we have invited two whose wit in cartoon and verse has pierced many a dark corner to illumine the contemporary medical scene. Vicky and Sagittarius are impressed with two things—the overworked doctor and the over-doctored patient. They are the expert witnesses, and what they say is there to be seen and read.

May we close by hinting that medical editors share with their colleagues in practice the privilege of being driven too hard. Our noses are dipped alternately in the paste-pot and the ink-bottle. With difficulty the editorial head is kept above paper, and the printer's devil is ever at his elbow. And after each week's journal has gone to bed there is the sudden waking in the night and a horror that what had better not be committed to print is now beyond recall. Then the pangs of conscience about unanswered letters and an ever-mounting pile of unread manuscripts. A long correspondence about a rejected manuscript from a foreign colleague ended by his remarking, "I am not trying to make of you a jumping Kangaroo, but I suppose not all the obstacles impossible to be removed or to be overcome." On this hopeful note we shall soon enter the New Year.

[Cartoon is by Vicky of the *News Chronicle*.]

THE DOCTOR AND THE MINISTER

"Now that we have got the National Health Service based on free prescriptions, I shudder to think of the ceaseless cascade of medicine which is pouring down British throats."—Mr. Aneurin Bevan.

The queues were grousing cheerfully
Beside the Doctor's door;
They would not go away without
The mixture as before,
And this was odd, because he said
They needed it no more.

The Doctor and the Minister
Were sitting hand in hand,
They wept like anything to see
The mixtures in demand.
"If they could be reduced by half,"
They sighed, "it would be grand!"

"One hundred million pounds per ann.
For mixtures we must vote.
The liquid doses that each day
Flow down the nation's throat,
If emptied out, would make a sea
On which the Fleet might float."

"The time has come," the Doctor said,
"To talk of vitamins,
Of carbohydrates, mineral salts,
And calories and greens,
Of fats, fresh air and exercise,
Biology and beans.

"But *Mist. Pot. Brom. et Nuc. Vom.* has
An almost mystic charm,
And if it does but little good,
It works but little harm."
"The Health Bill," sobbed the Minister,
"I view with grave alarm."

"I sympathize," the Doctor sighed,
"But still I greatly fear
If *Mist. Sod. Cit.* should be cut down,
Your votes would disappear."
"I know it," said the Minister,
And shed a bitter tear.

"You patients," cried the Doctor, "who
By bottles are allured,
Can run away and play to-day;
Your aches and pains are cured."
"If that is so," the patients said,
"Then why are we insured?"

The oldest patient winked his eye
But budged not from the spot.
"Tell that to the Marines," he said,
"We've come for you-know-what!"
"Nine million bottles seem," remarked
The Minister, "a lot."

The patients cried, "It's most unkind
To cross us off the list.
The doctors don't know everything—
Our aches and pains persist."
The Doctor rudely cried, "O, *Nux!*"
Then sadly wrote, "*Rep. Mist.*"

The Doctor and the Minister
Saw nothing could be done
As happy queues went skipping off
In search of Christmas fun;
Which was not odd, because they had
A bottle, every one.

SAGITTARIUS.

Correspondence

Displaced Registrars

SIR,—As a general practitioner I would like to protest at the recent cut in registrars. The registrars have stated their own personal problems, but let the rest of the profession realize what these dismissals mean. Before, the axe has fallen on hospitals and hospital expansion; now it is falling on the personnel of the service. How long before it will be our turn? Can we expect to improve our own conditions either in capitation rate or working conditions if we make no attempt to prevent this injustice?

Not only is any future improvement of the specialist services postponed by this cut, but it immediately throws 1,100 doctors into the general-practitioner market, and they could be used to dilute it. If the number of registrars is too many there must be an immediate need for increasing the number of posts with a specialist's status, otherwise there will be a fall in the quantity of out-patient consultations and in in-patient treatment. If there has been an excessive influx of the younger members of the profession into registrar jobs this is due to the unattractiveness of general practice, which implies the need for a reduction in the maximum number on the lists with an increase in the capitation rate.

In these matters the whole profession should work together and demand the withdrawal of this cut, and remove uncertainty from the future for registrars, for their future is ours.—I am, etc.,

Abersychan, Pontypool, Mon. A. S. JARMAN.

Training Registrars

SIR,—Now that the somewhat overdue review of registrar appointments is being undertaken is it not time for an equitable scheme for the training of consultants to be considered? At the moment there appear to be two classes of registrars, those at the teaching hospitals and those in the non-teaching hospitals. This has led to a very unfair discrimination in obtaining appointments, since the registrars from the non-teaching hospitals applying for consultant posts are often turned down on account of their lack of academic training. Would it not be better if the responsibility for the training of consultants and specialists could be fully undertaken by the teaching hospitals, with their university and academic background, and at the same time the large amount of practical experience offered by the non-teaching hospitals utilized in their training?

The following suggested scheme has been discussed with many of our colleagues, and met with their whole-hearted support.

The training of consultants and specialists shall be the entire responsibility of the teaching hospitals within the region. The number of trainee specialists entering upon a course of training each year shall be a fraction greater than the number of consultant and specialist vacancies occurring each year, in order to provide for wastage and competition. It is thus a definite trainee/vacancy ratio. The scheme should provide for a six-year training in which each trainee spends part of the time in the centre and part at the periphery. There shall be trainee posts six times the number of the estimated yearly output of trained specialists.

These trainee posts shall be allocated one-half to the recognized teaching hospitals and one-half to selected peripheral hospitals. The trainee shall move each year in accordance with a rotation plan such as first year in teaching hospital, second year in peripheral hospital, third year in teaching hospital, fourth year in peripheral hospital, fifth year in peripheral hospital, sixth year in teaching hospital.

The remainder of the peripheral hospitals in a region should have added to their staffs such further consultants or junior registrars as assistants as may be deemed necessary to carry out the work in each case.

Each year the vacancies in consultant posts should be open to competition by the specialists trained in accordance with this scheme or by consultants already in other posts.

The scheme is elastic and can be applied equally to each and every branch of consultants and specialists, since the number of trained specialists coming out each year bears a definite ratio

to the number of vacancies in each branch. Some alteration in the set-up of the teaching hospitals is inevitable, but as against this the whole of the training will be under their direct control. The consultants in the selected peripheral hospitals have an added incentive to keep their standard up to that of the teaching hospitals. The scheme eliminates the variation in standing of a trainee, since each receives both central and peripheral training, and at any stage it can be observed in which direction he is developing, and the training adjusted accordingly.

If the principle is accepted by the teaching hospitals, in order to set the scheme in operation the present registrars who are willing to transfer could be selected and appointed; the remainder should be allowed to finish their appointments under their existing contracts.—We are, etc.,

L. M. BILLINGHAM,
J. W. LACEY.

Chelmsford.

Registrars and Health Service Policy

SIR,—The proposed treatment of registrars is entirely uneconomic; these men have received long, expensive, and sometimes State-aided training; they have had the benefit of considerable experience in their specialties; they are, in fact, particularly valuable members of the profession. Secondly, the plan is both unjust and inhumane; these registrars, frequently with war service behind them, were misled by suggestions that there would be a great increase in the number of specialist jobs under the Health Service; they were encouraged to carry on training by Government grants and supernumerary appointments. It therefore behoves consultants to stand solidly behind them and see that the plan is altered.

The problem is obvious—too many training for too few jobs—and it can be tackled at both ends. First, we need more consultant appointments, and, if it is financial stringencies that are preventing them, there are many obvious ways of saving money in the Service—e.g., charging for spectacles, dentures, appliances, board and lodging while in hospital, etc. Furthermore, we should if necessary offer our merit-award money for the payment of new consultants. Secondly, we should slow down training. This should be done as any manufacturer would do if faced with a diminished demand for his goods: not by destroying stocks of the finished product but by slowing down production at the beginning until all the stocks are used. This policy would be achieved by allowing all present senior registrars who are suited to their jobs to remain in them indefinitely if they so desire, with the knowledge that in perhaps eight years there will be consultant posts for all who are of sufficient calibre. This blocking of the senior posts would discourage new entrants into the ranks of trainee specialists, and better be discouraged at the start than after full training.

Finally, I would add this. We are seeing the result of miscalculation and incompetent planning; are we sure that the same problem will not arise in regard to general practitioners? Each year our medical schools turn out more doctors—I believe my own school is planning to turn out twice as many as before the war—and yet I understand that the money available for paying general practitioners is constant. Are these increased numbers of doctors required, and, if so, can they be paid? This must be thought out now and not left until we are faced with large numbers of unemployed doctors.—I am, etc.,

PAUL HICKINBOTHAM.

Leicester.

Producing Anaesthesia of Trigeminal Nerve Distribution

SIR,—I am most interested in the letter (December 9, p. 1334) from Messrs. Brodie, Hughes, and Small, describing the occasional difficulties they have met with in resecting the third division of the sensory trigeminal root. Certainly the fibrous septum they describe running from the ganglion far into the sensory root might explain the difficulty of infiltrating the whole root with alcohol, but it would not explain the preservation of sensation in the mandibular branch unless a bundle is overlooked or intentionally left uncut in mistake for the motor root.

To obviate this, I would suggest using Frazier's method, which he adopted and published in 1919, for saving the motor root. He describes this root as issuing from beneath the ganglion, wrapped in bundles of sensory fibres, which he separates with the use of a faradic electrode, cutting only the fibres which do not respond by contraction of the temporal muscle.

I have included Frazier's account in a "History of the Treatment of Trigeminal Neuralgia," which the editor of the *Postgraduate Medical Journal* asked me to write, and which will appear shortly.—I am, etc.,

WILFRED HARRIS.

London, N.W.1.

SIR,—I would refer Mr. Brodie Hughes and Mr. J. M. Small (December 9, p. 1334) to Sicard (1932), who after a painstaking anatomical study of 42 cases wrote: "Nous pensons donc pouvoir conclure que, dans 25% environ des cas, *la racine motrice contient des fibres sensitives* soit par l'intermédiaire d'une grosse radicule venant directement du ganglion de Gasser, soit par l'intermédiaire d'une anastomose plus ou moins grêle avec une radicule sensitive. Ces fibres permettent d'expliquer la persistance ou le retour d'une légère sensibilité que l'on observe parfois dans le domaine du maxillaire inférieur après neurotomie totale et conservation de la racine motrice" (his italics). His drawings are convincing. The closer to the pons a sensory rhizotomy is made, the more likely the escape of these overcrossing fibres, so that one would expect the relapse rate to be higher after suboccipital than after subtemporal rhizotomy. This has been the experience of Olivecrona (1947), who found the respective rates to be 17.7% and 8.5%, and of Guidetti (1950), who found them to be 17.9% and 8.3%.

The immediate post-operative persistence of both sensation and the pain of tic douloureux despite complete sensory rhizotomy can probably be explained in no other way. For a delayed return of sensation and pain after initially adequate anaesthesia there is another possible explanation. Ganglion cells were found scattered in the sensory root in one human case by Stibbe (1936) and in three by Ferner (1940); if the sensory root were divided distal to such cells, the centrifugal fibres arising from them might regenerate.

When tic douloureux in the mandibular division is cured by rhizotomy, yet some sensation persists there, a third explanation must be considered—namely, overlap of the trigeminal area with that of the cervical nerves. Lewy (1938) claimed to demonstrate by quantitative electrical tests that this overlap always existed, though usually not demonstrable by ordinary clinical methods.—I am, etc.,

JOHN PENMAN.

Antihistamines and the Common Cold

SIR,—I have read the report (August 19, p. 425) and articles on the use of antihistamines in the prevention and treatment of the common cold with considerable interest but real disappointment, and I would like to reply.

The antihistamines, when used in the therapy of the common cold, probably are effective in correcting disturbed physiology only. They have little or no effect either upon the pathogenic organisms causing the disease or upon its fully developed pathology. The early symptoms of the common cold as well as those of many other infections and varieties of trauma of the respiratory tract represent disturbed physiology, with developing acute inflammatory oedema as the demonstrable lesion. As such it is reversible. Sneezing, rhinorrhoea, lacrimation, and the unproductive cough are actually exaggerated and often inappropriate physiological responses to non-specific irritant stimuli. The reaction is diffuse when caused by physical agents and inorganic chemicals. When due to viruses or bacteria, it assumes an allergic character and becomes sharply localized. When this sharply circumscribed oedematous process progresses to the point where necrosis begins to appear in the involved tissue, it becomes true pathology, is irreversible, and there is no drug or other form of therapy that will affect the lesion favourably. This can occur within six hours or less. It is believed

that this stage of the initial lesion of the common cold is analogous to the urticarial weal and the lesion of herpes simplex in humans, and to the Arthus phenomenon in laboratory animals.

There are several variable factors at play in every case where the common cold is contracted. Among these are

(1) The nature of the irritant. If it is due to a virus, or bacteria, or products from their growth, the degree of virulence is important.
(2) The size of the dosage implanted and, in the case of living organisms, the rapidity of growth.
(3) The immunity, if any, of the patient to the irritant then present.
(4) The general state of health at the time of the attack. This is governed by pre-existing pathology, the diet, vitamin intake, fatigue, and the degree of emotional adjustment
(5) The ability, or lack of it, to control the temperature and humidity of the immediate environment.

Further, it should be recognized that there are two groups of conditions and diseases which are often confused with the infectious common cold due to a virus, and are believed to have been included in most reported series of cases, including my own. These are

(*a*) "Traumatic," "allergic," or pseudo colds due to non-infectious irritants. They occur in every month of the year, in every country, in every climate, and as a group yield readily to antihistamine therapy.

(*b*) Respiratory diseases due to other viruses such as the influenzas, atypical pneumonias, measles, and those due to bacteria such as the streptococci, the exact diagnosis of which is often missed. These predominate in the winter months when human resistance is at its lowest ebb, and with the exception of those due to bacteria are refractory to all treatment.

According to our present knowledge the antihistamines accomplish their effects principally by blocking histamine and the action of acetylcholine. Thus the dose becomes the amount required to neutralize the effects of these chemicals, and not a stated number of milligrams. Furthermore, it has been my own experience that if symptoms are allowed to reappear after the first dose has been taken the cold will usually mature regardless of subsequent treatment, indicating the development of an irreversible lesion. Thus the neutralizing effect must be sustained as long as the irritant acts.

From the above it would seem reasonable to believe that colds have been and can be aborted when antihistamines are taken in adequate dosage while the initial lesion is in the stage of disturbed physiology and is still reversible, and when the effect of the drug is sustained during the action of the irritant. Those symptoms of the common cold due to disturbed physiology, and which result from the spread of the infection over the mucous membrane, can be alleviated even after the true pathology of the disease has developed.

But once definite pathology has developed no treatment can be more than palliative. The contradictory statistics reported to date accurately reflect the type of work that has been done and the results obtained. As yet no adequately scientific report has been made concerning the effect of antihistamines upon the experimentally induced cold.

I should add that all these opinions are my own, and must not be taken as representing the views of the Navy Department or the naval service at large.

—I am, etc.,

JOHN M. BREWSTER,
Captain (M.C.), U.S. Navy.

Philadelphia, Pa.

Causes of Death in Diabetes

SIR,—Always one appreciates comments on a printed paper, and especially some of the perfectly good points made by Dr. J. M. Sen Gupta (November 4, p. 1061). It was not my intention to give a detailed statistical presentation, because such material is available in other publications, including the pamphlet on Studies in Diabetes.

As regards the third paragraph, the reason that the total of the percentages exceeds 100 is that the item "gangrene" is a part of the total for cardiovascular renal diseases. If that entry of gangrene had been *indented* (see May 13, Table II, p. 1096) the misunderstanding would have been avoided.

I am sending the writer another publication to cover what he mentions, and will forward the same to anyone who wishes these.—I am, etc.,

ELLIOTT P. JOSLIN.

Boston, Mass.

Urethra Obstructed by Crystals

SIR,—I should like to report the case of a child of 13 months who had retention of urine, due to a collection of crystals in the urethra.

The child, a boy, suffered from bronchopneumonia, and was given 2 dr. (7 ml.) "cremor-merazine," followed by 1 dr. (3.5 ml.) every eight hours with 10 gr. (0.65 g.) potassium citrate. It is possible that an over-anxious mother increased the dose. The child's symptoms cleared quickly, but on the third day he became very ill, and was in obvious pain. On examination the doctor discovered a very much distended bladder which was not relieved by the usual remedies. As the child was in such pain an anaesthetic was given, and the bladder was emptied by the passage of a ureteric catheter. The urine contained crystals which could be seen by the naked eye and were confirmed by the pathologist's report. The child made an uneventful recovery.

I have seen two previous cases this year of ureteric obstruction following "sulphamerazine," one of which had to be relieved by the passage of a ureteric catheter, but this is the first case of urethral obstruction that I have seen, nor have I seen a case reported.—I am, etc.,

J. T. RICE-EDWARDS.

Newport, Mon.

Erythrocyte Sedimentation in Anaemia

SIR,—Dr. Richard Terry's admirable article (December 9, p. 1296) disposes so effectively of the method of "correction for anaemia" in the estimation of the E.S.R. that it is a pity that he thought it necessary (p. 1297) to make a ritual genuflexion in the direction of the Wintrobe technique. Surely once one has concluded that correction for anaemia is neither necessary nor desirable, the last argument in favour of this technique is disposed of. From a practical point of view the Wintrobe technique is very troublesome owing to the difficulty of filling and cleaning narrow blind-ended tubes, and the contraction of the scale from 200 to 100 mm. necessitated by the desire to use the tube as a haematocrit in order to be able to "correct for anaemia" makes the test less discriminating than the Westergren. Moreover, in my experience and that of others with whom I have discussed the problem, the Wintrobe technique gives much less reproducible results than the Westergren, when the same amount of technical skill and care is used. The only point that might still be adduced in favour of the Wintrobe technique is that since the double oxalate mixture does not affect the sedimentation rate while the citrate solution does, the Wintrobe is therefore a more "correct" method. Since, however, the E.S.R. is in the last analysis an empirical measurement of a little-understood phenomenon, surely our method of estimation should be such as can be carried out easily and reproducibly, rather than one whose advantages are purely theoretical.—I am, etc.,

B. M. WRIGHT.

Penarth, Glam.

SIR,—I was interested to read the article (December 9, p. 1296) by Dr. Richard Terry. His conclusion that "hypochromic anaemia neither invalidates the Westergren E.S.R. nor necessitates correction" reminds me of my conclusion in my paper in the *Edinburgh Medical Journal* (1945), **52**, 132, where I deduced that "the blood sedimentation diagram is parallel to the degree of anaemia only in anaemias due to haemorrhage and pernicious anaemia. In other types of anaemia there is no correlation between B.S. diagram and the degree of anaemia. The corrections of the B.S. results in anaemias are meaningless."

Having carried out until to-day almost 11,000 E.S.R. tests, many hundreds with different anaemias, I am more convinced now than five years ago that cases with different degrees of anaemia may have the same E.S.R., and cases with the same degree of anaemia different E.S.R.s, so that correction of the E.S.R. in anaemias seems really to be incorrect.—I am, etc.,

H. DLUGOSZ.

Wrexham, Denbighshire.

SIR,—I apologize for reviving an old controversy, but the recent article by Dr. Richard Terry (December 9, p. 1296) has raised several points which I wish to examine in the light of

my own experience. I beg leave to review this subject from a theoretical and practical standpoint to clarify my argument.

When the theory of sedimentation is examined it becomes clear that the sedimentation rate (S.R.) depends mainly on the size of the sedimenting particle. As this is determined mainly by the formation of large rouleaux or aggregates of cells it is unlikely that the size of the individual cell will be an important factor, although it may have a subsidiary influence—e.g., Bendien *et al.* (1932). The formation of aggregates of cells is in turn dependent on plasma factors, mainly on fibrinogen and globulin, but in a complicated protein balance—e.g., Gordon and Wardley (1943). This plasma protein balance has been termed "sedimentin" for convenience by Day (1939). If it is assumed that the *plasma* sedimentin concentration is the same in anaemic blood as in normal blood, the total *blood* sedimentin concentration will be increased in anaemic blood as there is more plasma (and fewer erythrocytes) in a sample of such blood. This increase in sedimentin would cause larger rouleaux and an increased S.R. Furthermore, as the percentage volume of packed cells (P.C.V.) is increased in anaemia, the sedimentin will have fewer cells to influence, and hence the effect will be correspondingly greater. It follows that the velocity of sedimentation in anaemic blood will be proportional to the speed in normal blood multiplied by $\frac{45\ (100 - \text{P.C.V.})}{55 \times \text{P.C.V.}}$, when P.C.V. is the observed percentage volume of packed cells, and 45% is the normal packed cell volume (Kellett, 1947). This calculation based on a double effect of anaemia agrees better with the correction chart of Rourke and Ernstene than the simple proportion correction of Della Vida. As aggregation is a result of surface action it would be more correct to say that the S.R. depends on the amount of sedimentin acting on the total surface of all the erythrocytes, but the above conception is sufficient to explain why the P.C.V. is a better single measure for correction than either the haemoglobin or erythrocyte count.

I have examined by the Wintrobe technique a series of bloods from cases of uncomplicated idiopathic hypochromic anaemia and pernicious anaemia. In 50% of cases of both types of anaemia I found the S.R. increased in proportion to the degree of anaemia as measured by the P.C.V., and in these cases the S.R. fell as the P.C.V. rose during recovery from the anaemia. In the other 50% of cases the S.R. was raised considerably less than might be expected from the P.C.V. determination. Hence, although I cannot agree with Dr. Terry in theory, some of my own results lend partial support to his findings. It is interesting to note that other authors who have found normal results fairly constantly in anaemia and oppose correction for anaemia have, like Dr. Terry, used a technique with citrate as an anticoagulant (Bouton, Cutler, Davis (1946), Day (1939), Reichel (1936), Smith (1938), Schuster, Sugarman, Westergren). On the other hand those who favour correction have used oxalate or heparin (Britton, Collins, *et al.* (1939), Ham and Curtis, Hynes and Whitby, Rourke and Ernstene, Wintrobe). Some workers have suggested that the greater length of the Westergren tube may avoid the anaemia error by reducing the effect caused by packing of cells on the base of the tube, or the retarding force of upward currents of displaced plasma. However, these ideas would not explain the acceleration which I would expect from the primary increased aggregation of cells in anaemia. Dr. Terry has drawn attention to the stabilizing effect of citrate in the Westergren technique, and it is possible that it is the anticoagulant which has caused the above divergence of results and views. It is interesting to note that Drs. R. J. G. Sinclair and J. J. R. Duthie in a recent article (December 2, p. 1257) obtained results in Westergren tests which suggested that anaemia was having an influence on the S.R., but that *oxalate* was used as the anticoagulant.

Dr. Terry states that in anaemic blood the concentration of citrate in the plasma is less, and that therefore its stabilizing effect should be less. This conclusion is fallacious, as the effect will depend on the mode of action of the citrate. It may be postulated that the stabilizing effect of citrate is due to some type of protective action on the surface of the red cells preventing rouleaux formation. Then, as the *amount* of citrate per *erythrocyte* is greater in anaemic blood, one would expect the greater stabilizing effect which the author found.

The occurrence (though less often) of a normal S.R. in anaemic blood tested by Wintrobe's oxalate method needs further explanation. Dr. Terry points out that plasma protein changes occur in anaemia which are not considered in correction methods. I agree with him, and believe that in chronic anaemias there is a tendency to stabilization brought about by changes in the plasma proteins, sometimes by a reduction in plasma fibrinogen. The question arises whether or not it is necessary to correct the S.R. for anaemia. In my opinion it is necessary in theory, but not necessary in routine clinical work. Against all complicated correction procedures it may be argued that correction may be unnecessary in some cases, that in others the anaemia may be part of the disease, and that the result is not clinically reliable in 100% of cases. I would therefore advocate a simple method of performing this very complex test, so that the time saved may if necessary be used for some unrelated method of assessment of toxaemia (such as the Arneth count).—I am, etc.,

Marking Varicose Veins

SIR,—The importance of multiple ligation of varicosities, combined with ligation of the internal or external saphenous vein at the groin or knee, is well recognized. With the patient in the erect position the larger channels can often be more easily palpated than seen, and communications with the deep system can be felt as holes in the deep fascia. The usual method of marking the suitable sites for ligation, by the use of an aqueous or alcoholic solution of dye, often fails because the dye runs when the limb is painted with the skin antiseptic. I have found that methyl violet dissolved in a cellulose cement, such as "durofix," adheres firmly to the skin; it resists the usual pre-operative cleaning and occasionally has to be scraped off with the knife. A greasy skin should be wiped with ether or acetone before applying the dye.—I am, etc.,

Plymouth. EDRIC WILSON.

Myocardial Infarction after Tetraethylammonium Therapy

SIR,—I agree with Dr. D. J. Livingstone (September 23, p. 713) that it could be "thought that in these cases tetraethylammonium therapy was at least a contributory cause of the acute cardiac lesions." I do not, however, see any conclusive evidence for this supposition. To my mind the lacking evidence could have been obtained if any intense drop in blood pressure had been revealed in consequence of the injections, especially if the signs of acute myocardial infarction had developed within a couple of hours of one of these injections.

Acute myocardial infarctions following an intravenous injection are not exceedingly rare. This is well known. I remember several such cases myself. One of them stands out most vividly in my memory.

A somewhat obese man in the middle forties got an intravenous injection of tetraethyliodophenolphthalein at five in the afternoon. He was a heavy smoker, but did not reveal any signs of coronary trouble until that time. Immediately after the injection he felt "just rotten." He experienced a profuse sweating and was afraid he would faint. He had to lie down. After ten minutes he felt much better and the *x*-ray examination was performed. On driving home he suddenly felt an excruciating pain in the left side of the chest, with dyspnoea. He had to stop; the pain got unbearable, and he could not move, but after about a quarter of an hour the pain lessened and he was just able to drive home. Completely exhausted, he could hardly climb the stairs to his flat on the second floor. The pains again got stronger, and his physician had to give him a morphine injection, repeated within half an hour. I saw the patient the next morning. The temperature was 101° F. (38.3° C.), blood pressure 75/110 mm. Hg. Humid rales were heard at both bases. The blood count gave 15,600 white cells. The electrocardiographic finding was that of a left-sided infarction. The patient recovered from this incident but was never the same man again. He developed a congestive heart failure and died about three years later.

I completely agree with the author that great care should be exercised in the use of tetraethylammonium chloride in any patient showing evidence of arteriosclerosis, especially, I would add, if the drug be given intravenously. Or, rather, it should never be given intravenously in people over 40.—I am, etc.,

Sydney, Australia. CHARLES ENGEL.

Fibrillation and Flutter

SIR,—Dr. G. L. Foss (December 2, p. 1252) in his interesting account of the treatment of thyrotoxicosis with 2-mercaptoimidazole records the conversion of auricular fibrillation to flutter. This he regards as a possible toxic manifestation, not mentioned in the literature. In theory, a stage of flutter may occur in every change from fibrillation to sinus rhythm, and I have been accustomed so to regard the flutter that is sometimes seen in thyrotoxic heart disease in the course of treatment. It follows that no medication is required beyond continuation of the antithyroid drug already in use. Here is a case in point.

A man aged 49, referred to me with fibrillation that I considered to be *thyrotoxic in origin*, developed flutter after two weeks on methyl thiouracil. After seven days' further treatment this reverted to sinus rhythm without the use of quinidine or digitalis. Each stage was confirmed electrocardiographically. Sinus rhythm persisted during the three and a half years that I had him under subsequent observation.

I think that Dr. Foss has been unduly harsh with himself in regarding this case of flutter as toxic in origin, and that, even if not mentioned in the literature, the sequence of events that I have described has been observed a number of times.—I am, etc.,

Cheam, Surrey. C. P. PETCH.

Euthanasia

SIR,—There are a few points in your very fair and, if I may say so, sympathetic leading article (December 9, p. 1318) on which I should like to comment, and one or two small corrections to be made. I will deal with the latter first.

(1) You more than once refer to "incurable disease," which term at once raises the objection that "diseases incurable to-day may be curable to-morrow." In my Society's Bill, as introduced in the Lords in 1936, the term "incurable disease" is not once employed; we only mentioned "incurable illness," which is quite another matter. There will always be incurable illness no matter what advances are made by medical science.

(2) You refer to the nearest relatives having to be informed. It is true that in the original draft of the Bill I did bring in the "nearest relatives," but we decided, under legal advice, to leave them out entirely in the revised Bill introduced by Lord Ponsonby.

(3) You state that "euthanasia is to be administered by the medical practitioner named in the permit." This also is not quite correct. Our Bill provides (Sect. 5 (1)): "Euthanasia *shall* not be administered by any person other than a medical practitioner licensed for the purpose." As a matter of fact, owing to the objection continually raised that "it is a doctor's business to cure and not to kill," my Society has now decided that when our Bill next comes forward the above clause, 5 (1), *shall be amended* by inserting the words "or other suitable person" after "medical practitioner." Incidentally, I may mention that it was never contemplated that many, if any, doctors in general practice would care to undertake this duty, even though it would be an act of pure mercy. In these days of *motor transport only* a very small number of "euthanisors"—or should we call them "mercy operators"?—would be required to serve the whole country, at least for some time to come. Moreover, our Bill does not stipulate that even the "euthanasia referee" need necessarily be a doctor—he might well be a lawyer. So that under *our Bill all* that would be asked of the medical profession would be the two medical certificates, testifying to what were matters of fact in the doctor's opinion, and there would be no actual obligation even to provide these. Hence the argument, so often used, that what is proposed would place an intolerable burden of responsibility upon the medical profession, and would confer upon it a power which might easily be abused, is entirely due to misapprehension and has no foundation in fact.

When Lord Chorley's motion in favour of voluntary euthanasia was debated in the Lords on November 28 (*Journal*, December 9, p. 1338) all the five medical peers present spoke against it. This, of course, was very unfortunate from our point of view and scarcely gave the motion a chance, but I may perhaps recall that the first president of our Society, who but for his untimely death would have introduced our Bill himself, was the late Lord Moynihan, the eminent surgeon and a past-president of the Royal College of Surgeons; also that one of our vice-presidents was the late Sir Humphry Rolleston, a past-president of the Royal College of Physicians. To-day, some 170 distinguished members of the profession, all of "Who's Who" status, and including 30 who have been knighted, have given us permission to use their names as being in sympathy with our objects.

As regards the religious objection, it is true that the Archbishop of York spoke strongly against the motion, but I would recall that when our Bill was before the Lords in 1936 the then Archbishop of Canterbury, although he voted against the Bill, said: "I must confess that this is, to me, a very difficult question, one in which principle and compassion contend, so that I find it not at all easy to make up my mind"; and I may mention that a number of distinguished churchmen, including the Dean of St. Paul's, have given us permission to use their names as being in sympathy.

Similarly, although the Lord Chancellor spoke strongly against the motion, we have a number of distinguished lawyers who are with us, and one of our vice-presidents was, until he retired, a judge of the High Court.

In concluding your leading article you say (quoting Lord Horder): "The good doctor will distinguish between prolongation of life and the unnecessary prolongation of the act of dying." Surely the "unnecessary prolongation of the act of dying" is very nearly if not quite what my Society is contending for.

It is often asserted that we are asking for the "right to kill." May I suggest that what we are asking for is rather "the right to die" (subject to certain necessary restrictions and safeguards), and for the right of *the sufferer to receive* such assistance from others as may be required in the exercise of this right.—I am, etc.,

Leicester. C. KILLICK MILLARD,
Hon. Sec., Voluntary Euthanasia Legalization Society.

SIR,—It was with profound disquiet that I read your leading article (December 9, p. 1318), where a subject of such gravity as euthanasia is discussed without so much as a reference to the fundamental issue which is at stake—I refer to the moral implications.

I would recommend, therefore, lest this issue be overlooked by irrelevant controversies over such matters as bureaucratic procedure, morale of the sick-room, and diagnostic errors, that we keep constantly before our minds those words of St. Paul: "None of us lives as his own master and none of us dies as his own master. While we live, we live as the Lord's servants, when we die, we die as the Lord's servants; *in life and in death* we belong to the Lord" (Romans xiv. 7–8).—I am, etc.,

Croydon. F. J. MOYNIHAN.

Cost of Academic Clinical Office

SIR,—If a wealthy man likes to indulge in lavish expenditure on travel, books, societies, journals, entertainment, etc., he is of course entitled to do so. In a nutshell the gravamen of Academicus (December 2, p. 1275) appears to be that he cannot eat his cake and have it. Possibly an ingenuous and spendthrift millionaire with an income of £100,000 and an expenditure of £99,800 might convince himself that he earns less than an Asiatic labourer, but he would convince nobody else—least of all the Asiatic labourer.—I am, etc.,

London, W.8. GEOFFREY G. SHERRIFF.

A Failing Policy

SIR,—The *title of your leading article* in the *Journal* (December 2, p. 1262) suggests that things might have been otherwise, and in the text you attribute failure to the Minister. Does not the real failure rest on those who agreed, against the wishes of the majority, to operate a policy which was doomed to failure? Certain powerful sections of the profession "saw their way" to operate parts of the scheme, and they evidently overruled the counsels of those who perceived in the main administrative framework an insuperable obstacle to sound planning. It is more likely that the historian of the future will be more astounded at this aspect than at the Minister who may have failed subsequently to develop some particular aspects of the scheme.

The White Paper of the Coalition Government, the schemes of the British Medical and other Associations, and the Bill itself all bore the hall-marks of political or medico-political expediency. No medical administrator of experience would have

produced a scheme which arbitrarily divided a personal health service into three lopsided divisions with no effective provisions for co-ordination or balanced economy. Certainly, no one whose vision went beyond the narrow confines of politics or the more specialized branches of curative medicine would have forgotten the vital role of preventive medicine. To forget that infectious-diseases hospitals, sanatoria, and, to a considerable extent, maternity hospitals were later adnexa of preventive medicine is on a par with the naive assumption that epidemics have had their day, that tuberculosis is a "general" rather than an infectious disease, and that all that remains of preventive medicine can be reduced to such simple terms as vaccination and immunization.

Having made a case, Sir, for the readjustment of the economy of the service, including the remuneration of those engaged in it, you conclude by saying that payment, or the lack of it, has nothing to do with the present discontent and disillusionment of the profession. Surely that is illogical. Let us face facts, if ever we are to advise the Minister on how best he can spend what money the Treasury will give him. At the present time the allocation of money for health services is roughly in the ratio of 1:12:24 for local health authorities, executive councils, and hospital boards respectively. Hospital administrative costs have shown the most spectacular increases without any increase in the number of available beds. It is almost impossible to obtain an analysis of these costs, but specialists' salaries are known to be a major item, and overhead costs, due to the cumbersome and wasteful system of management by boards, have shocked all who formerly managed the same hospitals.

Having dealt with statistics for more years than I care to remember, I know their limitations, and I am going to suggest that never have there been so many men, especially young men, in receipt of full specialist remuneration. Herein lies, I think, the failure to encourage the budding specialist. Having filled up the establishment there is little chance of succession for many years to come, and it is going to be a very difficult matter to persuade those who have suddenly made the grade that they must forgo some of their remuneration in order to bridge the gap which separates them from their less successful colleagues. The position of the *established* general practitioner, as compared with the entrant to general practice, is somewhat similar. The established doctor in either branch has experienced in the main a definite improvement in his finances as a result of the Act, and we know that the same holds true for dentists and opticians. If the Treasury can spare no more money, then some of this extra remuneration must be applied to the gradual advancement of recruits. I am aware that general practitioners, dentists, etc., are working hard for their money, but I have the impression that the unexpanded hospital service is top-heavy with specialists. Advice is of little use if it cannot be applied in practice—i.e., in hospital. Even in this age of substitution free spectacles or cough mixtures count for little to the chronic sick in their lonely attics, or to the bedridden consumptive awaiting admission to a sanatorium.

Some assume that the clock could be put back where it was on July 5, 1948, but that is manifestly impossible. The vesting date for practices, as well as for hospitals, is as irrevocable as that for the mines. It would appear to be an inevitable, if ironic, conclusion that the only way in which the profession can recast the health services in some semblance of a workable and economic proposition which will improve the health of the people and will, at the same time, attract recruits is to ask the Minister to introduce full State medicine. Those who may recoil, however, from such a suggestion should reflect on just how much they have gained or lost by their insistence on retaining what is little more than a travesty of freedom. We have been saddled with boards and councils whose members in the main know little of medical administration. In order to keep them on the rails they have been issued with directive circulars and supplied with technical officers. Some boards have ignored this guidance, and their management on the whole has not been of a high order. Nevertheless they represent expenditure which could be dispensed with. In a full State service they would disappear and the Minister himself would be directly responsible to Parliament. In their place there would be a small number of higher administrative officers—call them Civil Servants if you will—but the whole service, being highly technical, would inevitably develop on the advice of its technicians. Promotion would be a gradual process determined by the quality and service of the individual. At least we would be spared the unedifying spectacle of laymen being canvassed by prospective general practitioners, of specialists meeting in secret to share out distinction awards, and of the wide anomalies existing between those doing comparable work. The whole artificial and expensive barriers between regions, areas, and branches of the service would likewise disappear, with an improvement in balance and a great saving in man-power and money. There should be sufficient funds left over to provide and staff a number of hospital beds and perhaps one or two experimental health centres. As a realist, can one seriously lay much emphasis on health centres or on the Minister's failure to provide them? Until such time as practitioners pool their patients (an undesirable step) it is unlikely that they will favour communal consulting-rooms.

Finally, I would make a plea that the profession permit those who, by experience and training, have some knowledge of how a full service can be planned to draw up a draft scheme for the future, others having tried and failed.—I am, etc.,

Kirkcaldy. JAMES R. W. HAY.

Pulmonary Complications of Pertussis

SIR,—The annotation on this subject (November 18, p. 1162) states that in an article of mine I did not confirm previous suggestions that the high incidence was related to the severity of the disease. The article referred to contains figures to show that the incidence of pulmonary collapse rises with the severity of the disease.

My series of cases is also referred to as unselected, and it is said that 21% had persistent collapse for more than a year. The series was in fact selected, as all the cases were sufficiently severe to require admission to hospital, and the figure 21% refers to severe cases only.—I am, etc.,

London, S.W.1. DAVID NICHOLSON.

POINTS FROM LETTERS

Psychiatry and the Common Cold

Dr. M. C. ANDREWS (Wembley, Middlesex) writes: Is Dr. H. M. Feldman (November 11, p. 1120) serious when he writes about the emotional cause of the common cold? When I have toothache or a pain in my stomach I suffer from "a decrease of objective feelings of normal affection and sociability, and a tendency to self-absorption, a mood of irritability, and restlessness. . . ." This does not make me think I am suffering from "a basic mental conflict involving some interpersonal relationship." I suspect I have dental caries or have eaten bad food.

Technique of Ventrosuspension

Dr. E. HESKETH ROBERTS (London, W.1) writes: Statistics in gynaecological literature of the results of ventrosuspension by round ligament procedures are insufficient for the guidance of operators; the multiplicity of methods suggests there is scope for improvement, and it has not been emphasized sufficiently that there is a disturbing percentage of sequelae. . . . I found in 1945 that iliac pains were completely avoided by anchoring the plicated or shortened round ligament to the anterior wall of the uterus (utero-teretial suspension), instead of the anterior abdominal wall. . . . But occasional recurrence of retroversion was not prevented until the technique of utero-vesical suspension was added in 1946 . . . a foreshortening of the incised and lifted utero-vesical and para-vesical peritoneum to within 1 cm. of the bladder and stitching it to the upper anterior uterine surface (and laterally beyond the plicated round ligament but in front of the Fallopian tubes, which undergo no distortion). In 1947 I came to the conclusion that this foreshortening with advancement of the peritoneum was the essential portion of the operation to prevent recurrence, but that the utero-teretial plication was probably necessary to ensure sound healing and organization of the utero-vesical peritoneal suture line. After this deduction I substituted 40-day chromic catgut No. 3 for the fascial suture used in the 1946 plication. The relief of tension by plication of the inner two-thirds of the ligamenta teretia enables the use of a continuous suture of No. 1 chromic catgut for the peritoneum, thus diminishing the risk of adhesions due to the free ends of interrupted sutures. In four years I have had no recurrence of retroversion or iliac pains; follow-up is maintained for two years, and it is hoped to give more exact figures later. . . .

Obituary

HENRY MACCORMAC, C.B.E., M.D., F.R.C.P.

With the death of Dr. H. MacCormac on December 12, at the age of 71, after a long and painful illness, dermatology is deprived of one of its most eminent exponents. For about 40 years, and with seemingly increasing energy as he grew older, he applied himself ruthlessly and in defiance of failing health to the pursuit of his ideals. That he achieved his goal not only in this country but internationally is beyond doubt. To his British honours and degrees were added honorary membership of the leading dermatological societies of America, France, Belgium, and Denmark.

Elliott and Fry]

It was almost entirely due to his strenuous and persistent advocacy that skin diseases came to be recognized as an important cause of disablement and military wastage, and a classical contribution from his pen in the *British Journal of Dermatology and Syphilis* in 1917 on "Skin Diseases and their Treatment under War Conditions" is a lasting testimony to his efforts in that cause as well as to his skill and lucidity as an author. The C.B.E. which he was awarded in 1919 was an official recognition of the outstanding services he had rendered. During the first world war he was also awarded the Médaille d'Honneur de l'Assistance Publique for his services to the civilian population at and around Hardelôt-Plage, where, as a lieutenant-colonel in the R.A.M.C., he was in medical charge of No. 25 General Hospital for skin and gassed cases.

The son of John MacCormac, of Belfast, MacCormac graduated M.B., Ch.B. in 1903 at Edinburgh, and after coming to London soon established himself as assistant bacteriologist and medical registrar to out-patients at the Middlesex Hospital. Research work on the histology of cutaneous cancer probably accounts for his initial interest in dermatology and for his appointment as assistant in the dermatological department under Dr. J. J. Pringle, the acknowledged peer of such contemporaries as Radcliffe Crocker and Sir Malcolm Morris. To the experience gained there MacCormac added a study of the wealth of material at the St. Louis Hospital, Paris, under Professors Darier and Sabouraud. After taking the M.R.C.P. in 1909 he was appointed, on the death of his chief, physician to the skin department at the Middlesex Hospital. From that time he became prominent as a regular contributor to the literature and to the discussions and demonstrations of clinical cases at the Dermatological Section of the R.S.M. His name figures frequently in almost every volume of the *British Journal of Dermatology and Syphilis* since 1908. Not content with his clinical and teaching duties at the Middlesex Hospital and a growing private practice, he held dermatological posts at the Infants' Hospital, Vincent Square, St. John's Hospital for Skin Diseases, and the Seamen's Hospital, Greenwich, at the last institution gaining much valuable experience in the diagnosis and treatment of venereal diseases.

He became secretary of the Section of Dermatology of the R.S.M., and later president both of the Section and of the British Association of Dermatology. An honour he esteemed highly was the Lumleian Lectureship in 1945 at the Royal College of Physicians. He had been elected Councillor of the College in 1941. Among his later activities he sponsored and produced two films—on scabies and industrial dermatitis—and he was the first dermatologist to be appointed a medical referee. While he never wrote a textbook, he made himself responsible for the entire English edition of Jacobi's *Atlas of Dermochromes* (fourth edition), a work of the greatest value to students.

MacCormac—"Mac" to his many friends—never lost his inimitable Irish humour. An inexhaustible fund of topical anecdotes and a notable oratorical talent rendered him an indispensable adjunct to innumerable social and professional occasions. He was a loyal and lovable friend, and a generous supporter of many a young beginner. He held the unvarying affection and confidence of many grateful patients. He will be sorely missed by them and all his colleagues. Deepest sympathy is extended to his devoted wife, who for many years was his veritable right hand and secretary, and to a son at school.—H. C. S.

F. R. B. writes: To one whose difficult task it was to follow Dr. Henry MacCormac in some of his hospital work his death now, early in his retirement, causes profound sorrow. The details of his career will be more fully known and better recorded by his contemporaries; a younger man has perhaps had an equal opportunity of appreciating his great kindliness and generosity. Although in failing health, it was his great pride to keep on with his work, and his unspoilt, sprightly sense of humour, sometimes ironical but never unkind, gave his conversation an effervescent quality. It was difficult to believe that he could ever have been more light-hearted and youthful in outlook than he was in his seventies. Since the beginning of his illness last summer it has been obvious that it is not only among his colleagues and old pupils that "Harry Mac" will be missed, for innumerable patients have expressed their concern and sent messages of sympathy. His unfailing courtesy and kindly understanding will never be forgotten.

W. BROOKE PURDON, D.S.O., O.B.E., *M.C.*, M.B.

Major-General William Brooke Purdon, who was at one time Commandant and Director of Studies at the Royal Army Medical College, died in London on December 1, aged 68. He had been Ulster Agent in London since 1946. Brooke Purdon was born in Belfast and educated at Queen's College, where he studied medicine. He graduated M.B., B.Ch. in 1906, and joined the R.A.M.C. a year later. During the first world war he was awarded the D.S.O. and the *M.C.*, and was also mentioned in dispatches three times. In 1913 he took the D.P.H., and it was as a hygiene specialist that he became well known after the war. In 1923 he was appointed O.B.E. and an officer of the Venerable Order of the Hospital of St. John of Jerusalem. He was Assistant Director of Hygiene at the War Office from 1930 to 1934, and later became Professor of Hygiene at the Royal Army Medical College. During the second world war he was for nearly five years medical superintendent of Queen Mary's Hospital, Roehampton. From 1938 to 1941 he was honorary surgeon to the King. In 1946 he gave up his medical career to become the Agent in London of the Northern Ireland Government, and in this post he was remarkably successful. During his younger days he was a good rugby player, being capped for Ireland

several times. At the time of his death he was president of the London Irish Rugby Club.

Mr. Leon Gillis writes: We grew to know Major-General Brooke Purdon well during the war years when he was medical superintendent of Queen Mary's Hospital, Roehampton. As a doctor he served his patients to a far greater extent than if he had specialized in medicine or surgery. It is not only the physician or surgeon who can help his fellow men but it is also the good administrator. Here was a personality who was beloved by all who knew him. His cheery face and kindly expression will long be remembered at the hospital. To those of us who knew him intimately the depth of feeling that he showed for all people was something to be wondered at. He was the embodiment of kindness, and visited his patients through the most critical days of their illness with encouraging words. He was always ready to give credit where credit was due, and the discipline of the hospital was a thing to be admired. He had a host of friends throughout the world who kept up a regular correspondence with him. His fund of stories seemed endless, and the occasions were few when his extraordinary memory could not produce an appropriate narrative. He enjoyed a full life and died a man without enemies.

S. WATSON SMITH, M.D., F.R.C.P.

We announce with regret the death on December 15 of Dr. S. Watson Smith, a Past-President of the B.M.A. and a consulting physician at the Royal Victoria and West Hants Hospital, Bournemouth.

Sydney Watson Smith, a native of Dundee and son of the late Colonel W. Smith, J.P., qualified at the University of Edinburgh in 1903, proceeding M.D. in 1925. After qualifying he was house-surgeon and house-physician at the Dundee Royal Infirmary, and then continued his post-graduate studies in Edinburgh and London, eventually, in 1907, going into practice in Dundee, where he worked extremely hard. Although he had been a keen Territorial, failing health before the first world war compelled him to resign his commission. However, he succeeded in getting into the R.A.M.C., but was invalided out in June, 1918. Early in 1919 he began to practise in Bournemouth, becoming a consulting physician there in 1924. In 1925 Dr. Watson Smith took the Membership examination of the Royal College of Physicians of Edinburgh, and three years later that of the Royal College of Physicians of London. He was elected F.R.C.P.Ed. in 1930, and in 1938 the London college elected him to its Fellowship. Among the appointments he held in these years and subsequently were those of honorary consulting physician and honorary consulting dermatologist to the Royal Victoria and West Hants Hospital, and honorary consulting physician to the Royal National Sanatorium at Bournemouth. His advice was sought by colleagues over a wide area, including parts of the counties of Hampshire, Dorset, and Wiltshire. He made a detailed study of the severe typhoid epidemic at Bournemouth in 1936 and published an account of it in a booklet.

In 1934 the B.M.A. held its Annual Meeting at Bournemouth, and Dr. Watson Smith was then elected President of the Association. Those who were fortunate enough to be present at that meeting remember what an outstandingly generous host he was. In his presidential address he characteristically pleaded for a rational approach to medical climatology. Within the B.M.A. Dr. Watson Smith carried out much useful committee work, serving on the Council from 1934 to 1936 and on many of the Association's committees.

Dr. O. C. Carter writes: I had the privilege and pleasure of knowing Watson Smith intimately over a period of many years. I knew him as a consultant whose wisdom, knowledge, and advice were of inestimable help to me in the conduct of general practice, and I knew him as a friend and as a patient. During the preparation for the Annual Meeting of the B.M.A. in Bournemouth in 1934, as honorary local general secretary, I came a great deal in contact with Watson Smith as President-Elect, and during that year of preparation he spared nothing in time or energy. No one who attended the Bournemouth meeting will ever forget the magnificence of his presidential reception in the Pavilion, the cost of which was defrayed by him personally. He was the editor of the *Book of Bournemouth*, which was produced specially for the meeting and is now very hard to come by.

In 1935 he led the first world tour of the Association at the time of the Annual Meeting in Melbourne, where he installed the late Sir James Barrett as his successor in the presidential chair. Later he wrote the official chronicle of the world tour. During the time he was chairman of the local medical war committee—he was unanimously elected to this office in 1938, and he held it until illness forced him to give it up in 1944—I was its secretary, and he carried out his work with thoroughness, ability, and complete impartiality. Many have lost a great friend, a man of integrity, generous character, and great kindliness, and the profession has lost a noble colleague who was held in high esteem. He made no enemies, and no one begrudged him the great success which he made in his professional career.

Dr. FRANCIS MOLISON MILNE, consultant physician and pathologist to the Dundee Royal Infirmary, died in Dundee on October 28. He graduated M.A. with honours at St. Andrews University in 1897, and then proceeded to take the degree of B.Sc. He was interested in marine biology and was for a time assistant to Professor M'Intosh. He then turned to medicine and graduated M.B., Ch.B. in 1904. After a resident appointment at the Infirmary, he came to London as assistant to the pathologist at the London School of Clinical Medicine. In 1909 he returned to Dundee as assistant to the professor of pathology in the University of St. Andrews. In the same year he took the D.P.H. and was appointed lecturer in clinical pathology in the university, a post which he held until 1933, when he became a lecturer in clinical medicine. From 1919 to 1933 he was also physician for diseases of the skin at Dundee Royal Infirmary and in 1933 was appointed a visiting physician. He retired in 1938. Frank Milne was the possessor of a phenomenal memory. He was an interesting and inspiring teacher, seen at his best in impromptu clinical teaching, and many of his students, who will have learned of his death with deep regret, realize to the full the debt they owe to him for the clinical knowledge they acquired under his enthusiastic guidance in the medical out-patient department. Temperamental, yet one of the kindliest of men, his many quiet acts of practical kindness are cherished memories to very many of his colleagues and patients alike. Intensely interested in his fellow-men, he had innumerable friends and acquaintances in all parts of Scotland and in all walks of life. He had a fine knowledge of pictures and of books, and for 22 years had been a householders' representative on the Dundee Public Libraries Committee. He will be mourned by very many, both of the Town and of the Gown.—G. R. T.

W. F. D. writes: I pay tribute to Frank Milne after 35 years of his friendship—as teacher, senior colleague in forensic work, family physician, and finally beloved patient. Gifted with an encyclopaedic mind, knowledgeable beyond most in many diverse interests, his very diversity prevented him from becoming a genius. As a teacher he was ahead of his time—urging us students to do clinical pathology and post-mortem work not in the curriculum, and encouraging us to seek ward work in the Poor-Law hospital while its doors were still officially closed to students. In medico-legal work his help was invaluable; at necropsies, in framing reports, and in preparing evidence for the courts he had a knowledge of legal points and a balanced sense of fairness which made him an ideal adviser and critic. With apparently no spare time, he yet could give hints on gardening, nature study, bee-keeping, and holiday touring which always proved useful and practical. Soon after he retired war came. As his contribution to war work he took over the duties of skin specialist at Aberdeen. Travelling to and from that city proved arduous, and the trials of an early air raid precipitated a seizure. Crippled in body, his mind was unharmed, and with dauntless courage he continued to play his part as citizen and friend till a few weeks before his death. Many in Dundee besides his colleagues and patients loved and honoured the man and mourn his passing.

GEORGE HUGH CULVERWELL, Chief Home Office Inspector under the Cruelty to Animals Act, died on December 9, at the age of 63. His parents lived in Co. Down, and after leaving school he studied medicine at Trinity College, Dublin, where he was Stewart Medical Scholar in Natural Science. Among other academic distinctions he won the Purser Medal in physiology and the Dublin University Biological Association Medal. He graduated M.B., B.Chir. in 1913 and proceeded M.D. a year later. He took the D.P.H. in 1914. After serving in the R.A.M.C. during the 1914–18 war Culverwell spent a short period as school medical officer for Berkshire County Council. From there he went to the Home Office as a medical inspector in the reformatory and industrial schools department. His main preoccupation in this position was with the diet of the children. There was at that time an alarmingly high tuberculosis rate among them, and Culverwell tackled the problem from the public health standpoint. As a result of his work the diet of the boys and girls in these schools was greatly improved, particularly their milk allowance, and not only did the tuberculosis rate go down but the rate of growth of the children increased quite significantly. This achievement was assisted by the departmental sympathy which he mobilized, but it was nevertheless a remarkable one, and set a new standard for the care of deprived and delinquent children. For his work in the Children's Branch at the Home Office Culverwell was appointed O.B.E. In 1936 he transferred to that branch of the Home Office which administers the Cruelty to Animals Act of 1876 (experiments on living animals). Here for ten years he served as inspector. This period included the difficult war years, when his place of work was moved on a number of occasions, and the travelling he had to do was made more arduous by the circumstances of the war. In 1946 Culverwell became chief inspector, and remained in this position until his final illness.

W. L.-P. writes: In many ways Culverwell was one of the old school of administrators—unhurried, just and conscientious, and with an utterly inflexible standard of integrity and fair dealing. He would take infinite pains to explain to those who wanted to know the intricacies of the Act he was called upon to administer, and also to understand and solve the problems facing licensees under the Act. In all things he took the long view, for he was a man of clear vision, and would never commit himself to an opinion, or an action, until he was satisfied that it was correct and practicable both immediately and remotely. He never spared himself, for it was not his nature to give only half his energies to his work. Had he been differently constituted he might have been able to ease up in recent years, but as it was he was fully engaged right up to his last brief illness. His personal charm and courtesy endeared him to many, particularly to his more intimate friends, and those of his colleagues who had worked closely with him realize what a great loss his death brings. He was always ready with help and advice, and it was always good advice that he gave. If any man earned a quiet retirement it was Culverwell, but his own exacting nature and his sense of duty denied him this reward. He leaves a widow, a daughter, and a son.

Medico-Legal

ALLEGED 360-DAY PREGNANCY

The House of Lords by a majority (Lord Oaksey dissenting) on December 14 allowed the appeal of the husband who brought a divorce suit on the grounds that a baby born 360 days after the possible date of conception was not his.

On August 13, 1946, the wife gave birth to a child which weighed 8¼ lb. and was apparently normal in every way. The husband contended that he had been serving in Germany with the R.A.F. between August 17, 1945, and February 9, 1946, and that the child had been conceived in October or November, 1945, when he had no access to his wife. Judge Burgis, sitting as a Divorce Commissioner, first heard the petition and dismissed it, and the Court of Appeal ordered a rehearing. This took place before Mr. Commissioner Blanco White on March 24, 1949.[1]

Mr. Commissioner Blanco White said he was satisfied on the medical evidence that the child could not have been conceived as late as 186 days before the birth. Gestation periods of 346 days in 1947 and 349 days in 1948 had previously been accepted, and in this case the Commissioner, on the court's judicial knowledge of natural laws, could not say that 360 days was an impossible period, and he was not satisfied beyond reasonable doubt that adultery had been committed.

On July 22, 1949, the Court of Appeal by a majority (Lord Justice Denning dissenting) directed a new trial and gave leave to both sides to appeal to the House of Lords.[2] Lord Justice Denning then said that he would have been for allowing the appeal and granting a decree nisi.

In his judgment in the House of Lords Lord Simonds said[3] that the question that had then presented itself to the Commissioner was whether the fact that at least 360 days had elapsed between the last possible intercourse between husband and wife and the birth of the child, together with the medical evidence, put it beyond reasonable doubt that the child was not the child of the husband. The Commissioner had answered that question in the negative. Lord Simonds thought it clear that the Commissioner did not consider he would be justified in finding that adultery had been committed merely on the ground of lapse of time without medical evidence, and he found that the medical evidence adduced was unsatisfactory.

The appeals raised a question of peculiar difficulty which might be stated in this way: If a husband proves that his wife has given birth to a normal child 360 days after he could have had intercourse with her, and no proof of any adulterous intercourse by her is given, what, if any, further evidence is required that the child is not his child?

The utmost that a court of law could demand was that it should be established beyond all reasonable doubt that a child conceived so many days after a particular coitus could not be the result of that coitus. The court had judicial knowledge of the normal period of human gestation, but could the court altogether, and, if not altogether, within what limits, disregard the abnormal? Could the court find as a fact that adultery had been committed if the period of gestation had been abnormal and no evidence to explain it had been adduced? He thought it would appear fantastic to any ordinary man or woman that a normal child born 360 days after the last intercourse of a man and a woman was the child of that man, but the difficulty lay in drawing the line.

After referring to other long periods of gestation that had been accepted he said he must come to the conclusion that an additional period of 11 days, making 360 days in all, ought not to be regarded as making the vital difference so that the court could, without any further evidence, regard adulterous intercourse as proved beyond all reasonable doubt. In the present case the only medical evidence was that of one doctor.

[1] *British Medical Journal*, 1949, 2, 181.
[2] Ibid., 1949, 2, 337.
[3] *The Times*, December 15, 1950.

Lord Simonds said he had no hesitation in accepting that evidence as adequate to justify a finding that beyond all reasonable doubt the child was not the child of the husband. The doctor had not claimed to have studied the problem of the "maximum period from the time of sexual intercourse to the time of the impregnation of the ovum." But, said Lord Simonds, it was sufficiently clear from his answers that, while recognizing the possibility of some interval between coitus and fertilization, he regarded as impossible an interval which would defer the birth of a normal child to 360 days after coitus. Lord Simonds thought the doctor was entitled to say that as a matter of competent medical opinion without having made a special study of the subject. The Commissioner had not been justified in disregarding his evidence but should have made a decree for divorce.

The appeal of the husband was allowed, the cross-appeal of the wife dismissed, and the cause remitted to the High Court in order that a proper decree might be made.

Lord Oaksey said he was in favour of dismissing the petition and allowing the cross-appeal.

Universities and Colleges

UNIVERSITY OF LONDON

The following candidates have been approved at the examinations indicated:

POSTGRADUATE DIPLOMA IN PSYCHOLOGICAL MEDICINE.—J. A. Ardis, Laura M. Barlow, A. S. Clark, Ruth A. Cohen, R. B. Davis, J. R. E. Dobson, O. Elgarem, A. Elithorn, W. Fabisch, L. Ford, G. J. Goldberg, J. T. Hutchinson, W. A. MacIlrath, H. E. S. Marshall, J. K. W. Morrice, B. J. Phillips, R. M. Phillips, H. Pozner, A. A. Robin, E. Rosenthal, T. Schlicht, R. D. Scott, D. B. Stone, D. L. C. Thomas, W. L. Tonge, J. Towers, W. H. Trethowan, H. de B. Warren, C. H. A. Wedeles, A. C. Woodmansey, T. A. Wylie. (All with Mental Diseases (Psychiatry) in Part B.) The following candidates passed in Part A only: D. Anton-Stephens, P. G. Aungle, E. D. Barlow, F. B. E. Charatan, M. B. Contractor, W. A. Cramond, H. W. D. Davies, H. Duschinsky, Herta Graz, S.-E. Hamid, A. G. Hucker, M. A. Jackson, W. G. Joffe, J. C. Kerridge, C. S. Lindsay, C. Milne, D. W. Moynagh, J. Pullicino, E. Roderic-Evans, S. Smith, G. F. Spaul, S. J. G. Spencer, B. Steinberg, H. P. Tarnesby, G. I. Tewfik, Letitia E. Woodvine, D. M. Zausmer.

The following have been appointed, or nominated for appointment or reappointment, as representatives of the University on the governing bodies indicated in parentheses: Professor E. T. C. Spooner, M.D. (St. Thomas's Hospital Medical School); Professor L. P. Garrod, M.D., F.R.C.P. (Kentish Educational Foundation, St. Albans); N. A. Thorne, M.D. (Mandeville Street and Upton House).

The following have been recognized as teachers of the University in the subjects indicated in parentheses: *Westminster Medical School:* Mr. A. Lawrence Abel, Mr. S. O. Aylett, and Mr. David Levi (Surgery); Mr. A. B. Evans (Obstetrics and Gynaecology); Dr. Ronald Jarman (Anaesthetics); Dr. J. L. Lovibond (Medicine). *Royal Free Hospital School of Medicine:* Miss A. Josephine M. T. Barnes (Obstetrics and Gynaecology); Dr. Helen E. Dimsdale (Medicine); Mr. H. D. Johnson (Surgery). *National Institute for Medical Research:* Dr. W. S. Feldberg, F.R.S. (Physiology and Pharmacology). *King's College Hospital Medical School:* Mr. A. J. Heriot (Surgery). *Middlesex Hospital Medical School:* Dr. F. D. Howitt (Physical Medicine). *St. Mary's Hospital Medical School:* Dr. J. W. Litchfield (Medicine); Dr. E. Neumark (Pathology). *St. George's Hospital Medical School:* Sir William Paul Mallinson, B.M., M.R.C.P. (Mental Diseases). Mr. H. R. Wolfe has been granted probationary recognition as a teacher of surgery at University College Hospital Medical School for two years from October, 1950.

The following, who are already recognized teachers at undergraduate medical schools, have been recognized also as teachers at the institutes of the British Postgraduate Medical Federation indicated and in the subjects shown in parentheses: *Institute of Obstetrics and Gynaecology:* Mr. D. H. Macleod and Mr. W. N. Searle (Obstetrics and Gynaecology). *Institute of Ophthalmology:* Mr. A. G. Cross, Mr. E. F. King, and Mr. J. G. Milner (Ophthalmology).

The Leavesden Hospital, Abbots Langley, Watford, Herts, and the St. Pancras Hospital Mental Observation Unit (University College Hospital Group) have been added to the list of recognized institutions at which students may take the course on mental diseases for the M.B., B.S. degrees.

UNIVERSITY OF BIRMINGHAM

The new hostel for students in residence at Dudley Road Hospital, Birmingham, during their training in obstetrics came into use on December 1. The Council and the regional hospital board have agreed that the building shall be called the Hilda Lloyd Hostel in recognition of Professor Lloyd's distinguished work as professor of obstetrics and gynaecology and of the time and energy which she has given to the scheme.

The following lectures have been arranged to be delivered at Edgbaston: January 15, 1.45 p.m., Professor K. Mather, D.Sc., F.R.S., Professor of Genetics in the University, "Genetics and Human Affairs"; March 1, 1.45 p.m., Professor J. F. D. Shrewsbury, Professor of Bacteriology in the University, "Henry VIII: A Medical Study"; March 9, 1.45 p.m., Professor Shrewsbury, "St. Anthony's Fire."

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

At a meeting of the Faculty held on December 4, with the President, Mr. Walter W. Galbraith, in the chair, the following were admitted Fellows of Faculty *qua* Physician: J. O'D. Alexander, T. Chelvarajah, J. S. Creighton, A. S. Douglas, R. M. Kapadia, Joan B. Landsman, S. A. Mannan, G. C. Provan, W. G. Whyte.

Medical News

Unique Medical Library

One of the world's finest private collections of books on medical history, the library of Dr. Erik Waller, of Stockholm, has recently been placed at the disposal of the library of Upsala University, and will shortly be transferred there as a separate unit. The collection, which comprises over 20,000 volumes and about 5,000 dissertations, contains 150 incunabula and has long been internationally famous. Dr. Waller, who recently celebrated his 75th birthday, started his collection 40 years ago, his principal interest being in old manuscripts, of which there are over 50 dating from the thirteenth century. Later he turned his attention to building up a representative collection of works by the great masters of surgery and medicine. Among the many valuable volumes is one of the very few known copies of Andreas Vesalius's *Tabulae Anatomicae Sex*, published in 1538; several rare books by William Harvey, discoverer of blood circulation; and a complete set of works by and about the father of surgery, Ambroise Paré. Dr. Waller's library also contains the first medical book printed in Sweden (on pestilence), written by Lemnius, physician to King Erik XIV in the sixteenth century, and a valuable collection of the works of Linné (Linnaeus), including his doctoral thesis.

"Oesophageal Speech after Laryngectomy"

A 10-minute talking film has been made by Campbell Harper Films Ltd., Edinburgh, for the C.O.I. and the Department of Health for Scotland, to show to patients about to undergo laryngectomy, and to medical students and medical staffs, what a man without a larynx can do to talk aloud by means of controlled belching. The film was shot in Glasgow, mostly at the special club run by Mr. T. O. Howie, Surgeon to the Ear, Nose and Throat Department of the Victoria Infirmary. Patients after laryngectomy learn to speak again and lead completely normal lives, working amid the noise of an engineering shop, speaking on the telephone, dictating letters, and so on. The club, which is unique in Britain, enables the new patient to gain hope and confidence and lose his shyness when surrounded by others who have successfully learned to talk again. This rehabilitation could only have been adequately recorded by a talking motion picture, and an excellent film has been made of it at a very low cost (£750). The idea might well be extended to other disabilities.

R.A.F. Institute of Pathology and Tropical Medicine

To mark the twenty-fifth anniversary of the founding of the Institute the Director-General of the R.A.F. Medical Service (Air Marshal Sir Philip C. Livingston) and the Senior Consultant in Pathology (Air Vice-Marshal T. C. St. C. Morton) held a reception and lunch at Halton, Bucks, on December 12. Air Marshal Sir Harold Whittingham, wartime Director-General, spoke at the lunch, and demonstrations of the work of the Institute were on view.

Penicillin Spoils Cheese-making

Cows given penicillin as treatment for udder inflammations discharge enough of the antibiotic in their milk to kill the bacteria essential for normal cheese-making. This is still so when the milk from a cow under treatment is mixed with the milk of 200 normal cows, and consequently is a serious threat to the cheese industry. In Sweden, according to the Swedish International Press Bureau, steps are now being taken jointly by the dairymen and the Veterinary Board to ensure that penicillin is used only when really necessary, and that the milk from treated cows is kept separate.

Film Censorship

According to *The Times* the British Board of Film Censors will introduce a new category in the New Year. The X certificate will be applied to films wholly adult in theme or treatment, and no one under 16 will be admitted to them. It replaces the old H certificate, which was given only to horrific films, and follows the recommendation of the Departmental Committee on Children and the Cinema (see *British Medical Journal*, July 8, p. 96).

Wills

Dr. Waldemar Shipley West, late consulting physician, the Royal Bucks Hospital, left £8,524; Dr. Horace Potts, who practised in Great Yarmouth for 50 years, left £4,519; Dr. Harold Warburton Lewis, left £11,876; Dr. Angus Duncan Macpherson, assistant medical secretary of the British Medical Association from 1904 to 1935, left £50; Dr. Andrew Stewart Wilson, late resident physician and resident surgeon (ophthalmic), Aberdeen Royal Infirmary, left £25,865; Dr. Wyndham Anstruther Milligan, for 50 years practising in Mayfair, left personal estate in England and Scotland valued at £48,506. Dr. Ivor Isaac Price, senior consultant surgeon to the Whittington Hospital, London, N.19, and late senior resident surgeon and deputy medical superintendent at St. Mary (Islington) Hospital, left estate, "so far as at present can be ascertained," valued at £7,909.

COMING EVENTS

International Congress of Military Medicine

The 13th International Congress of Military Medicine and Pharmacy will be held at Paris in 1951 (June 17–23) and is open to all doctors, pharmacists, dentists, veterinary surgeons, and administrative officers on the active or reserve lists of all armed forces. The scientific meetings will be taken under the following heads: principles of tactical organization for first aid for large numbers of wounded; organization of training and provision of a career in military medicine; medical problems raised by aerial and submarine navigation; medical aspects of defence against atomic, biological, and chemical warfare; the role of the military pharmacist. Additional papers may be read if they are submitted before April 1, 1951. Full information can be obtained from the Secretariat-General of the Congress, Section Technique du Service de Santé, 8 bis, Rue des Récollets, Paris 10e.

Paris Course on Rheumatism

A course open to foreign as well as French doctors will be held from January 29 to February 4 under the direction of Professor M. F. Coste, of the Hôpital Cochin. Clinical demonstrations, laboratory technique, and lectures on recent advances are planned. Full information may be obtained from Dr. P. Galmiche, Hôpital Cochin, 27, Rue du Faubourg St. Jacques, Paris 14e.

Twenty-sixth Annual Congress of Anaesthetists

The twenty-sixth Annual Congress of Anaesthetists, sponsored by the International Anesthesia Research Society, will be held in London from September 3 to 7, 1951. Short papers will be read in the mornings and there will be demonstrations at various London hospitals. Scientific discussions and business meetings will be held in the afternoons. There will be an exhibition of apparatus and drugs, and facilities for scientific exhibits by anaesthetists. Anaesthetists who wish to attend are requested to write as soon as possible to a member of the London Committee stating whether they wish to read a paper, and, if so, its probable length. Manufacturers should address their inquiries to Mr. A. Charles King. The following are the members of the London Committee: Dr. R. W. Cope, Dr. Vernon Hall, Dr. Ronald Jarman, Mr. A. Charles King, Dr. C. B. Lewis, Dr. G. S. W. Organe, Dr. C. F. Scurr, and Dr. W. D. Wylie. Papers should be submitted before March 15, 1951, to Dr. R. W. Cope, University College Hospital, London, W.C.1.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

McLaren.—On December 7, 1950, at Westbay Nursing Home, Broughty Ferry, Dundee, to Patricia Annette (formerly Taylor), wife of Mr. William J. McLaren, F.R.C.S., a son.

DEATHS

Babington.—On December 10, 1950, at Margate General Hospital, James William Herbert Babington, M.D., Major, I.M.S., Ret., of 24, Devonshire Gardens, Margate.

Culverwell.—On December 9, 1950, George Hugh Culverwell, O.B.E., M.D., D.P.H., of Salthouse, Thorniaw Road, West Norwood, London, S.E.

Davies.—On December 5, 1950, at Stroud General Hospital, Albert Barnes Davies, M.R.C.S., L.R.C.P., aged 89.

Dempsey.—On November 25, 1950, Timothy Gerard Dempsey, M.B., B.Ch., of 28, Marvels Lane, London, S.E., late of Dublin.

Emerson.—On December 2, 1950, at Pershore House, Pershore, Herbert Bree Emerson, M.R.C.S., L.R.C.P., aged 82.

Fisher.—On December 6, 1950, at her home, St. Kitts, Uxbridge Common, Middlesex, Emma Christiana Rolfe Fisher, L.R.C.P.&S.Ed., L.R.F.P.S.Glas.

Forrest.—On December 7, 1950, at Delgany, Maple Road, Harpenden, Herts, James Aquilon Forrest, M.B., C.M., Surgeon Captain, R.N., retired, aged 79.

Frew.—On December 1, 1950, John Frew, M.B., Ch.B., D.P.H., of 103, Howard's Lane, Putney, London, S.W.

Galloway.—On December 9, 1950, at Hill Cot, Salcombe Hill, Sidmouth, Andrew Fleming Galloway, M.D., late of 11, Finsbury Square and Clarence Gate Gardens, London.

Graham-Yooll.—On December 11, 1950, at the Royal Infirmary, Edinburgh, Ralph William Graham-Yooll, M.B., Ch.B., of Cairnton, West Linton.

Kelly.—On November 28, 1950, at Douglas, Isle of Man, Thomas Kelly, L.R.C.P.&S.I.&L.M., 1, Salisbury Terrace, Douglas.

Kyffin.—On December 13, 1950, John Kyffin, M.R.C.S., L.R.C.P., of Windfall Cottage, Brookside, Oxford, formerly of Penrhyn, Gosport, aged 84.

Logie.—On December 6, 1950, at 90, Graham's Road, Falkirk, William Jamieson Logie, M.B., Ch.B.

Lyle.—On December 2, 1950, John Beattie Lyle, M.D., of Broxbourne, Barnsley Road, Wakefield, Yorks, aged 68.

MacKay.—On November 30, 1950, suddenly, in hospital, George Ross MacKay, M.B., Ch.B., of 20, Upper Tooting Park, London, S.W., aged 49.

Martyn.—On December 5, 1950, at 33, Berry Drive, Paignton, Gilbert John King Martyn, M.D., D.P.H., late of Bath, aged 81.

Muir.—On December 9, 1950, at White Cottage, Marley, Exmouth, John Muir, O.B.E., M.B., Ch.B., beloved husband of Dr. Jessie S. Muir (formerly McEwen).

Taylor.—On December 3, 1950, at Sunbury-on-Thames, Alexander John Reid Taylor, M.B., Ch.B.

Willmore.—On December 8, 1950, at the Westminster Hospital, James Graham Willmore, O.B.E., M.D., M.R.C.P., of Edgehill Farm, Petworth, Sussex.

EPIDEMIOLOGICAL NOTES

Poliomyelitis

Notifications in the week ended December 9 were: paralytic 73 (90); non-paralytic, 31 (38); total, 104 (128). The figures for the previous week, compared with which there was a total decrease of 24, are in parentheses.

Uncorrected notifications for the corresponding week in 1947 and 1949 totalled 76 and 134 respectively. Total uncorrected notifications for 1950 to and including the week under review are 8,483. The corresponding figures for 1947, 1948, and 1949 are 9,003, 2,308, and 6,617 respectively.

County areas with the most numerous notifications in the week under consideration were: Lancs 9, Warwick 9, Middlesex 7, Kent 6, Somerset 6, London 5, Surrey 5. Nineteen county areas in England notified no cases. The only notifications in Wales were Caernarvon 1 and Glamorgan 1. The decrease in incidence of the disease in England and Wales is well maintained.

Measles

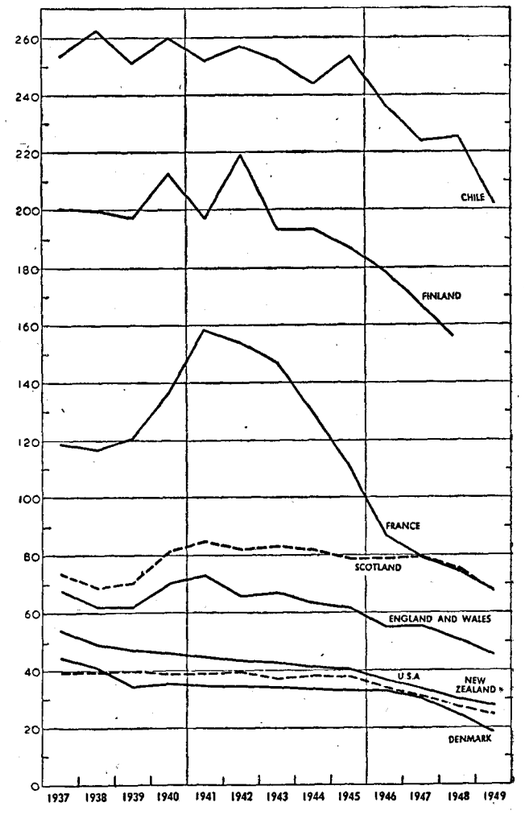
The biennial peak in the notifications of measles is due to occur in the early months of next year. Already the complaint has reached epidemic proportions. During the past two months the number of cases has increased at the rate of 1,000 a week. For the week ending December 2 there were 12,323 notifications. This is a steeper increase than that which occurred in the last epidemic period, but is offset by the fact that in 1948 the build-up, in the country as a whole, during the late summer and autumn was more substantial.

The incidence of summer cases this year was most marked in the Potteries and the north-east, but these districts have been relatively free in recent weeks. The majority of cases are now occurring in the counties around London, in Lancashire, and in Yorkshire (East and West Ridings). Of the county boroughs, Kingston-upon-Hull has been affected considerably more than any other. In November almost 3,000 cases were notified from this source. By contrast, the comparable figure for Newcastle-upon-Tyne was 15. The infection is reported to be of a comparatively mild form.

Dysentery

One of the chief features of the returns for infectious diseases during this year has been the large number of notifications of dysentery. During the week 856 cases were notified. This total exceeded the record high level of the preceding week by 230. Many of the large outbreaks have persisted over several weeks and have proved difficult to control. In practically all the outbreaks the Sonne type of organism has been responsible for the infection. The largest current outbreak is in Leicester C.B. Sporadic cases had been notified in this city up to the 31st week of this year, when the notifications rose from 2 to 22. In the following 18 weeks 651 cases were notified. Other notable outbreaks in the earlier part of the year included those at Yorkshire West Riding, where the notifications during the 7th to 14th week ranged from 110 to 205. The principal centres of infection during this period were Sheffield C.B., Leeds C.B., Bradford C.B., where 572, 252, and 134 cases, respectively, were notified during the eight weeks. Over 100 notifications a week were also reported in this county during the 18th–21st weeks. The largest returns during this four-week period were Sheffield C.B. 127 and Bradford C.B. 164. In the 12th and 13th week the notifications in Durham exceeded the 100 mark due to outbreaks in Blaydon U.D. and Starley U.D. During the week ending June 3, 180 cases were notified in Lancashire, of which Oldham C.B. contributed 78.

During the week ending December 2 the largest returns were: Lancashire 171 (Southport C.B. 42, Irlam U.D. 33, Oldham C.B. 15, Manchester C.B. 13, Liverpool C.B. 13, Bootle C.B. 9); Leicestershire 131 (Leicester C.B. 112); Yorkshire West Riding 93 (Saddleworth U.D. 23, Sheffield C.B. 21, Brighouse M.B. 12, Shipley U.D. 12); Durham 49 (Gateshead C.B. 13, Darlington C.B. 10, Stanley U.D. 10); Monmouthshire 46 (Newport C.B. 25, Abercarn U.D. 11, Risca U.D. 9); Shropshire 43 (Market Drayton U.D. 27, Drayton R.D. 9); Northumberland 26 (Newcastle-upon-Tyne C.B. 13, Rothbury R.D. 13); London 24; Cumberland 21 (Penrith U.D. 13); Surrey 20 (Esher U.D. 9); Essex 19 (Romford M.B. 10); Glamorganshire 16 (Cardiff C.B. 12); Kent 13 (Canterbury C.B. 9); Northamptonshire 12 (Kettering M.B. 12); Warwickshire 12 (Birmingham C.B. 10); Carmarthenshire 12.



Infectious Diseases

A further rise was reported during the week in the trends of measles and whooping-cough. The notifications of measles in England and Wales are now five times the number recorded in mid-September. The increase in the incidence of whooping-cough has not been so spectacular, because this disease has been running at a high level for several months, but it is now at the highest peak ever recorded. The incidence of dysentery in Scotland remained high; 73 of the 147 cases were notified in Glasgow. In England and Wales the notifications were the largest ever recorded, the largest centre of infection being Leicester C.B. 112. The other features of note in the returns were a small increase in primary acute pneumonia in Scotland and a small outbreak—5 cases—of paratyphoid fever in the burgh of Motherwell and Wishaw.

Mortality from Tuberculosis

The graph below shows deaths from tuberculosis per 100,000 inhabitants in certain countries from 1937 to 1949. It is reproduced from the *Epidemiological and Vital Statistics Report* (October, 1950) of the World Health Organization.

Mortality from Tuberculosis in Certain Countries, 1937–49: Rates per 100,000 Inhabitants

An article by Dr. J. B. McDougall, head of the tuberculosis section of W.H.O., discusses tuberculosis mortality in various countries for which "reasonably reliable" statistics are available. He says of England and Wales, "The most remarkable fact is that in view of the wartime experience the rates for the war years were not higher." He considers that our system of rationing of essential commodities, particularly food, "had much to do with the stemming of tuberculosis mortality during these critical years."

The steeply falling rates in France since 1943 are difficult to account for, and apparently French authorities are not unanimous about the cause. The most important single factor is thought to be the rise in the general standard of living. Dr. McDougall comments that Denmark "remains unique in its position concerning tuberculosis mortality." Fatal primary tuberculosis in young children especially is almost eradicated.

Week Ending December 9

The notifications of infectious diseases in England and Wales, during the week, included: scarlet fever 1,264, whooping-cough 4,431, diphtheria 49, measles 14,076, acute pneumonia 573, acute poliomyelitis 104, dysentery 933, paratyphoid fever 2, typhoid fever 6.

No. 48

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended December 2.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included) (b) London (administrative county) (c) Scotland. (d) Eire. (e) Northern Ireland. *Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for:* (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland. A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1950 (a)	(b)	(c)	(d)	(e)	1949 (Corresponding Week) (a)	(b)	(c)	(d)	(e)

Rate per 1,000 total births (including stillborn)			32					25		

* Measles is not notifiable in Scotland, and the returns are therefore an approximation only.
† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.
‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.
§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.
‖ Includes puerperal fever for England and Wales and Eire.
¶ Primary pneumonia no longer notifiable in Eire.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Glandular Fever

Q.—*Is there any specific treatment for glandular fever? If not, how should a case be treated?*

A.—There is no specific treatment for glandular fever. Recovery is invariable and there are no sequelae. The only value of a drug would be to cut short an attack, and there is no evidence that any therapy has this effect, although it has been claimed for innumerable methods of treatment.

Sulphonamides should not be given, as the bone marrow is in a sensitive state and a catastrophe may follow.

When the tonsils are severely affected with membrane formation, as in the anginose form, penicillin is of undoubted value, but not in other clinical forms. In ordinary cases with much enlargement of the cervical glands it is customary to cover the neck with cotton-wool. Otherwise treatment is purely symptomatic.

Rheumatoid Arthritis and Cortisone

Q.—*A patient, aged 64, with very severe long-standing rheumatoid arthritis, tells me that she has friends in America who would send her a supply of cortisone. Is it advisable to administer this drug in general practice? If so, what is the dosage, etc.?*

A.—In a long-standing case of rheumatoid arthritis neither cortisone nor A.C.T.H. (adrenocorticotrophic hormone) will repair existing damage. They act as a protection against the disease but are not in themselves a cure.

Cortisone should not yet be used in general practice. Experimental work is now being done to discover the best regime of treatment. It is particularly important to avoid overdosage and to determine the minimal amount for maintenance therapy. At this early stage in the use of cortisone laboratory control is necessary.

Backache in Bed

Q.—*What is the cause of pain in the lumbar region developing during recumbency in bed, the pain ceasing soon after rising and remaining in abeyance during the day, only to recur during the night? The pain is not uncommonly found in young adults in whom there is no reason to suspect arthritic changes in the spine. What are the cause and significance of this paradoxical symptom?*

A.—The commonest cause of a backache which develops during recumbency is an unsuitable bed—namely, one with a mattress which sags in the middle. Such a bed almost invariably aggravates backache, whatever its cause. The likely sites of pain are the interspinous ligaments and the capsule or other structures surrounding the zygapophysial and sacro-iliac joints. Pain is due to distortion of these structures resulting from the abnormal posture in lying. Symptoms are less likely to arise from muscle, for as a rule muscular pain comes on with exertion and is relieved by rest.

In a young adult complaining of backache, the diagnosis of ankylosing spondylitis should be considered, and, if necessary, the sacro-iliac joints should be *x*-rayed. Ankylosing spondylitis often starts with pain felt after a night in bed; it is usually months and sometimes years before the physical signs of joint disease are clinically manifest.

Keeping Vaccine Lymph

Q.—*How long will vaccine lymph remain active if kept in a refrigerator?*

A.—The Therapeutic Substances Regulations relating to vaccine lymph lay down that the container in which the lymph

is issued for sale shall bear a statement that the potency of the vaccine lymph cannot be assured for more than seven days from the date of completion of manufacture, unless the lymph is kept continuously at a temperature below 10° C. (50° F.), when the potency can be assured for 14 days; provided that it shall be permissible to state that if the lymph is kept continuously below 0° C. the potency can be assured for at least twelve months.

A temperature of 10° C. or 50° F. is approximately equivalent to the temperature of a domestic refrigerator. These regulations are conservative, and there is little doubt that the lymph will retain adequate potency for longer periods than those stated above. However, since there is no control of the conditions under which the lymph may be stored, neither the manufacturer nor the issuing authority can accept responsibility for the potency of the lymph if kept beyond these periods.

Twins and their Finger-prints

Q.—*Can identical twins be distinguished from each other by their finger-prints?*

A.—The distinction between monozygotic identical twins is best made on finger, palm, or toe prints (with decreasing certainty of differentiation). Cherrill, the New Scotland Yard expert, has yet, in spite of a special study of twin 10-print records, to find identical features. Newman, H. H. (*J. Hered.*, 1940, **31**, 119 and 419), has made an extensive survey of the genetics of the subject, and its criminal aspects have been studied by Johannes Lange in his *Crime as Destiny* (1931), Geo. Allen and Unwin, London. It is clear that in personality, character, and the minutiae of identity data no indistinguishable twins have yet been observed.

Prolonged Oestrogen Therapy

Q.—*A patient discovered that a few milligrams of stilboestrol, given to restrain lactation after a stillbirth, vastly improved a seborrhoeic dermatitis. Since then she has been taking 1 mg. every other day. The only untoward effect is that menstruation has become slightly irregular. If she stops the drug her skin condition relapses. (a) Is it harmful to continue stilboestrol indefinitely, if the menstrual flow does not become heavier? (b) Is libido likely to be affected? (c) Are her chances of conception altered?*

A.—(*a*) Continuous oestrogen therapy almost always leads to menstrual disturbances associated with intermittent or prolonged and sometimes heavy bleeding. Another possible sequel of long-continued oestrogen therapy is fibro-adenosis (generalized nodularity) of the breast with tenderness or pain. There may also be fluid and salt retention, with increase in weight. There is little evidence of permanent damage to the pituitary due to the inhibitory action of oestrogens. Nor is there sufficient evidence to say that exogenously administered oestrogen may be carcinogenic, though endogenous oestrogen may predispose to cancer. (*b*) No. (*c*) Continuous oestrogen therapy may inhibit ovulation.

It would be better to give the stilboestrol in doses of 0.5 mg. daily for the first 21 days of each 28-day cycle. This dose should not inhibit ovulation in any cycle (though a daily dose of 2 mg. probably would), and the week's rest from treatment in each month should lead to successful avoidance of the disturbances mentioned above. This dose, however, may prolong the cycle to five or six weeks. In that case the dose will need to be adjusted (either down to 0.3 mg. daily or up to 1 mg. daily) so that the period is not delayed.

Prolonged Quinidine Therapy

Q.—*Would the indefinite administration of quinidine sulphate, in a total dosage of 3 gr. (0.2 g.) daily, for the control of auricular fibrillation, cause any harmful effects? The case I have in mind is a man of 38 who had his first attack of auricular fibrillation about 10 years ago. Normal rhythm was restored, and he had no further treatment until six months ago, when he had another attack. This has responded to quinidine, the rhythm remaining normal so long as small doses are given. On withdrawing the drug, fibrillation begins again.*

A.—Quinidine in the dosage stated may be given indefinitely without harmful effects. Indeed, the dose could be increased considerably without fear. The usual amount given to prevent auricular fibrillation is 3–6 gr. (0.2–0.4 g.) three times a day. In his book on quinidine (*Quinidine in Disorders of the Heart*, reviewed at p. 1426 of this issue) Harry Gold states that one of his patients took 60 gr. (4 g.) daily for 14 years without ill effect. When, at the end of that time, auricular fibrillation could no longer be prevented the dose was increased to 75 gr. (5 g.), but this caused impairment of hearing and blurring of vision.

If quinidine does not cause toxic symptoms within the first five days of treatment, such symptoms will not arise later if the dose is not increased.

Post-operative Paralysis of Compressor Urethrae

Q.—*Is paralysis of the compressor urethrae muscle known to occur after a "punch operation" for the removal of an enlargement of the intravesical part of the median lobe of the prostate? If so, how is this paralysis caused? What are the prognosis and treatment?*

A.—Paralysis of the compressor urethrae after a "punch operation" may be due to over-stretching of the muscle from the introduction of a large instrument, or to division if a cut is made too low. In the former case ultimate recovery is likely, but in the latter the incontinence is likely to remain until subsequent fibrosis produces the opposite effect—namely, stenosis. Electrical treatment is not very certain in its results, but plastic operations have been used successfully in some cases to restore continence. It may well be, however, that an individual patient is best assisted by the wearing of an incontinence bag.

Rubber Sponge and Varicose Ulcers

Q.—*How should rubber sponge be used in the treatment of varicose ulcers?*

A.—The object of the rubber sponge is to produce extra pressure over the ulcer and its oedematous surroundings, especially in the case of ulcers in the malleolar sulcus. The rubber pad, which is preferably coated on one side with adhesive, can be used in the following way: an Unna's paste bandage is used to bandage the leg in the usual way, and the rubber pad, which has chamfered edges and is much larger than the ulcer, is then placed over the site of the ulcer. The pad is now pressed down on the ulcer by an elastic bandage or, if the patient is sensitive to these, by means of a strong elastic bandage in the day-time and a crêpe bandage at night. The extra pressure on the ulcer surface generally promotes rapid healing.

Coeliac Disease

Q.—*What are the latest views on the treatment of coeliac disease in a child of 3 years?*

A.—Recently the treatment of coeliac disease has been mainly dietetic. In particular the possible importance of carbohydrate-containing foods in aggravating some aspects of the syndrome has received attention (Sheldon, W., 1949, *Arch. Dis. Childh.*, **24**, 81). It would seem advisable to limit fats and to confine carbohydrate-containing foods to those best tolerated by the patient. A diet with a high-protein content is advantageous. Folic acid and other members of the vitamin-B complex do not appear to have any specific remedial action.

ATYPICAL PNEUMONIA*

BY

C. H. STUART-HARRIS, M.D., F.R.C.P.
Professor of Medicine, University of Sheffield

[WITH SPECIAL PLATE]

The existence of cases of pneumonia distinct anatomically from lobar pneumonia or bronchopneumonia and possessing a correspondingly diverse clinical course and aetiology has, of course, been recognized for a number of years. The era of treatment of pneumonia with specific antipneumococcal sera seemed to coincide with the recognition of such cases as indicated by Rufus Cole (1936), and the twin characters of lack of response to therapy and an unusual radiographic appearance in the chest led to the separation of such "atypical" cases from the main group of the pneumonias.

The use of the sulphonamide drugs only served to emphasize the unusual characters of atypical pneumonia, as even those sulphonamide derivatives active against the pneumococcus failed to influence its course. Then from 1938 onwards a number of authors in the U.S.A. (Reimann, 1938; Kneeland and Smetana, 1940; Longcope, 1940) published accounts of cases of atypical bronchopneumonia in young adults, some of which were of an unusual severity, though recovery was ultimately complete. These authors inclined to the view that they were in fact dealing with a new disease entity, though this view has since been challenged by others who consider that the widespread use of sulphonamides and, later, of penicillin has merely thrown the existence of unresponsive cases of atypical pneumonia into sharp relief.

Meanwhile the wider use of radiology in the investigation of influenza-like illnesses led to the discovery that such cases often showed areas of lung involvement radiologically, though clinical examination had failed to indicate such changes. Gallagher, in 1934, thus reported a series of sporadic cases in preparatory-school boys in Pennsylvania and regarded the lung lesions as being instances of "pneumonitis." His later series of cases in Massachusetts in the year 1939 to 1940 (Gallagher, 1940) partook much more of the character of an infectious disease.

About the same time, Bowen (1935) and Allen (1936), writing from U.S. Army stations, described radiologically similar cases of "pneumonitis" discovered among the hotchpotch of acute respiratory diseases seen in recruits and others during or even apart from outbreaks of so-called influenza. Thus the stage was set in the U.S.A. for a ready recognition of cases of acute respiratory disease with pulmonary lesions other than ordinary influenzal bronchopneumonia, when in 1942 and subsequently the opening phases of the war in America produced the inevitable wave of respiratory infections in Service establishments. The term "primary atypical pneumonia" thus sprang into existence and quickly displaced earlier terms, including that used by Scadding (1937) in describing a group of sporadic cases in England as "disseminated focal pneumonia."

Towards the end of the war explosive outbreaks of atypical pneumonia in the Allied Armies in Italy renewed interest in the condition, particularly as these were the first instances of actual outbreaks in British troops, and the brilliant work of Robbins and his associates (1946) in discovering that these outbreaks were due to the rickettsia of Q fever, *R. burneti*, served only to emphasize the aetiological obscurity of the earlier cases.

Though it must be clearly recognized that there are many respiratory-tract conditions in which a pneumonia atypical in course and character can be shown to exist, this paper is limited to a discussion of the syndrome of primary atypical pneumonia.

Primary Atypical Pneumonia

Definition and Aetiology.—This condition is best regarded as a syndrome of infection of the respiratory tract characterized by a varied symptomatology, by particular radiological changes in the lung, and by a lack of therapeutic response to sulphonamides or to penicillin. It is abundantly clear that the syndrome may be reproduced by many agents, chiefly of the virus or rickettsial group, and particularly the psittacosis group of viruses, *R. burneti*, and the influenza viruses. But by far the largest number of cases have yet to be proved aetiologically to be due to a particular agent, and the clinical account which will be given is largely based on such aetiologically unknown cases.

Epidemiology

Apart from Gallagher's account (1940), in which he considered that he was dealing with an infectious disease, many of the earlier reports consisted of sporadic unconnected cases Nevertheless, even among such cases transmission to other members of the family, or to doctors or nurses in contact with the patient, was described. Nor is it possible to say that such case-to-case contact was due

*Read in opening a discussion at a combined meeting of the Sections of Medicine and of Pathology and Bacteriology at the Annual Meeting of the British Medical Association, Liverpool, 1950.

to the operation of a particular causative agent, for though Eaton *et al.* (1941) described the recovery of a virus of the psittacosis group from cases in one such local outbreak, recent accounts from Scandinavia (Hogeman, 1948; Ginsberg, 1948) and the U.S.A. (Jordan, 1949) indicate that family transmission is possible and even frequent in cases of aetiologically unknown atypical pneumonia. The fact that the incubation period is prolonged (5 to 19 days) has been stressed by many workers from Gallagher onwards, and it is clear that such a long period may lead to the concealment of transmission by contact.

As seen in Service establishments in the U.S.A. in 1942 and onwards, cases of atypical pneumonia occurred in proportion to the general incidence of acute respiratory disease. Thus Dingle and co-workers at Fort Bragg (Commission on Acute Respiratory Diseases, 1944a) found a ratio of about 1 to 10 between cases of atypical pneumonia and the numbers of cases of acute respiratory disease. Such sporadic cases of atypical pneumonia bore no discoverable relation to cases of influenza virus infection or to psittacosis (Dingle, 1945), though transmission experiments in human volunteers, using filtered sputum and garglings, yielded successful results (Commission on Acute Respiratory Diseases, 1946).

The picture derived from these studies seemed to be that atypical pneumonia was a sporadic endemic disease. But it is necessary to emphasize that the Fort Bragg workers (Commission on Acute Respiratory Diseases, 1944b) and also Reimann (1947) have continually stressed the view that cases of bronchitis unaccompanied by atypical pneumonia and possibly other clinical conditions may in fact be caused by the same agents as those concerned in the cases of actual pneumonia. This may account for the increased incidence of atypical pneumonia during outbreaks of unspecified acute respiratory disease. All workers are, however, agreed that no considerable increase in incidence in cases of primary atypical pneumonia is usually experienced during outbreaks of actual influenza virus infection.

Until last year I had had no personal experience of cases of atypical pneumonia associated with influenza virus infection. However, during the influenza A outbreak of February and March, 1949, a number of cases of atypical pneumonia occurred both in Catterick Camp and among nurses at Leicester, and in at least two of four such cases serological proof was obtained that influenza virus A was concerned in the disease. A similar experience was earlier recorded by Zeigler and others (1947).

In Great Britain, cases of primary atypical pneumonia have been essentially sporadic in incidence, though Herxheimer and McMillan (1942) recorded a protracted outbreak in schoolboys. It must be pointed out that it is unlikely that school outbreaks of so-called influenza have in the past been sufficiently investigated radiologically for any evidence regarding the existence or otherwise of atypical pneumonia to be available. Nursing populations are, however, investigated more extensively from this point of view, and my colleagues Drs. Gifford and Worth have not unearthed any such cases in Sheffield in the past two years, though Dr. Joan Walker, at the Leicester Royal Infirmary, has been more successful. The recent occurrence of cases of Q fever among the staff at the Royal Cancer Hospital (MacCallum *et al.*, 1949) indicates the need for careful investigation of cases of acute respiratory disease of an unusual character. It is, moreover, clear from the experience in the Allied armies in Italy that Q fever may at times produce outbreaks of atypical pneumonia as explosive as influenza epidemics, and the high communicability of *R. burneti* has been stressed by laboratory outbreaks such as those at the National Institute of Health, Bethesda (Spicknall *et al.*, 1947).

Finally, the major stress of the incidence of primary atypical pneumonia has in the past fallen upon young adults, but the true incidence of infection by the causative agents of this syndrome must await the further delineation of these agents in the laboratory.

Clinical Features

The clinician's problem is twofold. First, the possibility exists that some of the simple cases of febrile acute respiratory disease occurring at any season of the year may exhibit radiological changes in the chest if, in fact, an *x*-ray examination can be made. Such opacities may be merely small areas of collapse as described by Ramsay and Scadding (1939) in cases of colds in those attending a tuberculosis clinic, or they may be actual instances of primary atypical pneumonia. Secondly, cases of pneumonia, particularly those not responding to treatment by sulphonamides or penicillin, may be admitted to hospital, and among these there may be examples of the syndrome of primary atypical pneumonia. It is perhaps necessary to stress that the latter cases may at first attract attention not so much by reason of the extent of consolidation but because there may be a clinical absence of such signs though radiological changes are demonstrable. Two such patients recently under my care at the Royal Hospital, Sheffield, may serve to illustrate the latter type of case.

Case 1

A housewife aged 29 was admitted to hospital on February 4, 1950, having been treated at home for a week as a case of pneumonia. Two weeks before admission cough and sputum, shivering, and sweating began, and these continued. There was some pain over the left costal margin a week before admission and also some malaise, but no headache, sore throat, or nasal symptoms.

On admission cough was frequent and irritating, and sputum was mucopurulent without blood. In spite of the low degree of pyrexia (100.6° F.—38.1° C.), tachycardia up to 110 was present and the patient was unusually dyspnoeic and cyanosed. Signs in the chest consisted of impaired percussion at the right base, numerous rales over the right middle and lower lobes, and a few rales at the left base. There was no bronchial breathing. A radiograph (Plate, Fig. 1) showed extensive mottling in the right lower and mid-zones, but there was also some mottling in the left lung; these changes persisted for 10 days after admission, with slower resolution in the right than in the left lung (Fig. 2). Sputum showed the normal range of nasopharyngeal flora. The leucocyte count was 10,400 with some shift to the left, and later 7,400. The sedimentation rate was 47 mm. (Wintrobe). The serum on the day of admission showed cold agglutinins in a titre of 1 in 1,200 using 0.2% group O cells, and had increased five days later to 1 in 2,000, and in a further eight days to 1 in 4,000. Convalescent serum did not fix complement with antigens of Q fever rickettsiae or psittacosis virus, nor did a rise in titre of antibodies for influenza viruses A or B accompany the disease.

Treatment with penicillin for the first two days after admission was changed to "aureomycin" because of the general clinical picture and the absence of response, but no immediate improvement was seen on a dosage of 2 g. daily, and the patient did not begin to enter convalescence clinically until two weeks after admission. The sedimentation rate did not fall until one month after admission. Of the patient's four family contacts, two had minor respiratory illnesses while the patient was in hospital, and one of these had a cold agglutinin titre of 1 in 128, two of the others being negative.

Case 2

A housewife aged 28 was admitted to hospital on January 12, 1950, having been treated by her doctor at home for a week as a case of pneumonia.

Six days previously she felt cold and unwell, and shivered. There was some pain, worse on coughing, over the left lower chest. The cough was at first dry; but, later, sticky pale sputum without blood was raised with difficulty. She received treatment with sulphonamide tablets but did not improve, nor did improvement follow the administration of penicillin at home. Headache, anorexia, and constipation were the only other symptoms noticed. There was no sore throat or coryza, nor was the voice hoarse.

On admission there was a low irregular fever, the patient was dyspnoeic though the respirations were not raised above 30, and there were periods of tachycardia up to 136. The chest showed slightly diminished movement and diminished air entry with only slight impairment of percussion over the right lower lobe. There were rales but no bronchial breathing. Radiographs showed some mottling over the right lower lobe, but four days later a remarkable miliary pattern of mottling was present in both lungs (Fig. 3). Sputum yielded a predominant growth of a pneumococcus which was sensitive to penicillin. The leucocyte count was 10,600 with a shift to the left, the sedimentation rate was 8 mm., and five days later the white cells numbered 11,600. The serum showed a cold agglutinin titre of 1 in 256 on admission and 1 in 10,000 five days later, rising to 1 in 20,000 eight days after this. The spleen was felt for the first time four days after admission.

Treatment with penicillin for the first six days produced no clinical improvement though the temperature fell. Aureomycin in a dosage of 0.5 g. six-hourly, given for four days, produced subjective improvement and a remarkable clearing of the *x*-ray shadows (Fig. 4). Sputum, if anything, increased, but was still raised with difficulty and was stringy and colourless. Convalescence was, however, slow and the enlargement of the spleen persisted even after discharge. The cold agglutinin titre had begun to fall four weeks after admission, but was elevated above normal for some further weeks. The convalescent serum did not fix complement with antigens of Q fever rickettsiae or psittacosis virus, nor did a rise in titre of antibodies for influenza viruses A or B accompany the disease.

This patient's relatives comprised four intercommunicating family groups, and, among 15 persons actually or remotely in contact with her, four cases occurred which were diagnosed by family doctors as cases of pneumonia, though none were admitted to hospital. Two of these cases fell ill nine days after the onset of illness in the patient, and the other two 15 days after the second illness. Eleven relatives were tested for cold agglutinins; one showed a titre of 1 in 800, two a titre of 1 in 256, and one a titre of 1 in 128, the remainder being 1 in 32 or less.

Comment

The patients were housewives aged 28 and 29, and had been ill at home in bed for a week, receiving treatment from their doctors as cases of pneumonia. Before admission symptoms had begun with shivering, cough, and malaise, the shivering having continued on and off in the second case but not in the first. Headache was present in one but not in the other. Both patients had an irritating paroxysmal cough, dry at first but later accompanied by a sticky mucopurulent sputum without blood. Neither had coryza, sore throat, or hoarseness of the voice. Both had complained of some pain over the lower chest, though this was not typically pleuritic in character.

The clinical picture in both these patients was that of a low fever, tachycardia, and an unusual degree of respiratory distress. Cough was both irritating and productive after admission. In Case 1 a respiration rate of 50 a minute was recorded, and the patient was cyanosed but the other was not. Physical signs in the chest in Case 2 consisted of little apart from rales, but Case 1 was cyanosed and showed some impairment of percussion at one base. *X*-ray changes exceeded in degree the clinical findings and are best visualized by inspection of the illustrations. Thus Case 2 showed a patchy mottling in the right lower zone and later an extensive miliary pattern of mottling in both lungs in spite of treatment with penicillin. Seven days after treatment with aureomycin the chest appeared clear radiologically. Case 1 exhibited a different radiographic picture on admission, with a dense opacity in the right lobe but also some mottling in the left lung. Treatment with aureomycin produced little change in the right lung though the left lung cleared seven days later.

Both patients had strikingly raised cold agglutinin titres. In Case 1 the titre was 1 in 1,200 on admission two weeks after the onset of symptoms, and 13 days later it was 1 in 4,000 (0.2% red cells). Case 2 had a cold agglutinin titre of 1 in 256 on admission and 1 in 20,000 13 days after admission and 19 days from the onset. The leucocyte count was 10,000 in both patients on admission, though this fell later and reached leucopenic levels in Case 2. A pneumococcus was present in the sputum in small numbers in Case 1 and in larger numbers in Case 2, but treatment with penicillin produced no obvious improvement. Aureomycin 0.5 g. six-hourly produced a remarkable clinical improvement in Case 2 but no clear-cut change in Case 1. Both patients were ill for at least three weeks and convalescence was slow.

Inquiry regarding the family contacts of Case 1 was negative, but of 15 individuals closely or remotely in contact with Case 2 no fewer than four suffered illnesses treated at home as cases of pneumonia by their family doctors. These illnesses occurred 10 and 21 days after the onset of symptoms in the patient herself. At least three of 11 relatives tested for cold agglutinins showed raised titres varying from 1 in 256 to 1 in 800.

These two cases illustrate most of the points emphasized by the large number of case reports in the literature. The fact that they were clinically ill enough to be regarded as cases of pneumonia yet lacked the dullness and bronchial breathing of ordinary pneumonic consolidation fitted in well with the radiological changes. The latter are often described as a veiling or hazy opacity, either hilar or peripheral in distribution, and cannot be said to conform to any one pattern, though the density is usually less than in bacterial pneumonia. Both mottled and homogeneous opacities occur as shown in the illustrative films of Cases 1 and 2. The absence of haemoptysis at the onset or of sharp pleural pain are also points worthy of emphasis. The benign prognosis even without specific therapy is a classical feature of the syndrome. Though some fatal cases have been reported by Parker and his associates (1947), it is exceptional for death to occur. On the other hand, some of the illnesses associated with agents of the psittacosis group have been fatal, as was the result in the elderly patient with Q fever at the Royal Cancer Hospital (Whittick, 1950).

Diagnosis

It seems remarkable that any syndrome due to a diversity of aetiological agents should nevertheless fail to exhibit characteristics corresponding to the various causes. Yet this seems to be true of primary atypical pneumonia. Q fever, for instance, is a general disorder with rickettsiaemia, yet without rash or constant enlargement of the spleen. The symptom complex is described as headache, chilliness, malaise, muscular aching, anorexia, cough, and pleuritic pain—which is clearly in no way

distinctive from that of atypical pneumonia. The fever may be trivial or may last more than a week, and the chest signs emphasized by most observers are rales in the absence of classical features of consolidation. These findings hold both for sporadic cases in the U.S.A. (Denlinger, 1949) and for the outbreaks in Italy (Robbins and Ragan, 1946; Feinstein *et al.*, 1946).

I was privileged to see a few patients in Italy under the care of Lieutenant-Colonel R. W. D. Turner in 1944, and two features which then seemed to me to differ from those of primary atypical pneumonia as seen in England were the frequent onset with sharp pleuritic pain and the fact that the lung opacity was often dense and suggestive of bacterial pneumonia, though other cases exhibited the typical hazy pattern already described. It is obvious that no sharp clinical distinction exists between Q fever and other members of the primary atypical pneumonia syndrome. The fact that radiological differences exist is suggested by a recent paper from California (Jacobson *et al.*, 1949) which analyses the *x*-ray findings in 77 cases of Q fever. Hilar and vascular engorgement was absent in these cases, and the lung opacities, often segmental or lobar in situation, were usually homogeneous rather than patchy, and rarely migratory.

Differentiation of cases of infection due to the psittacosis group of viruses is equally difficult clinically, for though severe and even fatal cases may be encountered there is evidence that ordinary benign cases of the atypical pneumonia syndrome due to psittacosis may also occur.

Atypical pneumonia due to the influenza viruses is, I believe, uncommon, and insufficient cases have been described for any diagnostic criteria to have been established other than laboratory data. But the resemblance of simple influenza and mild cases of atypical pneumonia is obvious, and the same may be said of ordinary febrile catarrh or acute respiratory disease.

Recognition of primary atypical pneumonia of uncertain aetiology depends upon the total clinical picture as already described, but may be assisted by serological tests such as the cold agglutination of human red cells and the agglutination of the streptococcus M.G. of Thomas *et al.* (1943). The position seems to me to be that, if the clinical picture is suggestive of an atypical pneumonia rather than influenza or lobar pneumonia, the finding of a raised cold agglutinin titre is an added support to the diagnosis, particularly if a rise in titre of the agglutinin accompanies the later stage of the disease. But rises in cold agglutinin titre to levels in excess of the usually accepted average range can certainly occur in many other conditions, such as glandular fever or as, for instance, in a recent case of influenza from whose garglings a strain of influenza virus B was obtained. This patient had a cold agglutinin titre of 1 in 128 on the first day of illness, rising to 1 in 512 a week later. Similar instances have been recorded by American workers.

It seems highly probable that the initially raised titre in such cases may be due to some recent infection such as primary atypical pneumonia, and that influenza stimulates an anamnestic response. I have little personal experience of the use of the streptococcus M.G., but it is stated that the results parallel those obtained in the cold agglutination test, though they may not coincide in individual cases.

Treatment

Until a year or so ago no treatment had been found to influence the course of primary atypical pneumonia except perhaps that due to psittacosis. In this disease penicillin, either alone or combined with sulphonamides, was reputed to have some effect. The introduction of aureomycin has fundamentally changed this position, as it is reputed (Brainerd *et al.*, 1949) to be active against psittacosis, Q fever, and the ordinary case of atypical pneumonia. The rickettsia of Q fever is, it is true, somewhat more resistant to aureomycin than most of the other rickettsiae, but encouraging results have been obtained in California (Lennette *et al.*, 1948; Brainerd *et al.*, 1949).

A number of authors (Kneeland *et al.*, 1949; Finland *et al.*, 1949; Collins *et al.*, 1950) have reported excellent results with primary atypical pneumonia of undetermined aetiology using doses of 2 to 4 g. a day for three or four days. The series reported by Meiklejohn and Shragg (1949) was noteworthy because of the use of controls alternating with the aureomycin cases but treated by penicillin. The fact that aureomycin is active against most bacteria associated with pneumonia makes such a controlled trial essential in the evaluation of the drug in primary atypical pneumonia. If for no other reason than the multiple aetiology of the syndrome, further therapeutic trials appear desirable.

Summary

Primary atypical pneumonia is a syndrome of respiratory-tract infection characterized by varied symptomatology, by radiological changes of a particular character, and by lack of therapeutic response to the sulphonamides or to penicillin.

The syndrome became recognized with increasing frequency from 1934 to 1940 partly because of the introduction of sulphonamides and the wider use of radiology, but possibly also because of its occurrence in young adults in a severe form. The psittacosis group of viruses, *R. burneti*, and the influenza viruses are established causes, but only of a minor percentage of cases of the syndrome.

Epidemiology varies from sporadic cases to explosive outbreaks, according to the causative agents. Family infection and case-to-case spread is found not only in psittacosis infections but also in cases of undetermined epidemiology. The incubation period is 5 to 19 days. The incidence increases during outbreaks of undefined acute respiratory disease.

Clinical features are those of a benign respiratory-tract infection with cough and sputum, fever, malaise, and headache. Signs suggest a bronchitis rather than a true consolidation. Radiographs reveal more extensive changes than the clinical signs suggest, and hazy opacities or diffuse mottling may be found contrasting with the denser opacity of bacterial pneumonia. Q fever may cause onset with pleuritic pain, but is not distinct clinically from other atypical pneumonias.

Diagnosis depends on the total clinical picture, but may be aided by cold agglutinin tests in that form of the syndrome of undetermined aetiology. Laboratory investigations are essential to the diagnosis of the particular agent concerned in the syndrome.

Treatment by aureomycin gives considerable promise of success in atypical pneumonia of undetermined aetiology, in Q fever, and, possibly, in psittacosis.

I wish to thank Dr. J. L. Grout, radiologist to the United Sheffield Hospitals, for permission to quote and to reproduce the radiological findings in the two patients. Cold agglutinin tests quoted were the work of Dr. M. Gatman, to whom I am indebted; and Dr. D. A. Tyrrell investigated the family illnesses quoted. I wish to thank Dr. B. P. Marmion of the Central Public Health Laboratory, Colindale, for allowing me to quote the results of the complement-fixation tests for Q fever and psittacosis in the two illustrative cases.

PRIMARY ATYPICAL PNEUMONIA*

BY

S. P. BEDSON, M.D., F.R.C.P., F.R.S.

Professor of Bacteriology, University of London

As my remarks will be concerned with the aetiology of this condition and its laboratory diagnosis I shall begin by defining what I understand by the term "primary atypical pneumonia," because not all, apparently, think alike on this point. For me this term refers to a clinical syndrome produced by a variety of infective agents, among which certain viruses, a rickettsia (*R. burneti*), and a fungus (*Coccidioides immitis*) have already been identified. Others would remove from this group those cases due to the psittacosis viruses, *R. burneti*, and *C. immitis*, and reserve the name primary atypical pneumonia for cases caused by the somewhat ill-defined virus of Eaton *et al.* (1942) and possibly, in addition, some as yet unidentified virus. While approving this endeavour to break down the conglomerate mass of atypical pneumonias into a number of aetiological entities, it seems to me that it would be most unfortunate if it resulted in the definition of a disease entity named "primary atypical pneumonia."

In my opinion the term should be used to describe a train of symptoms or cease to be employed. And although the name primary atypical pneumonia for this syndrome has little to recommend it I have no alternative to suggest. Certainly the term "virus pneumonia," which some would put in its place, strikes me as most unsuitable, for, apart from the fact that a rickettsia and a fungus figure among the causal agents of this syndrome, it is by no means every virus pneumonia which qualifies for inclusion in the group. Pneumonia due to the influenza viruses, for instance, does not, in my opinion, conform either in clinical pattern or in histological change to the pneumonia which we label "primary atypical"; and the giant-cell pneumonia of Hecht and the virus pneumonitis of infants described by Adams (1941) are further examples, though admittedly the virus aetiology of these two last conditions rests only on histological evidence.

I mention giant-cell pneumonia because I have had the opportunity of examining material from two cases which occurred at the London Hospital. Both occurred in infants in early convalescence from varicella, and death was due to a bacterial bronchopneumonia, but the histological changes of this terminal condition did not obscure the presumably earlier ones characterized by the formation of giant cells, often draped around the alveolar walls. Nuclear and cytoplasmic acidophil inclusions were numerous in these cells, and one is tempted to conclude that they represent parasitism by the varicella virus, a varicella pneumonia which had preceded and predisposed to the secondary bacterial infection. A similar giant-cell pneumonia has, however, been described in measles.

Primary atypical pneumonia might be described as an infective process of various aetiology, often with an indefinite onset, and characterized clinically by moderate fever, malaise, and a cough which is harassing though largely unproductive, at any rate during the first week of disease. Characteristically, there is a paucity of physical signs in the chest and the pneumonic changes might be overlooked were it not for *x*-ray examination; the shadows thus revealed are lacking in density owing to the incompleteness of the consolidation. Those cases which have come to post-mortem examination have shown histological lung changes which have been very similar whether the cause has been a virus of the psittacosis group, some other virus, or Q fever.

These changes, usually described as interstitial pneumonia, consist in a thickening of the alveolar walls due to congestion and infiltration with mononuclear cells and an exudate into the alveoli composed of serum, fibrin, red blood corpuscles, mononuclear cells, desquamated alveolar cells, and occasional polymorphonuclear leucocytes. Characteristically the exudate varies considerably from one part of the lung to another. It is usual to say that a failure to respond to sulphonamides is a distinctive feature of primary atypical pneumonia, but it must not be forgotten that a few strains of psittacosis virus are sulphonamide-sensitive. I have seen three human cases which undoubtedly responded to this treatment, and others have been described (Hinshaw, 1940).

Aetiology: Viruses of the Psittacosis Group

Turning now to the causation of this syndrome, the first group of agents that I would like to consider is the psittacosis viruses, and I mention them first, not because they play a preponderant part in the production of this condition, but because psittacosis virus was the first recognized cause of atypical pneumonia. I should perhaps point out for the benefit of those who have not followed the literature of this subject that psittacosis is not just one virus as at first believed, but a group of closely related viruses. And the primary hosts of these viruses are not

*Read in opening a discussion at a combined meeting of the Sections of Medicine and of Pathology and Bacteriology at the Annual Meeting of the British Medical Association, Liverpool, 1950.

confined to psittacine birds, but extend to many other avian species—various finches, sea birds, the pigeon, duck, and domestic fowl.

The name of ornithosis virus is used by some authorities for those avian strains which differ in minor ways from the original psittacosis virus. There is also evidence that the primary host range of this group of viruses may include mammals, for the virus of cat pneumonia described by Baker (1942) seems to belong to the group, and, more recently, Roca-Garcia (1949) has described naturally occurring infection of opossums in South America. There is even a suggestion that some strains of psittacosis virus have become adapted to man, using him as their only natural host: the S.F. virus of Eaton, Beck, and Pearson (1941) and the Louisiana pneumonitis virus (Larson and Olson, 1946) are examples in point; the readiness with which they pass from man to man is an important and striking feature of these strains.

The practical importance of all this recent work on the oecology of the psittacosis viruses is, of course, that the chance of man's contracting psittacosis is very much greater than was at one time believed. As already mentioned, some authorities would exclude psittacosis from the group of primary atypical pneumonias, and, while it must be admitted that the severe case of psittacosis, with its attendant toxaemia and typhoid state, presents a picture unlike that of primary atypical pneumonia, this is not true of the milder cases which constitute the majority of human infections with the psittacosis viruses. Human psittacosis, like any other infectious disease, can vary considerably in severity, and it is not by any means all cases of psittacosis that develop signs of pneumonic involvement; some of these infections may even be inapparent (Bedson, 1939).

Serological Investigation

Many of the milder cases with pneumonitis would have remained indistinguishable from the mass of primary atypical pneumonia had they not been picked up by the laboratory in the course of routine serological investigation. The diagnosis of psittacosis is essentially a matter for the laboratory, and though isolation of the virus is undoubtedly the most satisfactory evidence which can be adduced in support of this diagnosis it is not always practicable. The virus is best sought in the sputum, but this material is usually scanty or may even be absent, and the alternative procedure for obtaining material from the pneumonic foci by lung puncture can hardly be recommended as a routine. So the laboratory has to rely on the indirect evidence afforded by the complement-fixation test.

In this connexion it has to be observed that the antigen used as a routine in the psittacosis complement-fixation test is the heat-stable group antigen which is not only common to the viruses of the psittacosis group but also to lymphogranuloma venereum (L.G.V.) virus and other viruses belonging to the psittacosis-lymphogranuloma group. This means that a positive result indicates no more than infection with a virus of the psittacosis-lymphogranuloma group, and its correct interpretation can be made only in the light of the clinical findings. And, as in the case of any diagnostic serological tests, the demonstration of a rising titre of antibodies is much better evidence of active infection than the finding of even a high titre on a single occasion. There is evidence (Bedson *et al.*, 1949) that absorption of the serum with the group antigen discloses a specific antibody which can then be detected by complement fixation, the fresh unheated virus being used as antigen, but technical difficulties make it unsuitable as a routine procedure.

Skin Test

The question of whether a skin test might be of service in the diagnosis of psittacosis is worth investigation, though there is already a suggestion that infection with these viruses does not lead to the development of skin sensitivity to the same extent as in L.G.V. In the latter condition the percentage of reactors to the Frei test is high, approximately 95, and, since the active antigen in this test is the heat-stable group component which L.G.V. virus shares with psittacosis virus, one might expect that a heated preparation of psittacosis virus would successfully replace the orthodox Frei antigen, and that cases of psittacosis would give a positive Frei reaction. The former conjecture is more or less true: though there are some divergences between the skin reactions given by cases of L.G.V. to heated psittacosis and L.G.V. virus, the concordance is high (Bedson *et al.*, 1949). And, as Eaton, Beck, and Pearson (1941) have shown, the Frei test may be positive in psittacosis: they obtained five positive results in eight cases. I think it would be worth while skin-testing all cases of human psittacosis, using in parallel the orthodox Frei antigen and a similar preparation made from psittacosis virus. Those that reacted positively to one or both might then be tested with the acid extracts of the two viruses, which preliminary findings suggest contain the species-specific antigens (Barwell, 1949; Bedson *et al.*, 1949).

Incidence

Before leaving the question of the relationship of the psittacosis viruses to primary atypical pneumonia it might be useful to attempt some estimate of the proportion of cases with this aetiology. Where this rests on the demonstration of the virus in morbid material we are on sure ground, but extensive investigations on this point are few. Meiklejohn, Beck, and Eaton (1944) isolated viruses belonging to the psittacosis group from sputum and lung-puncture material in 10 out of 250 cases, and in a smaller group of 33 cases Glover and his colleagues (1948) obtained one positive result. As might be expected, serological evidence of infection with these viruses in atypical pneumonia is not only more abundant but places the incidence higher.

Smadel (1943), using the psittacosis complement-fixation test, demonstrated a rising titre of antibodies in 10 out of 45 sporadic cases of primary atypical pneumonia in eastern States of the U.S.A., and Eaton (1945), in reviewing the work done on this problem during the war, concludes that some 10% of the cases of this syndrome are due to viruses of the psittacosis group. My own experience during the war led me to a somewhat similar estimate. Relying alone on the demonstration of antibody by means of the psittacosis complement-fixation test, 9 out of 120 cases were diagnosed as psittacosis. The incidence of primary atypical pneumonia has returned to its pre-war sporadic level, but the investigations now being made by the Virus Reference Laboratory of the Public Health Laboratory Service should, in time, give us further and more conclusive evidence on this point.

The Virus of Eaton

It is not my intention to make more than a passing mention of those cases of this syndrome which are due to *C. immitis*, since infection with this fungus is confined to certain localities in North America. Nor shall I do more than refer to the virus of lymphocytic choriomeningitis as a possible cause of an occasional case. I propose now to pass to a consideration of the virus described in 1942 by Eaton, Meiklejohn, van Herick, and Talbot. Earlier I referred to it as ill-defined, but in doing so I was not questioning its existence so much as registering the doubt, which, to my mind, still exists concerning its relationship to respiratory disease in man.

This virus was first isolated by the intranasal inoculation of cotton-rats with sputum obtained early in the disease. Difficulty was experienced in adapting it to the cotton-rat, and there seems to have been some doubt concerning the six strains finally established. In the end it was concluded (Eaton, 1945) that they were in all probability a latent virus of the cotton-rat. However, Eaton and his colleagues (1944) have shown that a virus can be obtained from cases of primary atypical pneumonia by the inoculation of 12-day eggs with filtered sputum by the amniotic route.

Presumably this virus is the same as that with which they started in their earlier experiments; it can be maintained in eggs but, unfortunately, produces little or no visible change in the embryo, and one has to rely on subinoculation of hamsters and cotton-rats to demonstrate its presence. Nasal inoculation of these animals produces lung lesions in some 75%, and neutralizing antibodies for this virus are found in human convalescent sera. Whether or not Eaton's virus is responsible for those cases of primary atypical pneumonia not caused by known infective agents—the psittacosis viruses, *R. burneti, C. immitis*, and lymphocytic choriomeningitis—the vast majority in fact, remains to be shown, but there is good evidence that they are of virus aetiology. The absence of a demonstrable bacterial cause, the histological findings in the few cases that have come to necropsy, and the transmission of the condition to human volunteers by means of filtered sputum (Commission on Acute Respiratory Disease, 1945, 1946) all support such a conclusion.

The literature on primary atypical pneumonia during the recent war contains a number of claims that viruses have been obtained from this condition; but some of these claims were subsequently withdrawn, and in other instances the virus was lost before it could be characterized and its relation to the human disease established. The virus of feline pneumonia of Blake, Howard, and Tatlock (1942) possibly merits consideration, but, apart from this, Eaton's virus holds the field, though I should be surprised if his virus alone was responsible for this large group of atypical pneumonias.

Cold Agglutinins

It was hoped at one time that the occurrence in the serum of abnormal concentrations of cold agglutinins for human group erythrocytes might be of assistance in defining this group of primary atypical pneumonias, of which Eaton's virus is the possible cause. The original and independent observations of Peterson, Ham, and Finland (1943) and of Turner (1943) suggested that an increase in these antibodies was peculiar to primary atypical pneumonia among respiratory infections, and subsequent work by these and other investigators largely confirmed this.

When Eaton (1945) observed that this increase in cold agglutinins did not occur in cases of atypical pneumonia due to the psittacosis viruses—a finding in line with my more limited experience—and the same was said to be true of Q fever (Caughey and Dudgeon, 1947), it looked as though the development of cold agglutinins might be of service in defining the group of atypical pneumonias in which Eaton's virus was supposedly concerned. The development of agglutinins for the M.G. streptococcus had apparently the same significance; the development of these two kinds of antibody, though entirely distinct, occurred very largely in parallel. But more recent work has shown (Finland, Joliffe, and Parker, 1948; Morgan and Finland, 1948) that an increase in the titre of cold agglutinins can undoubtedly occur in psittacosis pneumonia, and, though there is no suggestion that this is more than an occasional happening, that it occurs at all seems to rob this test of much of its value.

It may be that the development of agglutinins for the M.G. streptococcus will prove a more useful test for the identification of atypical pneumonia not due to the psittacosis viruses or *R. burneti*. Further work on this point and on the usefulness of cold agglutination is required: the survey being made by the P.H.L.S. will no doubt supply the answers to these questions. But more important, obviously, is the provision of precise information concerning the causation of the large number of cases of primary atypical pneumonia which still remains unknown.

The December issue of *The Practitioner* (price 4s.) contains an important symposium on the medical aspects of atomic warfare, in which, in addition to orthodox and straightforward simple articles on such subjects as nuclear physics and the pathology of radiation injuries, a Home Office adviser describes and illustrates how to assess the probable casualties and damage from an atomic-bomb explosion in a built-up area; and the adviser in surgery to the Ministry of Health sketches the proposed first-aid and hospital organization in the event of war. In industrial areas the central hospitals will become lightly manned casualty transit centres, while most medical and nursing staff will move out to peripheral cushion hospitals situated on main roads and close to railways. Base hospitals will contain special centres and be either for acute or for "recovering" patients (continuous specialist supervision no longer needed), who will be transferred from the cushion hospitals by ambulance train or coach as soon as their primary treatment has been completed. The hospital service will be controlled from Whitehall through the regional hospital boards and through medical officers of the Ministry of Health posted at Army Command and Civil Defence Region headquarters. The First Aid service will be an integral part of the hospital service, and first-aid stations will be based on selected cushion and base hospitals. Each station will comprise a fixed first-aid post at the parent hospital, together with three mobile first-aid sections and a mobile gas cleansing unit, for each of which two light cars and a van will be provided, with a motor-cyclist as messenger. Ambulances will be the responsibilit. of the local health authority.

BLOOD VESSELS OF A GASTRIC ULCER

BY

JAMES A. KEY, F.R.C.S.

(From the Department of Surgery, King's College, Newcastle-upon-Tyne)

[With Special Plate]

It is no new idea that acute ischaemia can cause necrosis of the gastric mucosa. Disse (1904) claimed that the arteries supplying the gastric mucosa in man are virtually end-arteries, each one supplying 4 mm.² of surface mucosa, and that blockage of one or more of these vessels would cause local necrosis. Various theories have been suggested by Hofmann and Nather (1921) on how such a block may be produced. They present a long list from which to choose, including compression from without by the muscle coats of the stomach, spasm of the arteries, and thrombosis and embolism.

Recent work by Barlow (in the press) shows, however, that the vessels of the gastric submucosa and mucosa are not anatomical end-arteries, but that they anastomose freely with each other. Examination of Barlow's dissections suggests that it would require an extensive vascular block to render a patch of mucosa ischaemic. It is true, nevertheless, that the vessels in and around a chronic gastric ulcer show widespread occlusions; but in an acute ulcer this is by no means the case.

During the past year specimens of gastric ulcer removed at operation in our department have been examined by the methods of microangiography, designed to show the vessels without impedance of other tissues.

Method

On removal of the resected portion of stomach at operation the specimen is placed in a saline bath at 37° C., and kept there until injection is completed. A suitable artery, usually the left gastric or right gastro-epiploic, and the largest of the accompanying veins are cannulated. The cut ends of the stomach are clamped or oversewn to prevent leakage. A 10% solution of colloidal silver iodide is then injected into the artery at a pressure of not more than 160 mm. Hg, 70–90 ml. being the average quantity entering the vessels. In some cases 10–15 ml. of a solution of 10% bismuth oxychloride ("chlorbismol") is injected after the silver iodide. Bismuth oxychloride has a particle size too large to enter the capillaries, and it outlines the larger vessels very clearly. The vessel used for injection is then ligated, the stomach filled with cotton-wool to limit distortion, and the whole specimen immersed in 10% formalin for 24 hours.

After fixation the stomach is cut along the greater curvature, opened out mucosa uppermost, and radiographed. A further period of formalin fixation follows for 24–48 hours. Transverse sections 400 μ thick are made through the ulcer itself and for varying distances proximal and distal to it along the line of the lesser curve. These sections are then examined by the technique of microarteriography (Barclay, 1947).

Results

Normal Stomach

A transverse section of the normal healthy stomach in the line of the lesser curve shows a characteristic vascular pattern (Plate, Fig. 4), so regular and well defined that it is easy to detect the normal anatomical layers of the stomach wall. The vessels of the mucosa are rich and complex and those of the underlying submucosa present a typical ordered pattern. The vessels supplying the external muscle coats are seen as a longitudinal band running across the zone near the bottom of the section.

Chronic Ulcer

Figs. 1 and 2 show radiographs of two stomachs each containing a chronic gastric ulcer of the lesser curve, the first situated at the centre of the lesser curve and the other approximately 5 cm. from the pylorus. In both there is a well-marked ischaemic zone around the ulcer in which the larger vessels do not outline. Elsewhere the vessels of the stomach show normal filling.

Section through the ulcer itself shows that the floor of the ulcer consists of bloodless tissue throughout the whole thickness of the stomach wall; in this area there is a complete absence of all but very fine vessels (Fig. 3). The vessels of the mucous membrane, on the other hand, are normally filled right into the edge of the ulcer. The general picture contrasts sharply with that seen in a transverse section of the normal stomach.

Furthermore, sections taken from the lesser curve some distance from a chronic ulcer show that these changes extend as an ischaemic core quite deep to the mucosa for 1–2 cm. along the lesser curve. Fig. 6 shows such a section taken 1.6 cm. from the edge of a chronic gastric ulcer. There is a well-marked ischaemic zone in the centre of the section, with absence of all but very fine vessels. The overlying submucosa shows a marked derangement of the normal vascular pattern, although the vessels of the mucous membrane are normally filled. The appearances are those of an ischaemic process deep in the stomach wall, which undermines and eventually destroys the mucosa.

This method of microradiography demonstrates vividly the old pathological teaching, extensive vascular block and derangement around a chronic ulcer. It has been a constant finding in all the specimens of chronic gastric ulcer examined.

Such an ischaemic state might well explain why an ulcer does not heal, but rather persists and even spreads. It is not, however, evidence that such a vascular condition caused the original ulcer. It is indeed much more probable that the vascular block is the result of a chronic inflammatory state producing changes not dissimilar to those found in chronic ulceration elsewhere in the body.

An attempt was made, therefore, to find and examine small acute ulcers. Such ulcers are not commonly found in gastrectomy specimens, but occasional ones were detected remote from chronic ulcers and also in specimens removed urgently for haematemesis.

Acute Ulcer

The typical appearance of a transverse section through an acute ulcer is shown in Fig. 5. There is a marked increase in the blood vessels in the submucosa. Their arrangement is haphazard and diffuse, and the alteration of vascular pattern in the submucosa extends widely beyond the point where the mucosa is breached. The mucosal vessels themselves are well filled and appear to be normal right into the ulcer defect, and at one edge the mucosa has collapsed almost as if the foundations on which it rests have been disrupted.

The normal pattern (Fig. 4) contrasts as vividly with the vessels of an acute ulcer as it does with the appearances in a chronic ulcer, but in a very different way. The acute ulcer presents a picture of an acute vascular disturbance

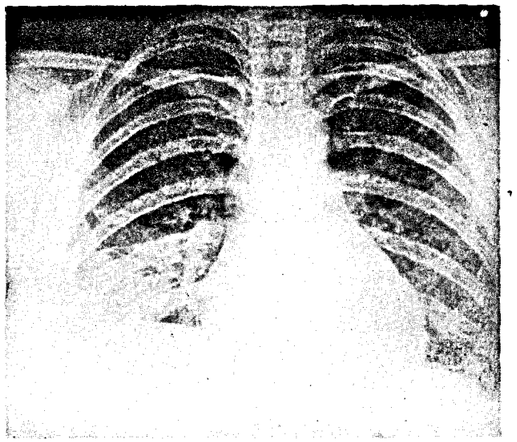

Fig. 1.—Case 1. Radiograph on February 7, 1950, ten days from onset. Moderately dense opacity right base, fine clouding left lung. Lateral view indicated involvement of both lower and middle lobes on right side.

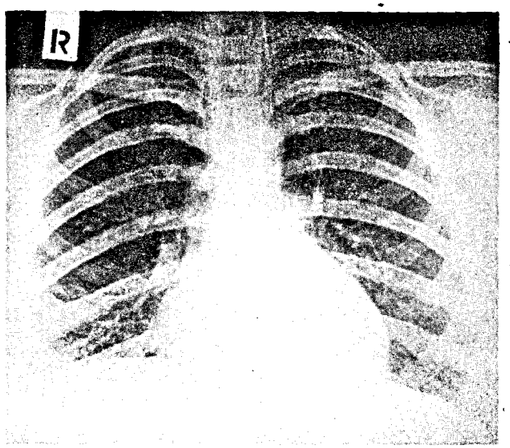

Fig. 2.—Case 1. Radiograph on March 7. Resolution complete left lung, almost complete right base. Clearing of latter first evident on February 17, but comparatively slow in progress.

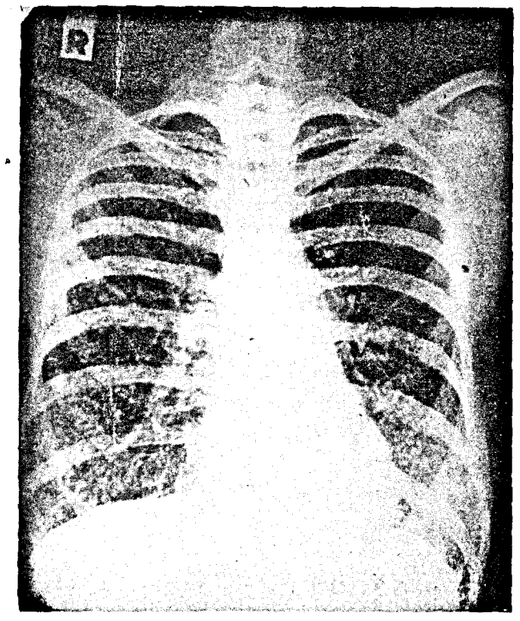

Fig. 3.—Case 2. Radiograph on January 17, 1950, twelve days from onset. Coarse mottling both lungs, uniformly distributed. No localized consolidation.

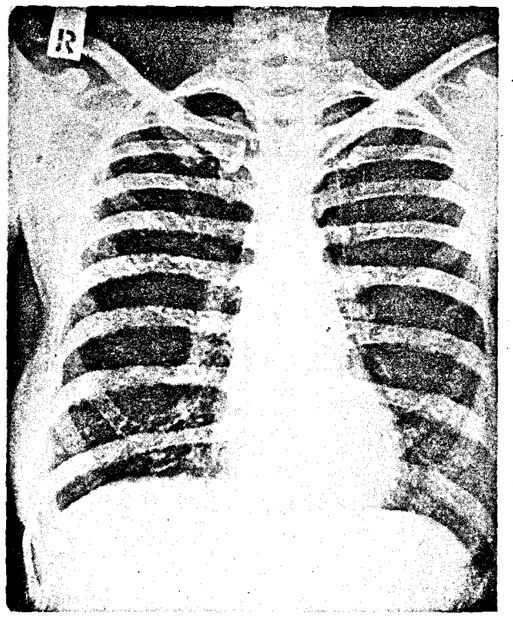

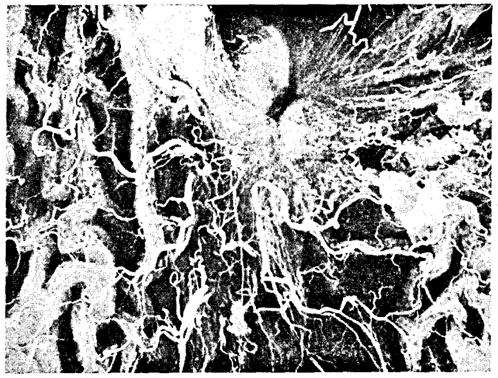

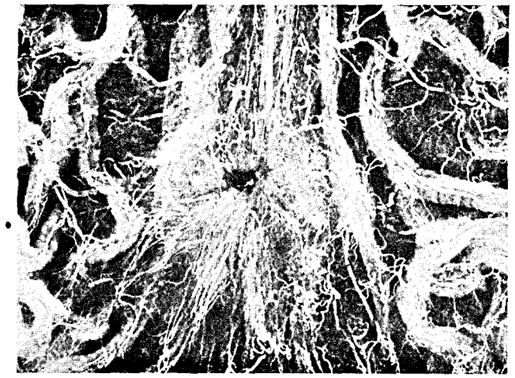

Fig. 4.—Case 2. Radiograph on January 24. Lungs now completely clear.

FIGS. 1 and 2.—Surface radiographs (× 78) of two specimens of chronic gastric ulcer situated on the lesser curve. The vessels have been injected with colloidal silver iodide. Each ulcer shows a well-marked surrounding ischaemic zone with absence of all but fine vessels.

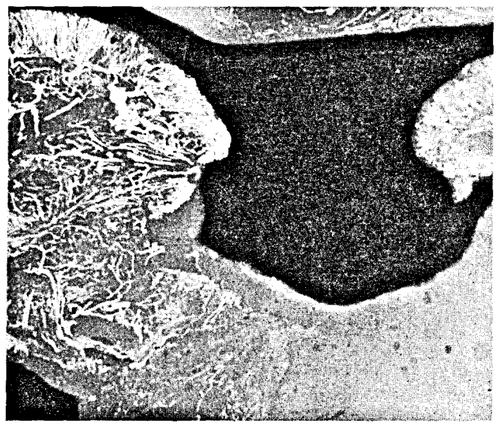

FIG. 3.—Transverse section (× 4) through the centre of a chronic gastric ulcer showing the well-marked ischaemic base, with only an occasional fine vessel running through it, and the normal filling of the vessels of the mucous membrane right up to the ulcer edge. (Section 400 μ thick.)

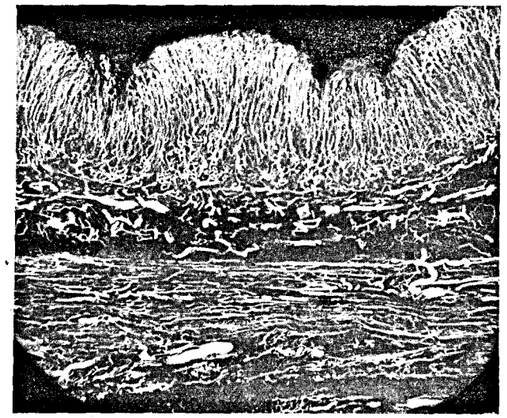

FIG. 4.—Transverse section (× 8.8) of normal stomach wall in the centre of the lesser curve. The vessels in the mucosa are well filled and the normal vessel pattern in the underlying submucosa is clearly seen. The fine vessels running longitudinally near the bottom of the section are those of the external muscle coats. (Section 400 μ thick.)

FIG. 5.—Transverse section (× 8.8) through the centre of an acute ulcer showing an increase in the size and number of vessels. Their arrangement is haphazard and diffuse and extends widely beyond the point where the mucosa is breached. (Section 400 μ thick.)

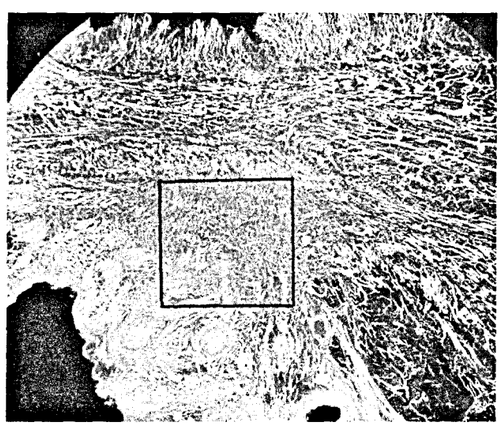

FIG. 6.—Transverse section (× 4.4) through the lesser curve 1.6 cm. from the edge of a chronic gastric ulcer. The outlined ischaemic area deep in the muscle wall is shown containing only fine vessels. (Section 400 μ thick.)

occurring chiefly just under the mucous membrane—a hypervascularity and derangement, an increase in vessels, and not an ischaemia.

Discussion

The method of studying vascular patterns in simple gastric ulcer by microradiography lends support to the hypothesis that in peptic ulcer an acute vascular disturbance occurs in the submucosa close to the mucous membrane, and that the breach of the mucosa itself results from this underlying vascular derangement.

Such a hypothesis is of interest when compared with the observations of Wolf and Wolff (1943) on their patient, Tom, who had a large gastric fistula. They noted that in states of acute emotion the exposed gastric mucosa became engorged and turgid, and finally produced here and there an acute erosion which bled from its congested edges.

The nature of the vascular disturbance found in association with acute ulcers has not so far been determined, but further studies by microradiography, and by coloured intravascular injections of arteries and veins, show that venous stasis is a predominant feature. That such a type of acute vascular reaction can produce ulceration elsewhere in the body is common knowledge. The surgeon called upon to operate on strangulation of the bowel often sees it.

It should be of interest to pursue the study of the vascular derangement of the stomach mucosa.

Summary

The vascular pattern of the normal lesser curve of the stomach, of a chronic ulcer, and of an acute ulcer, as shown by microradiography, are compared.

In a chronic ulcer there is widespread vascular occlusion in the base of the ulcer and extending along the line of the lesser curve deep to the mucosa.

In an acute ulcer there is an acute vascular disturbance occurring chiefly just under the mucous membrane—a hypervascularity and not an ischaemia.

It is a pleasure to acknowledge the continued advice of Professor F. H. Bentley in this investigation, and the assistance of Mr. J. E. Rogers, Mr. W. G. Leslie, and Mr. J. B. Wilson, of the departmental laboratories, in the preparation of specimens and microradiographs.

The shock of the two colliery disasters, at Knockshinnoch and at Creswell, which took place within three weeks of each other in September, may have obscured the fact that mining is actually getting safer in this country. Accident statistics recently issued by the Ministry of Fuel and Power in its *Statistical Digest for 1948 and 1949* display very clearly that, though between the wars there was little or no improvement in the safety record, since 1941 every year except 1947 has shown a further decrease in deaths and reportable injuries. Thus the numbers killed in 1920, 1930, and 1940 were 1,103 (or 0.88 per 1,000 men employed), 1,013 (1.07 per 1,000), and 923 (1.20 per 1,000) respectively, whereas in 1945 the figure had dropped to 550 (0.76), and in 1948 and 1949 had sunk to 460 (0.62)—less than half the average pre-war value. The reportable injuries show a similar though less striking trend: 4,287 (3.4 per 1,000) in 1920, 3,237 (4.2) in 1940, but only 2,180 (2.9) in 1949.

OBSERVATIONS ON BLOOD FLOW IN HUMAN INTESTINE

BY

JOHN GRAYSON, M.Sc., M.D.
B.M.A. Research Scholar, 1949–50
(From the Department of Physiology, University of Bristol)

In the past most of our information concerning the visceral circulation has been derived from animal experiments. It is difficult, however, to apply the results of such experiments direct to man, for anaesthesia, operative interference, and species difference are incalculable factors. There is urgent need for the better understanding of circulatory responses in human viscera, especially as regards their relation to the control of peripheral resistance. Indirect studies have been made in such structures as the liver (Bradley *et al.*, 1945) and the kidney (Goldring *et al.*, 1940).

Friedman and Snape (1946) and Shoshkes (1948) observed colour changes in colostomies and used them mainly in the investigation of local applications of drugs. Almy and Tulin (1947) made direct proctoscopic observations in young adults to demonstrate colonic responses to stress, but the role of the intestinal blood vessels in the integration of the circulation as a whole is still inadequately understood.

In a previous investigation of the problem I also used patients on whom the operation of colostomy had been performed, employing the temperature and colour of the intestinal protrusions surrounding the abdominal stoma to detect intestinal blood-flow change in these subjects. It was shown that vascular responses in the skin were often accompanied by opposite reactions in the bowel (Grayson, 1949a). Thus cutaneous vasodilatation produced by warming the body was accompanied by a pronounced diminution in bowel blood flow, whereas during the cutaneous vasoconstriction produced by cooling a limb an increase in bowel blood flow occurred. Again, during the spontaneous fluctuations which occasionally occur in the skin of a subject at rest, opposite fluctuations were usually observed in the bowel. In other experiments the intravenous administration of the dihydrogenated alkaloids of ergot—"hydergine" or dihydroergocornine—which act mainly as cutaneous vasodilator drugs, was followed by a marked diminution in bowel blood flow which accompanied the rise in skin blood flow (Grayson and Swan, 1950).

Although such opposed vascular responses have been a striking feature of the previous investigations, the skin and bowel circulations do not inevitably show opposite responses to all stimuli. For example, intravenous adrenaline or *nor*adrenaline produces vasoconstriction in both skin and bowel (Grayson and Swan, 1950). Again, where prolonged heating of the body produces a rise in rectal temperature the initial diminution in bowel blood flow already referred to is followed by an increase. Similarly, in experiments where the rectal temperature was lowered a diminution in bowel blood flow occurred (Grayson, 1949b). In these examples the blood flow changes in skin and bowel were similar and not opposite.

The present paper, however, is concerned only with the opposed reactions that take place between skin and bowel and their possible significance in the maintenance of blood pressure.

Methods

The temperature of any animal tissue exposed to an environment at a temperature different from that of the blood depends in part on the blood flow through the organ and can be used to detect blood-flow change. This

principle has been applied to the investigation of blood-flow reactions in many organs (Schmidt and Pierson, 1934; Barcroft and Millen, 1939), and is the basis for the wide use of skin-temperature measurements in the clinical assessment of cutaneous blood-flow change (Parmenter and Benedict, 1929).

In the present work the same principle was used to detect blood-flow changes in the tissue of exposed colostomies, caecostomies, or ileostomies. The experimental procedure, with its limitations, has been described elsewhere (Grayson, 1949a; Grayson and Swan, 1950). Briefly, however, temperatures were measured by means of fine needle thermocouples inserted into the mucosa or muscle layer of the colostomy, connected to a moving-coil galvanometer, whose movements were recorded continuously on a kymograph by means of a manually operated mechanical device (Schmidt and Pierson, 1934). The subjects, in general, were in late middle life and often in poor physical condition; the information refers only to the mucous or muscular coats of the bowel—ileum, caecum, or colon—not to the splanchnic area as a whole; but the method has afforded valuable qualitative information concerning the circulation in the human intestine.

Results

The following experiments were intended to relate the bowel blood-flow changes which occur during heating or cooling of the body to blood-pressure changes, and to investigate the mechanism by which such changes are effected.

Methods

The temperature of the muscle coat of the colostomy was recorded, together with the temperature of the dorsum of the right index finger and, where possible, the rectal temperature. Blood pressure was measured by the auscultatory method. Cutaneous vasodilatation was produced by covering the body with blankets. The area of skin exposed to the room air was thus reduced, and the total reflex vasoconstrictor effect of cold at the body surface thereby diminished, which permitted passive dilatation without change in rectal temperature. Cutaneous vasoconstriction was produced either by removing blankets from a subject previously covered, thus increasing the peripheral cold stimulus, or by immersing a limb in cold water.

Effect of Decreasing Cold

In the experiment shown in Fig. 1 the effects accompanying reflexly induced cutaneous vasodilatation are shown. The subject was an elderly man with a colostomy of the descending colon, performed nine months previously. He lay on a couch throughout, and temperature and blood-pressure observations were made as described above. The initial readings were taken with the subject completely exposed to the room air at 20° C. He was then covered with blankets, except for the colostomy and a small area of abdominal wall surrounding it. The skin temperature of the right index finger rose rapidly, and simultaneously the systolic and diastolic blood pressures began to drop. After 25 minutes of warming, the blood pressure reached a minimum and then rose again to resting levels. The colostomy temperature began to fall with the rise in skin temperature and continued to fall while the blood pressure was rising. Similar results were obtained in eight other cases. In some cases the bowel reactions were also accompanied by a distinct pallor of the colostomy.

Removing cold stimulus from the body surface thus produced a diminution in blood flow in the bowel. The fact that the diminution in bowel flow continued even during the rise in the blood pressure which occurred after 25 minutes of warming suggested that it was due to an active intestinal vasoconstriction and was not, therefore, simply a passive effect of falling blood pressure.

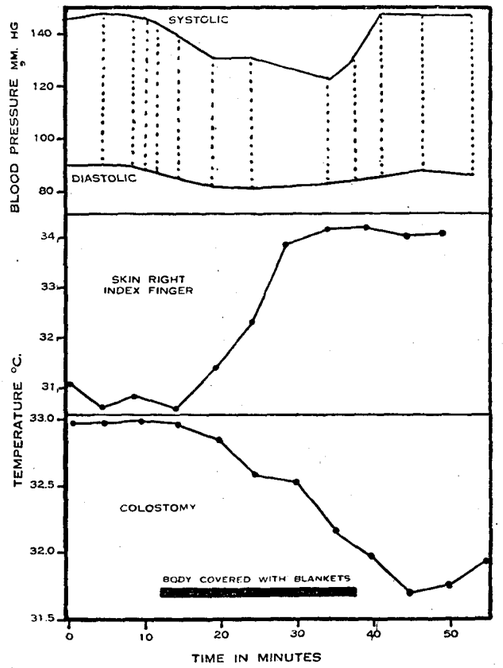

FIG. 1.—Blood pressure and temperature reactions—colostomy and skin—during removal of cold stimulus. The subject was exposed to the room air for 40 minutes before covering.

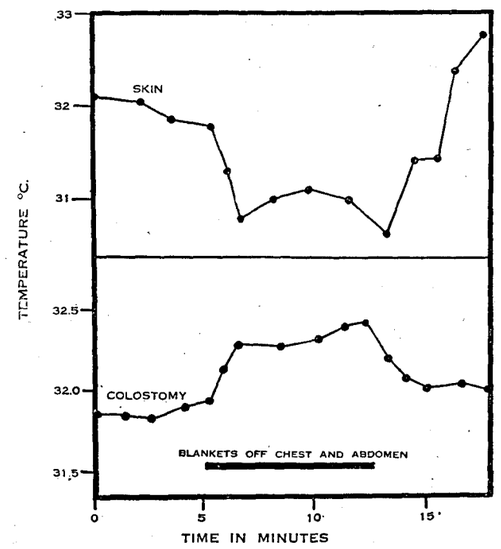

FIG. 2.—Temperature reactions—colostomy and skin—on exposing the body surface to cold. The subject was covered for 40 minutes before exposure to the room air.

Effect of Increasing Cold

Experiments were performed on subjects previously covered with blankets for resting periods of half an hour. Peripheral cold stimulus was increased by uncovering a part of the body or by immersing a limb in cold water.

Fig. 2 shows the effect of exposing the upper abdomen and chest to the cold of the room. There was no drop in rectal temperature. There was a rise in systolic and diastolic blood pressures, a drop in skin temperature from the right index finger, and an increase in the temperature of the exposed colostomy. On covering the abdomen and chest again the blood pressure, skin temperature, and colostomy temperature returned to resting levels. Similar results were obtained on all occasions. In some cases in which the colostomy tissue was pale to start with there was visible flushing. Cold stimulus therefore caused an increase in the bowel blood flow. In some cases the blood pressure returned to resting levels while the bowel temperature was still rising, suggesting that the increase in bowel blood flow was the result of vasodilatation in the bowel blood vessels.

Similar results were obtained when a limb was immersed in water, provided no change occurred in rectal temperature. Fig. 3 shows the result of an experiment in which an arm was immersed in a stirred water-bath at 16° C. Vasodilatation took place in the bowel and was maintained until after the rectal temperature had fallen. Fig. 4 shows the result of an experiment where an arm was immersed in cold water for 12 minutes after previous occlusion of its circulation by means of a sphygmomanometer cuff inflater to 200 mm. Hg. Immersion of the occluded limb produced a marked increase in colostomy temperature and flushing of the bowel, which accompanied a pronounced drop in skin temperature from the opposite index finger (not shown in diagram) and a rise in blood pressure. The blood pressure began to fall after five minutes' immersion and returned slowly to baseline. Release of the occlusion pressure produced a fall in rectal temperature, a further drop in the temperature of the opposite index finger, and a fall in bowel temperature below its original resting level.

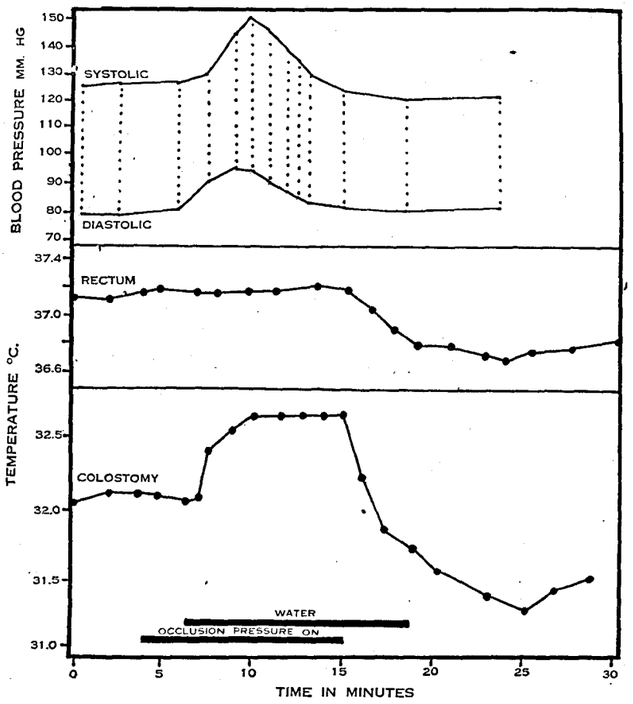

FIG. 4.—Blood pressure and temperature records—colostomy and rectum—following occlusion of the right arm and immersion in water at 16° C.

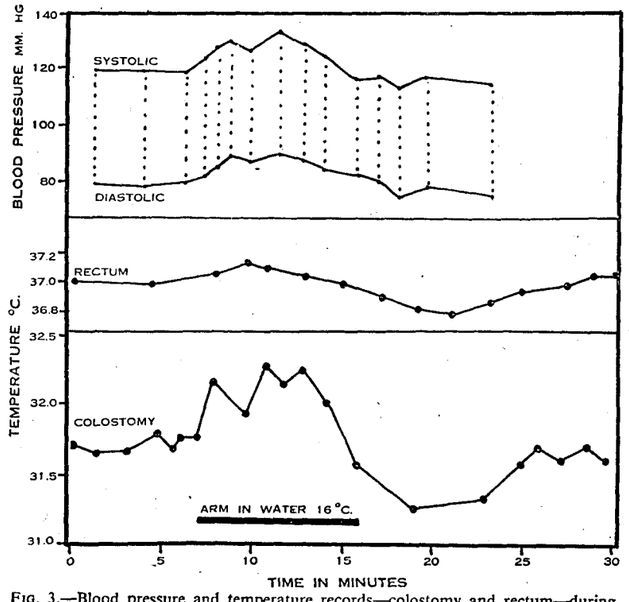

FIG. 3.—Blood pressure and temperature records—colostomy and rectum—during immersion of an arm in water at 16° C.

Effect of Locally Applied Procaine Hydrochloride on Bowel Responses

The investigation of the nervous pathways which may be involved in the control of the intestinal circulation afforded considerable difficulty. The efferent nerves supplying the colostomy cannot be easily blocked; nor has a colostomy subject been found on whom a total sympathectomy has been performed. It is hoped that recent work with new techniques may give a direct answer to this problem, but meanwhile an indirect approach has been found necessary, using local analgesic infiltrated direct into the colostomy tissue.

In one experiment a patient with two abdominal stomata was used. The intestinal tissue surrounding the upper stoma was infiltrated with 0.5 ml. of procaine hydrochloride, and the tissue of the lower stoma with 0.5 ml. of physiological saline—both solutions warmed to 32.5° C.—just

below initial bowel temperatures. The temperature of the procaine-infiltrated stoma rose from 32.6° to 33.5° C. and remained steady at the new level. The temperature of the lower stoma was unaffected by saline infiltration. In 15 experiments in which the procedure was used procaine infiltration caused an increase in recorded colostomy temperature. The extent of the increase depended in part, however, on the initial temperature of the bowel.

Fig. 5 shows the results of three experiments in which procaine was infiltrated near the recording thermocouple. The colostomy temperature after infiltration rose from

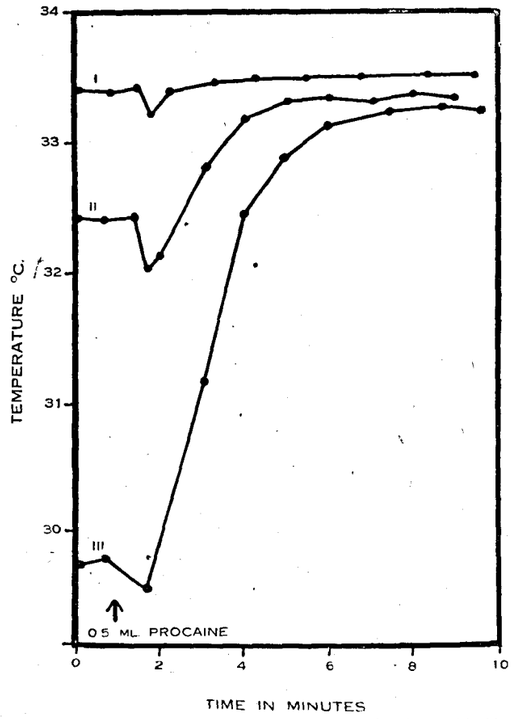

FIG. 5.—Effect of local infiltration of procaine hydrochloride on colostomy temperature in three subjects. The solution in each case was warmed to just below the initial colostomy temperature.

29.7°, 32.4°, and 33.3° C. to about 33.5° C. Colour changes were also observed, and colostomies which were pale or pink in colour flushed bright red after procaine infiltration. Colostomies which were already red and hot showed no colour change. It must be concluded, therefore, that infiltration with procaine causes relaxation of vasomotor tone in the colostomy tissue.

Effect of Intravenous Adrenaline in the Presence of Local Procaine

Intravenously administered adrenaline or *nor*adrenaline has previously been shown to produce vasoconstriction in the human bowel (Grayson and Swan, 1950). Fig. 6 shows the results of intravenous *nor*adrenaline administered to a colostomy subject with two abdominal stomata, the upper stoma having previously been infiltrated with 0.5 ml. of 1% procaine. A similar drop in bowel temperature occurred in both stomata. Similar results were obtained in two other experiments using adrenaline, and it is concluded that the action of circulating adrenaline or *nor*-

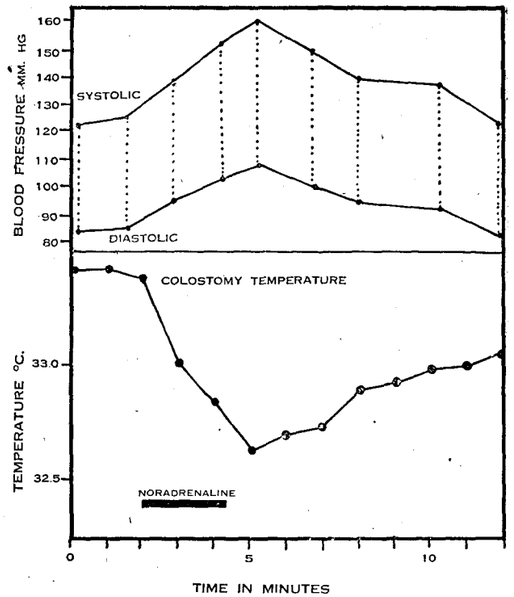

FIG. 6.—Effect of intravenous *nor*adrenaline on the temperature of a procaine-infiltrated colostomy. The lower stoma of the same colostomy—not infiltrated—showed a similar drop.

adrenaline is undiminished by the presence of local procaine. Procaine has already been shown to abolish the resting tone of the blood vessels of the colostomy. It must be concluded, therefore, that adrenaline or *nor*adrenaline plays little part in the maintenance of this tone.

Action of Heat and Cold in the Presence of Procaine

Fig. 7 shows the result of an experiment using a colostomy subject with two abdominal stomata. The upper stoma was infiltrated with 0.5 ml. of 1% procaine. The lower stoma remained unanaesthetized. The subject was covered with blankets and the legs placed in hot water. The skin temperature of the lower, unanaesthetized, stoma fell concomitantly, whereas no change occurred in the temperature of the upper, anaesthetized, stoma.

In a different subject, the left arm was immersed in cold water. Vasoconstriction occurred in the skin with an increase in recorded bowel temperature. The arm was removed from the cold water and immersed in water at 36° C. The skin temperature and the colostomy temperature returned rapidly to resting levels. The bowel was then infiltrated with 0.5 ml. of 1% procaine. Its temperature rose from 32° to 33.9° C. Placing the arm in cold water now had no effect on the bowel temperature. Similar results were obtained in two further experiments using different subjects.

In these experiments, therefore, infiltration of the bowel with procaine prevented the intestinal vasoconstrictor action of external heat and the intestinal vasodilator action of external cold. In view of the fact that the action of adrenaline or *nor*adrenaline is unaffected by the presence of procaine these effects in the unanaesthetized subject cannot have been brought about by the circulation of these sympathomimetic drugs. It is not possible, unfortunately, to be certain of the precise action of locally infiltrated procaine. The experiments show that it relaxes vasomotor

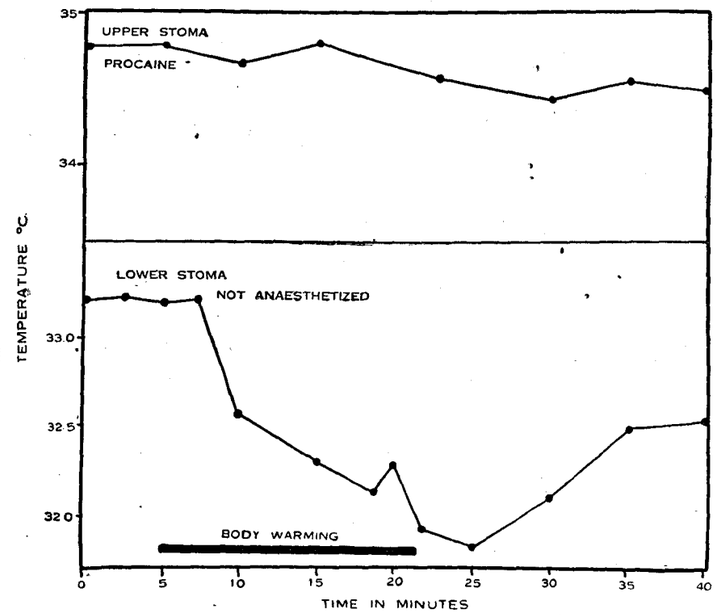

FIG. 7.—Effect of locally infiltrated procaine on the intestinal vascular response to heat

tone, but whether this is accomplished through blockage of the terminal ramifications of the vasomotor nerves or through some direct action on the blood-vessel wall it is not yet possible to say.

Discussion

Almy and Tulin (1947), using direct proctoscopic examination of the intestinal mucosa in man, showed that stress resulting from mechanically induced headaches or painfully cold stimuli produced hypertension, pallor of the skin, and a significant engorgement of the mucosa. In the present work similar effects were frequently produced by much more moderate stimuli. Thus, cooling the body surface caused a rise in blood pressure, vasoconstriction in the skin, and vasodilatation in the bowel. On the other hand, warming the body surface produced opposite effects. It seems that under a variety of conditions, apart from those described by Almy and Tulin, there is a relation between the cutaneous circulation, the blood pressure, and the intestinal circulation. The mechanism of the skin reactions will be considered first.

Cutaneous blood-flow changes in response to alterations in external temperature were once thought to be largely initiated by minute fluctuations in blood temperature and mediated through the sympathetic nerves (Pickering, 1932). Although there can be little doubt that big changes in blood temperature exert central vasomotor effects, recent work leaves little doubt that cutaneous vascular responses of the type used in the present work are mainly reflexly initiated in the skin and occur regardless of change in blood or rectal temperature (Kerslake and Cooper, 1950). Exposing the abdominal wall to the cold of the room initiates reflex cutaneous vasoconstriction; covering the body with blankets removes the surface stimulus of cold and produces passive vasodilatation (Grayson, 1950).

The changes in bowel blood flow which accompany the cutaneous reactions are not brought about simply by alterations in blood pressure. A diminution in bowel flow often occurred with a rising blood pressure, and an increase in bowel flow has been observed while the blood pressure was falling. The intestinal vascular responses must therefore be due to active vasoconstriction or vasodilatation. Three possible mechanisms suggest themselves. Intestinal vascular responses could be brought about by the liberation of some unspecified humoral agent; they could be effected by direct skin-initiated reflexes, analogous to the cutaneous vascular responses; or they could be the reflex result of the blood-pressure changes which occur during heating or cooling the body.

Friedman and Snape (1946) showed that mild pain or apprehension produced blanching of the mucosa of a child's colostomy. This was thought to be an effect of adrenaline liberation. In the present experiments, however, procaine infiltration of the colostomy eliminated the possibility of adrenaline or noradrenaline being humoral agents responsible for the intestinal vasoconstriction accompanying body-warming. Thus it is not likely that reflex stimulation or inhibition of the suprarenal medulla is responsible in any way for the effects described. It is hard to picture any alternative humoral mechanism which could act similarly, and it seems most probable that the intestinal vasoconstriction and vasodilatation observed in these experiments are brought about through efferent nervous pathways.

The present work does not finally answer the question of the initiating mechanism where the bowel blood-flow reactions are opposite to those in the skin. The possibility that cooling the skin produces vasodilatation in the bowel through direct reflex pathways cannot be eliminated. But it should be remembered that opposed reactions in the skin and bowel occasionally occurred spontaneously without stimulation of the skin. The intravenous administration of hydergine or dihydroergocornine, again, produces opposed skin and intestinal responses. These drugs act principally on the skin vessels, producing profound vasodilatation and a drop in blood pressure. They also cause vasodilatation when applied direct to the bowel wall, yet when administered intravenously they produce marked intestinal vasoconstriction. It is hard to avoid the conclusion that intestinal vasoconstriction is produced, here, in response to general circulatory demands, the need for a decreased intestinal blood flow overriding the local vasodilator action of the drugs.

In all the reactions which have been considered a change in blood pressure was a constant feature. Thus removal of cold stimulus from the surface of the body produced cutaneous vasodilatation accompanied by a drop in blood pressure which preceded the intestinal vasoconstriction. Again, cutaneous vasoconstriction was accompanied by a rise in blood pressure which preceded the intestinal vasodilatation. It is suggested that these intestinal effects might well be the result of blood-pressure changes which act through carotid sinus, aortic, or other similar reflexes to modify intestinal vasomotor tone and thereby restore the peripheral resistance. If further work should confirm this

suggestion it is evident that the vascular responses described are fundamental to the peripheral regulation of blood pressure.

Summary

Blood-flow changes in human intestine have been detected by means of temperature records from the exposed intestinal tissues of colostomies.

Cold stimulus applied to the body surface produces cutaneous vasoconstriction, intestinal vasodilatation, and a temporary rise in blood pressure.

Removal of cold stimulus from the surface of the body produces cutaneous vasodilatation, intestinal vasoconstriction, and a temporary fall in blood pressure.

Procaine hydrochloride infiltrated into the exposed bowel relaxes vasomotor tone and prevents the occurrence of vasoconstriction in response to heat and of vasodilatation in response to cold, although the vasoconstrictor action of intravenous adrenaline or *nor*adrenaline is not affected.

It is suggested that the intestinal effects are brought about reflexly through the alterations in blood pressure.

I am grateful to Professor R. J. Brocklehurst for his help and advice, and to Mr. C. J. Wilks for technical assistance.

HEXAMETHONIUM BROMIDE IN DUODENAL ULCER

BY

L. D. W. SCOTT, M.D., M.R.C.P.

AND

J. A. SIMPSON, M.B., M.R.C.P.

(From the Peptic Ulcer Clinic, Western Infirmary, and the Southern General Hospital, Glasgow)

Paton and Zaimis (1949) have shown that hexamethonium produces blockade of autonomic ganglia. When given intramuscularly it constantly inhibits gastric secretion and motility (Kay and Smith, 1950a). When given by mouth it has a similar though less constant action (Kay and Smith, 1950b). These properties suggest that it may be of value in the treatment of duodenal ulcer.

To evaluate a method of treatment for duodenal ulcer is peculiarly difficult, for it must be based almost entirely on the subjective evidence of the relief of symptoms, and, moreover, there is the danger that improvement due to spontaneous remission may be attributed to the treatment. This paper reports a therapeutic trial designed to avoid these fallacies.

Method of Study

Selection of Cases.—Twenty male patients were taken from those attending the Peptic Ulcer Clinic at the Western Infirmary. Their ages ranged from 21 to 62 years. All had both clinical and radiological evidence of duodenal ulcer and had had symptoms for more than six years. All were suffering severe disability which was refractory to medical treatment and which would ordinarily have merited gastrectomy. Patients known to have pyloric stenosis were excluded, but one patient accepted for trial was later found to have this complication.

Plan of Trial.—Alternate patients were allocated to one of two groups. Group A received hexamethonium bromide (500 mg. at 8 a.m., 2 p.m., and 8 p.m.). Group B received a powder of similar bromide content and similar taste and appearance, consisting of potassium bromide (3 gr.–0.2 g.) made up to bulk with lactose. In all other respects the treatment and assessment of the two groups were identical. The allocation of patients to the two groups and the dispensing of the appropriate powders was done by one of us (L. D. W. S.), who took no part in assessing the results. The assessment was made by A. W. K., who had no means of distinguishing the two groups until the completion of the six-months period of observation. At the outset of this investigation little was known of the side-effects produced by the prolonged oral administration of hexamethonium bromide. It was therefore considered necessary to admit the patients to hospital for six weeks. Thereafter they returned to work and were treated as out-patients for a further 18 weeks. All patients were given ordinary diet from the main kitchen of the hospital unless they complained of severe dyspepsia. Alkali was used only when pain was severe. The patients were encouraged to be up and about during the day and were allowed home on pass one day a week, leaving hospital after lunch and returning at night. After discharge from hospital they were encouraged to take ordinary diet and resume full activities.

Clinical Assessment.—Success or failure in treatment was judged on clinical grounds. The assessment was made on a numerical basis. While in hospital, twice a day each patient was asked by the ward sister if he had any dyspepsia, and the answer was recorded on a chart. If there had been no complaint of any gastric upset a nought ("0") was recorded. Water-brash, heartburn, or discomfort was represented by "1," mild pain by "2," fairly severe pain by "3," and very severe pain by "4." After leaving hospital patients were instructed to keep a similar pain chart. They reported weekly, when further assessment was made by interrogation.

Clinical Results

Group A.—Of the 10 patients treated with hexamethonium bromide six completed the course of 24 weeks. Four were adjudged to be greatly improved, three having remained symptom-free for from 14 to 20 weeks, and the fourth complaining of occasional mild heartburn lasting no more than 10 minutes at a time. Two continued to have mild symptoms. One defaulted after eight weeks though suffering no more than mild dyspepsia at that time. One patient, after seven weeks' treatment without relief, was found to have pyloric stenosis. Two patients suffered severe relapses after periods of improvement and were assessed as failures in the 15th and 23rd weeks.

Group B.—Of the 10 patients treated with potassium bromide, two completed the trial of 24 weeks. None remained symptom-free throughout the period of observation. Two, though continuing to have dyspepsia, were regarded as somewhat improved. The remainder either gained no relief, or relapsed and were accounted failures, in the 2nd, 4th, 7th, 10th, 11th, 12th, 13th, and 15th weeks.

Side-effects

As hexamethonium bromide given by intramuscular injection is known to cause hypotension in some individuals, particular attention was paid to the cardiovascular system. At first the blood pressure and the pulse rate were recorded twice daily, but in the absence of any noteworthy changes these observations were made only once daily in the later stages of the patients' stay in hospital. A close watch was kept for syncopal attacks, and daily inquiry was made regarding faintness and lightheadedness. Inquiry was also made concerning difficulty in reading as a result of paralysis of accommodation, and a daily note was made of the size of the pupils. The occurrence of constipation, which might conceivably follow the continued use of a ganglionic blocking agent, was also recorded. Since the two groups of patients were indistinguishable, these records were necessarily made in all cases and were not confined to those patients taking hexamethonium bromide.

Group A.—In the group taking hexamethonium bromide the side-effects were with one exception slight or inconstant. The exception was a patient who experienced difficulty in reading while in hospital and who had a minor syncopal attack due to hypotension after dismissal. The dose of the drug was then reduced to 500 mg., taken on retiring, and no further trouble was experienced. This patient developed achlorhydria in response to the drug and was ultimately classed as greatly improved. While in hospital two patients in this group had lightheadedness on standing up and four experienced blurring of vision. These side-effects were noticed only during the first week of treatment or after testing the patient's response to hexamethonium bromide. In this test the patient fasted for a period of seven hours and it seems clear that side-effects are much more likely to occur when the drug is taken in the fasting state. It was further noted that the development of side-effects did not necessarily parallel the change in gastric acidity; hypotension and hypochlorhydria might occur separately. In the continued trial, four patients complained of constipation, which responded to simple measures.

Group B.—Of those patients given potassium bromide, one complained of difficulty in reading for a period of 24 hours and two developed constipation, which they attributed to the treatment.

Effects on Gastric Acidity

Gastric analyses were begun at 9 a.m., after a 12-hour fast. The fasting juice was aspirated, and specimens were removed at half-hour intervals thereafter for three hours. Special precautions were taken to empty the stomach at each aspiration. The volume of each specimen was measured and free and total acids estimated, using the usual double indicator.

Before beginning treatment, two such tests were made on successive days in each case. These analyses were intended to show the gastric acidity in the untreated patient and to serve as a control for future observations.

Subsequently, gastric analysis was made four hours after the administration of a powder. This analysis was intended to serve as a test of each patient's response to hexamethonium bromide, and the interval of four hours was chosen, since it is known that when the drug is effective by mouth a lowered acid level can be expected at this time (Kay and Smith, 1950b).

Once treatment had been started, at weekly intervals an "interval gastric analysis" was made 13 hours after the last dose of powder. These tests were planned to demonstrate any possible cumulative effect resulting from continued administration of the powder.

Results of Gastric Analyses

The results of two preliminary control analyses on each patient confirmed that the level of gastric acidity in any individual may vary from time to time even under standard conditions. Allowance had to be made for this before crediting any observed alteration in acidity to the treatment.

Group A.—In the group of 10 patients taking hexamethonium bromide three developed achlorhydria, as judged by Töpfer's reagent, in response to a test dose. The anacidity persisted during the three hours of the test. Two of these patients were eventually regarded as greatly improved (Fig. 1). One patient, who also became symptom-free, showed a substantial reduction in acid level. An unaffected acid level was found in the remaining six patients; one of these became symptom-free (Fig. 2). In four cases "interval gastric analyses" showed some reduction in the level of gastric acidity, which was maintained throughout the period of observation in hospital (Fig. 3). There was, however, no evidence of progressive diminution of the acid level in response to continued treatment. We

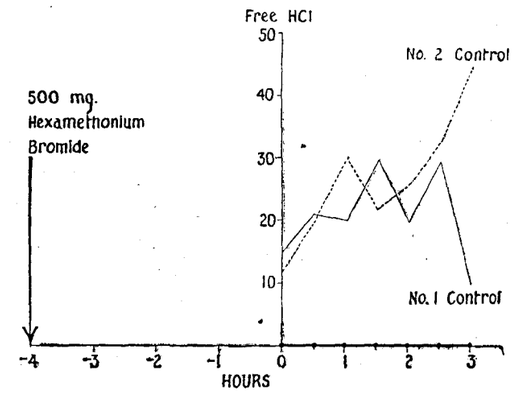

FIG. 1.—Case showing achlorhydria after a test dose of hexamethonium bromide. (The readings for the treated case lie on the base line.) This patient became symptom-free.

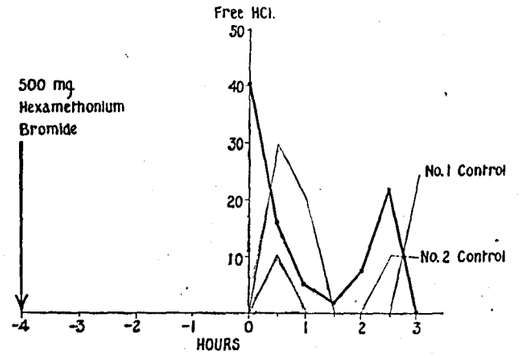

FIG. 2.—Case showing an unaffected acid level after a test dose of hexamethonium bromide. This patient became symptom-free.

have therefore been unable to show that hexamethonium bromide has any cumulative action on the gastric secretion of hydrochloric acid.

Group B.—None of the patients taking potassium bromide showed any change in the acid level that could be attributed to it even on the most optimistic evaluation.

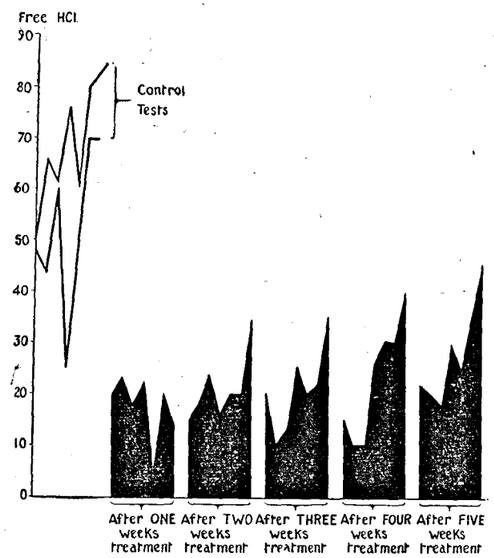

FIG. 3.—Case showing a consistent reduction in acid level as judged by weekly test meals, done 13 hours after the last dose of hexamethonium bromide.

This observation was of importance, since it also showed that the rest in hospital, the freedom from home cares, and the diet taken would not of themselves result in a lowering of gastric acidity.

Discussion

We have already referred to the difficulties in the way of assessing accurately the results of treatment in duodenal ulcer. In particular, there is the fallacy of attributing to the method of treatment under survey improvement due to spontaneous remission. Moreover, in view of the small number of cases in this series and the short period of observation, it is clearly not justifiable to come to any definite conclusion. The results obtained so far do, however, give some evidence of the value of hexamethonium.

It should be noted that all the cases were of the most severe type and completely refractory to orthodox medical treatment. It is therefore not surprising that in Group B (potassium bromide) only two of the ten cases showed partial improvement. On the other hand, in Group A (hexamethonium bromide) the almost complete relief of symptoms in four cases and the partial relief in another two suggest that hexamethonium may be of value in the treatment of duodenal ulcer. If this is so, it remains to be seen how it acts.

We have shown that when taken by mouth the drug can lower the acid level in some cases. However, this action is inconstant and may not be responsible for the clinical improvement. In Group A we observed indisputable lowering of the gastric acidity in four cases. Three of these were ultimately classified as successes and one as a failure. On the other hand, we were unable to show any fall in acidity in one patient who became symptom-free. It is not yet certain that patients showing a marked lowering of gastric acidity at the beginning of treatment will continue to do so after prolonged administration of hexamethonium. Since this drug has a greater effect on gastric acidity in the fasting subject (Kay and Smith, 1950b), its eventual place in the treatment of peptic ulcer may be to control nocturnal hyperacidity. On the other hand, too much attention may have been paid to change in gastric acidity and the action of hexamethonium as an inhibitor of gastric motor activity ignored. Study is continuing on this point.

Useful information has been gained about the side-effects after prolonged administration of hexamethonium. With one exception these effects were slight and the patients were able to continue normal work. Lightheadedness and blurred vision were infrequent, and occurred during the first few days of treatment or when the patient had been fasting. Serious constipation did not occur. The one exception complained of blurred vision and had a minor syncopal attack due to hypotension, but became symptom-free on a single dose of 500 mg. of hexamethonium bromide on retiring. Although the side-effects were infrequent and of a minor nature, we suggest that care should be used, especially in the early days of treatment and when the drug is taken in the fasting state.

Summary

A controlled investigation of the treatment of duodenal ulcer by hexamethonium bromide is reported. While not conclusive, it provides evidence of marked improvement in four and some improvement in two of the ten treated cases. The clinical improvement was not always accompanied by demonstrable reduction in the acidity of the gastric juice. Side-effects occurred most often at the beginning of treatment or when the drug was given to fasting patients.

We are indebted to Professor C. F. W. Illingworth for his direction and helpful criticism throughout this investigation. We wish to acknowledge the assistance given by Dr. A. N. Smith, Dr. Mary Forbes, and Dr. John Raeside. Our thanks are also due to May & Baker Ltd. for generous supplies of hexamethonium bromide.

An international standard for the adrenocorticotrophic hormone (A.C.T.H.) has been established by the Expert Committee of the World Health Organization on Biological Standardization. The committee also set up international standards for fifteen other biological substances, including anti-Rh, anti-A, and anti-B blood-grouping sera; lecithin and cardiolipin, recently introduced with great success in diagnostic tests for syphilis; tubocurarine, used to obtain muscular relaxation of the patient in anaesthesia; streptomycin and dihydrostreptomycin, the latter being considered to be less toxic than streptomycin and therefore less likely to produce side reactions; aureomycin and terramycin, two new antibiotics which have proved successful where penicillin has previously failed; and diphtheria toxoid, for immunization against diphtheria. A standard was also set up for hyaluronidase (spreading factor), used for intracutaneous injections in small children where intravenous injections would be difficult or impossible. A W.H.O. Expert Committee which had been asked to investigate the possibilities of producing dried smallpox vaccines for the Tropics, where it has been difficult, owing to climatic conditions, to conserve liquid smallpox vaccines in a fresh and active state, recently set up guiding principles to be followed by manufacturers of dried vaccines.

POLIOMYELITIS IN LONDON IN 1949

BY

G. E. BREEN, M.D., D.P.H., D.O.M.S.
Late Epidemiologist, London County Council

AND

B. BENJAMIN, B.Sc., F.I.A., F.S.S.
Statistician, Public Health Department, London County Council

After a respite of but one year poliomyelitis struck again at the population of London County. In 1948, in London as elsewhere, the incidence of the disease fell to the endemic level of the years preceding the first explosion of 1947, but in 1949 the second epidemic occurred of much the same proportions as the first. In 1947 there were 702 "corrected notifications" in London, with a fatality rate of 7%; in 1949 there were 668 corrected notifications, with a fatality rate of 7.1%. There were, however, peculiar differences between the two epidemics, which are recorded here to add to the patient accumulation of evidence which may yet provide the solution to the epidemiological riddle presented by poliomyelitis.

Timing

Both summers were on the whole hot and dry compared with the damper, cooler summer of 1948. The climatic conditions are compared in Table I. It will be seen that the summer rainfall in 1947 and 1949 was much lower than in 1948, whereas the temperatures were higher. The epidemic rise began almost at the same time in the two years.

As has already been recorded in detail (Daley and Benjamin, 1948), the rise in notifications in 1947 occurred in the week ending May 31, while in 1949 the disease became epidemic about the middle of June. Whereas, however, the first epidemic gathered momentum rapidly, especially during July, and reached a sharp peak at the end of August, the 1949 outbreak grew slowly, so that even in July there was doubt whether it would reach the proportions of the 1947 outbreak. The notifications, however, climbed gradually and steadily through August, remained more or less stationary in September and October, and finally reached a late peak at the beginning of November. Decline was at first as rapid as in 1947, but through December the incidence stabilized at an abnormally high level, and the usual

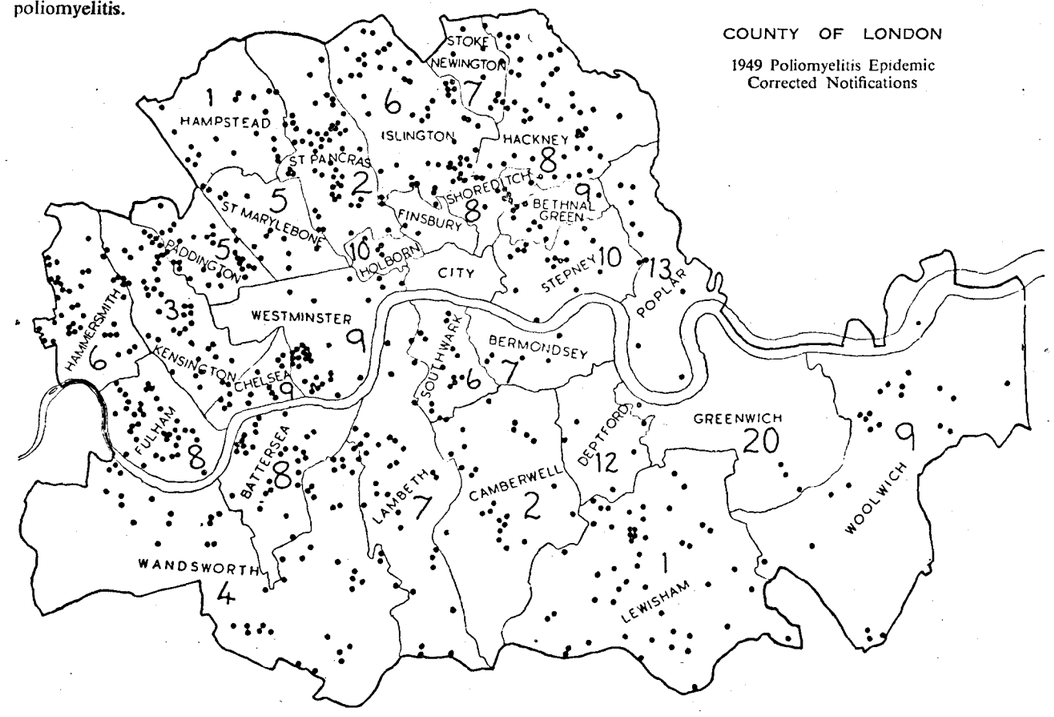

TABLE I.—*Weather Conditions 1947–9 (From the Royal Observatory, Greenwich)*

Month	Mean Daily Temperature (° F.)			Mean Degree of Humidity*			Mean Weekly Rainfall†

† Rain collected in a gauge whose receiving surface is 5 in. (12·7 cm.) above the ground. The figures are the means of the sums of the weekly rainfall.

interepidemic level was not reached until the middle of January, 1950.

There is no obvious climatic reason why the 1949 epidemic curve should have begun to rise so slowly, but it is possible that the fall in temperature during September may have checked any tendency to an accelerated rise, and the sharp drop in temperature (with rising humidity) in late October may have contributed to bringing the outbreak to an end. In 1947 the epidemic curve began to fall with the temperature, but the rapid decline, despite a high average temperature, suggests that the epidemic had exhausted itself regardless of climatic changes.

Geographical Distribution

The distribution of cases* in London in 1949 is shown in the accompanying map. This picture is strikingly at variance with that for 1947 (Daley and Benjamin, 1948), when, though there were isolated areas with a statistically significantly higher or lower incidence than average, the complete map gave a general impression of wide scatter, no area escaping. In 1949 the incidence was higher to the north of the Thames than to the south, and there were wide areas—for example, in Deptford and Greenwich—without recorded cases.

The numbers in the map indicate the week of epidemic rise in notifications (week ending June 18=1) in each borough. Here again there are differences. In 1947 any suggestion of spread from foci was effaced by the rapid diffusion of the attack throughout the county. The slower epidemic rise of 1949 made it possible to discern directions of spread, of which there may have been two main streams: (*a*) from Hampstead in the north-west, southward and eastward, the eastward branch finally turning south to take in Deptford and Greenwich; (*b*) from Lewisham in the south-east in a north-westward and westward direction.

Age Distribution

Here the most striking difference between the two epidemics is discernible (Table II). For some time observers in the U.S.A. have noted that the age incidence of the disease has tended steadily to rise, an observation that was confirmed in London in 1947, when only 27.9% of cases occurred in children under the age of 5 (Table III). But in 1949 the age incidence returned abruptly to its former proportion, and 53.3% of the cases occurred among children under 5. This is appreciably higher than the figure of 41.8% for the "endemic" years 1937 to 1946. Not, indeed, since 1932 has so high a proportion of cases occurred in children under 5.

TABLE II.—*Age Distribution of Poliomyelitis Cases,* 1937–49*

* "Cases" here and elsewhere in this article means "corrected notifications."

Possible Association with Inoculation

There has been a full discussion elsewhere (Bradford Hill and Knowelden, 1950) of the possibility that in some cases, and in certain circumstances, poliomyelitis may follow immunization, and since investigations are still proceeding it is not proposed to comment on this feature at present. We should stress, however, that this association, even if proved, is *not* responsible for the sharp differences in age distribution as between 1947 and 1949.

All cases notified in London were closely investigated in order to trace any history of recent inoculation.† Out of a total of 356 cases under age 5 only 58 had any such history, and only in 33 did any genuine association between paralysis and injections appear to be established; in 8 there was some doubt, and in the remaining 17 the doubt was considerable. These additional cases may have accentuated the eventual character of the outbreak, but they are not relatively numerous and cannot be the cause. We must also remember that some unrecognized "immunization" cases may—and perhaps must—have occurred in 1947. Inoculation trauma may be an important problem, but it did not colour the epidemiological picture in London in 1947 or 1949 to any important extent.

Sex

The usual preponderance of males was seen, especially between the ages of 1 and 4, where there were 181 male to 132 female cases—a ratio of 1.37 to 1, compared with 1.34 to 1 in 1947 (Table IV).

TABLE IV.—*Male/Female Ratio in 1947 and 1949*

Age	1947	1949
Under 1 year	1·67	1·15
1–4 years	1·34	1·37
5–9 ,, ...	1·64	1·24
10–14 ,, ...	1·20	1·50
15–24 ,, ...	0·68	0·75
25+	1·14	0·94
Total	1·21	1·21

In view of the small numbers involved the differences between the ratios in 1947 and 1949 cannot be regarded as statistically significant. Taken together, they indicate that the excess of males is greater at younger ages and is actually replaced by an excess of females after age 15.

Diagnosis, Progress, and Fatality

By courtesy of the medical superintendents of the hospitals concerned the following statistics were obtained of their poliomyelitis admissions in 1949, and they are compared with similar figures for 1947 (Table V).

TABLE V.—*Diagnosis, Progress, and Fatality in 1947 and 1949*

Sample from London Hospitals	No. of Cases		% of Confirmed Cases	
	1947	1949	1947	1949
Admitted with diagnosis of poliomyelitis	686	655	—	—
Diagnosis confirmed	391	354	100	100
Paralytic cases	255	218	65	62
Residual paralysis	159	162	41	46
Deaths	20	25	5	7

† "Recent inoculation" means inoculation within the four weeks preceding notification.

Multiple Cases

In 1949 more than one case in the same family was reported 14 times; in 1947 this occurred 27 times. This difference is not statistically significant. Multiple cases in 1949 were more numerous north of the river (11) than south of the river (3). Indeed, there were more multiple cases in St. Pancras (4) than in all South London. The numbers involved were, however, so small that the results cannot be regarded as statistically significant.

Discussion

The most striking features, then, of the 1949 epidemic are (*a*) the return of the age incidence to its usual level, and (*b*) the geographical distribution. In regard to age incidence, it seems reasonable to suppose that the herd immunity of the population was raised considerably during the 1947 epidemic. Thus infants born after the middle of 1947 may have had a very much lower herd immunity than the remainder of the population. It is mainly the increased incidence in the first two years of life that has caused the alteration in the percentage age distribution.

If we compare the numbers of cases at each age in 1949 with those which would have been expected if the same total of cases had been distributed as in 1947 (Daley, 1948) we obtain the differences shown in Table VI.

TABLE VI.—*Difference in Actual and Expected Cases for 1949*

Age	Actual Cases, 1949	Expected on 1947 Distribution	Difference
0–	43	30	+13
1–	116	42	+74
2–	87	45	+42
3–	73	31	+42
4–	37	38	−1
5–9	123	161	−38
10–14	50	84	−34
15–24	63	123	−60
25+	76	114	−38
Total ..	668	668	

It will be seen that the largest difference, both absolutely and relatively, is in infants between 1 and 2 years of age, and that differences are positive—that is, actually greater than expected—for infants who at the time of the 1947 epidemic were under 18 months of age and who presumably were not exposed to infection as much as older infants. Many of them would have been young enough possibly to have had some temporary protection from their mothers if the latter had experienced an infection—clinical or subclinical—at any time.

The number of cases occurring in 1949 in each borough at ages 0–14 has been compared with that expected on the basis of the average county rate, and the excesses and deficiencies have been worked out. The following are regarded as statistically significant: Hammersmith, +14.7 (high); Kensington, +13.0 (high); St. Pancras, +14.9 (high); Westminster (City), +12.3 (high); Finsbury, −4.9 (low); Poplar, −7.4 (low); Deptford, −8.5 (low); Greenwich, −12.5 (low); Lewisham, −13.1 (low); Bermondsey, −7.0 (low); and Lambeth, −13 8 (low). In general, boroughs north of the river had an incidence higher than average, while the converse was true of the southern boroughs. A greater number of births in the north than in the south might be a possible explanation of this phenomenon, but in fact the infant population (0–4 years) forms a smaller proportion of the total in the north than in the south (7.6 as compared with 8.8).

Higher local immunity after the 1947 epidemic might perhaps have influenced the local distribution of cases—high-incidence areas in 1947 having a low incidence in 1949—but the relationship is not a simple one. In 1949 Hammersmith, Kensington, St. Pancras, and Westminster showed a higher-than-average incidence; and, while Kensington and St. Pancras were areas of notably lower-than-average incidence in 1947, Westminster was only slightly so and Hammersmith was not so at all. Again the low-incidence areas in 1949 were Finsbury, Poplar, Deptford, Greenwich, Lewisham, Bermondsey, and Lambeth. Of these Lewisham, Bermondsey, Deptford, and Finsbury had a higher-than-average incidence in 1947, but Lambeth and Greenwich were only average, and Poplar was much lower than average in *both* epidemics.

Boroughs, of course, are not closed communities; on the contrary, neighbouring communities affect each other, and this prevents their behaving as independent variables. Consider two neighbouring communities A and B. Suppose that in 1947 A had higher-than-average incidence while the incidence in B was only average. Let us assume that from causes other than relative immunity the incidence in B in 1949 is much higher than average; it would constitute a large reservoir of infection so close to A as perhaps to outweigh the advantage of the immunity gained by the high incidence of A in 1947, and so lead to A again having a higher-than-average incidence. This would need to happen only to a small extent to upset the simple correlation between 1947 and 1949; in fact, it did happen only to a small extent, and not in any instance where deviations from average were statistically significant in both years. Examples are Fulham, Chelsea, and Hackney—above average in 1947, surrounded or bordered by high incidence in 1949, and again above average in that year.

Conversely, there will be some boroughs which experienced low incidence in 1947 and which would be expected to be above average in 1949 but failed to be because they were surrounded by small reservoirs of infection. Examples of this are Stepney and Poplar, Camberwell, Greenwich, and Woolwich. The result is to obscure the effect of the 1947 epidemic in modifying the herd immunity in 1949, and, by the same token, it invalidates any attempt on this occasion to relate the inter-borough variations to social factors such as housing or economic environment.

Summary

An account is given of the outbreak of poliomyelitis in 1949 in the administrative County of London. The effect of the earlier outbreak in 1947 in raising herd immunity may perhaps be seen in the much younger age distribution of cases, which reverses the trend of the last twenty years, and to some extent in the changed geographical distribution of cases.

A sample of hospital admissions indicates that the percentage of paralytic cases was approximately the same as in 1947.

Sex ratios were not significantly altered. The fatality rate (approximately 7%) was the same in both outbreaks. The 1949 outbreak showed a more leisurely development both in time and in space than the previous epidemic.

Our thanks are due to Sir Allen Daley for permission to publish this account and for helpful criticism; to Dr. J. S. Anderson, Grove Hospital; Dr. J. F. Armstrong, Brook Hospital; Dr. H. S. Banks, Park Hospital; Dr. W. H. Kelleher, Western Hospital; and Dr. R. Swyer, St. Ann's Hospital, for their kindness in furnishing statistics of their poliomyelitis admissions in 1949.

Medical Memoranda

Gummatous Infiltration of Oesophagus Masquerading as Carcinoma

The operation of transthoracic partial oesophagogastrectomy has passed the experimental stage and is now regarded rightly as the routine procedure in the operable case of cancer of the lower oesophagus. This extensive operation, performed as it is on patients often debilitated by slow starvation, carries with it a mortality above that of most standardized procedures for the resection of carcinoma elsewhere. It therefore behoves the surgeon to be very certain of his diagnosis before embarking on the operation, and the report of the following case may serve as a reminder that other pathological conditions may mimic malignant disease.

CASE REPORT

The patient, a man aged 77, first attended hospital in May, 1948, with a five-months history of increasing difficulty in swallowing solid food. He felt as if the food stuck at the lower end of the sternum, and on frequent occasions he had regurgitated his meal almost as soon as he had taken it. At the time when he was first seen he had reduced his diet to semisolids and fluids only. He did not complain of pain, and he denied marked loss of weight. There was no relevant past history. The patient was an intelligent but frail old man showing signs of loss of weight. Except for obvious anaemia there were no abnormal physical signs. Blood examination showed: Hb, 38% ; R.B.C., 2,830,000 ; C.I., 0.68 ; W.B.C., 5,600 ; and W.R., ++. A barium swallow was reported as showing "undoubted carcinoma of lower third of the oesophagus," and comparison with a film taken three months previously showed considerable extension of the disease. The patient was admitted for oesophagoscopy and biopsy. At the time of the instrumentation there was a technical failure and the procedure was abandoned. It was considered that, as radical resection would not be possible in view of the frail condition of the patient, further instrumentation was not desirable. He was referred to St. Bartholomew's Hospital with a view to treatment by irradiation, but it was considered that he was unlikely to benefit by this form of therapy.

Over the next few months, contrary to all expectation, the patient's condition did not deteriorate and it became obvious that doubt must be cast on the diagnosis. He was readmitted for oesophagoscopy, and a granular area at the lower end of the oesophagus was observed. Biopsy from this area revealed no carcinoma. In view of the very strongly positive W.R. the patient was put on iodides, and within a short time his swallowing had improved dramatically. He now eats any food without discomfort or difficulty, and at nearly 79 years of age is in very good health.

COMMENT

In view of the strongly positive W.R. and the marked improvement on iodides, it can be assumed reasonably that the patient was suffering from a gummatous infiltration of the oesophageal wall. Such cases, although rare, are well recognized, and Guyot (1931) was able to collect 55 cases from the literature when reporting two from his own practice. The symptoms produced by this lesion are indistinguishable from those associated with a carcinoma, and the resulting stenosis may be as complete. Even with antisyphilitic treatment subsequent dilatation of the resulting stricture may be necessary. Perforation of a gummatous lesion has also been reported (Rodrigo Sabalette and Garcia Martinez, 1945).

A positive W.R. is not always present to help the diagnosis, and of course such a finding is a common accompaniment of carcinoma. Oesophagoscopy may leave the surgeon quite sure that he is dealing with a malignant lesion, and Abel (1929) reports a case in which the lesion appeared so typical of carcinoma that, in spite of a negative biopsy, the condition was treated with radium applicators. Subsequent progress of the disease and further repeated biopsies left no doubt that the condition was due to a gummatous lesion. Leucoplakic patches may sometimes be seen in the oesophageal mucosa above the site of a gummatous infiltration, but ultimately the diagnosis must depend on repeated biopsies, persistently negative for carcinoma, and the response of the symptoms to antisyphilitic treatment.

STANLEY O. AYLETT, F.R.C.S.,
Surgeon, Metropolitan Hospital.

Oedema of Glottis Treated by Tracheotomy

A generation ago emergency tracheotomy was largely performed in cases of laryngeal diphtheria, but, fortunately, since the widespread use of immunization in this country it is now rarely necessary. That it may still be required occasionally is shown by the following case.

CASE REPORT

A road-sweeper aged 34, of good physique and in good health, reported sick at 1.30 p.m. on September 26, 1949, complaining of difficulty in swallowing of recent onset. Examination showed an apparently normal throat. An anodyne was prescribed and he was sent home to rest. At 4.30 p.m., on an urgent call, he was seen at home and was obviously very ill ; a respiratory stridor was audible throughout the house. The patient was pacing the room, occasionally grasping a bed rail in an effort to draw breath. Unable to speak, he made signs that he was choking. It was obvious, in view of his wild behaviour and "bad" colour, that there was a need for tracheotomy.

At 4.35 p.m. a vertical midline incision was made from the cricoid level downwards for 1½ in. (3.75 cm.), without anaesthetic. Much dark blood oozed from the purplish tissues. The trachea was identified by touch. After displacing the pretracheal muscles to either side and extending the incision downwards better exposure was gained. The point of a pair of aural forceps penetrated the trachea below the first ring, acting as a guide to the scalpel, which was used to divide three rings below this point. A blast of air indicated restoration of an airway. There was improvement in the general condition, and bleeding ceased with oxygenation of the tissues. A temporary tracheotomy tube was fashioned from a wide-bore male rubber catheter in which air-holes were cut ; it was secured by a safety-pin before introduction. The patient was noticeably shocked, and the initial cyanosis had given way to a greyish tinge ; there was extensive sweating.

To ease respiration he was kept upright during conveyance to hospital, and the edges of the trachea had to be kept apart with aural forceps. In the operating theatre a metal tracheotomy tube was inserted without difficulty. No anaesthetic was required. He was then transferred to a warm bed and given an injection of morphine, ¼ gr. (16 mg.), later repeated. Penicillin was injected to prevent respiratory complications. On the following day continuous glucose-saline to a total of 2 litres was given intravenously because of the inability to swallow.

Recovery was gradual. On September 27 he was still unable to breathe through mouth or nose. The fauces were swollen symmetrically as in bilateral quinsy, but differed in that the tonsils were healthy and the tissues pale and watery ; his temperature was 98.4° F. (36.9° C.). A diagnosis of oedema of the glottis seemed to be indicated. On September 28 he breathed through his nose. Extension of the oedema below the mandible caused a "double chin." Next day he started a light diet. Oedema of the fauces was subsiding, and on September 30 the tube was removed. Subsequent progress was satisfactory, and the patient returned to work three weeks later.

The origin of the oedema of the glottis was investigated, but no definite conclusions were reached. Questioning on September 27 did not elicit a history of the patient having been stung by a wasp or bee on the previous day. He had not felt a pain in the throat whilst eating his lunch. It seems likely that local trauma to the throat was responsible, and that this occurred during the lunch meal. In spite of the lack of positive evidence the possibility that he swallowed a wasp without noticing cannot be excluded.

COMMENT

The treatment of allergic oedema of the glottis may be said to depend upon the stage at which the condition is recognized. Many, perhaps most, cases may be seen at an early stage before any considerable swelling has occurred, as when a patient can report with certainty that he has been stung in the throat. Here treatment by an immediate subcutaneous injection of adrenaline, followed by full doses of antihistamine drugs, may be completely successful. Other cases are, for various reasons, seen at a later stage. These include patients in remote country districts where distance obviates early consultation. The absence of a clear-cut history, as in this case, may lead to a late diagnosis. Here the need for tracheotomy, as shown by severe and increasing asphyxia, may arise.

My thanks are due to Dr. H. O. Lyne and the staff of the Whitby War Memorial Hospital for their valuable help in the management of this case.

Oesophageal Foreign Body Precipitating Dissecting Aortic Aneurysm

In the case reported below it is probable that the disturbance incident on a realization by the patient that she had swallowed a fish-bone precipitated commencing aneurysm of the aorta in a predisposed subject. The eventual cause of death was rupture into the pericardium. The double pathology must be extremely rare, and for this reason the case is recorded.

CASE REPORT

The patient, a woman aged 44, was admitted to hospital as an emergency case at 10.30 p.m. on January 29, 1950. Two hours before admission she swallowed a fish-bone (plaice) and immediately coughed and had a severe substernal pain ; the severity was such that she broke into a sweat. She vomited twice on her way to hospital ; on the second occasion the vomit consisted of some frothy blood-stained fluid containing two small fish-bones. The substernal pain did not change in character or position after the vomiting.

Examination showed her to be a pale woman who, although in pain, was stoical, cheerful, and in full possession of her faculties. The temperature and pulse were normal. Examination of the heart and lungs revealed no abnormality. The blood pressure was 140/80. Indirect laryngoscopy showed a healthy larynx and clear pyriform fossae.

Oesophagoscopy was performed under general anaesthesia about half an hour after admission. The oesophagoscope was passed easily. As it went through the cricopharyngeus a little blood-stained froth came into view. A vertical superficial laceration about 1 cm. in length was present on the right postero-lateral wall of the oesophagus at 37 cm. from the incisor teeth. No foreign body was found.

Soluble sulphadimidine 1 g. was ordered to be injected four-hourly, and it was decided to give nothing by mouth for eight hours.

Recovery from the anaesthetic was normal. The substernal pain persisted and omnopon ½ gr. (22 mg.) was given for its relief at 3 a.m. on January 30. At 7.15 a.m. the patient became cyanosed over the face, neck, and chest, and the neck veins were congested. The pain shifted from the substernal region to the epigastrium. It is not known if the onset of this cyanosis was sudden, because she was not under continuous observation and it might have been gradual over about half an hour. On examination she was found to have a pulse of 120, with a poor volume. The blood pressure was 90/60. The lungs were normal to percussion and auscultation, and the heart sounds were normal. There was a slight epigastric fullness and a little guarding over the right upper rectus.

She was given continuous oxygen with a B.L.B. mask, and radiographs of the chest taken with a portable machine were normal.

At about 10 a.m. she was examined by Mr. R. G. Macbeth and Dr. E. M. Buzzard. By then her blood pressure had improved a little and was 110/80. It was decided that she was suffering from a cardiac failure. There was no evidence of an acute abdominal condition or of respiratory disease. Nikethamide 1 ml. hourly was ordered, and she was given hourly drinks of glucose and lemon-water. The oxygen was continued.

A physician under whose care she had been previously was consulted by telephone during the day. He stated that she was a hypertensive, though this was apparently not known to the patient or to the doctor who had sent her into hospital. A diagnosis of coronary thrombosis was suggested.

Her condition improved during that day, and the following night the epigastric pain slowly disappeared, but cyanosis always returned when the oxygen was withheld.

The next day an electrocardiogram was done, but the typical appearances of coronary thrombosis were not seen. Throughout this day her condition was unchanged. The next morning, February 1, the pulse rate was 80 and the blood pressure 190/120, but the cyanosis and engorgement of the neck veins persisted. At 9.30 a.m. she suddenly died just as an examination was about to be made of her heart.

Post-mortem Summary.—Spontaneous rupture of aorta with dissection and eventual rupture into the pericardium causing haemopericardium and death. Ante-mortem superficial laceration of the posterior wall of the oesophagus. Early nephrosclerosis.

Histological examination of the aorta showed an increase in sudanophil material in the media but no unequivocal findings of cystic medionecrosis. It is possible that the findings indicate an early stage in the development of this condition. Evidence of hypertensive changes was also found.

I would like to thank Mr. R. G. Macbeth, into whose ward the patient was admitted, and Dr. E. M. Buzzard. My thanks are also due to Dr. R. A. Sladden, who performed the post-mortem examination.

E. H. HADFIELD, B.M., B.Ch.,
Department of Otolaryngology,
Radcliffe Infirmary, Oxford.

The Ministry of Health announces that enrolments in the National Hospital Service Reserve in England and Wales at the end of September reached 4,573, an increase of 1,350 since last June. Membership consists of 372 trained nurses and 4,201 auxiliaries. The immediate target for the Reserve is 30,000. Wales has recruited a total of 840 members. In England the South-west Metropolitan Hospital Region has enrolled the highest number of recruits, the total reaching 627 ; the Newcastle Hospital Region came next with 387 ; and Sheffield R.H.B. a close third with 386.

Reviews

ATOMIC WEAPONS

The Effects of Atomic Weapons. Prepared for and in Co-operation with the U.S. Department of Defense and the U.S. Atomic Energy Commission, under the Direction of Los Alamos Scientific Laboratory, Los Alamos, Mexico. (Pp. 456; illustrated. £1 5s. 6d., or $3.) New York, Toronto, London: McGraw-Hill Book Company, Inc.

This book, despite five editors and 90 contributors in 438 pages of text, gives a straightforward and comprehensive account of the effects of the atomic explosions in Japan and at Bikini. It is designed as a source of scientific information for those with some technical knowledge who are engaged in planning civil defence.

It starts with an account of the principles underlying an atomic explosion, with a few words about nuclear structure and isotopes and an account of nuclear fission, chain reaction, the production of fissionable material, and fission products. This brief introduction is followed by a longer section describing an atomic explosion, first in the air and secondly under water, taking in turn the effects of shock, the physical damage from blast, the thermal radiation and incendiary effects, the radiations emitted, and the radioactive contamination that results.

The section on the measurement of nuclear radiations deals first with the properties and effects of ionizing radiations, then the instruments used for measuring them, and finally their measurement with particular relation to the detection of radioactive contamination following an explosion. Decontamination is then discussed, and the rest of the book is about protection and the effects on those who are exposed.

The book has been well edited, it is easy to read, and will be most useful to those responsible for civil defence. It does not gloss over the appalling effects of atomic explosions, and makes it clear that such an attack on an unprepared city might produce tens of thousands of casualties. These would mostly be due to burns and wounds, but several thousand cases of radiation sickness would be added as a new feature for civil defence to cope with. It makes it equally clear that preparation and warning would largely restrict the casualties to the main zone of blast; they might well be reduced to a quarter or less. The writers do not discuss the organization, preparation, and techniques required to deal with such situations, nor do they give any information about the hydrogen bomb.

Much of this information has been known to those working in civil defence for some time. Those responsible are of the opinion that, terrible as an atomic attack would be, it could be faced by a resolute, trained, and informed public. This book will help by providing information, and as such is welcome. It is unfortunate that in an otherwise excellent production the quality of many of the photographs reproduced should be so bad.

D. W. SMITHERS.

SLIT-LAMP MICROSCOPY

Spaltlampen-mikroskopie des hinteren Augenabschnittes. By Karl Hruby. (Pp. 164; 52 illustrations. M. 28.60.) Vienna and Innsbruck: Urban and Schwarzenberg. 1950.

The practice of slit-lamp microscopy is at present almost exclusively confined to the anterior segment of the eye. The usual techniques allow the study of the anterior vitreous, but the technical difficulties in obtaining a view of the deeper layers and of the fundus are such that, though fundus examination is feasible by special attachments to the slit-lamp, such examinations are infrequent. In his monograph on slit-lamp examination of the posterior segment of the eye, K. Hruby discusses fully the means that have been adopted to obtain an optical section of the deeper layers of the eye, and describes his own device of a pre-set lens −55D, which seems a less exacting procedure than the use of a special contact lens; in fact some of the more recent models of slit-lamps are equipped with the lens he designed.

No matter what device is used, slit-lamp microscopy of the posterior segment of the eye involves a small angle between the axis of observation and the axis of illumination. This makes the localization of depth difficult, and the diffuse red light from the fundus makes an optical section also difficult to obtain. The favourable conditions in the anterior segment of the eye therefore do not exist here. Within the limits thus imposed it is none the less possible to obtain valuable information that cannot be got otherwise. A whole series of membranes in the vitreous and retina can be differentiated. Posterior vitreous detachment, which in the past has largely been a pathological conception, can be shown as a clinical entity. Its bearing on retinal detachment arising from tears due to shrinking of adherent vitreous is obvious. The recognition of different types of vitreous detachment has become possible, as has differential diagnosis between the various types of vitreous haemorrhage. Disturbance in the normal relationship between a retinal detachment and the well-demarcated vitreous, induced by a diathermy puncture which perforates the retina and penetrates into the vitreous, has become apparent. Such punctures produce a sub-vitreal in addition to a sub-retinal fistula, and post-operative vitreous haemorrhage is a possible consequence. A striking development is the possibility of distinguishing between oedema and hole formation at the macula.

These are some of the considerations brought out in Hruby's excellent monograph. It is to be hoped that the technical difficulties presented by slit-lamp examination of the posterior segment of the eye will not deter further studies.

ARNOLD SORSBY.

HISTORY OF GYNAECOLOGY

The Genealogy of Gynaecology. History of the Development of Gynaecology Throughout the Ages. 2000 B.C.–1800 A.D. By James V. Ricci, A.B., M.D. With excerpts from the many authors who have contributed to the various phases of the subject. Second edition, enlarged and revised. (Pp. 494. $8.50.) Philadelphia: The Blakiston Company. 1950.

This work first appeared in 1943, and it has now been reprinted in an enlarged and revised edition. Dr. Ricci, who is clinical professor of gynaecology and obstetrics in New York Medical College, has produced a scholarly work which has obviously entailed a long and strenuous period of study.

Having adopted the bibliographic route of approach to his subject, he gives numerous quotations from the older writers, and also many case histories which may still be read with interest and profit by the present generation of gynaecologists. Particularly interesting are his earlier chapters on the ancient and mediaeval periods, and these indeed form the major portion of the treatise, only the last hundred pages being devoted to developments since the Renaissance. Extracts are given from the Kahun Papyrus, which forms what is probably the earliest known textbook of gynaecology. The gynaecology of Hippocrates and, of course, that of Soranus of Ephesus are studied in detail. Although the Arabian writers reveal some progress in the subject, as also do the works of the women practitioners of the School of Salerno, it was not until anatomy was established on a sound basis that gynaecology assumed a scientific aspect, and not until the eighteenth century that it became firmly adopted as a special branch of medicine.

An ample bibliography accompanies each chapter: for example, the section on the eighteenth century is followed by a list of no fewer than 704 references. Although this wealth of detail interferes a little with the readability of the historical narrative, it is probable that the author intended his book to be mainly a work of reference, and as such it will certainly prove invaluable to the gynaecologist as well as to the medical historian. There are no illustrations and no index of subject-matter, only an index of personal names—defects which might well be remedied in future editions.

DOUGLAS GUTHRIE.

FORENSIC MEDICINE

Lehrbuch der gerichtlichen Medizin. Edited by Professor Albert Ponsold. (Pp. 568; 169 figures; bound, M. 49 or $11.65.) Stuttgart: Georg Thieme. 1950.

This is a textbook of forensic medicine addressed to both the medical and legal professions, and the use of technical terms has accordingly been reduced to a minimum. It is a clear and straightforward presentation of current opinion and accepted procedures and covers much the same ground as the larger English works. The author has enlisted the help of no fewer than 16 collaborators—a sufficient indication of the specialized nature of the subject to-day.

Of the less technical articles two deserve special mention. The first is a 65-page treatise on medical ethics by Professor E. Schmidt, of Heidelberg. This is an able and comprehensive discussion of the doctor's obligations and reflects the true Hippocratic spirit. Although written with constant reference to German law, much of it is of general application. It demonstrates the doctor's need of both professional associations and defence societies. The second article is one on forensic psychiatry, by another Heidelberg professor, H. J. Rauch. This is full of good sense and equally well written. It shows the value of medico-legal societies in enabling doctors and lawyers to gain clearer conceptions of each other's functions and problems. How far societies of the various types mentioned exist in Germany is not clear.

The book deserves to be widely read in Germany; its appeal to foreigners will naturally be limited. It may help teachers of forensic medicine with the presentation of material; it may also be useful to those interested in German law, and such readers may be assisted by the excellent *Manual of German Law* recently published by H.M. Stationery Office for the Foreign Office.

RAYMOND WHITEHEAD.

DICTIONARY OF PSYCHO-ANALYSIS

Freud: Dictionary of Psycho-analysis. Edited by Nandor Fodor and Frank Gaynor. (Pp. 208. $3.75.) New York: Philosophical Library, Inc. 1950.

The editors of this dictionary were inspired to provide a glossary of psycho-analytical terms by quoting from the most unimpeachable source of information—namely, the writings of Freud. The only comparable publication is the *Glossary of Psycho-analytical Terms* published as a research supplement to the *International Journal of Psycho-analysis*, but this is mainly for the use of translators, for it contains few definitions and gives no references.

Valuable as the present volume may be for those who are already passing familiar with psycho-analytical theories, it does not fulfil the publisher's expectation that it will satisfy the needs of the general reader. Its defects are indeed manifest on the first page. "Abstinence—sexual" is dismissed with a reference to the distinction between abstinence from sexual activity in general and abstinence from heterosexual intercourse in particular. And the layman will scarcely be enlightened by the bald information that "Adaptability—cultural" is the personal capacity for transformation of egoistic impulses under the influence of the erotic impulses. On the same page "Aggression," a concept vital to psycho-analytical theory, is dealt with in three somewhat superficial and unsatisfying references. In the case of "Abasia," the definition proves to be a clinical reference to the unconscious symbolism of walking in cases of hysteria.

Obviously the success of such a venture depends on the judgment of the editors; and in this instance they have often done less than justice to the wealth of material at their disposal. The idea of the book is, however, an excellent one, and a second edition should be prepared as soon as possible in which much more copious and informative quotations are given and the date of each paper is inserted in the margin. As it stands, a mixture of undated citations is calculated to give the uninformed reader misleading impressions.

BRITISH MEDICAL JOURNAL
LONDON
SATURDAY DECEMBER 30 1950

PUBLIC HEALTH SALARIES

In the second half of 1948, when there was much discussion about the remuneration of consultants and of general practitioners, efforts were at the same time being made to improve the lot of those many medical men and women in the Public Health Service who were by professional standards being underpaid. Attempts were made to set up Whitley machinery to review the terms and conditions of service of doctors in the Public Health Service, and it seemed that this review was being blocked by the associations of local authorities, due no doubt to their fear of the repercussions on their other professional employees if the salaries of medical officers were brought into some sort of relationship to the remuneration of general practitioners and consultants recommended by the Spens Committees. When met in January, 1949, the Council of the B.M.A. decided to inform the Minister of Health of "the serious unrest and dissatisfaction among members of the Public Health Service occasioned by the continued delay in opening negotiations on the new scales and conditions of service." The Council also decided that, if by February 28, 1949, negotiations had not been started through Whitley machinery, advertisements from local authorities would not be accepted by the *British Medical Journal*. The *Lancet*, *Public Health*, and the *Medical Officer* agreed to take a similar line of action. As negotiations were not started, such refusal to accept advertisements came into operation. It was not until March 16, 1950, that both staff and management were able to avail themselves of the conciliation mechanism afforded by the Whitley Council Committee "C." The discussions continued over four months, and during this period agreement was reached on a number of important points. There remained over, however, a number of matters principally concerned with levels of remuneration on which there was a conflict of opinion between the management and the staff side. Fortunately, however, both agreed to submit those matters on which there was disagreement for arbitration before the Industrial Court set up in accordance with the provisions of the Industrial Courts Act, 1919. It is interesting to note that the case was presented to the Industrial Court by counsel for both sides, the management side having given a lead in this direction.

A table on the first page of this week's *Supplement* (which sets forth an abridged version of the Court's own summary of its award) shows for quick comparison the salaries on the Askwith scale in operation up to this moment, the adjustment claimed by those representing the staff, the offer made by the management side, and, fourthly, the award of the Court. For example, an assistant medical officer's present maximum is £935 a year; the staff claimed that the maximum should be increased to £1,680; the management offered a maximum for its higher grade of £1,100; the Court's maximum is £1,150. For a medical officer of health there was no maximum laid down in the Askwith scale, this depending on the discretion of the authority; the staff side claimed a highest maximum (that is, for a population of 600,000 or over) of £3,600; the management offered a maximum of between £2,400 and £3,000; the Court awarded a maximum (that is, for population of between 400,000 and 600,000) of £3,000. We understand that the offer made by the management side to the Industrial Court was higher than the offer it had been willing to discuss with the Whitley Committee.

It may be worth while drawing attention to some of the principal points of the award. First of all, those in the Public Health Service will be pleased with the decision of the Court that the application of the award should be national—that is, include Scotland as well as England and Wales. The management side wanted to introduce a number of grades of assistant medical officers and of senior medical officers, and it is particularly satisfactory that the Court has taken the staff view that such grades are undesirable and in its award does not allow for them. The Court has also accepted the staff contention that for part-time work medical officers of health should be remunerated on the basis of the Spens formula for consultants. The Court has also made an award of £100 a year to the medical officer of health who is employed by more than one authority. All the approximately 2,000 medical officers concerned in the award will go to the appropriate point in the new scale—that is to say, each officer will be placed at the point in the new scale which he would have reached had the scale been in force when he was appointed to his present post. In any negotiation no side can get all that it wants, and the staff side are disappointed that the awards to assistant medical officers and senior medical officers were not higher. The Court has referred back to the Whitley Committee the question of mixed appointments and also appointments held by deputy medical officers of health and divisional or area medical officers.

It was just a year and a half ago that the whole question of arbitration was keenly debated by the Annual Representative Meeting and subsequently discussed between the B.M.A. and the Ministry of Health and in the Committee Stage of the National Health Service (Amendment) Bill.[1] In the House of Commons Mr. Aneurin Bevan was supported by Mr. Walter Elliot, speaking for the Opposition, that arbitration should not be compulsory, and he approved of the Minister's suggestion to create a special section of the Industrial Court concerned with the National Health Service. Mr. Bevan made this statement: "If both sides agree to go to arbitration, obviously the Minister would accept the consequences."[2] He emphasized that if the Minister agreed to go to arbitration this involved acceptance of the results, though he added the rider that the House of Commons would always have the power to throw out any regulation the Government might issue in connexion with an award by the Court. Although the Minister is not directly involved in the present case, it is assumed that both the staff side and the management side—that is, both public health officers and local authorities—will accept the award, even though the award has no binding legal force. It would obviously be absurd for either party going voluntarily to arbitration to say in effect that it would accept the arbitration award if favourable to itself and reject it if it was unfavourable. The very fact of agreeing to go to arbitration implies acceptance of the arbitrator's decision. Although those representing the medical officers will feel disappointed over some of the decisions of the Court, nevertheless they must feel that they have made substantial gains. For the profession generally it is satisfactory to observe that the use of the conciliation machinery afforded by the Whitley Council has cleared up a number of points of difference between the staff and management and that voluntary resort to arbitration has, with the exceptions mentioned, resolved the deadlock.

HAEMOLYTIC DISEASE OF THE NEWBORN

The discovery and application of a rational therapy for haemolytic disease of the newborn have followed a pattern set by earlier important advances in medicine. First the new knowledge became widely disseminated and utilized. Then ancillary but essential diagnostic and therapeutic discoveries were made and almost at once generally applied. At the same time other variations and refinements in treatment arose locally which were not universally accepted as improvements. It is probable that the diagnosis and treatment of haemolytic disease of the newborn in the larger towns of Great Britain and many other countries are now as efficient as present knowledge permits. There is still much room for improvement in areas without the facilities offered by an efficient blood-grouping laboratory, but at the main centres any dramatic improvement in treatment must await some further fundamental discovery such as might lead to effective antenatal prophylaxis or treatment. This does not mean that any one school is achieving the best possible results, for that could come only from the adoption of all possible improvements in technique, however small they might be. Such improvements can be discovered only by a statistical assessment of the results obtained by empirical variations in method. The total effect of many small improvements brought to light in this way might be substantial.

Thus, now, as after other basic medical discoveries, a time has come to pause for reflection. The stream of theoretical discoveries with a direct clinical application has slowed, so that any assessment now undertaken will not tend to be confused by the uneven application of major improvements in diagnosis and therapy. Every encouragement ought now to be given to the initiation of comparative studies and to the analysis and publication of records of the investigation and treatment of large numbers of cases.

The diagnosis of immunization by the Rh factor is a relatively simple matter, but the assessment of the prognosis for a given pregnancy is one of great difficulty, likely to cause anxiety not only in prospective parents but in pathologists and clinicians as well. The publication last year by Mollison and Cutbush[1] of an account of their investigation of the criteria of severity of the disease has placed this type of inquiry on a much firmer basis. Davidsohn[2] in a later paper covered part of the same ground and reached several of the same conclusions. Opinions differ about the prognostic value of maternal-serum examination, but there is general agreement that a high titre of incomplete anti-D indicates a poor prognosis. In rare cases, such as one described by Davidsohn, a rise in titre may occur in a previously immunized woman carrying an Rh-negative foetus. While the titre of antibody is thus less important as a guide to prognosis than the woman's previous obstetric history, the time of first appearance of antibody is probably of importance, since Murray and Taylor[3] conclude that the presence of antibody in the first four months of pregnancy indicates previous immunization. They consider that the presence of antibody throughout pregnancy is as unfavourable as a previous history of haemolytic disease. Other workers lay less stress on the importance of repeated antibody tests.

Mollison and Cutbush have shown that from the moment of birth much more definite conclusions can be reached. It is essential, however, that in every case

[6] *J. Obstet. Gynaec. Brit. Emp.*, 1947 **54** 281.

a specimen of cord blood should be carefully taken. Later examinations of capillary blood are, by comparison, almost useless. The most important test is the estimation of cord haemoglobin. Infants with less than 8 g. per 100 ml. are very likely to die within 24 hours of birth, while those with more than 14.5 g. will probably recover without treatment.

Antenatal testing of the mother and the testing of the child at birth are only preliminary steps to the important one of treating the affected child, and it is here that the assessment of the effects of differences in practice are of the greatest importance. The best method of assessment is by means of surveys planned in advance, but much can be learned from the analysis of existing records of hospitals which treat large numbers of cases. It is, however, almost useless to compare the results obtained in successive periods of time. The comparison must be between cases treated within the same period, and they should be studied by a clinician and a statistician who are both aware of the possible hidden fallacies of such a method. One of the most important of all institutions treating cases of haemolytic disease of the newborn is the Children's Medical Centre, Boston, where the pioneer work of Dr. L. K. Diamond and his colleagues has greatly influenced the treatment of this disease. Serious consideration must therefore be given to the observation of Allen, Diamond, and Watrous[4] that in a series of 179 cases of the disease all infants given exchange transfusions with female blood survived, compared with only 80% of those similarly treated with male blood. The number, 42, treated with female blood was somewhat small, but the result is nevertheless highly significant in the statistical sense. The authors themselves have analysed the data with very great care in order to detect possible statistical fallacies. The most important of the possible sources of error is the selection of blood with a high packed-cell volume for the more seriously affected children: such blood would more commonly be of male origin. Such selection had probably taken place, but a separate analysis of the more serious cases still showed a markedly significant superiority in female blood.

These findings, if confirmed, must be taken fully into consideration in planning treatment, but the difficulties of applying them are such that most clinicians will probably demand independent evidence, and especially will they require to see series of cases treated with statistical control applied at the time rather than afterwards. One such series has already been made known by Van Loghem and his colleagues,[5] who have given exchange transfusions with male blood to 151 infants and with female blood to 68 infants, the mortalities being respectively 17.2 and 16.2%, an insignificant difference.

If indeed female blood is eventually proved to have a specific therapeutic value, then it will be necessary for the National Blood Transfusion Service to supply selected female Rh-negative blood for all cases of haemolytic disease. This would be an immense and difficult task, requiring among other things a special increase in one part of the donor panel, which would take considerable time and effort to achieve. Therefore, until superiority of female blood is finally established, it should be reserved for use by clinicians who will co-operate fully in obtaining statistically analysable results.

Both in antenatal investigation and the treatment of established cases there are still many relatively minor details to be learnt, and all who have extensive and uniform series of cases ought to consider analysing and publishing them. It is still uncertain what are the chances of an Rh-negative woman married to an Rh-positive man becoming immunized by pregnancy. Boorman, Daley, and Dodd[6] have made a valuable contribution to this study, but the number of cases studied antenatally must be multiplied many times before an accurate estimate of the chances of immunization can be made for all possible combinations of ABO groups of both partners (which markedly influence the result), with both heterozygous and homozygous Rh-positive husbands.

When it comes to treatment the number of variables is so great that no single investigator can adequately cover them all. The best hope of reaching firm conclusions would appear to lie in co-operative researches such as the therapeutic trials at present being organized among a number of centres by the Blood Transfusion Research Unit at the British Postgraduate Medical School.

LOSS OF VISION

To Government Departments, economists, and sociologists a census of the population provides valuable knowledge about the country's needs for food, houses, and materials of all kinds. In a smaller way the register of blind persons is equally helpful—for instance, to the pensions department for estimating the cost of pensions for the blind; to the National Institute for the Blind, the county associations, and local authorities for arranging training and visiting and for estimating the staff required; and to ophthalmologists and sociologists for assessing the value of their work to the community and for determining the direction of future research. Under the aegis of the Medical Research Council Professor Arnold Sorsby has compiled a memorandum[1] on the causes of blindness in England and Wales which should prove a valuable document to those engaged in the care of the blind and the prevention of blindness. The report contains a mass of facts, and from these the author draws certain conclusions and makes some forecasts about the future. He refers once again to an old difficulty—the definition of blindness—and his sensible remarks about this will be read with special interest by those who are called on to complete the forms of certification.

In the chapter entitled "The Changing Background" Sorsby quotes figures endorsing his view that the almost total eradication of ophthalmia neonatorum as a cause of blindness is one of the outstanding medical advances of the present century. He points out that this was achieved, first, by preventive measures such as the Credé method of instilling silver nitrate into the eyes of newborn infants, secondly by legislation, notification, and systematic treatment, and finally by academic research which led to the use of the sulphonamides and penicillin. The reduction in blindness from phlyctenular ophthalmia in children is also shown in figures; the older generation of ophthalmologists well recognizes the great change in the incidence of this now rare disease resulting from better hygiene, better feeding, school medical inspection, and, not least, the removal of patients from the slums to the country. The value of vaccination is again shown by the smallpox figures: in a period up to 1814 "two-thirds of those who applied for relief" (at the Liverpool Institute) "had lost their sight by smallpox," but well before the end of the nineteenth century this disease had ceased to be a significant cause of blindness in England and Wales.

The form (B.D.8) for certification of a blind person divides the causes of blindness into five groups. In 1948 there were 77,390 registered blind persons in England and Wales, 7,586 of them having been admitted to the register in that year. An analysis of 17,430 certificates showed that 59.9% of the blind came into the first group, which includes congenital, hereditary, and developmental defects (9.9%), complications of myopia (10.8%), primary glaucoma (13.4%), and senile cataract (24.6%). Infectious and bacterial causes (12.3%) make up the second group, traumatic causes (1.6%) the third group, general diseases (11.6%) the fourth group, and diseases of unknown aetiology—such as optic atrophy, iridocyclitis, choroidal lesions—the last group (14.6%). When the cause of blindness is dissimilar in the two eyes trauma takes a much higher place, being the reason for loss of sight in nearly one-third of the cases in this category. In 5% the cause was sympathetic ophthalmia. Some 25,000 people are blinded from glaucoma, myopia, and the congenital anomalies. There is no reason to assume that this number can be reduced in the immediate future (except perhaps in the case of glaucoma, and that would require a perfect organization in the ophthalmic branch of the National Health Service). About 20,000 people are blind from cataract, but effective treatment could reduce this number by at least one-third. In the fairly recent past the infectious diseases were the cause of blindness in about 10,000 individuals. In the near future such a figure may seem as much a matter of past history as blindness from smallpox had become by the end of the last century. Professor Sorsby writes:

> "With full allowance for a continuing decline in the frequency of blindness from infectious diseases and for the possible elimination of a substantial proportion of blindness from cataract, an optimistic assessment would still leave well over 50,000 irremediably blind in the country. Since 'senile' causes of blindness are so prominent in any analysis of the blind population, the present shift towards an older population emphasizes that this estimate may well be too low."

Rehabilitation schemes have been of great benefit to the blind and also to the partially sighted. The Faculty of Ophthalmologists has given full support to the expansion of this work,[2] and it is evident that the Ministry of Health is working in the same direction, for under the National Assistance Act of 1948 power has been given to local authorities to establish observation registers of partially sighted persons and to allow them to use the welfare services to which the blind are entitled.[3] Prior to 1948 some voluntary associations were prepared to watch and help those who had serious defects of vision. Before a new name is added to the register of partially sighted persons certification by an ophthalmologist is necessary, and the new form of blind certificate will incorporate particulars relating to the partially sighted. The ophthalmologist will be asked to consider whether the applicant (though not blind) is substantially and permanently handicapped by defective vision due to congenital causes, illness, or injury. Such registers are now coming into use and are undoubtedly serving a useful purpose. The patient is seen by a home visitor, if possible within a fortnight of his registration, in his own home, and on her report the local authority generally decides what line to take. All the welfare services of the local authority are at the patient's disposal—such as instruction in Braille and handicrafts. In some cases a partially sighted person may be eligible for admission to convalescent or residential homes run by voluntary societies, and his industrial training may be undertaken by the Ministry of Labour under the Disabled Persons (Employment) Act, with the exception of those who are liable to become blind within two to four years. There is a certain amount of variation in the interpretation of the scheme and in the work of the rehabilitation officer: but the lot of the partially sighted is often most difficult to alleviate, and this provision by the State for their care is of great assistance. It is hoped that in the future its scope will be extended.

ATYPICAL PNEUMONIA

The treatment of pneumonia with sulphonamides, which adequately control the common bacterial causes of this condition, threw into relief a group of ill-defined infections which failed to respond to such treatment. This group is now divisible into three categories: they are Q fever, due to *Rickettsia burneti* and only recently recognized as existing in this country, infection with one of the psittacosis group of viruses, and "primary atypical pneumonia," which is also a virus disease. Two papers in this issue give valuable accounts of these conditions. That by Professor C. H. Stuart-Harris traces the steps by which the last-named came to be recognized as a separate entity, and describes the features of a remarkable outbreak as well as the clinical picture of the disease itself. Professor S. P. Bedson precedes an account of the aetiology and laboratory diagnosis of all these forms of pneumonia by proposing that the term "primary atypical pneumonia" should be applied, if used at all, to all of them. Terminology is, of course, always difficult when aetiology is uncertain, as it inevitably is when such a case is first seen. Unfortunately there seem to be no clinical features by which any of these infections can be distinguished from the rest. Perhaps the term "atypical" or "non-bacterial" pneumonia would best describe the group and any aetiologically undiagnosed case. If the cause can be ascertained specific names already exist for the disease due to two of them, and it remains to find a satisfactory term for the third.

The test for cold agglutinin affords the criterion in diagnosing infections in the third category—"primary atypical pneumonia" in the narrow sense of the term—and fortunately this is an investigation which any laboratory can undertake. The serological tests for psittacosis and Q fever are much more specialized, and although the Public Health Laboratory Service will undertake them there is inevitably considerable delay before the answer is available. Probably the great majority of sporadic cases are never fully diagnosed: the best opportunity for studying such infections is when they occur in outbreaks. Fortunately all three groups respond to treatment with the newer antibiotics, and the time may come when such treatment will be found so generally successful that the niceties of laboratory diagnosis will be regarded as superfluous. Or will the universal employment of these drugs bring to light a form of non-bacterial pneumonia unresponsive to them, and thus presumably due to a hitherto unrecognized agent?

VASCULAR CHANGES IN GASTRIC ULCER

The blood supply of the stomach is of obvious importance in the study of acute and chronic gastric ulcers. The method of microradiography described by Mr. J. A. Key in this issue demonstrates clearly the well-known vascular block in the neighbourhood of a chronic ulcer. It is generally accepted that this change is probably secondary to the ulcer and increases with its chronicity, and it is easy to visualize a stage being reached when the ischaemic base of the ulcer could no longer either contract sufficiently or nourish the regenerating epithelium. Failure to heal is then not a result of the inadequacy of the physician or the neglect of the patient but of the ischaemia induced by the chronic ulceration. It is likely that such ulcers may persist for years, often with long periods of freedom from pain, yet remaining a constant menace to the patient. A clear conception of the ischaemic ulcer will be a help to the clinician when he has to treat a persistent ulcer and may encourage him to recommend operation.

The development of acute gastric ulcers appears to be related more to hyperaemia than to ischaemia. Key observed hypervascularity and local derangement of the blood vessels in acute ulcers, which supports the hypothesis that an acute vascular derangement close to the submucosa is the first change and that the breach in the mucosa is secondary. The nature of this vascular disturbance is not fully defined, but venous stasis appears to be a prominent feature. It is possible that these observations may link up with the studies of Davies and Longmuir[1] on the experimental production of acute ulcers in the isolated frog mucosa. They found that acute ulcers occurred when acid secretion was rapid and there was insufficient CO_2 to neutralize the alkalis formed concomitantly with acid in the oxyntic cells. The necrosis of cells was due not to the external action of acid but to the internal effect of the unneutralized and equally potent alkali. With dilatation of the small vessels and venous stasis the blood supply to the individual secreting cell might well be reduced and the requirement of the cells for the essential CO_2 might no longer be met. Ivy, Grossman, and Bachrach[2] state that all haemorrhages into the mucosae which have been directly observed, except those due to mechanical trauma, have been preceded by congestion of the mucosa. Haemorrhagic erosions have been produced by a certain concentration of intravenous caffeine sodium benzoate and histamine. Caffeine causes considerable capillary and venous engorgement at a time when histamine is stimulating secretion.[3] Wolf and Wolff[4] noted the development of acute haemorrhagic erosion when the exposed gastric fistula in their much discussed patient Tom became engorged and turgid. The factors which promote venous engorgement in the stomach may repay further study. Localized thrombosis of veins of the mucosa or submucosa has not been reported, and little is known about the contractability of the muscularis mucosae, which might conceivably occlude venous return. Partial occlusion has occurred with a sustained intragastric pressure of water of 10–20 cm., with resulting foci of haemorrhages and haemorrhagic erosions.[5]

TUBERCULOUS STUDENTS

The Tuberculosis and Diseases of the Chest Group Committee of the B.M.A. referred in its recent report to the special needs of students who contracted tuberculosis, suggesting that "the development of some scheme to enable the student to continue his studies and to have early rehabilitation while still under medical supervision would be of great value." In our correspondence columns this week the trustees of the British Student Tuberculosis Fund describe the plans which have been made to meet these needs and appeal for contributions towards the sum of £50,000 required to establish and equip a suitable centre. The committee of students responsible for carrying out the preliminary work collected much useful information abroad. "They manage these things better in France" seems to be as true of the treatment of students with tuberculosis as of the matters to which the phrase more commonly refers, and for reasons as little obvious. Besides the luxurious sanatorium of St. Hilaire de Touvet and three centres in the Black Forest, the French have institutions at Villiers-sur-Marne in Picardy, at Besançon in Burgundy, at Belledonne in the Isère Department, and three centres in Paris—in all a total of over 1,000 beds. In these centres students are treated in a university atmosphere and can to a large extent continue their studies while under medical care. The incidence of pulmonary tuberculosis in students is much higher in France, but the needs of the individual student in Britain are just as great, and there has been strong feeling that a scheme similar if simpler than the French might well be introduced here. Just before the war tentative approaches were made by the British Medical Students' Association to the Ministry of Health about the setting up of a sanatorium for students. But the great cost of a fully equipped sanatorium and the serious shortage of nurses put such a scheme out of the question.

Accordingly, when late in 1949 the British Medical Students' Association, the International Student Service, the National Union of Students, and the Scottish Union of Students formed a co-ordinating committee to consider what could be done for students with tuberculosis, it was agreed to aim at setting up not a full-scale sanatorium but a cross between that and what the French call a "post-cure," with the latter, as it were, dominant. In other words, what the committee wanted was a centre run in conjunction with a university to which a student could go as soon as his sputum was negative and he was well enough to get up for a few hours a day. In such a centre he would be encouraged to return to his course of study, but, if this should prove impossible owing to the practical nature of the course, he would at least have a chance of spending his time profitably in an academic atmosphere instead of vegetating in a hospital ward. The French experience shows the remarkable value of quite a small amount of teaching from visiting tutors supplemented by a good library and—less tangible but not less important—an atmosphere conducive to work. It is unfortunate that clinical medical students should be incapacitated by tuberculosis about five times as commonly as the general run of students, for, apart from engineers, it is the clinical medical student for whom the centre can offer least in the way of rehabilitation. Nevertheless, clinical medical students are just as anxious for the introduction of the centre as their less susceptible colleagues, for, after all, occupational therapy for a cobbler is not necessarily cobbling. During 1950 the co-ordinating committee, now augmented by representatives of the university medical officers and the various national organizations interested in tuberculosis, has investigated the different aspects—medical, organizational, educational, and financial—of setting up such an institution, drawing freely for advice from the "Fondation 'Sanatorium des Etudiants de France'" and from those who are in charge of sanatoria in this country. It is to be hoped that its work will have the success it deserves.

HERPES ZOSTER AND THE NEW ANTIBIOTICS

The newer antibiotics have proved of value in the treatment of various rickettsial diseases, of lymphogranuloma venereum, and atypical, so-called virus, pneumonia. These, however, are not typical virus diseases. Herpes zoster is an affection associated with the presence of a filterable virus. It runs a self-limited course, is not usually of much significance or severity, and clears to leave no serious sequel other than a few small scars. There is more than a suspicion that it may upon occasion be provoked by emotional disturbance. All these features will make the clinician cautious of any claims suggesting that a new therapeutic measure is effective in the treatment of this disease or is a specific remedy. Results must be carefully assessed against the yardstick of the natural history of zoster. Antihistaminic drugs were recently hailed as the appropriate treatment of zoster, and the present tendency is to claim first place for the newer antibiotics. It would seem quite certain that "aureomycin" and "chloromycetin" are in no sense a specific remedy either for herpes zoster or for herpes simplex. Good results have attended the treatment of several series of cases now reported—treatment generally conducted in hospital. The results are not, however, so good as to convince the impartial clinician that they are significant so far as zoster itself is concerned, and there is no laboratory evidence to suggest that these antibiotics have any specific effect upon the virus. Both herpes zoster and herpes simplex have been observed to arise and to spread in patients receiving these antibiotics for other reasons.[1 2]

Occasionally herpes zoster has serious complications. The lesion may involve a vital structure such as the eye; secondary infection may start gangrenous ulceration in the tissues affected; and there may be spread of infection to motor elements causing paralysis, or spread through the central nervous system giving rise to encephalitis. One troublesome complication is post-herpetic neuralgia, which is apt to arise within the distribution of the affected dorsal roots in elderly patients. If aureomycin or chloromycetin can be shown to control any of these complications it may have a place in treatment, especially in the elderly, provided there are no serious side-effects.

Finland and his colleagues[3] reported some success with aureomycin in a series of 24 cases of herpes zoster, but the results were not assessed against those which might have been obtained in a parallel series, untreated or treated by other means. Dawson and Simon[4] also reported good results with chloramphenicol in four relatively young patients, but no success in two cases of post-herpetic neuralgia. Most reports suggest that these antibiotics tend to prevent further spread both in herpes zoster and in herpes simplex infection,[5 6] and this may be by control of secondary infection or by some non-specific effect of the antibiotic on the tissues. There is not yet sufficient evidence that these drugs have any advantage over those already in use, but further controlled investigations are required before a firm answer is possible.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

BRONCHIECTASIS

BY

F. P. LEE LANDER, M.D., F.R.C.P.

Assistant Physician, Brompton and Royal Free Hospitals

The clinical picture of bronchiectasis detailed by Laennec was one of heavy infection existing in the walls of dilated bronchi and in the surrounding interstitial tissue. This was demonstrated at post-mortem examination. With modern techniques these dilated bronchi can be demonstrated in the living patient, and it is now known that dilated bronchi can exist without producing any respiratory disturbances at all. Such cases are referred to as "dry" or "uninfected" bronchiectasis.

Further studies have shown that the bronchial walls dilate and lengthen with each inspiration, and that they are not rigid tubes of unvarying calibre. Also, if any part of the intrathoracic contents shrinks, the bronchi dilate beyond their normal inspiratory size, this being part of the compensating mechanism. Should this shrinkage of the parts of the lung be temporary, then the bronchial dilatation may also be temporary.

If, as is often the case, the shrinkage of part of the lung is due to an infective cause, this infection will affect the dilated bronchi and the surrounding interstitial tissue, and produce secretions which will stagnate in the incompetent dilated bronchi. The intensity and the virulence of the infection vary, and may produce a very variable clinical picture. Of equal importance to the virulence of the infection are the number and the distribution of the affected bronchi.

Aetiology

The most common causes of bronchiectasis are the respiratory disorders of childhood. First and foremost is whooping-cough, followed very closely by measles, with its attendant bronchopneumonia. Primary lung tuberculosis in the child often leaves behind, in healing, an area of atelectasis and bronchiectasis. Bronchitis and asthma add their quota to the total. Inspired foreign bodies, which include debris from nasal and oral infections, contribute a small number of cases. The frequency with which tracheotomy scars are seen in the necks of adult sufferers suggests that in the past diphtheria claimed a few cases. In early adult life pulmonary tuberculosis begins to play a part in the causation of bronchiectasis, and as life advances this becomes more common. Finally, in middle and later life bronchial carcinoma produces a number of cases in which bronchiectasis is an unimportant part of a more devastating complaint.

Symptoms

As has already been stated, many cases are completely symptomless and are discovered accidentally. These require no treatment. Those persons, however, who seek advice because of disability due to infected bronchi give a very characteristic history. Their lives are chequered by one respiratory disease after another, starting in childhood with an attack of whooping-cough. Bronchitis, pneumonia, and pleurisy occur and recur, and in the intervals between they have chronic cough with copious purulent sputum. Occasional slight haemoptyses may occur. In many patients the cough and sputum disappear in the summer or during spells of dry weather. When the infection is more virulent, the child may show retarded growth, both physically and mentally. So much of the lung may be at fault that dyspnoea is a prominent feature.

As adult life is attained, a certain stability is reached and acute episodes become less frequent, without, however, any amelioration of cough and sputum. Dyspnoea becomes more pronounced as life progresses, and by the age of 40 it is the most distressing symptom. Occasionally haemoptyses occur of such a size that they may overshadow the other symptoms. In a few cases haemoptyses at infrequent intervals may be the only complaint. This point should be kept in mind when investigating and treating cases of haemoptyses. In the past, many patients have spent months in sanatoria on account of this symptom, which later has been shown to be due to dilatation of the bronchi and not to tuberculosis.

Signs

The signs of bronchiectasis may be as fugitive as those of pulmonary tuberculosis. There may be only an area of diminished breath sounds to suggest that emphysema is masking the deeper-lying dilated bronchi. In more marked cases, especially those of lobar distribution, dullness to percussion, with either absent breath sounds or loud bronchial breathing, is present. Numerous rales may be heard in the suspected area. Displacement of the heart to the affected side is present in unilateral cases. When the upper lobe is at fault deviation of the trachea to the side of the faulty lobe is found. Clubbing of the fingers is a variable finding, and in some cases may be very pronounced. Its presence seems to depend on the extent to which lung is involved rather than on the degree of dilatation or the intensity of infection. This is a generalization which has many exceptions.

Though bronchiectasis can occur in any part of the lung, lower-lobe disease is the most common. As the result of intensive investigation, involvement of isolated segments of the lung is being found more often. These questions of distribution of the disease are of great importance in planning treatment for the individual case.

Radiological Appearances

Bronchiectasis can be diagnosed with some degree of certainty from a plain radiograph of the chest. The ultimate diagnosis depends, however, on the display of dilated bronchi outlined by a radio-opaque oil.

The radiological changes suggesting the presence of bronchiectasis are of two main varieties: (1) atelectasis and (2) the compensatory mechanisms which attend collapse: localized emphysema, displacement of the mediastinum, and distortion of the diaphragm all point to a diagnosis of bronchiectasis (see Figs. 1 and 2). The dilated bronchi themselves throw no shadow. Occasionally dilated bronchioles and alveoli have a "soap-bubble" appearance.

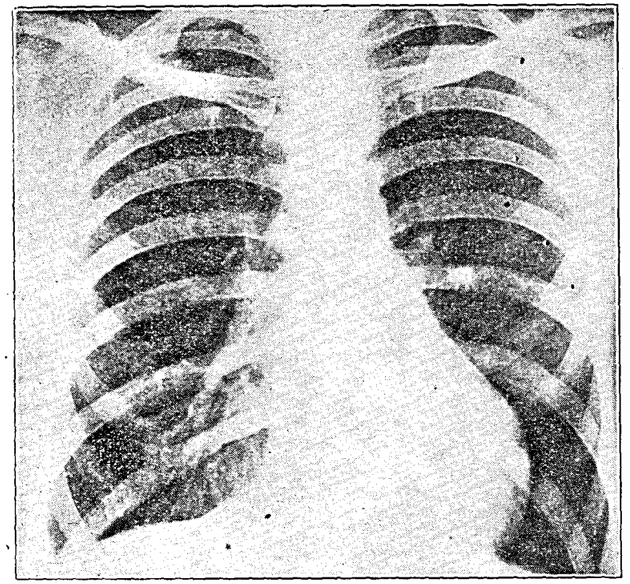

FIG. 1.—Radiograph of chest of a man aged 40 who attended on account of a small haemoptysis. The heart is displaced to the left, and there is a localized area of emphysema in the left costophrenic angle.

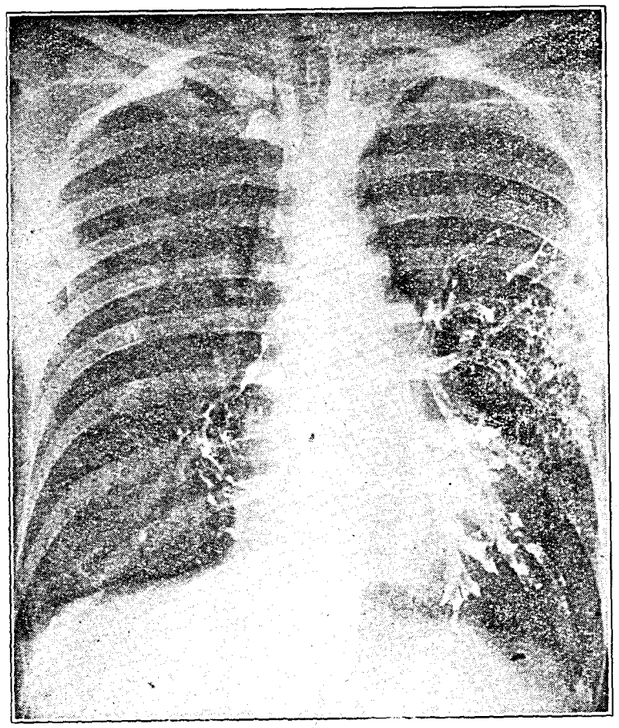

FIG. 2.—Bronchogram of the same patient as in Fig. 1. The diagnosis of bronchiectasis is confirmed.

Differential Diagnosis

It is of great importance when considering the diagnosis of bronchiectasis to look further and to try to determine the cause of the condition. Thus foreign bodies and neoplasm must be considered, and, if necessary, bronchoscopy must be performed to exclude these causes. A stricture with partial occlusion of a main bronchus must be considered because of the greater liability to recurrent infection in these cases. Recurrent bronchitis and unresolved pneumonia may mark an underlying bronchiectasis.

The diagnosis is made by outlining all the bronchi in both lungs with radio-opaque oil. This technique is complicated and time-consuming, and should be done only in a department used to the procedure.

Treatment

The treatment of bronchiectasis lies in the eradication of infection in the dilated bronchi. This can be accomplished by posturing the patient so that he empties his bronchi at frequent intervals, and by giving him the drug specific to the organisms found in his sputum. The posture to be adopted depends on the bronchi which are affected. If they are anterior to the bifurcation of the trachea the patient should lie on his back on a bed, with the foot raised 6 to 9 in. (15 to 23 cm.) from the ground. If the left lung is involved he should lie partly on his right side; if the right lung is affected he should lie partly on his left side. If the bronchi involved lie posterior to the bifurcation of the trachea the patient must lie on his face mainly on the unaffected side, again with the foot of the bed raised. This raising of the bed can be accomplished by putting the bar connecting the legs of the bed on a low chair.

At first, sleeping all night in this position is necessary; more drastic postures can be adopted during the day. These consist of hanging over the edge of the bed so that the chest is almost vertical, head down. Upper-lobe disease, of course, does not need these postures, as the patient is draining his bronchi in the normal upright position.

The best results are obtained if this posturing is combined with a course of penicillin injections. Half a million units of procaine penicillin intramuscularly for 14 days in those whose sputum contains a majority of penicillin-sensitive organisms may produce complete cessation of the sputum. In some the sputum continues, though with decreased bulk, owing to the persistence of Gram-negative organisms. In such cases a short course of streptomycin injections, 1 g. a day for five days, will help. If the original sputum examination shows a large number of Gram-negative organisms, then combined streptomycin and penicillin can be used.

Penicillin by inhalation does not give any better results than penicillin by intramuscular injection, but in a case with a large amount of purulent sputum and widespread disease both

methods can be used simultaneously. The inhalation can be given by means of a Collinson inhaler, but this method needs an oxygen cylinder; there are many portable "atomizers" on the market which are efficient, and many of them can be hired. The amount to be inhaled is about 5 ml., containing 100,000 units. The inhalations should be repeated three or four times a day.

The advances in surgical technique in recent years and the discovery of the sulphonamides and antibiotics have made lobectomy and pneumonectomy safe procedures. The mortality from these operations is probably less than the overall mortality from bronchiectasis. For this reason, many physicians and surgeons advocate operative treatment in all cases of bronchiectasis. This attitude is a lazy one, and ignores the possibility of giving an individual prognosis. All physicians must have seen patients with bronchiectasis who have lived long and useful lives in spite of their complaint. From the study of individual cases, by repeated examinations with radio-opaque oil, it can be shown that bronchiectasis is not always, or even often, a progressive disease. Whether the life of a bronchiectatic patient is worth living depends on the mental attitude of the sufferer, not on the presence of dilated bronchi.

If a patient is not prepared to practise postural drainage or to face the possibility of recurring infections necessitating a further course of penicillin injections, then the surgical removal of the affected lobes must be advised. Similarly, there are patients to whom the burden of their complaint is so overwhelming that surgery offers the best chance of a happy life. Lobectomy may be a life-saving procedure in certain cases—for example, in the case with recurring, ever-increasing haemoptyses, and also in the case of a virulent infection which is only partially or temporarily controlled by antibiotics.

Some patients suffer so severely from recurrent infections which, although controlled at the time by antibiotics, nevertheless disorganize their lives so much that they are unable to earn a living. Such a case is best treated by the surgical removal of the diseased areas. It is the physician's duty to consider whether a patient would best be treated by surgery. The practicability of operation is decided by the surgeon.

In cases in which all five lobes of the lung are involved, surgical removal of the disease is obviously impossible, but bilateral disease is not of itself a contraindication to operation. No patient should be advised to have a bronchiectatic area of lung removed until the full benefit of a course of postural drainage and penicillin treatment has been obtained. Nor should operation be advised for at least a year after the presence of the bronchiectatic lesion has been first demonstrated.

Complications

Chronic bronchitis is such a common complaint in the temperate zones that great care should be exercised in determining whether the symptoms present are not in fact due to this complaint rather than to the presence of a few dilated bronchi.

The occurrence of tuberculosis in cases of bronchiectasis is frequent enough to raise the question of whether the bronchiectasis may not have been tuberculosis from the start In some cases, however, there is no doubt that the bronchiectasis was present first, and that the tuberculous infection occurred at a later date. There is no evidence to suggest that a subject with bronchiectasis is more liable to develop pulmonary tuberculosis than a person with normal lungs.

Cerebral abscess is a complication which occurs in a number of the more severely infected cases. Its incidence has not been established, though figures as high as 15% were given when bronchiectasis was diagnosed only in the very severe cases—before the introduction of bronchography in 1922. Amyloid disease is so rare a complication that it may be said not to constitute a risk.

Repeated infections in the bronchiectatic area are really part of the natural history of the disease, and this complication is by far the most frequent and the most serious hazard.

Prognosis

The outlook for uninfected cases of bronchiectasis is good. Such patients are able to lead a useful, full-employed life, marry and have children, and live to a ripe old age. The danger of a second infection lurks in the background, but with modern antibiotics this complication is not as serious as it was in the past.

Where the infection is virulent, death may occur a few months after the onset, or during a succeeding lung infection, but here again modern therapy will probably control the infection and render the case suitable for surgery.

Where the disease is very widespread and beyond the scope of surgery the outlook is not so good, and if the infection cannot be controlled by antibiotics, then life is not likely to be prolonged. Cases of this severity, however, are rare.

During the first year of the disease it is always possible that re-expansion of the lung will occur, and infection die out; consequently, the bronchiectasis may also disappear.

Most mortality figures were established before the modern improvements in diagnosis, and all of them were produced before the introduction of modern therapy. At the best they cannot help in evaluating a particular patient's chances of survival.

HEBERDEN SOCIETY

The annual general meeting of the Heberden Society was held on December 8 and 9 at Westminster Hospital Medical School, with Dr. W. S. C. Copeman, the president, in the chair. The president for 1951, Sir Henry Cohen, was elected, with Lord Horder as president-elect. During the meeting it was announced that Professor E. C. Kendall had accepted an invitation to give the Heberden Oration for 1951.

The society was welcomed to the medical school by Sir Adolphe Abrahams, the dean, and the first session was devoted to addresses on the endocrine aspects of rheumatic disease by Professor E. C. Dodds and Dr. Peter Bishop.

I.—ENDOCRINE ASPECTS OF RHEUMATIC DISEASE

Professor E. C. DODDS said that he proposed to give a brief account of the physiology and biochemistry of the suprarenal glands. In their history there were two dates of principal concern: the first was 1563, when these very unobtrusive bodies were first discovered and were given the name of suprarenal capsules; and the other 1849, when Addison drew attention to the importance of the suprarenals in the disease that bears his name. His description was remarkably succinct:

> "The leading and characteristic features of the morbid state to which I would direct attention are anaemia, and general languor, and debility, a remarkable feebleness of the heart's action, irritability of the stomach, and a peculiar change of colour of the skin occurring in connexion with a diseased condition of the suprarenal capsules."

Between those two dates, so far as the suprarenal glands were concerned, there was a complete blank in history.

In 1856 Brown-Séquard proved that in animals removal of the suprarenals was attended by symptoms similar to those of Addison's disease, followed always by death. This observation stimulated physiologists and biochemists to attempt the preparation of a suprarenal extract capable of keeping adrenalectomized animals alive. This was achieved in 1929, when Swingle and Pfiffner produced by a complicated process a stable product which they called "cortin." Cortin was standardized on adrenalectomized dogs and cats, and it was shown to be possible to keep the animals alive more or less indefinitely by its use. This work was followed by an intensive chemical investigation, but it was not until 1934 that Mason and Kendall, at the Mayo Clinic, isolated a crystalline material from the suprarenal cortex. It was then quickly shown that there were a large number of substances in the suprarenal cortex which had life-saving properties for the adrenalectomized animal, but which differed in certain biological characteristics. One type of substance had its effect mainly on the deposition of glycogen in the liver, and another primarily on electrolyte distribution.

Cortisone and its Analogues

Professor Dodds then gave a brief account of the chemistry of the steroids, to which group all these cortical substances belonged. In showing the formulae he said that they looked very complicated, and their synthesis was quite a task in itself; indeed, the total synthesis of these various substances had not yet been reached. One of the most important of the substances isolated from the adrenal cortex was corticosterone. This would maintain the life of the adrenalectomized animal, but mainly it acted on the glycogenic mechanism. In 1936 a substance was isolated by Kendall and his colleagues which was known as 17-hydroxy-11-dehydrocorticosterone; this was cortisone, which produced the extremely dramatic changes of which Dr Bishop would speak later. Cortisone was first prepared from ox suprarenals, but large-scale production by this method was out of the question, as the yield was so minute. On the other hand, the problem of total synthesis on any scale approaching the commercial was almost equally formidable. However, work on this was being undertaken in this country under the direction of Sir Robert Robinson.

All the cortisone made to-day was made from a derivative of the bile acids, by a synthesis worked out by Professor Reichstein. There were 30 stages in the synthesis, and this and the limited amount of bile acid available accounted for the relative shortage of the final product.

What were the prospects of producing an analogue? When the work on cortisone was first published everybody tried to find a substitute, and there had been high hopes—and still were—that a substance might be prepared which would bear the same relation to cortisone as stilboestrol bore to oestrone—namely, a cheap, simple substance which had the same biological action as the naturally occurring product but could be made easily. Up to the present there was no evidence that this could be done, but that might be simply because investigators were not working on the right lines. It was interesting to note that any molecular modification of cortisone (except substitution of an OH group at 11) was attended by complete loss of activity.

Finally, Professor Dodds referred to adrenocorticotropic hormone (A.C.T.H.), the preparation of which presented a less difficult problem. It was possible to collect pituitaries, obtain an extract from the anterior lobe, purify it, and produce A.C.T.H. economically.

Pituitary Control of the Suprarenal Cortex

Dr. P. M. F. BISHOP said that about a year ago he gave a talk to a group of rheumatologists and suggested that he need not apologize for trying to teach them the elements of endocrinology, because he imagined their ignorance of that subject was as great as his own of rheumatology. During the past year, however, the endocrine education of the rheumatologist had outstripped the rheumatological training of the endocrinologist, thanks largely to Professor Hans Selye's oration to the Heberden Society (*British Medical Journal*, 1950, **1**, 1362 and 1383), to Dr. Hench's more recent visit, and to many other events which had brought the two subjects closer together.

The pituitary secreted a number of hormones besides that which nourished the adrenal cortex. Professor Selye had indicated how the pituitary might be stimulated to produce adrenocorticotropic hormone in excess by the various stresses which could provoke the "alarm reaction."

The speaker then described Compounds E (cortisone) and F, which were secreted by the adrenal cortex, and the substances responsible for the excretion of 17-ketosteroids in the urine. There was also to be extracted from the adrenal cortex an amorphous fraction which had so far resisted crystallization, so that little was known about it from a chemical point of view. It was known to prolong life in adrenalectomized rats, and it was believed that it was actually secreted by the adrenal cortex itself. Furthermore, there was associated with the adrenal cortex, though not necessarily secreted by it, a factor which could be relatively easily synthesized and was available in the form of deoxycortone (D.C.A.), and was mainly concerned in mineral and water metabolism. This had the properties of causing retention of sodium chloride and water, regulating the circulating blood volume, increasing the excretion of potassium, and controlling the blood pressure, so that in Cushing's syndrome there was a tendency to a lowered serum potassium, and in Addison's disease hypotension with a raised serum potassium and weight loss.

In cases of adrenocortical over-activity, the clinical features might be either those of Cushing's syndrome or of the adrenogenital syndrome. Those were the two extremes, and a series of symptom-pictures lying between them might also occur. In the adrenogenital syndrome, for instance, some of the symptoms of Cushing's syndrome, such as hypertension, might be seen. In treating patients with A.C.T.H. there was a possibility of undesirable side-effects due to the over-activity of the adrenal cortex. Rounding of the face was characteristic of Cushing's syndrome and was probably related to an alteration of fat metabolism. Other side-effects were acne, hypertrichosis, amenorrhoea, hypochloraemic alkalosis, hypertension, and osteoporosis; the last was a rare effect, but had been described in a few cases. These side-effects might be seen with either A.C.T.H. or cortisone overdosage.

The relationship between the adrenal cortex and the adrenocorticotropic hormone was particularly interesting. Stress stimulated the pituitary so that there was excessive secretion of A.C.T.H., while at the same time there was diminished secretion of growth hormone, lactogenic hormone, and gonadotropic hormone. It had been suggested that the central receptors of stress impulses might be situated not in the pituitary itself but in the hypothalamus, whence the impulses might be transmitted to the pituitary.

Experiments had been undertaken to find out whether A.C.T.H. was the only stimulating factor to the adrenal cortex. It was well known that during stress the adrenal gland produced adrenaline, and there was no doubt from experimental work that adrenaline could stimulate the pituitary to produce excessive adrenocorticotropic hormone, so that the sympathetic nervous system might well play a part in promoting the secretion of A.C.T.H.

When the level of cortical hormones in the plasma rose the production of A.C.T.H. was inhibited. But in stress it was possible that, although the cortex was stimulated to produce its hormones in excess, the tissues were particularly receptive, so that the final amount of cortical hormones circulating in the blood stream would be less than normal, and would thus continue to provide a stimulus for the further production of A.C.T.H. It was possible, therefore, that in stress there were two other factors besides the direct stimulus to the pituitary—namely, the stimulus from adrenaline and the stimulus from the diminished circulation of cortical hormones in the blood.

Various clinical trials had been reported in which insulin had been used with cortisone, and it had been suggested that this would lower the dose of cortisone necessary. That work had not been confirmed, and indeed there were a good many contradictions about it.

Risks of Cortisone and A.C.T.H. in Tuberculosis

Dr. Bishop then discussed the effect of cortisone and A.C.T.H. on tuberculous lesions. One of the experimental observations had been that cortisone prevented the formation of granulation tissue, and thus it had seemed that cortisone might prove helpful in allowing anti-tuberculous chemotherapeutic agents better access to the tubercle bacilli. But in fact cortisone did not break down already formed granulation or connective tissue, and experiments with A.C.T.H. and *para*-aminosalicylic acid and streptomycin had shown that there was no real improvement effected by the addition of A.C.T.H. Quite apart from that, however, recent work by Hart and Rees at the National Institute for Medical Research had shown that in mice with experimentally produced chronic pulmonary tuberculosis the administration of cortisone had given rise to severe exacerbations of the disease and a high mortality. In mice, unlike the human, there was no fibrous-tissue reaction, and what was seen was probably due to a lymphocytic response or possibly to depression of mitosis in the tissues.

Was it wise, then, to treat cases of Addison's disease with cortisone? It seemed an obvious application, but if the disease was due to tuberculous involvement of the adrenals an old tuberculous lesion might easily be reactivated. It was certainly necessary to be sure that a patient was not suffering from tuberculosis before administering either cortisone or A.C.T.H., and with that word of warning he would leave the subject at the present moment.

A vote of thanks to the two speakers was proposed by Dr. W. S. C. Copeman.

II.—STUDIES IN RHEUMATIC DISEASE

The annual meeting was continued on December 9 at Westminster Hospital Medical School under the presidency of Dr. W. S. C. Copeman.

Psoriasis Arthropathica

Dr. F. FRANÇON, of France, gave a short communication on psoriasis arthropathica. This condition, he said, was not common, but every physician would meet with several cases in his practice. It appeared to be more common amongst women, though psoriasis itself was more common amongst men. Clinical manifestations fell into two groups: in the first the condition began insidiously, starting in the joints of the fingers, and was followed by anaemia, muscular wasting, and loss of weight; in the second group, which was the more frequent, there was some fever and an acuter arthritis, and either large or small joints might be affected. Both types tended to run a chronic course. During the acute phases a gradually increasing number of joints were affected, but between these acute phases there were remissions, sometimes lengthy. As remissions were spontaneous it was difficult to assess the value of therapeutic procedures, but he had found a certain value, as a routine treatment, in gold injections given intravenously. But the treatment must be under close supervision, and irritating ointments on the skin must be avoided while gold was given.

Biochemical Changes in Rheumatic Fever

Dr. JAMES REID described an attempt to discover the abnormal changes in acute rheumatic fever by simultaneous biochemical and clinical investigations during treatment with salicylates. The findings were briefly as follows: disappearance of the acute manifestations, such as fever, tachycardia, and acute arthritis, was associated with the transfer of water from the cells to the extracellular fluids, increase in nitrogen and potassium excretion, and retention of sodium and chloride. At this point the patient passed from the acute rheumatic to the convalescent phase, in which the principal features were weakness, fatigue, and high sedimentation rate. The transition from the convalescent phase to normal, indicated by a progressive fall in the sedimentation rate, was associated with the removal of the excess water from the body by diuresis, an increase in the excretion of sodium and chloride, and a diminution in nitrogen and potassium output.

The main clinical and biochemical changes resulting from the administration of A.C.T.H. and cortisone were the same in character as with salicylates. The suggestion of a common action was strengthened by the observation that, in addition to similarity of clinical and biochemical effects, the side-effects were also similar. Salicylates could produce a mild Cushing's syndrome, with swelling of the face and acne.

Splenectomy for Rheumatoid Arthritis

Dr. FRANCIS BACH reviewed a small series of patients treated some years ago by splenectomy, and also in more detail the laboratory and clinical investigations in a second group on whom this operation had been performed within the last two years. He suggested that the spleen should be considered as an endocrine organ, which possibly played a part in the mechanism of rheumatoid arthritis. He was not suggesting that the spleen should be removed in all cases of rheumatoid arthritis, but that the spleen and bone marrow should be studied. In the 'thirties various cases of Still's disease in which splenectomy had been performed were reported, and in 1938 splenectomy was done in three of his own patients who were suffering from active and advanced rheumatoid arthritis, and during the last two years another small group had been subjected to the operation. The clinical improvement following splenectomy had impressed him: In some of the cases the rheumatoid arthritis had remained, even over 12 years, relatively inactive. The "fire" had gone, and the patients were left with the "ashes." In no instance had there been a flare-up. He thought that his few results might well encourage some to study in more detail the relationship between the spleen, the adrenal cortex, and the bone marrow.

Familial Ankylosing Spondylitis

Dr. R. M. MASON described a family in which there were three established cases of ankylosing spondylitis, with clinical and radiological confirmation, also one suspected case, and in the father's ancestry two presumptive cases. The cases in the living family were in the father and two children, and in another daughter the condition was suspected. The father's maternal grandfather was reported to have had a disability which resembled that of ankylosing spondylitis, and so had one of his sons. The disease might have been transmitted through the mother of the present head of the family, though she herself was not affected. All the members of this family, however, lived under the same external environment in Cambridgeshire, and it was possible, though unlikely, that the environment contained the operative factor.

Several members cited experiences of this condition with possibly some familial character.

Psychological Factors

Dr. C. J. M. CLARK read a short paper on psychological factors in the assessment of rheumatoid therapy. He stressed the importance of such factors in influencing the nature and severity of the symptoms in rheumatoid arthritis, and suggested that this influence was affected by alteration in the intensity of pain appreciation, thereby modifying joint pain, tenderness, and range and performance tests. To eliminate these effects when evaluating new therapeutic substances in rheumatoid arthritis, he advocated the use of an inert control substance without the knowledge of either the patient or those in clinical charge of him; also the arrangement for a preliminary period of observation and assessment, and the simultaneous assessment of all available objective data, such as measurement of joint swelling, temperature observations, and laboratory tests.

In reply to questions Dr. Clark confessed that he by no means understood the mechanism of these psychological factors. Some patients improved although they had no faith in the therapeutic substance or placebo presented to them. Another point was the way in which the effect of the placebo wore off for no apparent reason. Yet another factor not easy to understand was the latent period before improvement occurred; also the reason why some patients responded to one type of placebo and not to others.

Nova et Vetera

AN EIGHTEENTH-CENTURY MEDICAL DIARIST

The Diary of Sylas Neville, 1767–1788. Edited by Basil Cozens-Hardy, D.L., M.A., F.S.A. (Pp. 357; *illustrated.* £1 1s.) London: Oxford University Press (Geoffrey Cumberlege).

Diarists achieve popularity by exploiting their own personalities in their strength and weakness, by describing the social life of an age that has disappeared, or by recounting great events which they have lived through, whether as participants or spectators. The diary of Sylas Neville comes into the first and second classes. It has a special interest for medical readers because the author entered Edinburgh University as a medical student at the age of 30 in the year 1771, and he took an M.D. degree there in 1775. When his journal opens, in 1767, he is living in lodgings in London. He is a violent Republican who looks back to the "glorious days of the Commonwealth" and celebrates January 30 as the day of the "deserved death of the tyrant Charles I" by dining on calf's head and drinking the health of the King's judges in champagne and claret. When he goes to the theatre to see Garrick as Richard III and is squeezed out of the crowded pit, he consoles himself by the thought that he would not have received much pleasure if he had "got in, as that calf-headed son of a whore, George III, was there." He is a devotee not only of the theatre but also of music and the arts, and he belies the common conception of the eighteenth-century Englishman by being a lover of natural beauty. Like those other diarists Pepys and Boswell, he is not blind to feminine beauty, but congratulates himself that "every connexion I have had with women of the town was accompanied with my earnest endeavours for their reformation." He is a great sermon-taster, ardently anti-Roman, and is most religious when the small circumstances of his life go awry through his own fault: "Something very disagreeable happened. I wish it may not be attended with any bad consequences. O Lord, strengthen me to put my trust in Thee." When things go well he is correspondingly grateful, as on the unexpected appearance of his lost luggage: "I return thanks to God for that mercy."

Studentship in Edinburgh

He set up an establishment at Scratby House, in Norfolk, but when his fortune ebbed (in one year he spent nearly four times his income) he disposed of his lease and went to Edinburgh to study physic. The intellectual life of Edinburgh, "the Athens of the North," was then at its zenith, and the university was as distinguished in medicine as it was in history and philosophy. He began by attending Alexander Monro's lectures on anatomy and Joseph Black's lectures on chemistry. The medical student of that day found his curriculum as full as it is in 1950: "It would take half a man's lifetime to read all he showed us to-day, and some of them are not worth reading as may be seen from the notes I took of the lecture. This study is begun. I wish to God it was finished!" A little later he records that Dr. Hutton told him that the more medical knowledge is acquired the more it is realized how little efficacious is the art of medicine, but the physician may do much good "by affording that satisfaction which attends the persuasion of being under the care of a skilful person."

Neville was a hypochondriac, and he availed himself fully of the expert opinion that surrounded him in Edinburgh. Having an inflamed eye, he consulted Professor Home concerning it one afternoon and then took advantage of Professor Monro's advice the same evening, reminding himself that "medical assistance gratis is one advantage the students have." He was sometimes aware of the cause of the disturbances of his somatic functions: "Very ill all yesterday with the pain in the stomach, headache, etc., which I attribute to vexation arising from a dispute with Russell [his mistress] last night." He must have hoped that his fellow members of the Medical Society would not be equally percipient, for, having heard that the society had imposed some fines for non-attendance, he wrote the following appeal in the Society's book: "'S.N.' appeals that his eyes continue so much affected that he is hardly able to go on with any business, and besides he has for two weeks past a return of the stomach complaints, to which he is exceedingly liable, and therefore hopes that the Society will sustain this as a sufficient excuse for his bad attendance." He frequently consulted the beloved and famous Professor of Medicine, William Cullen, concerning his indigestion, and when Cullen had finished a lecture on dyspepsia he turned to Neville and said, "Doctor, I wish I could cure your dyspepsia; I should think half a dozen lectures well bestowed!"

The diary gives a full description of his progress in Edinburgh—his friendships, his enmities, his dirty lodgings, his "vivas" conducted in the Latin tongue, his M.D. thesis in Latin on the *Prognostick in Fevers*, and his culminating honour of presidency of the Medical Society. His first communication to the Medical Society was a commentary on an Aphorism of Hippocrates which he read and defended on Christmas Eve, 1774, as he writes, "Much better than I expected, as it was the first time of my speaking at public business and in the Latin tongue. I thank God for this mercy." His second paper was on the "Use of Wine in Typhus," which he "recommended in the warmest manner." The diary contains much comment on medical education which is not irrelevant to-day. For example, William Cullen said to him that "it is a bad lecture that is delivered in language for printing; that it is too stiff and formal; that even the correcting an error in expression makes a greater impression on the hearers and affords an opportunity for illustration by comparing the two expressions." It would be a mistake to assume that it was in 1950 that serious attention was first given to the subject of medical pedagogy.

His Epitaph

From Edinburgh he went to London to the lectures of John Hunter, "an ill-natured, waspish creature." He then lived in Italy for three years, forgetting the theory of medicine and ignoring its practice, the while his financial embarrassment was steadily increasing. He settled in Norwich, hoping in half-hearted fashion that practice would come to him, but for obvious reasons it never did. He lived in Norwich till he died in his 100th year, spending some of his leisure in writing dishonest begging letters to wealthy noblemen, and, curiously enough, these letters were not entirely unproductive, for in the last forty years of his life he subsisted almost entirely on charity. His epitaph is written in a letter by Sarah Read, his illegitimate daughter, who achieved respectability as headmistress of a school in Hertfordshire. "I am much surprised," she writes, "that a man of Dr. Neville's abilities should have so greatly abused them throughout the whole course of a long life. . . . He possessed every blessing that the world can bestow, yet they were all lost in folly and inconsistency, looking after the things of this world which he never attained and entirely losing sight of a Blessed Eternity. . . . But he is gone to give up his awful account and it does not become me to censure."

For those interested in the medical history of the eighteenth century, the diaries of Sylas Neville have an especial value. Mr. Cozens-Hardy has edited them with scholarly care and put us greatly in his debt. Neville is not a Pepys or a Boswell, but his diary equals in interest that of Parson Woodforde. Mr. Cozens-Hardy states in his introduction that "limitation of space made it necessary to cut down the very full account of his five years as a medical student." Edinburgh medical graduates will not be alone in wishing to have the Edinburgh diary printed as Sylas Neville wrote it.

D. V. HUBBLE, M.D.

According to the annual report for 1949–50 of the Central Office of Information the cost of publicity for the campaign for immunization against diphtheria was about £30,000 for the year. A survey showed that about half the mothers of immunized children under 5 years old had been induced to get their children treated as a result of the propaganda. Deaths from diphtheria in England and Wales have shown a drop every year since 1941, when the publicity campaign started, and numbered 85 in 1949.

Reports of Societies

ROYAL SOCIETY OF MEDICINE

THE PRACTICE OF EXPERIMENTAL MEDICINE

Professor R. A. McCANCE, president of the Section of Experimental Medicine, gave his inaugural address on December 12. It was entitled "The Practice of Experimental Medicine," and in it the speaker discussed the moral, ethical, and legal aspects of experimental work on human beings.

This was a delicate matter which demanded the serious thought and consideration of all those interested in medicine to-day. Professor McCance pointed out that, although Claude Bernard's writings entitled him to be regarded as the "father" of experimental medicine, John Hunter, Jenner, and Harvey had been brilliant exponents of it long before his time. The speaker then went on to a definition of the word "experiment." This should always involve a change of conditions with subsequent observation of the results. In one sense the attempt to cure an individual patient might be regarded as an experiment if the results were observed and followed up, but for the present discussion he preferred to extend the definition of the term to include anything done to a patient which was not generally accepted as being for his direct therapeutic benefit or as contributing to the diagnosis of his disease.

The study of man must always take first place in any department of experimental medicine, although much of the work could often be done on animals. Species differences sometimes introduced difficulties, however, and one of the attributes that made for success in experimental medicine was the instinct which told the investigator when to check his results on a second species and, above all, when to turn from animals to man.

Experiments on Man

If one wished to make experiments on animals in this country one had to comply with the law and obtain a licence from the Home Office, and no one would wish to do otherwise. Human beings were the only mammals for which a vivisection licence was not required; but the use of one's fellow-creatures as experimental animals raised all kinds of issues which had never been seriously faced.

Professor McCance discussed the position as regards both patients in hospital and normal healthy people. The experiment might be one of commission, and consist of making some test on a person for which there was no obvious or immediate need. Equally, it might be one of omission and consist of withholding treatment from a "control." How much should be done without asking the person's permission? No experiment could be carried out on healthy persons without their co-operation and consent, but when a person came into hospital many investigations and tests were made as part of the hospital routine, and it was easy, without upsetting the patient in any way, to make other simple tests which, although they might help to define the effects of disease on function in general, might be of no direct benefit to the particular patient concerned. If an investigator decided to ask a patient's permission to make some investigation on him, he was at once up against the difficulty of explaining exactly to a patient the nature and object of his work. He could tell the patient only in very general terms what his experiment would involve, explain the nature of the risk (if there was any), and ask for his co-operation. The whole responsibility always lay with the investigator. The patient trusted the staff of the hospital, of which the investigator was one, and the investigator, knowing this, might dispense with the formality of asking for "permission" when his tests simply involved procedures which were commonplaces of clinical practice. He generally preferred to take the patient into his confidence over anything more elaborate, and this was where conscience and judgment became so important. Patients should be aware that at the best hospitals experimental work was carried out, not only for the advantage of the immediate sufferers but also for the benefit of mankind, and that they themselves owed incalculable advantages to work of this kind which had already been done on others. In actual fact patients rarely refused permission for investigations to be made on them, and many appreciated the extra attention which it involved. Opposition to experimental work was more likely to come from the physicians under whom the patients had been admitted, and from the nursing staff. There was one fundamental difference between the investigator and the physician. A good investigator must be interested primarily in his problem. The physician was concerned all the time with his patients. The physician was sometimes apt to be rather intolerant of the investigator, forgetting that the treatment he was prescribing was the result of experimental medicine, and that what he would have regarded as an unjustifiable experiment 20 years ago might have become one of his standard diagnostic or therapeutic procedures.

The basis of all successful experimentation was control of the conditions, and for much work in experimental medicine normal men and women were far more suitable than patients in hospital wards. In enlisting subjects, it was always a great help to have made the same experiment on oneself first and to be prepared if necessary to do so again. An experienced laboratory worker was probably the ideal experimental subject, though much useful work had been done with students, Service personnel, and also with groups of conscientious objectors during and just after the war.

Professor McCance concluded with the following words: "The medical profession has a responsibility not only for the care of the sick and for the prevention of disease but for the advancement of knowledge upon which both depend. This third responsibility can only be met by investigation and experiment, and from the nature of things it is always likely to remain the task of a few men and women specially gifted or trained for the purpose. Some of these people have in the past sacrificed considerable wealth for the mental satisfaction of their work. This may not have to be so in the future, but all such practitioners have a right to expect the fullest co-operation from their medical colleagues, from nurses and other assistants, from hospital managements, from patients and relatives, and from the community at large."

MANCHESTER MEDICAL SOCIETY

Dr. J. H. KELLGREN, in discussing pain as an aid to diagnosis before the Section of Odontology of the Manchester Medical Society, said that the study of experimentally produced pain in normal human subjects had led to the development of a useful vocabulary for describing the different pains of disease and injury.

The simplest description of pain was in terms of its distribution and time-intensity curve. Thus a needle pricking the skin produced a momentary pain felt at a point which could be located with considerable accuracy, while cardiac angina was a continuous steady pain felt widely within the chest and often spreading into the arm and jaw. There were three fundamentally different types of pain, subserved by different types of nerve fibre and accompanied by different reflex phenomena—namely, the aching-deep, the pricking-burning (first cutaneous), and the itching-stinging (second cutaneous) types.

Toothache

The teeth gave rise to only two forms of sensation—pressure and pain; thus behaving in this respect like all deep somatic tissues. Stimulation of carious teeth with an alternating current produced toothache of maximal intensity for a few minutes, the pain spreading widely in the face and head, with lacrimation and injection of the conjunctiva; later, the face felt stiff, and diffuse pain developed in the face and head. This was accompanied by deep tenderness of the muscles and periosteum and by cutaneous hyperalgesia, lasting for many hours, with abnormal sensitivity in the tooth to mechanical and electrical stimuli and to cooling. Anaesthesia of the sensitive tooth which was the source of pain invariably produced complete relief.

Pain, however, might be referred to the teeth from other structures such as the temporal and masseter muscles, or be due to irritation of the dental nerves somewhere along their courses to the brain. In these instances the tooth would probably not be so abnormally sensitive to stimuli, and anaesthetizing the tooth would have only a moderate and variable effect upon the pain. The temporomandibular joint may be another source of obscure pain felt deeply in the face, local analgesia of the joint helping to establish the source of pain.

The effect upon pain of alterations in the local circulation was also of interest; in the head the arteries were closely surrounded by pain nerves, and an abnormal amplitude of pulsation in the arterial tree caused severe pain as in migraine and the histamine headache. In these conditions arterial occlusion relieved the pain. Venous congestion might also have a marked effect upon pain in various conditions.

Correspondence

Thiouracil and Vertigo Epidemica

SIR,—Dr. C. Barrington Prowse in his paper (December 9, p. 1312) describes, under the heading of "a toxic effect of thiouracil hitherto undescribed," a complex of symptoms which rather suddenly appeared during the treatment of a case of thyrotoxicosis with thiouracil. The patient complained of difficulty in focusing her eyes; she had horizontal nystagmus, felt "light-headed," and stated that everything she looked at "seemed to be jumping about." After another four days she developed intense vertigo, and movements caused nausea and sickness. During the next three weeks she gradually improved.

I should like to draw your attention to the fact that the described illness in every regard is similar to cases observed and published in the Scandinavian countries under the heading of "vertigo epidemica" or "neurolabyrinthitis epidemica." Many observations of epidemic appearance of these symptoms—more or less prominent—have been made. The strong horizontal nystagmus was a characteristic phenomenon in the cases observed.

I suggest that the symptoms observed in Dr. Barrington Prowse's case have not been side-effects of thiouracil, but have been complicating vertigo epidemica or neurolabyrinthitis epidemica.—I am, etc.,

Bispebjerg Hospital, Copenhagen. E. MEULENGRACHT.

Tuberculosis as a Prescribed Disease

SIR,—In your annotation (December 9, p. 1321), referring to my dissension from a recommendation of the Industrial Injuries Advisory Council that tuberculosis may be presumed to have been contracted at work up to two years after employment ceased, you state:

"He also considers that there should be a definite minimum qualifying period of six months' employment (the council's recommendation is six weeks) before the presumption is permitted that the infection was a result of previous employment."

I fear you have confused two issues. The council's recommendation of six weeks (with which I am in agreement) is in respect of a person who enters the nursing profession and contracts the disease within the first six weeks of such entry, because the consensus of medical opinion is that the period of incubation is six weeks, and therefore if a person shows the disease within the first six weeks the odds are that she acquired it before starting nursing.

As the council's recommendation at present stands, however, a nurse who shows the disease only *after* giving up her work need have worked no minimum qualifying period whatsoever before being eligible for benefit. Consequently, to take the extreme, a woman might enter the profession and be attached to a T.B. sanatorium for one day only, and 23 months afterwards contract the disease. As she can prove that for the period of one day (or even, say, one week) she was in "close and frequent contact" she will get the benefit of presumption. This, to my mind, is taking matters too far, which is why I ventured to dissent, and suggested that in order to obtain the benefit of presumption a person must have been in the nursing profession for a minimum period of six months.

I am aware that it is open to the Ministry to rebut the evidence, but I am informed on the highest medical advice that rebuttal in the case of a person who can prove "close and frequent contact" would be extremely difficult. You will also appreciate that there is no quantum of time laid down in respect of "close and frequent contact."—I am, etc.,

London, S.W.1 T. A. E. LAYBORN.

Truth about Tuberculosis

SIR,—Please accept my thanks for the publicity you have given to the urgent need for a thorough overhaul of our tuberculosis service (e.g., December 16, p. 1373). For over 20 years I have tried to interest our profession in the idea that this disease of tuberculosis should and could be prevented and cured. We all know that many cases of tuberculosis do in time get cured by nature and not by any medical treatment, and yet no one has shown the profession and the public how it is done. I trust that you will force the Ministry of Health to inform the public what happens to all those persons who have had our sanatorium treatments. Let the public now be told the truth. Is it a fact that nearly 50% of all sanatorium patients have died from tuberculosis within five years of their admission? Do patients get admitted into our sanatoria when there is no chance of their either getting cured or having their disease permanently arrested?—I am, etc.,

Itchingfield, near Horsham. S. G. TIPPETT.

Tuberculosis and the Health Service

SIR,—When I read the headlines (taken from the Report of the Tuberculosis Group) in the *Birmingham Mail*, December 14, "Tuberculosis Provisions a 'National Scandal,' Sufferers Die Without a Chance in Life," and the headlines in the *Daily Mail*, December 15, "We Could End T.B. in a Generation, Doctor Points the Way," with the statement that "tuberculosis could be wiped out in a generation if there were more nurses, more beds, better after-care, more machines for mass radiography, and isolation of infected persons," I was shocked. Is there any truth? It was a relief to see your leader of December 16 (p. 1373), and, like many others, I wished that the following words from it had been given at least equal publicity: "Behind all the discontent and argument stand the facts that *the mortality from tuberculosis is decreasing rapidly*, that the number of new cases is increasing, that *the average age at the time of first infection with tubercle bacilli is rising*, and that *the expectancy of life of tuberculous persons is lengthening*."

If it were realized by the members of the general public that most of us have had tubercle and have recovered from it without knowledge or treatment, that the statements which I have italicized are true, and that the increased number of new cases has merely come from the application of more and more tests—i.e., mass radiography, etc.—they would be less scared by the propaganda of fear to which our tuberculosis experts are subjecting them. Cleveland has just completed its mass radiographic survey of 688,204 people with 23 *x*-ray units, to find that it has 27% less tuberculosis cases than was estimated—i.e., about the same percentage as we have; but it has its slums, as we have.

I have carefully read through the Report of the Tuberculosis Group. Is not the dominant note self-interest? Read these recommendations:

"A chest clinic serving, as recommended, a population of 200,000 would need an establishment of one consultant, two assistant physicians, and an appropriate staff of registrar grade. The lay staff would comprise one almoner, five health visitors and clinic nurses, and five clerks."

"A large full-time clinic for chest diseases (all kinds) established in a general hospital will require its own permanent and specially trained auxiliary staff."

"The medical officer of health should delegate the supervision of the work of these visitors to the physician for chest diseases." Why?

"A first class *x*-ray unit and provision for tomography is regarded as essential if the necessary quality and comparability of radiographs are to be maintained. The radiologist should be willing to leave the routine reporting to the chest physician." Naturally.

"Regular consultation sessions between sanatorium physicians, physicians concerned with clinic work, and other interested persons (especially thoracic surgeons) should become routine practice both in clinics and sanatoria." More and more sessions.

"Medical staff, especially in sanatoria, may have to be increased during the summer to allow for holidays."

"No medical officer should remain in mass radiography for less than one year or more than two." Why?

"The terms of service for chest physicians must, therefore, be the same as for other consultants."

Such are the modest terms for the chest physician. But what about his handmaids, the nurses? Are they to be upgraded? Let us see:

"... inclusion of tuberculosis in the general nursing curriculum and the regular secondment [surely enforcement is better English?] for three months of all student nurses from general hospitals to hospitals specializing in chest diseases."

"Voluntary secondment of trained staff for six or twelve months would also be most useful."

"Nurses in general training who present minimal lesions to be advised to accept temporary secondment to sanatorium nursing." (As it could be said that the majority of radiographs of nurses show some minimal lesions, what a power is to be given to the chest physician: he would never be in want as long as the general hospital had nurses. But I found a study of the case histories in the *Prophit Tuberculosis Survey* rather ominous in this respect.)

In the light of these recommendations I am fully in agreement with the final request of the Tuberculosis Group that "this comprehensive and forward-looking report should receive the attention it deserves." And, having disposed of it, we should endeavour to get our available slender resources devoted to bettering those things which we have proved are lowering fast the death rate: improvement in the housing of the people to a state which would permit the general practitioner to treat the patients in the best place—the home—and the provision of good, fresh, wholesome, nourishing, cheap food. For, as the Brookings Research Institution report recently stated, "Standard of living has more influence on health than has quantity of medical care." It has been my experience that increase in the number of staff leads not to a reduction, as one would expect, but to an increase in the number on the waiting-list. Every man and woman has something which the doctor could advise on or treat.—I am, etc.,

Birmingham. JAMES F. BRAILSFORD.

SIR,—It is indeed unfortunate that the Tuberculosis and Diseases of the Chest Group committee did not have as a member a director of a mass radiography unit. This would have prevented it coming to such dogmatic and misguided conclusions on the working of these units. Most chest physicians are already fully occupied and will not relish the descent upon them of large numbers of harassed patients waiting for diagnoses to be made on their radiographs. Following a miniature film, the patient will have been recalled to the unit for a large film and then referred to his general practitioner, who may, or may not, refer him to a chest clinic. This procedure may possibly occupy up to two weeks or more, especially in the case of a busy chest clinic working on an appointment system. All the time a patient is waiting to hear the result of his radiograph, and, having been recalled for a large film, he is undergoing a severe mental strain. To prolong this time unnecessarily is indeed cruel, and in the long run bad propaganda for the mass radiography service.

The medical director of a mass radiography unit should be competent to make a diagnosis on the majority of large films, and indeed his work will lose a lot of interest to him if he is not prepared to do so. Only three or four persons out of every 1,000 examined are found to have active tuberculosis. Most of the remaining cases of abnormalities come under the heading of minimal lesions or presumably inactive disease. These cases constitute the biggest difficulty in diagnosis. Where there is any doubt about activity radiologically, the patient should be seen by the medical director for a clinical examination, which should include the taking of a personal and family history, sputum examination, etc. He can then advise and, in many cases, allay the patient's worst fears. As a result of the examination it may be thought that the patient should be under observation, and his practitioner can be advised to refer him to the chest clinic at a later date for a further radiograph. To refer all cases of inactive disease immediately to the clinic is unnecessary, time-consuming to the patient, and additional work for the chest physician.

Whether a mass radiography unit should follow up cases with minimal lesions, rather than pass them on to the chest clinic, must depend very much on the area covered, as a patient cannot be expected to travel long distances to the unit when there is a chest clinic much nearer his home.

The committee does not give its reasons for suggesting that a medical officer should not remain in mass radiography for more than two years. At a recent conference of medical directors it was the general opinion that a career could be made in mass radiography and that the work did not become tedious. It must be remembered that a unit director has the unique experience of reporting on 1,000 chest *x*-ray films a week. Being medical director of a unit making 40,000 examinations a year is not a full-time occupation, provided he has the assistance of an efficient organizing secretary and can confine himself to clinical work and the general direction of the unit. The medical director should preferably also be in charge of a chest clinic serving a population of about 40,000, or, if this is impracticable, act as assistant at a larger clinic. It is quite wrong to think that his time-table "is so irregular as to prevent him fitting into a clinic time-table." Clinic work enables a medical director to keep abreast of modern trends in the prevention and treatment of tuberculosis, and also helps him to appreciate the difficulties of chest physicians to whom his cases are referred. Most mass radiography units serve the areas of several chest clinics and are likely to do so for some time to come. The unit should be in the charge of a medical officer who can co-operate with all the chest physicians concerned, and not under the direction of one of them.—I am, etc.,

Aylesford, near Maidstone. G. I. REES-JONES.

Dead Bodies in Water

SIR,—The correspondence you have received on this subject (December 16, p. 1389, and earlier) may appear to be of academic rather than practical interest, but I would draw your correspondents' attention to an article by a Special Correspondent in *The Times*, December 12, p. 5, entitled "High Speed Flying—Research into Stress and Strain on Pilots." Among other things the writer describes experiments carried out at the R.A.F. Institute of Aviation Medicine, Farnborough, on the design of a new life-jacket, and states: "... At Farnborough these jackets are tested in a water tank to discover, for example, the way in which an *unconscious man* will float, and—typical of the thoroughness of the institute—the subject is actually anaesthetized while in the water." The italics are mine.

It is true that the above experiment relates only to an unconscious man, but I suggest that the attitude assumed by a body of either sex in the water may be of importance for searching aircraft of the Air Sea Rescue Service. If the pilot of a spotting aircraft was able to judge, by some simple criterion, whether the body was male or female and alive or dead, then, especially in times of war, it would prevent other lives and craft being risked until such time as the corpse could be retrieved. Such knowledge may also assist a pilot in peacetime when searching an area in which several aircraft or ships are known to have foundered, or in flood disasters. In the latter case the point mentioned by Dr. Willoughby, whether the element in which the body is found is salt or fresh water, may be important.—I am, etc.,

London, E.7. J. A. COPPING.

Exercises in the Bath

SIR,—In answer to Sir Adolphe Abrahams's criticism (December 9, p. 1329) of my paper (November 18, p. 1153) I reply that the expression oxygen pulse is well known as expressing the amount of oxygen used per beat of the heart, in oxidizing waste products. The table showed that the total oxygen used in Togna's case was much greater in exercise in the air than in exercise in the bath. So, too, it was of course very much greater in the case of the famous marathon runner. A remarkable result was that Togna's oxygen pulse-rise equalled that of the marathon runner when doing most of his exercises in the bath. This I attribute to the fact that Togna by years of exercise in the bath has developed his muscles and lessened his adipose tissue to a great extent. The figures given in my table confirm those found by Professor G. P. Crowden. I emphasize the oxygen pulse-rise as expressing the efficiency of the circulation in removing waste products. If Sir Adolphe Abrahams had studied Togna's pamphlet, to which I apologize for not giving the reference, published by the Caxton Press, he would, I think, have not made an unmerited sneer at "effortless splashing about in warm water." He would have realized that the exercises are designed to bring every muscle into action, and self massage of the muscles and the skin in all parts, which result in an efficient oxidation everywhere, and this without undue effort or strain.

"The corpulent middle-aged and elderly" will not have "the psychical advantage of believing that they are even surpassing their more vigorous self-exhausting brethren," but will find great advantage to their health.

Dr. N. J. Ainsworth will also find the answer to his letter in Togna's pamphlet, and Togna, I know, would be glad to demonstrate his exercises to these critics.—I am, etc.,

Lowestoft. LEONARD HILL.

Congenital Deformities

SIR,—Having read with interest Dr. A. K. Duraiswami's article on "Insulin-induced Deformities in Chick Embryos" (October 28, p. 1002) it would be as well to point out that any application, even tentative, to congenital deformity in humans would be premature. His findings that insulin applied to the growing chick embryo during the organo-genetic period causes stunting of growth, associated at different periods with skeletal abnormality or generalized imperfect bone formation, with the suggestion that certain human abnormalities may be caused in a similar way, might lead to confusion of thought on this difficult subject.

Mr. Denis Browne's use of the word "foetus" (December 2, p. 1277) without qualification is misleading in this respect.

In a paper I gave recently I pointed out that certain deformities, including congenital pseudarthrosis and club-foot, can be accounted for by spatial impairment occurring at the 7th to 10th week of intrauterine life, a period when organo-genesis is ending and the foetus becomes rigid (i.e., capable of acting as a lever) and fills the uterine cavity for the first time.—I am, etc.,

Sheffield. G. C. GORDON.

Popliteal Ligation for Post-phlebitic Leg

SIR,—Division of the superficial femoral vein in Scarpa's triangle having proved of but temporary value, the protagonists of this principle, nothing daunted, have transferred their attentions to the lower end of the main deep venous trunk. It is perhaps an advantage that they have slid down the venous banister at one fell swoop and not stopped at the various landings in Hunter's canal, for at least when this method has proved itself a failure they can go no further.

As I understand Mr. A. J. Walker's recent paper (December 9, p. 1307), his thesis is that when the main deep venous channel of the lower limb is incompetent, following recanalization of a thrombotic process, it is useless in the erect posture and should be divided, the limb blood returning to the heart via a collateral deep circulation. Surely it is to be expected that as the collateral veins slowly open up to accommodate the increased flow their valves will cease to meet in the midline and they too will become incompetent. In the course of time (follow-up time), we shall be left without any competent deep veins in the lower limb, in contradistinction to the original condition, when at least we had a certain proportion.

No doubt it will be argued that the incompetent superficial femoral vein is of no value at all and therefore its removal from the circulation can do no harm. I submit that this argument is based on false premises, for, even if we admit (and it has yet to be proved) that in the erect posture the flow within it is retrograde and the collateral veins are bearing the brunt, this is not so at night, for during recumbency the incompetent vein can act like any hollow tube and pass blood centripetally to the heart, thus relieving the strain on the collateral veins; following popliteal ligation the collateral veins have no such respite. It must be remembered that the average person spends at least one-third of his life in bed.

Of the 27 legs Mr. Walker lists as having been followed up, 23 still showed oedema. As oedema is the main cause of gravitational ulceration, it is to be expected that the hopes expressed for an eventual happy result will remain unfulfilled.

Finally, Sir, the most adequate commentary upon the success of this procedure is provided by the patients themselves, for it is noted that out of the 26 patients followed up only 11 thought they had benefited. It would be interesting to learn whether these 11 patients are at the 3-month or 15-month end of the follow-up table.—I am, etc.,

London, W.1. STANLEY RIVLIN.

Heredity and Leg Ulcers

SIR,—With regard to the most interesting article by Dr. S. T. Anning (December 9, p. 1305), I note that in his group of cases he states that "the presence of a familial tendency to ulceration is usually associated with the inheritance of varicose veins." I am wondering whether he has also noted something which has always intrigued me, and that is that so frequently the same type of varix is transmitted from parent to child. For example, "athletic veins" may be transmitted, and, in cases where the main saphenous vein appears to be normal, "hair veins" only will be seen in successive generations. Furthermore, one frequently sees a similar pattern in the arrangement of the varices in both mother and child.

I do not know whether this observation has been noted elsewhere, but there is no doubt that in a varicose clinic this further remarkable facet of heredity may be observed.—I am, etc.,

London, W.1. R. ROWDEN FOOTE.

Transmission of Kala-azar

SIR,—Two letters (November 4, 1060; December 9, p. 1333) have appeared recently in the *Journal* claiming that the "sandfly theory" has been exploded, and expressing great concern that the textbooks should no longer deceive their readers by statements that kala-azar is transmitted by sandflies but should confine themselves to facts. This opens up a big question: what exactly is a fact?

There is a story—which I feel sure must be a classic but which I only heard in a sponsored broadcast in the United States—of a British professor of medicine (or of some medical subject) who concluded his course of lectures with the remark, "Gentlemen, probably half that I have told you in the course of these lectures is untrue; unfortunately, I don't know which half," or words to that effect.

The fact that kala-azar is transmitted from man to man by the agency of sandflies of several species is as established a fact as the majority of statements that appear in textbooks. It is the opinion of an overwhelming majority of those qualified by experience to express an opinion on this subject, and no arm-chair criticisms by scientists, or others, who have had no practical experience of kala-azar, or of the other leishmaniases, is likely to upset a theory based on the work of scores of research workers in many countries over a period of many years.

The critics complain that those in a position to do so have not attempted to answer their criticisms. This is not very surprising. No new facts have been brought to light, and, although some of the criticisms point out genuine gaps in the story of the transmission of kala-azar by sandflies, we (if I may include myself among those who helped to build up the sandfly theory) are fully aware of these and hope that our successors in this field will attempt to fill them. Other criticisms are based on false premises and yet others are merely silly. Many of the founders of the sandfly theory have left that particular field, are now otherwise busily engaged, and are not unnaturally unwilling to engage in a battle of words

I will not embarrass you by answering their numerous criticisms point by point, as this would occupy many pages of your valuable

journal, but perhaps, Sir, you will allow me space to make one comment by way of justification on each of the types of criticism specified above.

It is of course obvious that sandflies do not feed on raisins in nature. The fact, however, that they readily feed on raisins in the laboratory indicates that they are not pure blood feeders, as was at one time supposed. In the wild state they have a wide choice from the juices of fruits and latices of plants. The nature of their choice might explain some of the apparent anomalies in the distribution of kala-azar.

There is no justification for the statement that the sandfly *Phlebotomus argentipes* lives only five days in nature, just because in one particular experiment survival for longer than five days could not be demonstrated. In the laboratory they will live for several weeks under conditions of temperature and humidity which they could enjoy in nature in the endemic areas, at least for several months in the year.

The suggestion that throughout the whole of the monsoon months sandflies could never find a dry enough spot to "bite" on the skin of man is merely silly.

Although the late Dr. Clifford Dobell never, as far as I remember, took any active part in the investigation of this particular problem, one would naturally respect his opinion. It is therefore a great pity that the contents of his letter were not made public earlier in order that one might have ascertained which were the particular criticisms that he considered valid, and also possibly why he chose this indirect method of expressing his disapproval of the sandfly theory.—I am, etc.,

Journal of Tropical Medicine and Hygiene. L. EVERARD NAPIER.

Modified Caesarean Section

SIR,—Dr. John P. Erskine may have raised a very valid criticism (December 9, p. 1335) of a T-shaped incision in the lower uterine segment for caesarean section, although I have never seen it used nor heard of its being employed until now. A few years ago I saw a "silent" uterine rupture in a patient who had had a previous classical and a previous lower-segment caesarean section. The resulting T-shaped scar had given way at the juncture of the two incisions, and the intact membranes were bulging through. The rupture was discovered in the course of an elective repeat caesarean section, performed after labour had just started. As the result of this case, I wondered if it were a wise procedure to perform a lower-segment section where there had been a previous low classical operation, unless the lower-segment incision could be placed well below the lower end of the vertical one. There may be a similar danger in a T-shaped incision in the lower segment. At any rate, I consider that it is safer to gain further access by turning up the ends of the transverse lower-segment incision—that is, by making it U-shaped.—I am, etc.,

Manchester. T. F. REDMAN.

Orf in Man

SIR,—I was interested in the letter from Dr. A. K. Rankine about orf in man (December 2, p. 1279). I have seen a few of these cases in my time, and always associated with sheep. Might not these cases be due to sheep pox? The loculated pearly blister is a little suggestive.—I am, etc.,

Kirriemuir. R. D. CAMPBELL.

Hexamethonium in Hypertension

SIR,—With reference to the use of hexamethonium bromide in the treatment of hypertension (A. Campbell and E. Robertson, October 7, p. 804), I would like to record a case of severe hypertension in a girl who received quite large doses of penta- and hexamethonium bromide without any significant change in her blood pressure.

She was 16 years old, height 65 in. (163 cm.), weight 117 lb. (53 kg.), and found to have a blood pressure of 210/140 mm. Hg at routine examination.

Special tests revealed no apparent cause for her hypertension. Renal function was good, her fundi normal, and urine examination revealed no red cells or casts. Renal radiographs showed very slight dilatation of her right renal pelvis. Radiograph of her heart and E.C.G. were normal.

A screening test was performed with 17 mg. of compound 933F intravenously to exclude a phaeochromocytoma. This produced a sharp rise in blood pressure, a so-called negative response.

After three days' rest with barbiturate sedation the blood pressure settled down to an average level of 200/140 mm. Hg.

Pentamethonium bromide was commenced in doses of 25 mg. intramuscularly 8-hourly, and rapidly increased to 100 mg. 8-hourly as the blood pressure did not fall. Readings such as 180/140 (lying), 160/125 (sleeping), and 180/150 (standing) were representative. For several more days, during which mydriasis was noted, the dose was increased to 150 and then 200 mg. 8-hourly with no effect.

At this stage 75 mg. was given intravenously. The lowest reading following this was 180/135 mm. Hg.

Injections were abandoned and 750 mg. of hexamethonium bromide was given 6-hourly as tablets: again with no response. Increasing the dose to 1 g. and then 2 g. four times a day gave readings such as 220/150 (lying), 180/125 (sleeping), 185/150 (standing).

The trial ended at a dosage of 2.5 g. 6-hourly with the patient complaining of some nausea and inability to focus. The patient was not questioned about constipation. She has now been referred for further investigation with a view to sympathectomy.

This case seemed ideal for a trial of these ganglionic blocking agents, as vascular degeneration had not yet appeared. Although I cannot offer an explanation for this failure I hope to have the opportunity for further trial of what appear very promising drugs.—I am, etc.,

Sydney, Australia. ZELMAN FREEMAN.

Red Cell Stippling in Poisoning

SIR,—I should like to draw attention to the fact that substances which belong to the same chemical group of heavy metals have a similar action on red blood corpuscles, or, more precisely, that bone marrow made anoxaemic by poisons of a certain chemical group shows similar biological response. This may not seem surprising, but I could not find any reference to the fact that basophil stippling of red blood corpuscles can occur alike in chronic lead, bismuth, and mercury poisoning.

It is a well-known fact that the blood picture of patients suffering from chronic lead poisoning shows a secondary anaemia and punctate basophilia or stippling. I took the opportunity of examining the blood of patients who had received comparatively large doses of bismuth or mercury by injections or as ointment, as used in antisyphilitic treatment in the days before penicillin. These patients showed no sign of bismuth or mercury poisoning, but, just as in lead poisoning, supravital staining with brilliant cresyl revealed basophil stippling of the red blood cells.—I am, etc.,

London, W.9. W. GROSS.

Emotions and the Skin

SIR,—The interesting findings of two American authors to which you refer in your annotation (December 9, p. 1322), though running counter, as you say, to prevailing clinical opinion, are very much in agreement with now fairly generally accepted views on psycho-dynamics. While it may be difficult to distinguish between hostility and resentment, one cannot fail to see that language has coined quite a number of words, all expressing some sort of enmity, but by no means of identical meaning. The slightly different shades to which they appear to give expression correspond with the chiaroscuro in the texture of the hostile sentiment, which in its emotional organization quite naturally shows infinite varieties. There is, I think, unanimity regarding the part sublimation plays in the process of sentiment formation. Though sublimation is not necessarily preceded by repression, there can be no sublimation without inhibition of primitive instinctual drives, and whether a healthy sentiment emerges or a morbid complex would very much depend on circumstances. In conditions of illness, whether purely mental or associated with physical disease, one invariably finds inhibitory factors of a high degree of intensity, the elimination of which alone quite frequently removes symptoms. The absence, therefore, of aggressive fantasies during a period in which urticaria is present would not indicate the absence but the inhibition or repression of aggressive sentiments. If repressed, hostility is "not felt" and "there is nothing the patient can do." Nothing, indeed, but develop urticaria (or neurosis) from emotional constipation. And the cure depends on the purgatory effect of emotional discharge.

The results which Drs. Shorvon, Rook, and Wilkinson (December 9, p. 1300) obtained through "abreaction" methods would appear to be to some degree only in agreement with these views. But it should be noticed that the authors, though emphasizing that their method works through the release of pent-up emotions originating in traumatic experiences, also say that it is not necessary to "abreact specific incidents accurately." This would confirm the view that the curative effect lies in a "general release of tension and aggression." The histories of the five cases published would appear to support this. They make it also quite clear that treatment has "of course" to be supplemented by other psychotherapeutic measures, including social readjustment.

Though the use of drugs may present an improvement on the original Breuer–Freud technique, producing a semi-hypnotic state, which I have been practising in suitable cases ever since the Swiss psychiatrist Ludwig Frank revived it in 1913, it should be remembered that, unless it has been made part only of a psychotherapeutic plan, abreaction has generally been found unsatisfactory.

On the other hand, the beneficial effect of the release of inhibited affect may have been underestimated in the past. It is certainly not incidental that the rediscovery of cure by "disinhibition" and excitation was made in America, where Andrew Salter (*Conditioned Reflex Therapy*, Creative Age Press, N.Y.) claims to achieve miraculous cures of practically all neuroses by the "reconditioning" of inhibited emotions. His method is simple enough and could be employed by any practitioner interested in psychotherapy and not put off by Salter's "disinhibited" view that psycho-analysis "should go out in the jungle and die." Strangely, his conditioned-reflex therapy does not at all clash with analytical methods, so long as they are "active." In fact, child analysts, romping with their little patients and allowing themselves not only to be loved but also to be kicked in the transference situation, have long been using similar methods.

The theoretical foundation of the conditioned-reflex therapy, based as it is on Pavlov and behaviourism, is over-simplified, but it has the advantage of being expressed in physiological terms, the desirability of which is stressed, Sir, in the last sentence of your annotation.

Whether "feeling-talk" works equally well in this country remains to be seen. Anyway, I have made use of it in a few suitable cases and must say it refreshed not only the patient but myself as well.—I am, etc.,

London, N.W.11. B. C. SAALER.

Survival on Less than One Kidney

SIR,—In the *British Medical Journal* of August 26, 1939 (p. 445), I reported the case of a woman of 39 in whom the whole of the left kidney and nearly 30% of the right one were removed for calculus and sepsis. It is interesting to report that the patient, now 52 years of age, is in perfect health and has just completed a strenuous motor tour of Europe. She places no restrictions on her solid or liquid diet, and there is no infection in the urine or symptoms of ill-health of any kind. The blood pressure, which was 164/90 mm. Hg at the time of the operation, remains on the high side. She is short of veins and not anxious to have pyelograms, but the plain shadow of the right kidney is large and circular. As observations on the effect of removal of more than 50% of the total kidney substance are uncommon, this annotation to my original article of 1939 may be of interest.—I am, etc.,

Johannesburg. R. CAMPBELL BEGG.

B.M.A. Policy

SIR,—I write to congratulate Dr. R. Prosper Liston on his letter (December 16, p. 1389). All that he says is only too true, and it is essential that the B.M.A. should produce, without further delay, a plain simple statement of constructive character, to make known to the Minister and to the public the necessary alterations to produce a satisfactory Health Service.

Recent Guild meetings in this area have emphasized the fact that most doctors are chiefly interested in improving the existing Health Service, rather than in demands for larger capitation rates, and it is imperative that the B.M.A. should produce a positive policy to improve the Health Service. Only this, I think, will unite all branches of the medical profession.—I am, etc.,

Stonehouse, Glos. W. G. MURRAY-BROWNE.

British Student Tuberculosis Fund

SIR,—Though such centres are well known abroad and though the need for such a centre has recently received recognition in the B.M.A. Report on Tuberculosis, there exists in this country no particular institution in which students with tuberculosis can receive medical treatment while continuing their studies. The British Co-ordinating Committee for Student Health, which represents the British Medical Students' Association, the International Student Service, the National Union of Students, the Scottish Union of Students, the British Tuberculosis Association, the Joint Tuberculosis Council, the National Association for the Prevention of Tuberculosis, the Tuberculosis Group Committee of the B.M.A., the Association of University Teachers, the Association of Principals of Technical Institutions, and the Associations of Teachers in Colleges and Departments of Education, is organizing a Trust Fund with the primary object of establishing such a centre, and the committee would, through the courtesy of your columns, like to invite donations, large and small, to this fund.

It is quite impossible at the present moment to set up a full-scale sanatorium treating students in all stages of tuberculosis. It is intended that the centre now proposed should cater for students already sufficiently recovered to be able to take advantage of the educational facilities that it is part of the scheme to provide. It is at this stage that occupational therapy—and for a student his education is occupational therapy—is of most help; it is at this stage that the present inability to continue his studies is most disheartening to the student, and, most conveniently, it is at this stage that the demand for skilled nursing is least. Even from the point of view of the treatment of tuberculosis in the non-student population, the centre is likely to prove an asset, since the transfer of students to the centre from sanatoria would lead to the earlier freeing of sanatorium beds.

The arguments for setting up a centre especially for students do not apply exclusively to those usually called "students," and for this reason it is intended to make the centre available to senior as well as junior members of universities and other institutes of higher education, to research students as well as undergraduates, to university and college teachers as well as those *in statu pupillari*.

Any donations to the fund should be sent to one of us, c/o British Student Tuberculosis Fund, Tavistock House South, Tavistock Square, London, W.C.1. Cheques should be made payable to the British Student Tuberculosis Fund.—We are, etc.,

F. R. G. HEAP.
C. R. MORRIS.
ALAN F. ROOK.

London, W.C.1.

POINTS FROM LETTERS

Haematemesis from Leeches

Dr. W. L. FERNANDO (Kandy, Ceylon) writes: There is a very simple method I employ to remove leeches, which are very common in this district in Ceylon. Touch the leech with a piece of common salt or pour a little salt water into the nose (if there): the leech falls out like a ball. Some people use the skin of a lime, or lime juice (see *Journal*, October 14, p. 891; November 4, p. 1058).

Obituary

Sir LEONARD PARSONS, M.D., F.R.C.P. F.R.C.O.G., F.R.S.

Sir Leonard Parsons, known throughout the world as an authority on diseases of children, died suddenly in Birmingham on December 17, aged 71. For many years he was one of the leaders of the medical profession in Birmingham, having been professor of paediatrics and dean of the faculty of medicine in the university and physician to the Queen Elizabeth Hospital and the Children's Hospital.

Leonard Gregory Parsons was born in Birmingham in 1879, and was educated at King Edward's School and Birmingham University. Graduating M.B., B.S. in 1905, he proceeded M.D.(London) in 1907. Two years later he became a Member of the Royal College of Physicians of London, and thereafter he rose steadily to high rank in his profession, being appointed to the honorary staff of many hospitals in and around Birmingham. He always greatly valued his short period as a general practitioner, and it is significant that he developed his special interest in paediatrics during his many years of work as a general physician. He commenced his long career as a lecturer with the Arris and Gale Lecture at the Royal College of Surgeons in 1912. Elected a Fellow of the Royal College of Physicians in 1923, he was Goulstonian Lecturer in the following year. In 1928 he gave the Ingleby Lecture at the University of Birmingham, in 1931 the Radford Memorial Lecture at the University of Cincinatti, in 1937 the Withering Lecture at Birmingham, in 1938 the Schorstein Memorial Lecture at the London Hospital, in 1943 the first Charles West Lecture at the Royal College of Physicians, in 1945 the Blair-Bell Lecture at the Royal College of Obstetricians and Gynaecologists, in 1946 the Blackader Lecture in Banff before the Canadian Medical Association. He gave the Harveian Oration at the Royal College of Physicians this year on October 18, when he took as his subject "The Influence of Harvey and his Contemporaries on Paediatrics." Only a fortnight ago he gave the Harben Lectures at the Royal Institute of Public Health and Hygiene.

Walter Stoneman, London.

Honours fell in a continuous shower on Leonard Parsons. In 1930 he was vice-president of the International Congress of Paediatrics in Stockholm; in 1932 he was president of the Section of Disease in Childhood of the Royal Society of Medicine, and in the same year was vice-president of the Section of Diseases of Children at the Annual Meeting of the B.M.A.; from 1942 to 1945 he was president of the British Paediatric Association; and in 1942 he was awarded the Moxon Medal by the Royal College of Physicians. The Royal College of Obstetricians and Gynaecologists elected him a Fellow in 1944. He was awarded a knighthood in 1946 in recognition of his fine work for children during the war years. In 1948 his election as a Fellow of the Royal Society for his studies on child health and the wasting disorders of children was a final distinction which gave him great satisfaction: among clinical paediatricians only Parsons and the late Sir Thomas Barlow have achieved this honour in the present century. In 1948 also he was president of the Section of Child Health at the Cambridge meeting of the B.M.A.

During the first world war Parsons served in the R.A.M.C. For two years he was in charge of the medical division of the 36th General Hospital, British Salonika Force, being attached to the Serbian Army. Later he was in charge of the medical division of the 48th General Hospital. For his services he was awarded the Order of St. Sava of Serbia in 1917. In the second world war his knowledge and experience proved of the greatest value to the Ministry of Health. Not only was he Hospital Officer, No. 9 Region, but he was always at hand to give wise advice on the development of the child health services at a time when the promotion of such services was of the greatest importance to the nation.

We are indebted to Professor A. V. Neale for the following appreciation: With the passing of Sir Leonard Parsons the British medical profession and many of his numerous friends abroad will detect a loss which will be in many ways irreparable. To those of us who have, so to speak, grown up under his guiding hand and spirit there is a great deal which can never be put down in the written word. His whole professional life has been an ebullition of activity, with a constant emphasis on the exploration of the causes and treatment of disease in infancy and childhood. Sir Leonard's ability to combine those forces necessary to the truth and exactitudes of research with the pleasant human relations of team activity were outstanding, and a twinkling of an eye or a slight raising of the brow meant more than mere approval or disapproval—it meant one was either accepted or not. His genial face nearly always radiated a sense of mental comfort which attracted all, whether it be a visiting professor or a newly arrived medical clerk.

It is doubtful if any contemporary has covered a wider range of daily effort and conscientious attention to a multitude of responsibilities. His amazing abilities to expand his interests and duties almost continuously, and long after he officially retired from his hospital appointments, kept all his friends in constant wonder, and more so because he at no time showed any failing mental strength or wish to evade any service to which he thought he could make a personal and experienced contribution. It may be truly said that he canalized his life to continued work, so much so that his junior colleagues were always somewhere behind when it came to the latest publications on some topic or technique. In fact it is doubtful if anyone will ever know how Sir Leonard could keep increasing the spatial width of his reading and writing. To one who had an intimate knowledge of his methods in the preparation of some of his famous lectures, it was clearly seen that there was a most uncommon power of concentration on detail, and before the finished article had appeared in print it had probably been sifted and almost rewritten a dozen times. Anyone who has followed "L. G.'s" career will have noticed an evolution of the lecturer's art in putting forward pure and plain English, coupled here and there with some apt stanzas, usually from his beloved Milton. It is probably correct to say that his favourite poem was Francis Thompson's "Ex Ore Infantum," and one of the last things the writer heard him speak upon was his pleasure that this poem had been included in a recent broadcast in the Children's Hour.

In the field of paediatrics and child health he was a great leader at a time when it was highly important for the public and the profession to understand that this was a vast and widening field of activity, in which at last the serious things of early life and the realities concerned with mental and physical health in the formative years would receive attention, especially in the mind of the undergraduate and postgraduate, with, ultimately, an appropriate diffusion throughout the medical profession.

In all this Sir Leonard achieved greatness, more especially so in "fathering" a fine school at Birmingham, wherein can be seen an invaluable legacy in the way of clinical tradition, fine buildings (including the now well-known "Parsons Block" for sick infants), and an influence which will pass on to his successors as a noble testimony of what is right, just, and honourable in human relationships. In the University of Birmingham his service as dean of the Faculty of Medicine has been both distinctive and distinguished. He had the ability to get things done and to find the right people for the staff. The spirit of corporate unison in the various departments is a testimony to his work. Anyone who visited him in his dean's office was always pleasurably received in the finely panelled room, which seemed to match in dignity and simplicity the man who was aware of everything and everyone going on or about the place.

His earlier researches are best recorded in his studies on renal rickets, coeliac disease, and dyshaematopoietic anaemia. He later gave strong and lasting views on "rhesus incompatibility" and, in fact, suggested the generic group name "Haemolytic Disease of the Newborn." In 1933 the comprehensive *Disease in Infancy and Childhood* appeared and set a new high standard in English medical publication: his co-editor in this work was the late Sir Gilbert Barling. At the present time his last book, *Advances in Paediatrics*, is just off the press, and many of his friends will no doubt cherish a copy in affectionate memory of a great author and editor. Without doubt "L. G." regarded his recently delivered Harveian Oration as a suitable time and place to expound his mature and profound philosophy, and for many months he had been in a spiritual communion with his great predecessor, to such an extent that he pictured Harvey reading the Gospel of St. Luke at the Battle of Worcester.

His love for his colleagues and friends was ever apparent, and no man has left a greater mark of respect, especially in the Midlands. We are reminded that "holiness not merely energizes; by its divine reinforcement of the will it wrings from the body the uttermost drop of service, it averts age, and secures a vital vigour to the last."

G. E. G. writes: Sir Leonard Parsons's great international repute rests securely on the foundation of his work in paediatrics and in medicine. Of his long record of service to the hospitals, especially the Children's Hospital and Medical School of Birmingham, as a clinician and teacher, and of his promotion and direct participation in research right up to the time of his death, others are better qualified to write. He took a leading part in the reorientation of paediatric thinking which has led to the present emphasis on the teaching of child health rather than of children's diseases. Here was an active clinician who yet could pursue research up to the very end of his career and, more important still, teach and inspire a whole generation of young aspirants in paediatrics in whom his work will live on. His mark is clearly to be seen on many of the new paediatric departments which are now developing.

Such a life would have seemed full enough to any man, but Sir Leonard also found time to contribute a notable share to the planning and administration of hospitals. In 1939 he was Group Officer for the Emergency Medical Service in Birmingham and later Hospital Officer for the Midland Region. In 1943 he was one of the small band of hospital surveyors, and undertook a strenuous and detailed survey of the Sheffield–East-Midlands Region. Later still he was one of the small group of senior consultants which was responsible for the Ministry's memorandum on the development of consultant services. He was a member of the Birmingham Regional Hospital Board and of the board of governors of the United Birmingham Hospitals, and during all this time carried on his work as dean of the medical school. The tale of his activities is so long as to seem beyond the power of any one man, yet he did it all well and neglected none of it. Few of his contemporaries can have had so wide an influence on the development of medicine.

Above all this, Sir Leonard was respected and loved as a man. He had qualities of character which led many to him in time of trouble, and none lacked solace, as the writer has great reason to know. He leaves such a gap in the lives of many as none can fill, and the sympathy of all who knew them must go to Lady Parsons, who shares in full measure his own great qualities.

Professor K. D. Wilkinson writes: Early in 1912 Leonard Parsons was appointed assistant physician to the General Hospital in Birmingham, and from that date we were closely associated. It was slowly that I came to know him, for he was always rather shy and diffident, so that he appeared to teach with a conscious effort—indeed, sometimes he seemed to prefer listening to talking. Both teaching and writing appeared to be rather a toil at first, and his writings used to show signs of hard work, while his lectures were somewhat hesitant. Leonard always did what he considered his duty however hard that might be; he never spared himself or gave up trying, and gradually he became both an able speaker and an accomplished writer.

He had many difficulties to contend with. When the first world war began he was an impecunious young physician who had only just begun to make a living, for practice came slowly to a physician in those days, and hospital work consisted entirely of long and wearisome out-patient sessions. He was married and had two children, yet in 1916 he went out to Salonika and was away for three years. After he came back he slowly built up a practice, and established his reputation as an able clinician, as an outstanding paediatrician, and as a brilliant research worker. He worked hard to elucidate those problems associated with the disorders of children and when he could afford it financed the laboratory work necessary for the research to advance. He had a special capacity for stimulating the enthusiastic co-operation of many younger men, so that the problems of anaemia and endocrine disorders were solved.

No one who worked with him failed to respond to his influence, and all who came to know him developed a personal affection for him and a great regard for his ability and integrity. One of his outstanding characteristics was a real, active, personal faith, which made him unwilling to miss his Sunday public worship. He did not smoke or drink alcohol. In all the 38 years of our friendship I have never known him say an unkind word of anyone; indeed, his judgments were inclined to be unduly generous, and at all times he was eager to do a kind action even at personal inconvenience.

Sir Leonard was seldom ill, and he enjoyed a wonderfully happy home life, for his wife was always eager to conserve his energies for his work, and his son fulfilled his highest hopes by following in his footsteps with conspicuous success. He leaves a great circle of friends who rejoice in the memories of his friendship while they mourn his loss.

HENRY MacCORMAC, C.B.E., M.D., F.R.C.P.

E. R. A. M. writes: Henry MacCormac will be remembered with affection and admiration in the industrial field, as well as in university and hospital circles. He was a medical referee under the Workmen's Compensation Acts for many years and was appointed to the Advisory Panel on Dermatological Problems in Industry when it was constituted by the Minister of Labour and National Service in 1942. Perhaps he found it a relief to apply his talents to matters which affect the economies of so many people and as an outlet for his great humanity. His wisdom and philosophy, his tactful and unassuming approach to controversial matters, inspired a solution to many difficulties, and very welcome was his gift of humour when argument toiled on too long. He was generous in thought and word and courageous when courage was necessary, and his comradeship and these other fair qualities will keep his memory fresh in circles where men have to get together to get things done. (An obituary notice of Dr. Henry MacCormac was published in last week's *Journal*.)

Mr. ERNEST ETHELBERT HUGHES, who was for many years on the surgical staff of the Ancoats Hospital, Manchester, died on November 5. He was born in Hale, Cheshire, in 1879, the third son of a family of seven. He was educated locally, and on leaving school he qualified as a dispenser. For a while in this capacity he worked as assistant to a doctor near his home, and at the same time prepared for his preliminary medical examination. As an undergraduate in Manchester he worked hard and took many prizes. He joined but little in the athletic side of university life, but already he showed a serious musical appreciation. In 1904 he graduated M.B., Ch.B., and for six months was a house-physician at the old Manchester Royal Infirmary. On leaving hospital he went for a time as assistant in a general practice to a doctor in Cheshire (and devoted his spare time to learning the 'cello). Before long he had made up his mind to go in for surgery as a career. In 1907 he became resident surgical officer at the Manchester Children's Hospital, and in 1908 he was appointed demonstrator of anatomy at the university. In 1912 he was admitted F.R.C.S. and was awarded the gold medal in the Ch.M. examination at Manchester. The following year he became resident surgical officer at the Royal Infirmary. During the first world war he saw service as a surgeon in Mesopotamia, Egypt, East Africa, India, and France. He returned home in 1919, and the following year was appointed surgeon to the Ancoats Hospital. Other surgical appointments came to him, but it was at Ancoats where his main life work lay. Though working as a general surgeon, he had developed a special interest in genito-urinary surgery, and before long he started the special department which later became a notable feature of the Ancoats Hospital. He was a member of many surgical societies and associations: in 1935 he was elected president of the Manchester Surgical Society. His contributions to medical literature were not numerous, but they were carefully presented and were mainly in his special line of genito-urinary surgery. He was of a sensitive, retiring nature, and, though by no means unapproachable, his shyness prevented more than a comparatively few knowing him well. He had an extraordinary capacity for work, and at one period of his life went for 10 years without a holiday. He read widely, and his verbal knowledge of Shakespeare was prodigious. He played golf regularly and loved a game of bridge. By his juniors he will long be remembered as a friendly teacher and a careful and dexterous surgeon, thoughtful for and attentive to his patients and their friends and considerate to his colleagues and his nurses. He married in 1922, his wife also being a member of the medical profession.—E. S. B.

JAMES GRAHAM WILLMORE, who died in London on December 8, at the age of 70, was for many years a medical officer at the Ministry of Pensions. He studied medicine at the Westminster Hospital, qualifying in 1906. Nearly 20 years later he graduated M.D., C.M. at McGill University, where he won the Sutherland Gold Medal. In 1924 he was admitted M.R.C.P. His early interest in tropical diseases and pathology was shown in his appointment as physician to the Bacteriological and Quarantine Service of Egypt and as pathologist to the Queen Charlotte Hospital. In 1918 he published an article on "Dysentery in the M.E.F." Willmore began his long service with the Ministry of Pensions in 1921, and he spent almost all his time in its hospitals. He became a principal medical officer in 1932, and for many years acted as consultant in medicine and pathology both at Queen Mary's Hospital, Roehampton, and at the headquarters of the Ministry. He was also consultant physician to Mount Vernon Hospital, Hampstead. He retired from the Ministry in 1946, and a year later he was appointed O.B.E. Willmore was always a student, ever seeking new discoveries and new lines of thought. He read widely, and his retentive memory enabled him to bring readily to bear on any problem the researches and opinions of workers in many fields. He delighted in the intricacies of pathology, and the diagnostic approach to rare or aberrant symptoms rejoiced his heart. While sometimes the trees were the more fascinating, he did not forget the wood, and his clinical judgment and practice were broadly and soundly based on a wealth of knowledge and experience. Some 20 years ago he lost through accident the sight of one eye, and that of the other steadily decreased almost to blindness. But with admirable courage he made his diminishing vision serve him to the uttermost. His alert, inquiring, inquisitive mind accorded well with a trim, active body, blended with true courtesy of manner and kindness of heart. "Willie" was dear to all who knew him and will live in their memory as one to whom the ideals and purpose of his profession were everything, and in whom learning, modesty, and enthusiasm made the physician all of us would wish to be.—A. S.

Dr. E. DOROTHEA BLUNT, who was for 20 years in practice in Hastings, died there on November 1, at the age of 49. She was educated at Oxford High School, the London School of Medicine for Women, and the Royal Free Hospital, graduating M.B., B.S. in 1927. After qualifying, Dr. Blunt took the post of gynaecological obstetrical house-surgeon at her own hospital, and then became assistant M.O.H. for maternity and child welfare in Birmingham. She remained interested in obstetrics, and took the D.R.C.O.G. in 1937 while in general practice. In 1929 she came to Hastings as partner to the late Dr. Conroy Morgan, and after his retirement continued in practice alone. Somewhat shy and retiring by nature, Dr. Blunt nevertheless built up a large practice and was looked on by her patients as a friend as well as a doctor. She never refused a plea for help either from her patients or her colleagues, and was quite unsparing of time and energy if she felt she could be of use to anyone. She served on the local panel committee for many years, and, after 1948, on the local medical committee of the executive council; she was also on the house committee of St. Helen's Hospital and on the tuberculosis care committee, and had several times been on the executive committee of the Hastings Division of the B.M.A. Her balanced judgment and sound comments were invaluable in committee work. She was an active member of the Order of St. John, being a divisional surgeon, and had reached the rank of Serving Sister. For many years her health had been very poor, but in spite of her friends' persuasions she refused to curtail her work and carried on under immense difficulties until 36 hours before her death.—C. N. W.

Medical Notes in Parliament

The Registrar's Future

On December 15, on the motion to adjourn for Christmas, Sir HUGH LUCAS-TOOTH raised the question of hospital registrars and of the circular *Review of Appointments to Registrar Grades*. Registrars, he said, were trained and qualified doctors, the pick of the profession. They were salaried members of the hospital staff and, although not fully qualified specialists, did specialist work without supervision, acquiring skill with a view to becoming fully qualified specialists or consultants. Registrars had existed in hospitals for a long time, and since the inauguration of the National Health Service their numbers had greatly increased. The country had then been told that the present 5,200 specialists, for the most part-time, would be increased to 7,500 full-time specialists. The increase was to be of the order of 100%.

Mr. A. BEVAN asked when the profession had been told this.

Sir HUGH replied that the increase had been set out in *Development of Consultant Services*, published about the time the National Health Service Bill was introduced. This document had been republished early in 1950.

Mr. BEVAN said they were not told that at all in that document.

Sir HUGH LUCAS-TOOTH replied that a large proportion, if not all, of the medical profession had understood the document as he did. He went on to say that hospitals had been told they could and should increase the numbers of registrars on their staffs. That increase had been needed because of the added work of the hospitals. The result was that the country now had some 2,800 registrars on hospital staffs, about 1,400 being senior registrars. A high proportion of these senior registrars were over 30 years old and probably facing their heaviest family responsibilities. He admitted that 2,800 registrars were too many. The hospitals could not at present absorb the new specialists who would come forward from the establishment. Something had to be done. Mr. Bevan had faced the situation by bringing out the circular under discussion. Sir Hugh asked the Government what figure it had in mind if it no longer aimed at 7,500 specialists, and when it intended to achieve the new total.

Not Economy

He accepted an assurance already given by Mr. Bevan that he had not been prompted by economy in the action he had taken. Indeed, it was obvious. Mr. Messer, chairman of the Central Health Services Council, had said that the registrars would have to be replaced by consultants, hospital medical officers, or general practitioners, who would cost far more. The circular had struck dismay in the breasts of all those concerned with the Health Service. Even the Socialist Medical Association had put a warm protest to the Minister. To tell men who had already had their careers disorganized by the war that they could seek posts overseas or in the Forces was the epitome of psychological ineptitude. There was a sense of injustice and of personal waste among those affected, and a waste to the community of the effort and time required to train these men. Too many patients were chasing too few doctors, dentists, and hospital beds. That caused trouble in other departments of the Health Service and was at the root of the present difficulty. Something must be done to bring the demand for hospital beds and specialist attention into line with supply, but the circular under discussion would aggravate the trouble.

Mr. F. MESSER said he thought it his duty to convey to Mr. Bevan the widespread feeling aroused by the circular. A registrar was a man who had decided to follow a particular line in medicine or surgery. It was not easy for him to switch. In a teaching hospital he followed his specialty, and in addition a large part of his time was taken up with teaching others. It was obvious that at present there were too many registrars, but the Minister's approach to the matter might have been made differently so that those who believed he had a case for reducing the number of registrars could have discussed with him how this could be done with the least hardship. In Mr. Messer's region nine major hospitals would be affected by implementation of the circular. He said that in these they could not have unskilled people doing the work which the registrars were doing. Unless there was a comparable addition to replace the registrars they would have to close 400 beds. His region was about to lose 80% of its registrars. He urged Mr. Bevan to consult the teaching hospitals and the regional boards before he implemented his circular.

Mr. HENRY BROOKE said the regional hospital boards had not been consulted over the drafting of this circular but were expected to maintain the quality and quantity of hospital service despite it.

The Minister's Reply

Mr. ANEURIN BEVAN said he was glad that the question had been raised and in so temperate a manner. That was, however, not the atmosphere in which it had been discussed in some of the medical journals and some of the daily newspapers. It was about time that some publicists developed a responsible attitude towards the Health Service. The situation concerning registrars was clear. There were admittedly more registrars than the Ministry could find consultant posts for. It was not he who had appointed the registrars. Responsibility for that lay with the hospital boards and the teaching hospitals.

Sir HUGH LUCAS-TOOTH said these had been given encouragement.

Mr. MESSER pointed out that management committees, not regional boards, were responsible for the appointment of registrars.

Mr. BEVAN accepted the correction. The position was a direct consequence of the fact that authority lay with the teaching hospitals and the management committees. To Sir Hugh Lucas-Tooth's assertion that the Ministry had encouraged a lavish appointment of registrars, Mr. Bevan replied that the language of the booklet to which Sir Hugh had referred was very cautious. It was incorrect to say that the Ministry of Health led people to believe that there might be such an enlargement in the number of consultants as the number of registrars appointed would indicate. What happened was that a large number of doctors returned from the Forces and were anxious to take posts in the hospitals for training as consultants. Under that pressure many more posts had been provided than were reasonable. Considering the extraordinary increase he believed that what the Ministry had done was justified. The circular suggested that for England and Wales the totals should be 600 senior registrars and 1,100 registrars. It asked boards to consult and submit proposals about training posts for each region within the total. It proposed steps for bringing existing numbers and new recruits down to the approved establishment, and suggested alternative arrangements at this level of staffing when the volume of hospital work necessitated them.

Misunderstandings

Practically every pronouncement on this matter had been wrong. The *British Medical Journal*, which ought to know better, quoting, with unusual enthusiasm, the Socialist Medical Association, had said that the circular showed a total failure to understand the importance of the contribution made by registrars to the hospital service. One could not have, in a responsible journal, a more juvenile misunderstanding. Sir Hugh Lucas-Tooth had pointed out that, if the number of registrars was cut drastically, some people must be found—it might be the same people—to do the work. That, said Mr. Bevan, was exactly what the Ministry said. It was the result of consultations with representatives of the medical profession, to whom the whole matter had been made perfectly clear.

Dr. CHARLES HILL intervened to point out that the circular had made it plain that the employment of substitutes, who would be the same people doing the same work, was intended as a strictly interim arrangement.

Mr. BEVAN said that was so. Medical teams were going round the country setting out the establishments for the hospitals. Hospital work must be carried on by adequate establishments. All the Ministry was trying to do was to relate the number of trainees to the number of consultant posts which might be available.

Sir HUGH LUCAS-TOOTH asked whether Mr. Bevan had obtained agreement in his consultations.

Mr. BEVAN said agreement was not obtained. The Ministry of Health represented the interests of the community as a whole. Its critics were a specialized sectional interest.

Mr. HUGH LINSTEAD remarked that Mr. Bevan had not got agreement with the regional hospital boards, the management committees, or the medical profession.

Mr. BEVAN retorted that he expected to get agreement with the House of Commons. He hoped the House was considering whether the claims of certain people had been balanced against the claims of the community as a whole.

Mr. LINSTEAD said the House that day had no opportunity to express an opinion.

Mr. BEVAN said the question of registrars was to be discussed by the regional hospital boards. The Ministry hoped to have their observations by the beginning of the year. Before the issue of the circular a full explanation of the position had been sent on July 6 to the Joint Committee of Consultants and Specialists, with statistical information. The draft of the circular had been twice discussed with their representatives. The profession had recognized the need for action, but had not agreed with the exact form it should take. That was not unusual. The proposed number of trainee posts had been related to an annual demand of 150. The number needed to replace wastage was unlikely to be more than 100 in any of the next five years. The Ministry was increasing the specialist posts.

What was wrong in saying that posts were available in the Colonial Medical Service? More doctors were needed there.

Conditions of Appointment

Mr. LINSTEAD said that registrars, according to the Ministry of Health's conditions for their appointment, had assumed they had a four-year appointment before them.

Mr. BEVAN replied that their appointments were reviewed from year to year to see if they were making the grade. The circular did not invalidate his assertion. The circular did allow for an increase in specialist posts, but it was unwise to enlarge the number of these posts until the Ministry had the hospitals in which work could be found for specialists. He remarked that the number of trainees at present was nearly 3,000. In 1938 it was not more than 750. The proposed new total of 1,700 was nearly two and a half times the figure before the war.

Dr. HILL asked whether the figure of 750 included all the categories which had been renamed registrars.

Mr. BEVAN replied that it represented all those considered to be in training for specialist posts. He said that in one London hospital, a teaching hospital, the number of in-patients in 1949 was down by one-quarter, compared with 1938. The number of out-patients was up by one-sixth. But the number of registrars was two and a half times as great.

General Practitioners and Hospitals

He hoped to get selected general practitioners to do some of the work in the hospitals. He desired that the general practitioner should be more closely associated with hospital work. Resistance to this often came from inside the medical profession. It must not be assumed that complete harmony existed between specialists and general practitioners. When management committees and regional boards tried to arrange that general practitioners should have access to hospitals, the difficulty had sometimes been with the consultants concerned. The Ministry was anxious to ensure that, when new people were required, some should be general practitioners working part-time.

Mr. WALTER ELLIOT said the Opposition would take the earliest opportunity to have a more extended discussion on registrars.

Distinction between Hospital Staff and Trainees

Mr. BEVAN said the longer the discussion the more he would be pleased. The suggested number of registrars for each region must be divided between teaching and non-teaching hospitals and between different specialties. He would invite regional hospital boards to comment on the new establishments. Revert-

ing to the circular, Mr. Bevan said its main purpose was to have in future sufficient doctors to do the normal work of the hospital, and also an identifiable number of registrars who were training to be consultants. In the past the necessary general hospital work had been performed by persons who at the same time were training to be consultants. Because of this there had been a tendency to enlarge the category of registrars.

Cancer Propaganda

On December 14 Brigadier F. MEDLICOTT asked Mr. Bevan to make it more widely known that valuable remedial measures could be taken in many instances if cancer was diagnosed in its early stages.

Mr. ANEURIN BEVAN replied that the Central Health Services Council had recently advised that it was undesirable at the present time for any cancer publicity to the general public to be carried out by the Government.

Malaria Control.—Campaigns are in progress in Mauritius, the coastal belt of British Guiana, Tobago, and a number of experimental areas in East and West Africa. In Cyprus steps are being taken to prevent re-importation of malaria-carrying mosquitoes, of which the island was declared free at the beginning of 1950. The question of total eradication in hyper-endemic areas in Africa was examined at the Malaria Conference held at Kampala from November 27 to December 9 under the joint auspices of the World Health Organization and the Commission for Technical Co-operation in Africa south of the Sahara.

Day Nurseries.—About 13,000 children under the age of 2 are attending day nurseries.

Cleanliness.—The Minister of Food has instructed the agents of his department in the meat trade to issue suitable overalls and head-coverings to meat porters and make their wearing of them compulsory.

Conveniences.—Neither the Minister of Transport nor the Minister of Health has power to make regulations for compulsory provision of public conveniences at omnibus stations and termini.

Universities and Colleges

UNIVERSITY OF MANCHESTER

The following candidates have been approved at the examinations indicated:

FINAL M.B., CH.B.—*Old Regulations:* H. G. Arnall, R. B. Haigh, J. M. Midgley, R. E. Raworth, Gertrude H. G. Robinson. *New Regulations:* D. Ashworth, Margaret Bentley, Constance M. Bevan, J. C. Canney, E. H. Cooper, D. Davies, B. Didsbury, J. Ellis, G. R. Gates, R. Hinchcliffe, J. T. W. Howe, G. Howitt, T. R. Hunter, A. Hyman, J. E. Kench, J. H. Latchford, M. B. Raby, Carolyn C. Rigby, Kathleen M. Rushton, Janet Savatard, H. Selcon, Lorna J. Shankland, A. Sippert, G. Sullivan, D. W. Sumner, S. E. Sutton, Olive M. Thomas, C. F. H. Vickers, Margaret R. Walley, B. Ward, G. R. Whittaker, D. Wolman.

DIPLOMA IN PSYCHOLOGICAL MEDICINE.—Z. Finkelstein, L. G. Nicol, Margaret I. Platt, Susanne Shafar, T. P. Smith.

The Services

A *Supplement* to the *London Gazette* has announced the following awards:

Four Clasps to the Territorial Efficiency Decoration.—Major (Honorary Lieutenant-Colonel) J. C. MacKay, O.B.E., M.C., T.D., R.A.M.C.

Three Clasps to the Territorial Efficiency Decoration.—Lieutenant-Colonel T. A. S. Samuel, M.C., T.D., R.A.M.C.

1st Clasp to the Territorial Efficiency Decoration.—Colonel H. Sissons, O.B.E., T.D., late R.A.M.C.; Lieutenant-Colonel W. Bowater, M.C., T.D. (retired); and Majors C. K. D. Edwards, T.D., T. T. S. Hall, M.B.E., T.D., and A. McN. Tomlinson, T.D., R.A.M.C.

Territorial Efficiency Decoration and 1st Clasp.—Honorary Lieutenant-Colonel H. S. Allen, O.B.E., late R.A.M.C.; Lieutenant-Colonels A. P. McEldowney, W. D. F. Lytle, O.B.E., and D. H. Young, O.B.E.; Major (Honorary Lieutenant-Colonel) T. McK. Robb; and Major C. N. Suter, R.A.M.C.

Territorial Efficiency Decoration.—Major N. H. H. Longton and Captain F. E. D. Griffiths, R.A.M.C.

Medical News

Popular Health Journal

Family Doctor is the title of the new popular health magazine which the British Medical Association is publishing next year. It is being brought out under the general direction of the Editor of the *British Medical Journal* and edited by Dr. I. H. Flack, formerly assistant editor of the *Journal*. The first issue will be on sale at the bookstalls on March 20, 1951. A monthly magazine, it will be fully illustrated, and the price will be 1s. It should prove of particular interest to doctors and their families and to all workers in the public health service.

Family Doctor is a new attempt to provide education in healthy living. Its 72 illustrated pages will include articles on how the body works, antenatal care, difficult children, whooping-cough, first-aid, and on such general topics as playing-fields, the Boat Race, cookery, and spring-cleaning. It is hoped that the medical profession will do what it can to establish *Family Doctor* as the most important medium of popular health education in this country. A special order form has been included with the subscription forms sent to every member of the British Medical Association in the past few days. The subscription of 14s., which includes postage, ensures that *Family Doctor* will be sent direct from B.M.A. House to addresses in the United Kingdom and overseas. Alternatively, local newsagents are ready to accept orders and arrange for regular delivery.

Peckham Health Centre

The Pioneer Health Centre at Peckham, which has been closed since March, has just been bought by the London County Council for about £60,000. According to a *Daily Telegraph* report, an antenatal centre and day nursery are to be opened there, while the swimming-bath, gymnasium, and lecture hall will be used by the education service. Later it is planned to open a National Health Service health centre, with special maternity and child-welfare facilities. It is expected that the full scheme will cost £126,000.

Research in Social Medicine at Oxford

The annual report of the Institute of Social Medicine, of which the late Professor J. A. Ryle was first director, describes some of the investigations in progress there. Among the long-term studies, the child health survey is now in its fifth year and 580 of the children are more than 1 year old, so that some conclusions on normal growth and development are already possible. In particular, the current generalization that smaller babies grow more rapidly and catch up with the larger babies at one year has not been substantiated. The 5-year-olds, and also many undergraduates, are being somatotyped by Sheldon's method, in which photographs of each individual are taken in three standard positions against a grid, and the individual's dimensions thus recorded and later compared with his psychological development. The average heights and weights of Oxford undergraduates have been found to be approximately the same now as forty years ago, but still taller and heavier than other young men of the same age, as judged from National Service medical examinations. A big investigation on tuberculosis in industry has already shown that morbidity rates are higher in large than in small boot and shoe factories (see *British Medical Journal*, 1949, 1, 926), which may be correlated with the relatively poorer ventilation of large workshops. The pattern of tuberculous infection found in Northampton suggests that the disease can spread from one house to neighbouring households.

The 1951 Census

On Sunday, April 8, 1,200 census officers (normally the registrars of births and deaths), and 50,000 enumerators, will conduct the national census in England and Wales. There will be some new questions since the last census in 1931—the age at completion of full-time education, availability of piped water supply, and queries on certain other household arrangements. The age at which a person has the right to make a separate confidential return, instead of providing information to the head of the household, has been lowered from 21 to 16. A preliminary report showing the number of people of each sex in each district of the country will be issued in June, 1951. A further early report will be based on a detailed analysis of 1% of all the returns, but the full record will come out in instalments over a period of years. The total cost is estimated to be £1,250,000.

North of England Obstetrical and Gynaecological Society

At a meeting in Liverpool on October 27 Mr. F. J. Burke described some interesting cases of placenta accreta. In one no decidua had formed in the cavity of the uterus and the placenta had eaten its way through the posterior wall right to the peritoneal cavity. The main cause of placenta accreta was a defect in or absence of the basal decidua, a thin but vital layer which prevents excessive infiltration of the trophoblast. It was usually said that the villi are attached to muscle, but Mr. Burke said he found that the invading villi appeared to exert a destructive effect on the muscle fibres over a wide area; they were replaced by a thick layer of hyaline or fibrinoid tissue. Dr. M. B. Bruce reported a case of twins in which a double placenta had been delivered between the first and second child, both infants surviving; and Mr. Vincent Corbett read a short paper on the aetiology of foetal malformation, based on the records of the Liverpool Maternity Hospital.

Ulster Paediatric Society

At a meeting on Tuesday, December 12, with Dr. Robert Marshall in the chair, Professor W. F. Gaisford spoke on "Recent Developments in Antenatal and Neonatal Paediatrics."

In Brief

At the recent celebration of fifty years' unbroken work at the Lebanon Hospital for Mental and Nervous Disorders, Asfuriyeh, near Beirut (see *Journal*, November 4, p. 1069), the medical director, Dr. W. M. Ford Robertson, and two Lebanese members of the local committee—Drs. Amin Khairallah and Joseph Hitti—were decorated by the President of the Republic with the golden medal of the Lebanese Order of Merit.

Sir Gordon Gordon-Taylor, consulting surgeon to the Middlesex Hospital and the Royal Navy, left London on December 19 for a four-week visit in Pakistan arranged by the British Council.

COMING EVENTS

British Association of Physical Medicine

A short course of lectures on the various aspects of physical medicine will be delivered on Fridays and Saturdays, January 5–13, and will be suitable for candidates preparing for Part II of the Diploma in Physical Medicine. Further details can be obtained from the honorary secretary, British Association of Physical Medicine, 45, Lincoln's Inn Fields, London, W.C.2.

Tuberculosis Health Service

A conference on "The Administration of the Present and Future Tuberculosis Health Service" will be held at 2.15 p.m. on Saturday, January 13, in the Cowdray Hall of the Royal College of Nursing, with Dr. Philip Ellman in the chair and Dr. G. E. Godber, deputy chief medical officer of the Ministry of Health, the principal speaker. The fee, including tea, is 4s. 6d., which should be paid before January 6 to the Secretary, Public Health Section, Henrietta Street, London, W.1.

Subnormal Children

Three courses will be held in 1951 on educationally subnormal children and mental defectives. The courses are intended especially for school medical officers and certifying officers. They are organized by the University of London in co-operation with the National Association for Mental Health. The following are the dates of the courses: February 19–March 9; April 16–May 4; and October 1–19. Full particulars may be obtained from the Educational Secretary, National Association for Mental Health, 39, Queen Anne Street, London, W.1.

International Society of Surgery

The 14th congress will be held in Paris, September 24–29, 1951, the fiftieth year of the Society's existence, under the presidency of Professor René Leriche. Instead of a series of comprehensive reports on selected topics, eleven problems of the day have been chosen and speakers have been selected to give the addresses and open the discussions. Anyone attending the congress may take part in the discussions (five-minute limit) by writing to their delegate to the Scientific Council before August 1. The British delegate is Sir James Learmonth, 22, Braid Avenue, Edinburgh, 10. The subjects and speakers selected are:

(1) "Pulmonary Resection for Tuberculosis."
(2) "The Future of the Cavity Remaining after Pneumonectomy," C. Price Thomas (London).
(3) "Extracorporeal Circulation to Facilitate Surgery of the Cavities of the Heart," Jongbloed (Utrecht).
(4) "Restorative Vascular Grafts and the Effect of Cold on the Tissues as Related to Transplantation," E. Rehn (Freiburg im Breisgau).
(5) "Allergy and Abdominal Surgery," P. Valdoni (Rome).
(6) "Surgery of the Sympathetics and Vascular Diseases of the Brain," A. De Sousa Pereira (Porto).
(7) "Spontaneous Internal Fistulas of the Biliary System," P. Mirizzi (Cordoba, Argentine).
(8) "The Post-operative Malady," E. Elman (St. Louis).
(9) "Influence of the Conceptions of Speranski, Leriche, and Ricker Upon the Future of Surgery," C. Henschen (Basle).
(10). "Sequelae of Post-operative Venous Thrombosis," C. Bauer (Mariestad) and H. Peiper (Mayence).
(11) "Portal Hypertension," A. Blakemore (New York).

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday

●ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.—January 1, 3.45 p.m., "*Blood Grouping and Transfusion*," by Dr. H. F. Brewer.

Tuesday

●INSTITUTE OF DERMATOLOGY, Lisle Street, Leicester Square, London, W.C.—January 2, 5 p.m., "*Hysteria Cutis*," by Dr. W. J. O'Donovan.

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—January 2, 5 p.m., "*Science and Art of Refraction*," by Dr. T. H. Whittington.

Wednesday

●INSTITUTE OF DERMATOLOGY, Lisle Street, Leicester Square, London, W.C.—January 3, 5 p.m., "*X-ray Technique*," by Dr. C. W. McKenny.

●ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.—January 3, 3.45 p.m., "*Disorders of Bone Metabolism*," by Professor N. F. Maclagan.

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—January 3, 5.30 p.m., "*Headaches*," by Mr. L. H. Savin.

YORKSHIRE SOCIETY OF ANAESTHETISTS.—At General Infirmary at Leeds, January 3, 8 p.m., "*Anaesthesia for Babies and Children*," by Dr. Robert Cope.

Thursday

FACULTY OF HOMOEOPATHY.—At Royal London Homoeopathic Hospital, Great Ormond Street, London, W.C., January 4, 5 p.m., "*Low Potency Prescribing*," by Dr. D. M. Cameron.

●INSTITUTE OF DERMATOLOGY, Lisle Street, Leicester Square, London, W.C.—January 4, 5 p.m., "*Cutaneous Syphilis*," by Dr. J. L. Franklin.

●ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.—January 4, 3.45 p.m., "*Blood Grouping and Transfusion*," by Dr. H. F. Brewer.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.—January 4, 5.30 p.m., "*Diseases of the Blood Connected with Oto-rhino-laryngology*," by Sir Lionel Whitby.

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—January 4, 5 p.m., "*Methods of Examination*," by Mr. C. M. Shafto.

Friday

INSTITUTE OF NEUROLOGY, National Hospital, Queen Square, London, W.C.—January 5, 5 p.m., film of a hemispherectomy performed by Mr. R. A. Krynauw.

●ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—January 5, 5.30 p.m., "*Physiology of the Eye*."

APPOINTMENTS

DOLTON, E. G., M.B., B.S., F.R.C.S., Thoracic Surgeon to Stoke-on-Trent Group of Hospitals.

HOSPITAL FOR SICK CHILDREN, Great Ormond Street, London, W.C.—*Part-time Orthopaedic Registrars (Registrar Grade)*: B. M. Hay, M.B., Ch.B., F.R.C.S.. J. D. Cronin, M.B., B.S., F.R.C.S.

LIVINGSTONE, F. D. M., M.B., B.Chir., D.P.H., Medical Officer of Health, Warwickshire United Districts, and Central Area Medical Officer, Warwickshire County Council.

NELSON, A. JOHN, M.B. Ch.B., D.P.H., Consultant in V.D. Control, New York State Department of Health, Albany, New York.

WITTKOWER, ERIC, M.D., Associate Professor of Psychiatry, McGill University, Montreal, Canada, from March, 1951. Dr Wittkower graduated M.D. at the University of Berlin in 1924, and in 1936 he took the Scottish Conjoint qualification. He is Consultant Psychiatrist on the staff of St. Bartholomew's Hospital and the Tavistock Clinic. He takes up his duties at McGill University in March, 1951.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Fisher.—On December 14, 1950, at King's College Hospital, London, S.E., to Sheila (formerly Penny), wife of Dr. Oliver Fisher, M.R.C.P., a son.

DEATHS

Banks.—On December 17, 1950, at "Mervyn," Lanark, Thomas Wilson Banks, M.B., C.M.

Ford.—On December 18, 1950, at Hertford County Hospital, Alma Percy Ford, M.R.C.S., L.R.C.P., D.P.H., The Arches, Digswell, Welwyn, Herts.

Hughes.—On December 14, 1950, Muriel Hughes, M.B., Ch.B., D.P.M., of Capesthorne, Wythenshawe Road, Northenden, Manchester.

Larkam.—On December 8, 1950, Edward Thomas Larkam, M.D., D.P.H., of 978, Warwick Road, Acocks Green, Birmingham, aged 84.

Lowe.—On December 12, 1950, at sea, John Russell Lowe, M.B., B.Ch., Rostrevor Road, Rathgar, Dublin, Eire, aged 28.

MacCormac.—On December 12, 1950, at his home, 71, Bathgate Road, London, S.W., Henry MacCormac, C.B.E., M.D., F.R.C.P., 23, Wimpole Street, London, W.

McEldowney.—On December 8, 1950, at his home, 205, London Road, Portsmouth William Patrick McEldowney, M.B., B.Ch., aged 87.

McGlashan.—On December 15, 1950, at University College Hospital, William Reid McGlashan, M.B., Ch.B., D.P.M., of Ellingham, St. Martin's, Guernsey C.I.

MacVea.—On December 12, 1950, at Netherton, Ayr, George Anthony MacVea, L.R.C.P. &S.Ed., L.R.F.P.S.Glas., of Belingwe, Turnberry, Ayrshire.

Parsons.—On December 17, 1950, at Hillfield, Four Oaks, Birmingham, Sir Leonard Gregory Parsons, M.D., F.R.C.P., F.R.S., aged 71.

Wainwright.—On December 10, 1950, George Bertram Wainwright, O.B.E., M.B., B.Ch., of Freelands, South Cerney, Glos., formerly of Winchester.

EPIDEMIOLOGICAL NOTES

Infectious Diseases

The chief features of the returns during the week were a further large increase in the number of notifications of measles and a large rise in the number of cases of dysentery. The record high level of dysentery in England and Wales in the preceding week was exceeded by 77, and in Scotland the incidence was very high. The chief centres of infection in the two countries were Leicester C.B. 130 and Glasgow 59. The outstanding return for measles was from Lancashire, where there were 934 more cases than in the previous week.

Whooping-cough

The returns of whooping-cough for the past four weeks in England and Wales have been the highest ever recorded since notification of this disease was started 11 years ago, and they are about five times the level of the corresponding period of last year. 20.000 more cases of whooping-cough have been notified this year than in the same period last year and about 10,000 more than in 1948.

During the recent weeks one-third of the total cases have been notified in London and the adjacent counties of Surrey, Kent, Essex, and Middlesex, while one-sixth of the notifications were contributed by Lancashire. The number of deaths per 10.000 cases in the great towns for the first 49 weeks of the year was 28 in 1950, 65 in 1949, and 59 in 1948. It would appear probable from these rates that the increase in the number of notifications is one of book-keeping and that it does not represent a real increase in the incidence of the disease.

Week Ending December 16

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,348, whooping-cough 4,503, diphtheria 50, measles 14.223, acute pneumonia 684, acute poliomyelitis 107, dysentery 1,214, paratyphoid fever 5, typhoid fever 2.

No. 49

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended December 9.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1950 (a)	(b)	(c)	(d)	(e)	1949 (Corresponding Week) (a)	(b)	(c)	(d)	(e)

* Measles is not notifiable in Scotland, and the returns are therefore an approximation only.
† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published
‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.
§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.
‖ Includes puerperal fever for England and Wales and Eire.
¶ Primary pneumonia no longer notifiable in Eire.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Repeated Abortions

Q.—*A patient, aged 24, has been pregnant at least three times without a pregnancy progressing beyond four months. Three years ago, after being married for nine months without apparently conceiving, she developed increasingly severe dysmenorrhoea. A dilatation and curettage was performed, and she conceived shortly afterwards, but had a miscarriage at three and a half months, her membranes rupturing spontaneously four days before painful uterine contractions developed. A further curettage two years later showed a carneous mole. She conceived again nine months later (in June this year), and all appeared well until at 20 weeks she had a further rupture of membranes at night when asleep, and a complete abortion four days later. W.R. negative; Rh positive; and no history of intercourse for the two months prior to the last abortion. This case history does not seem typical of the usual "habitual" abortion, and I would be grateful for suggestions about treatment or investigation. Is vitamin E indicated in this type of case?*

A.—The unusual feature of this abortion habit is the suggestion that rupture of the membranes is the first part of the mechanism of the abortions. This immediately raises the possibility of an incompetent internal cervical os, which by failing to support the membranes leads to abortion—a mechanism which has been studied by A. F. Lash and S. R. Lash (*Amer. J. Obstet. Gynec.*, 1950, 59, 68). In this case it may be that the dilatation of the cervix for dysmenorrhoea resulted in tearing at the level of the internal os. This possibility should be investigated, and hysterography should be carried out to exclude an intrauterine septum or other malformation. If the findings are negative a glucose-tolerance test is indicated to make certain that a diabetic or prediabetic state is not present. Other investigations should include an estimation of the basal metabolic rate, careful blood-pressure records, and possibly renal function tests.

The treatment will depend on the results, but empirical measures such as the administration of vitamin E should be used only when very full investigation has failed to reveal the cause.

Cystine Calculi

Q.—*A multipara, aged 28, had her right kidney removed three years ago because of stone formation. I understand that the stones, which had completely disorganized the kidney, were mixed cystine and phosphatic stones. Since recovering from her operation she has formed at occasional intervals cystine stones in the remaining kidney. These have once or twice blocked the ureter with alarming suddenness, but fortunately each one has been fairly quickly passed. We have tried to keep the urine alkaline, the patient has been put on large quantities of milk, and her renal tract is kept under observation by x-ray. What further measures should be taken to prevent the formation of these stones?*

A.—Cystine calculi are attributable to a metabolic error about the essential nature of which we are ignorant. We can, therefore, seek to control their occurrence only in the following ways: (1) By free diuresis. (2) By continuous alkalinization of the urine. (3) By maintenance of an adequate vitamin-A level. (4) By sterilization of any urinary tract infection.

With the exception of alkalinization all these measures are applicable to the prevention of stone from whatever cause. There being only one kidney, it is clear that the patient is constantly at risk from obstruction. Fortunately cystine calculi are usually visible by *x*-ray, despite statements to the contrary.

and since their surface is smooth they can usually be passed down the ureter and voided. If a calculus lodges in a dependent calyx every effort should be made to move it while it is still small. Skipping and, even better, horse-riding may be recommended. If these measures fail the patient should be placed in such a position that the mouth of the calyx is its lowest point, and percussion or vibration should then be instituted over the organ. Prior to this manœuvre sufficient fluid should be given to promote thorough diuresis. Control of infection is almost always possible nowadays with adequate typing and antibiotic sensitivity assays.

Buried Alive

Q.—*An Indian yogi recently spent eight hours in a pit 6 ft. × 6 ft. × 6 ft. (1.82 m. × 1.82 m. × 1.82 m.), which was covered over with planks and earth. If it be assumed that the man was small and that his basal metabolic rate was at the lower limit of normality, can this feat be regarded as being remarkable?*

A.—Assuming the yogi's chamber to be airtight, and his metabolism to be that of an ordinary man sitting at rest, the carbon dioxide in the air would rise after eight hours to about 3% and the oxygen fall to about 17%. These changes in the respired air would be smaller in proportion to the sluggishness of yogi metabolism and the leakiness of the roof. The metabolism of soil itself is too slow to affect the issue. Vitiation of the air to this degree would have only trivial effects, chiefly a slight deepening of the respiration, and a mild headache on returning to a normal atmosphere. Considerably worse conditions have been experienced by respiratory physiologists and submarine crews without harm. If, however, the yogi spent 24 hours in the pit, it would indeed be worthy of remark.

Intravenous Procaine

Q.—*What are the indications for intravenous procaine? What unpleasant reactions have been recorded from its use?*

A.—Procaine belongs to a group of compounds known as "alkamine esters," all of which have a similar basic structure. Their main action may resemble that of atropine, curare, an antihistaminic, or a local analgesic. Whatever the main action, they all show the other effects to a lesser degree. Procaine, like several other local analgesics, also has a quinidine-like action on the heart.

Procaine in suitable dilution can therefore be used intravenously for a wide variety of conditions. As a general analgesic, it may be administered for the relief of pain—for example, in burns or after operation. In peripheral vascular disease it is said to be equally as effective as sympathetic block. As an antihistaminic it not only controls the irritation of urticaria but also terminates the attack. Procaine is as potent as quinidine on the heart, and its prophylactic use in cardiac surgery reduces or eliminates serious arrhythmias.

Individual tolerance for procaine varies greatly, and it is advisable to run the intravenous drip slowly, increasing the rate gradually until the desired effects are obtained. As a guide, not less than 15 minutes should be taken to give 0.5 g. (as a 0.2% solution) of the drug to a fit adult. In the debilitated a much longer time should be allowed.

Signs of approaching overdose are tinnitus, aphonia, and tremor. If these are ignored, consciousness may be lost and convulsions ensue. If at any moment the injection is stopped, recovery occurs promptly owing to the rapid breakdown of procaine in the body.

For further information the reader is referred to a recent review of the subject by Mushin, W. W., and Rendell-Baker, L., *Lancet*, 1949, **1**, 619.

Treatment of Epispadias

Q.—*A 5-year-old school-child suffers from dribbling urinary incontinence which accompanies a second-degree epispadias. Operative treatment is postponed till a later age, and parental care is rather poor. What is the best management of such a case, particularly in school? Are any large-sized pads available, and would their use, with ointment, be helpful? What are the chances of a reconstructive operation restoring some degree of continence?*

A.—There are residential schools in some localities which cater for children with these disabilities. Inquiries should be made of the lady almoner at the hospital the child is attending. No special pads are made, and very frequent changes of napkins are needed to prevent the child from getting sore. Soreness is best relieved by putting the child at bedtime on a pad of wool without napkins. Zinc and castor oil ointment should be applied several times a day to hasten healing of the skin. The prospect of regaining sphincteric control after operation is entirely dependent on the extent of the malformation. Unless there are special contraindications the child should be old enough at 5 for operation to be undertaken.

Tumour in Abdominal Wall

Q.—*What is the best treatment for desmoid tumours of the rectus abdominis? A woman of 29 had her first confinement, which was normal, two years ago. During the last three months she has noticed a painless swelling developing just to the left and below the umbilicus. This consists of a hard ovoid tumour about the size of a Jaffa orange; its margins are not too well defined. Histological examination of the tumour is not yet complete. The patient is otherwise perfectly well.*

I understand that x-ray therapy produces only slight response in desmoid tumours, so a radical excision has been recommended. This would prove a formidable undertaking in this patient, and I would like to know if it is the best procedure.

A.—From the description, the tumour in the abdominal wall may prove to be a fibrosarcoma rather than a desmoid. This is the more likely since it appeared almost two years after the pregnancy and seems to have grown very rapidly. This worsens the prognosis. Whichever diagnosis proves correct, the tumour is not likely to prove sensitive to irradiation, and this form of therapy is most suitable as an adjuvant. The mainstay of treatment must be wide excision if this is at all possible, and the gap in the abdominal wall must be closed by flaps of muscle or aponeurosis, appropriate movement of the integument, and by grafting. A preliminary dose of not more than 1,500 r should tend to limit the chance of recurrence, and if surgery is wholly out of the question long-continued therapy at a low dosage is the only alternative.

Guaiacol

Q.—*Is there any danger in the intramuscular injection of guaiacol, made up in either sterilized olive oil or pure chloroform?*

A.—Certainly guaiacol should never be given in chloroform by intramuscular injection. It can be given by this route in olive oil, but even so the injection is not free from danger, and if guaiacol is to be given at all it should be given by mouth. However, in 1938 guaiacol preparations were removed from *New and Nonofficial Remedies* (published by the American Medical Association) because there was no evidence that they have a therapeutic value (*J. Amer. med. Ass.*, 1938, **110**, 209). The toxic effects of guaiacol are similar to those of phenol. Locally it has an irritant action; generally it causes cardiovascular collapse.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology, Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

TAVISTOCK SQUARE, W.C.1

SUPPLEMENT TO THE

BRITISH MEDICAL JOURNAL

LONDON SATURDAY JULY 8 1950

British Medical Association

ONE HUNDRED AND EIGHTEENTH ANNUAL MEETING, LIVERPOOL AND SOUTHPORT, JULY 13-21, 1950

President-Elect: Sir HENRY COHEN, M.D., F.R.C.P., F.F.R., J.P., Professor of Medicine, University of Liverpool.
Local General Secretary: T. R. ROBERTON, M.B., CH.B., D.P.H., B.M.A. Regional Office, Medical Institution, Mount Pleasant, Liverpool, 3.
Executive Officer: G. A. PECK, B.Sc., B.M.A. Regional Office, Medical Institution, Mount Pleasant, Liverpool, 3.
Local Science Secretary: A. MACDONALD, M.D., Department of Bacteriology, School of Hygiene, Mount Pleasant, Liverpool, 3.

PROGRAMME

SCIENTIFIC SECTIONS

The clinical and scientific work will be divided among twenty Sections, meeting on Tuesday, Wednesday, Thursday, and Friday, July 18, 19, 20, and 21. All the Sections will meet in the University, apart from the Clinical Demonstrations.

Below is a list of the names of the Sections and officers appointed to each, together with programmes.

ANAESTHETICS

President: KATHARINE LLOYD-WILLIAMS, M.D., F.F.A. R.C.S. (London).

Vice-Presidents: T. CECIL GRAY, M.D., F.F.A. R.C.S., D.A. (Liverpool); N. S. WALLS, M.B., Ch.B., M.Sc., Ph.D., D.A. (Birkdale); H. J. BRENNAN, M.D., F.F.A. R.C.S., D.A. (Manchester).

Hon. Secretaries: J. B. HARGREAVES, M.R.C.S., L.R.C.P., D.A., 17, Beach Lawn, Waterloo, Liverpool, 22; WILLIAM W. MUSHIN, M.B., B.S., F.F.A. R.C.S., D.A., Department of Anaesthetics, The Royal Infirmary, Cardiff.

Official Reporter: Dr. W. W. MUSHIN.

Meeting-place: Lecture Theatre, Physics Building.

Tuesday, July 18.—10 a.m., *Paper:* Applied Pharmacology in Anaesthesia for Abdominal Operations, by Dr. STUART C. CULLEN (U.S.A.). 2.30 p.m., *Paper:* Resuscitation of the Newborn, by Dr. G. ORGANE (London), followed by Dr. R. J. MINNITT (Liverpool). Tea interval, followed by *Paper:* Anaesthesia in the Newborn, by Dr. T. N. P. WILTON (Bristol), followed by Dr. G. JACKSON REES (Liverpool).

Wednesday, July 19.—2.30 p.m., *Papers:* Analgesia in Anaesthesia, by Dr. L. RENDELL-BAKER (Cardiff); Sudden Death during Operation due to Undetected Paraganglioma, by Dr. S. B. DARBISHIRE (Ulverston); An Artificial Respirator, by Dr. J. ESPLEN (Liverpool); Some Therapeutic Applications of Nerve Blocks, by Dr. ERIC STEELE (London).

ANATOMY AND PHYSIOLOGY

President: Professor A. DURWARD, M.D., F.R.S.Ed. (Leeds).

Vice-Presidents: Professor R. A. GREGORY, M.R.C.S., L.R.C.P., Ph.D. (Liverpool); Professor J. M. YOFFEY, D.Sc., M.D., F.R.C.S. (Bristol); Professor G. M. WYBURN, M.B., Ch.B., F.R.F.P.S. (Glasgow).

Hon. Secretaries: T. G. RICHARDS, M.D., "Whiteheys," College Avenue, Formby, Lancs; J. G. WARBRICK, M.B., Ch.B., Department of Anatomy, University of Glasgow, Glasgow.

Official Reporter: Professor J. M. YOFFEY.

Meeting-place: Anatomy Theatre, Medical Building.

Wednesday, July 19.—10 a.m., (1) *Film:* The Lymphatics, by Professor J. M. YOFFEY (Bristol). (2) *Discussion:* Tissue Grafting. To be opened by Professor G. M. WYBURN (Glasgow). 2.30 p.m., *Symposium* on Histology and Physiology of the Suprarenal Cortex. To be opened by Dr. M. H. POWER (Mayo Clinic, U.S.A.), Biochemical Studies of Patients with Hypofunction or Hyperfunction of the Adrenal Cortex; followed by Mr. K. C. RICHARDSON (London), Histology and Histochemistry of the Adrenal Cortex; Dr. G. W. HARRIS (Cambridge), Neural Control of A.C.T.H. Secretion; Dr. M. VOGT (Edinburgh), Control of the Activity of the Adrenal Cortex; and Professor J. M. YOFFEY (Bristol), The Adrenal Cortex and Lymphoid Tissue.

CHILD HEALTH

President: Professor NORMAN B. CAPON, M.D., F.R.C.P. (Liverpool).

Vice-Presidents: R. W. BROOKFIELD, M.D., F.R.C.P., Ph.D., D.P.H. (Liverpool); Professor WILFRID GAISFORD, M.D., F.R.C.P. (Manchester); WILFRID SHELDON, M.D., F.R.C.P. (London).

Hon. Secretaries: JOHN D. HAY, M.D., M.R.C.P., D.C.H., 12, Rodney Street, Liverpool, 1; GEORGE NEWNS, M.D., M.R.C.P., 27, Devonshire Place, London, W.1.

Official Reporter: Professor W. S. CRAIG.

Meeting-place: Chemistry Theatre, Gossage Buildings.

Tuesday, July 18.—10 a.m., *Discussion:* The General Care of the Physically Handicapped Child. To be opened by Dr. C. D. S. AGASSIZ (Carshalton), Clinical Aspects; followed by Dr. H. M. COHEN (Birmingham), Administrative Aspects; Dr. M. D. SHERIDAN (London), Aspects of the Handicap of Deafness; and Dr. ALAN MABERLY (London), Psychological Aspects.

Wednesday, July 19.—10.15 a.m., *Clinical Demonstration* at Child Health Department, Alder Hey Hospital, Liverpool. 2 p.m., *Discussion:* Surgical Conditions in the Newly Born: Diagnosis, Prognosis, and Treatment. To be opened by Mr. DENIS BROWNE (London), followed by Mr. R. H. FRANKLIN (London) and Dr. G. J. REES (Liverpool), Anaesthetic Aspects.

Thursday, July 20.—10 a.m., *Discussion:* Breast-feeding. To be opened by Dr. F. C. NAISH (York), The Achievement of Successful Breast-feeding; followed by Dr. H. K. WALLER (Tunbridge Wells), Mr. K. C. RICHARDSON (London), and Mr. E. C. FAHMY (Edinburgh). 4 p.m., The Dawson Williams Prize Lecture by Professor A. A. MONCRIEFF (London), Child Health and the Future.

Friday, July 21.—10 a.m., *Discussion:* Epidemiology in Relation to Child Health. To be opened by Professor S. G. GRAHAM (Edinburgh), Infection in the Maternity Hospital; followed by Dr. W. N. PICKLES (Aysgarth), Infection in the Private House; Dr. R. McL. TODD (Liverpool), Infection in the Hospital Ward; Dr. K. M. HIRST (London), Infection in Nurseries; and Dr. J. C. RYLE (Shrewsbury), Infection in Schools.

DERMATOLOGY

President: R. STOPFORD-TAYLOR, D.S.O., M.B., Ch.B., F.R.C.S.Ed. (Liverpool).

Vice-Presidents: GODFREY BAMBER, M.D., F.R.C.P. (Liverpool); JOHN FRANKLIN, M.D., M.R.C.P. (London); A. O. FERGUSSON ROSS, M.D., D.P.H. (Liverpool); C. W. MACKENZIE, M.B., B.Ch., M.R.C.P. (York).

Hon. Secretaries: NETTA HAY, M.D., 12, Rodney Street, Liverpool; GEOFFREY A. HODGSON, M.B.E., M.D., 143, Cathedral Road, Cardiff.

Official Reporter: Dr. J. T. INGRAM.

Wednesday, July 19. Meeting-place: School of Tropical Medicine (Combined Meeting with Section of Tropical Medicine).—10 a.m., *Discussion:* Parasitology in Relation to Dermatology. To be opened by Professor R. M. GORDON (Liverpool) and Dr. R. M. B. MCKENNA (London). Invited speakers: Colonel NAPIER, Brigadier BOYD, and Dr. DOUGLAS FRESHWATER (Liverpool).

Thursday, July 20. Meeting-place: Chemistry Theatre, Muspratt Laboratories.—10 a.m., *Discussion:* The Uses and Abuses of Chemotherapy in the Treatment of Venereal Diseases. To be opened by Dr. ROBERT LEES (Manchester) and Dr. S. M. LAIRD (Ipswich). Invited speakers: Dr. D. J. CAMPBELL (Sheffield), Dr. D. I. WILLIAMS (London), and Dr. A. S. WIGFIELD (Worcester). Afternoon, (1) Dermatological Clinical Meeting in Liverpool Royal Infirmary. (2) Venereological Clinical Meeting, Demonstrations of Cases of Lymphogranuloma Venereum and Chancroid.

DISEASES OF THE CHEST AND TUBERCULOSIS

President: H. MORRISTON DAVIES, M.D., M.Ch., F.R.C.S. (Ruthin).

Vice-Presidents: O. F. THOMAS, M.R.C.P., D.P.H. (Liverpool); T. HOLMES SELLORS, D.M., M.Ch., F.R.C.S. (London); J. L. LIVINGSTONE, M.D., F.R.C.P. (London).

Hon. Secretaries: F. RONALD EDWARDS, M.D., Ch.M., F.R.C.S., 75, Rodney Street, Liverpool, 1; A. F. FOSTER-CARTER, D.M., Brompton Hospital Sanatorium, Frimley, Aldershot, Hants.

Official Reporter: Dr. A. F. FOSTER-CARTER.

Meeting-place: Surgery Theatre, Medical Building.

Wednesday, July 19.—10 a.m., *Discussion:* Resection of Lung for Pulmonary Tuberculosis. To be opened by Dr. O. F. THOMAS (Liverpool), followed by Mr. RONALD EDWARDS (Liverpool), Mr. JOHN BICKFORD (Liverpool), and Mr. J. R. BELCHER (London). 2.30 p.m., *Discussion:* The Clinical Interpretation of Pain in the Chest. To be opened by Dr. DONALD LEEMING (Southport), followed by Dr. RHODES ALLISON (Manchester).

Thursday, July 20 (Combined Meeting with Section of Preventive Medicine).—10 a.m., *Discussion:* The Care of the Tuberculosis Patient in the Home. To be opened by Professor F. R. G. HEAF (Cardiff), followed by Dr. R. GRENVILLE-MATHERS (Wallasey) and Dr. W. GRAY (Liverpool). 2.30 p.m., *Clinical-Pathological Demonstration* given by the members of the staff of the Liverpool Thoracic Surgery Centre at Aintree Hospital.

GERIATRICS

President: C. O. STALLYBRASS, M.D. (Heswall).

Vice-Presidents: J. P. HERON, M.Ch.Orth., F.R.C.S. (Huyton, near Liverpool); J. H. SHELDON, M.D., F.R.C.P. (Wolverhampton); MARJORY W. WARREN, M.R.C.S., L.R.C.P. (Isleworth).

Hon. Secretaries: ROBERT KEMP, M.D., M.R.C.P., Newsham General Hospital, Anfield, Liverpool, 6; L. Z. COSIN, F.R.C.S., Oxford United Hospitals, Cowley Road, Oxford.

Official Reporter: Dr. TREVOR HOWELL.

Meeting-place: Lecture Theatre, Physics Building.

Thursday, July 20.—10 a.m., *Discussion:* Activity in Advancing Age. To be opened by Dr. MARJORY WARREN (West Middlesex Hospital), followed by Mr. J. P. HERON (Liverpool), Orthopaedic Disabilities; Dr. TREVOR HOWELL (Battersea), Arthritic Difficulties; Dr. HIRSCH (Brussels), Arteriosclerosis; Dr. ROBERT EVANS (Liverpool), Pulmonary Fibrosis; *Occasional Paper:* Mortality in Geriatric Surgery, by Dr. LOUIS CARP (New York). 2 p.m., *Clinical Demonstration* at Newsham General Hospital (late Belmont Road Hospital).

Friday, July 21.—10 a.m., *Discussion:* The Link between Hospital and General Practice in the Treatment of Elderly Patients. To be opened by Dr. C. T. ANDREWS (Truro), followed by Dr. VISCHER (Basle), Dr. I. HARRIS (Bootle), Dr. A. FRANKLIN (Garston), Dr. E. L. ROBERTS (Formby), and Dr. K. B. GIBSON (Liverpool). 2 p.m., *Clinical Symposium* on the Overall Care of Old People in the Community. To be held at Fleetwood Road Hospital, Southport.

MEDICAL GENETICS

President: C. P. BLACKER, M.D., F.R.C.P. (London).

Vice-Presidents: Professor L. S. PENROSE, M.D. (London); Professor A. SORSBY, M.D., F.R.C.S. (London); J. A. FRASER ROBERTS, M.D., F.R.C.P. (London).

Hon. Secretary: C. O. CARTER, B.M., B.Ch., M.R.C.P., Department of Morbid Anatomy, Hospital for Sick Children, Great Ormond Street, London, W.C.1.

Official Reporter: Dr. J. A. FRASER ROBERTS.

Meeting-place: Anatomy Theatre, Medical Building.

Thursday, July 20.—10 a.m., *Discussion:* Contribution of Genetics to Medical Practice. To be opened by Professor L. S. PENROSE (London), followed by Dr. R. R. RACE (London), Some Practical Aspects of Blood-group Genetics; Dr. J. A. FRASER ROBERTS (London), A Clinic for Genetic Advice; and concluded by Professor F. A. E. CREW (Edinburgh).

MEDICINE

President: E. N. CHAMBERLAIN, M.D., F.R.C.P. (Liverpool).

Vice-Presidents: H. S. PEMBERTON, F.R.C.P. (Liverpool); Professor ROBERT PLATT, M.D., F.R.C.P. (Manchester); P. H. O'DONOVAN, M.D., F.R.C.P. (Nottingham).

Hon. Secretaries: E. WYN JONES, M.D., F.R.C.P., D.P.H., 31, Rodney Street, Liverpool, 1; C. ALLAN BIRCH, M.D., F.R.C.P., D.C.H., Millside, Slades Hill, Enfield, Middlesex.

Official Reporter: Dr. K. M. A. PERRY.

Tuesday, July 18. Meeting-place: Arts Theatre, Victoria Building.—10 a.m., *Discussion:* Modern Conceptions and Therapeutics of Cardiac Failure. To be opened by Professor E. P. SHARPEY-SCHAFER (London), followed by Dr. RICHARD BAYLISS (London), Dr. PAUL WOOD (London), and Dr. WILLIAM EVANS (London).

Wednesday, July 19. Meeting-place: Arts Theatre, Victoria Building (Combined Meeting with Section of Surgery).—10 a.m., *Discussion:* Ulcerative Colitis. To be opened by Professor T. L. HARDY (Birmingham) and Mr. A. HEDLEY WHYTE (Newcastle), followed by Dr. J. W. PAULLEY (Ipswich) and Mr. HAROLD C. EDWARDS (London). 2.30 p.m. (Combined Meeting with Section of Pathology and Bacteriology), *Discussion:* Atypical Pneumonia. To be opened by Professor C. H. STUART-HARRIS (Sheffield) and Professor S. P. BEDSON (London), followed by Dr. THOMAS ANDERSON (Glasgow), Dr. JANET NIVEN (London), and Dr. M. G. P. STOKER (Cambridge).

Thursday, July 20. Meeting-place: Lecture Theatre, Engineering Building.—10 a.m., *Discussion:* Antihistamine Compounds. To be opened by Professor J. H. BURN (Oxford), Pharmacological Aspect; and Professor D. M. DUNLOP (Edinburgh), Clinical Aspect; followed by Dr. LESLIE GAY (Baltimore). *Occasional Paper:* Present Position with Regard to Vitamin B_{12}, by Dr. J. F. WILKINSON (Manchester), followed by Dr. DOUGLAS RIDING (Liverpool).

NEUROLOGY

President: Professor Sir HUGH CAIRNS, K.B.E., D.M., F.R.C.S. (Oxford).

Vice Presidents: S. P. MEADOWS, M.D., F.R.C.P. (London); HUGH GARLAND, T.D., M.D., F.R.C.P. (Leeds); G. F. ROWBOTHAM, F.R.C.S. (Newcastle-upon-Tyne).

Hon. Secretary: A. SUTCLIFFE KERR, F.R.C.S., 75, Rodney Street, Liverpool, 1.

Official Reporter: Dr. T. ROWLAND HILL.

Meeting-place: Room 31, 1st Floor, Victoria Building.

Thursday, July 20.—10 a.m., *Discussion:* The Diagnosis and Treatment of Pain in the Upper Limb. To be opened by Dr. M. J. MCARDLE (London) and Dr. M. KREMER (London) on the medical aspect, followed by Dr. J. W. D. BULL (London) (radiological), Mr. W. R. HENDERSON (Leeds) (neurosurgical), Mr. D. LLOYD GRIFFITHS (Manchester) (orthopaedic), and Mr. D. M. MORRISSEY (Birmingham) (costoclavicular syndrome). 2 p.m., Visit to the Spinal Injury Unit at Southport Promenade Hospital. Short Talks by Mr. A. SUTCLIFFE KERR (Liverpool) (general management of paraplegia) and Mr. J. COSBIE ROSS (Liverpool) (urological aspect of paraplegia); followed by demonstrations in the wards, Physiotherapy and Recreational Departments.

Friday, July 21.—10 a.m., *Discussion:* The Treatment of Parkinsonism. To be opened by Dr. HUGH GARLAND (Leeds) and Dr. G. E. SMYTH (Manchester), on the medical aspect, followed by Dr. DENIS LEIGH (London) (new drugs and psychological) and Professor GEOFFREY JEFFERSON (Manchester) (neurosurgical).

OBSTETRICS AND GYNAECOLOGY

President: A. A. GEMMELL, M.D., F.R.C.S.Ed., F.R.C.O.G. (Liverpool).

Vice-Presidents: E. CHALMERS FAHMY, M.B., Ch.B., F.R.C.S.Ed., F.R.C.P.Ed., F.R.C.O.G. (Edinburgh); CHARLES D. READ, M.B., F.R.C.S.Ed., F.R.C.O.G. (London); PERCY MALPAS, M.B., Ch.B., Ch.M., F.R.C.O.G. (Liverpool).

Thursday, July 20.—10 a.m., *Discussion:* Intestinal Parasites of Man in Great Britain. To be opened by Professor J. J. C. BUCKLEY (London) and Dr. C. A. HOARE (London).

REGISTRATION FEE AT ANNUAL MEETINGS

The expenditure arising in connexion with the Annual Meeting has in the past been met from a guarantee fund raised by the local profession, supplemented by a grant from the Council of the Association. The Council considers that the time has come when the proportion of the expenses falling upon the local profession should be minimized. With this object in view the Council, while continuing the central grant, has decided that members attending the Annual Meeting (other than members of the Representative Body and overseas visitors) should be asked to pay a fee of one guinea towards the expenses of the Meeting. The fee of one guinea will be payable when members register at the Reception Office, St. George's Hall, Liverpool.

BADGES

Members will not be admitted to the Scientific Sections unless wearing badges. They should therefore make a point of being at the Reception Office, St. George's Hall, by *9.30 a.m.* on the first day of their attendance at the Annual Meeting in order to register and obtain their handbook, badge, registration card, and tickets.

Officers of Scientific Sections should inquire for special badges at the Reception Office.

TICKETS

It is regretted that no tickets for functions or excursions can be issued in advance.

All tickets for functions at Southport will be available from July 13 at the A.R.M. Inquiry Office, Floral Hall, or at the Ladies' Club, Prince of Wales Hotel.

All tickets for functions at Liverpool will be available from July 17 at the Reception Office, St. George's Hall, or at the Ladies Club, Adelphi Hotel.

REGULATIONS REGARDING DRESS

Robes with hoods (scarlet, if available) are to be worn at: the Official Religious Service, Tuesday, July 18, at 3 p.m.; the President's Address, Tuesday, July 18, at 8.30 p.m.; and the President's Reception, Tuesday, July 18, at 9.30 p.m.

Robes are *not* to be worn at Civic Receptions at Liverpool or Southport.

Robes may be hired from Messrs. Ede and Ravenscroft, Ltd., 93, Chancery Lane, W.C.2, or Messrs. Ravenscroft and Willis, 4, Hardman Street, Liverpool, 1, and early application is advised, as the supply of gowns is limited. A representative of Messrs. Ravenscroft and Willis will be in attendance at each of the functions at which robes will be worn.

Evening Dress (Tails or Dinner Jacket) with Decorations is to be worn at the President's Reception, Annual Dinner, and both Liverpool and Southport Civic Receptions.

Evening Dress without Decorations should be worn at the Representatives' Dinner and the Representatives' Dance.

OFFICIAL RELIGIOUS SERVICE

The Official Religious Service will be held in Liverpool Cathedral on Tuesday, July 18, at 3 p.m. and the sermon will be given by The Right Rev. The Lord Bishop of Birmingham. Those wishing to take part in the Procession should be at St. James' Schools (opposite Cathedral main door) at 2.15 p.m. prompt. The procession will move off at 2.45 p.m. Members not taking part in the procession and members of the public should be in their seats in the Cathedral by 2.30 p.m.

CAR PARKING

Windscreen labels may be obtained at the Reception Offices in Southport and Liverpool.

Free Car Parking is available in Southport on the Foreshore, Sea Bathing Lake, Floral Hall, Pleasureland, and Eastbank Street.

The charge for car parking in Liverpool is 6d. a day up to 6 p.m. and 1s. after 6 p.m.

SOUTHPORT CORPORATION FACILITIES

The Southport Corporation has kindly offered the free use of the following amenities, and tickets will be available at the A.R.M. Inquiry Office and at the Ladies' Club: Bowling Greens, Victoria Park (weekdays only); Tennis Courts, Victoria Park: Municipal Golf Links, Park Road; Pitch and Putt Course, Princes Park (weekdays only); Sea Bathing Lake, Princes Park: Pier; Deck and other chairs on the Foreshore, the Promenade, and for Band performances in the Municipal Gardens and the Floral Hall Gardens; Car parks on the Foreshore and at the Sea Bathing Lake, Floral Hall, Pleasureland, and Eastbank Street.

BANKING FACILITIES

The Westminster Bank will have a temporary office at the Annual Meeting Exhibition at Liverpool this year, where full banking services will be available for the convenience of exhibitors and the medical profession attending the meeting. Mr. G. W. Hales, manager of the Tavistock Square Branch, will be in charge of this office and will welcome any inquiries.

9.30 a.m. to 6.00 p.m.—L.16. Coach Tour to Windermere. Ticket 20s., including Lunch and Tea.
9.30 a.m. to 6.00 p.m.—L.17. Visit to Chester. Ticket 15s., including Lunch and Tea.
10.00 a.m. to 12.30 p.m.—L.15. Visit to Pilkington's Glass Works, St. Helens. Ticket 3s. 6d.
10.00 a.m.—Treasurer's Cup Golf Competition—Royal Liverpool Course, Hoylake.
10.00 a.m.—*Scientific Sections*—University.
2.00 p.m.—Sailing Match at West Kirby. B.M.A. v. West Kirby Sailing Club.
2.00 to 6.00 p.m.—U. Visit to Evans Biological Institute, Runcorn.
2.00 to 6.00 p.m.—U.19 Visit to Sudley Hall, Speke Hall and Aerodrome. Ticket 5s., including Tea.
2.30 p.m.—*Scientific Sections*—University.
4.45 p.m.—B.M.A. Films—St. George's Hall.
7.30 for 8.00 p.m.—Annual Dinner—Adelphi Hotel. Ticket £2 2s., including Wines.
8.30 p.m.—Wallasey Division Dance (with buffet supper)—Hotel Victoria, New Brighton. Ticket £1 1s.

Friday, July 21

9.00 a.m.—Reception Room open—St. George's Hall.
9.00 a.m.—Exhibition open—St. George's Hall.
9.30 a.m.—Pathological Museum open—Department of Pathology, University.
9.30 a.m.—Ladies' Club open—Adelphi Hotel.
10.00 a.m. to 12.30 p.m.—L.20. Coach Tour of Wirral. Ticket 4s.
10.00 a.m.—*Scientific Sections*—University.
2.00 to 6.00 p.m.—U.21. Coach Tour to Beeston, Delamere, and Chester. Ticket 9s., including Tea.
2.00 to 6.00 p.m.—U.22. Motor launch trip on Mersey.
2.30 p.m.—*Scientific Sections*—University.
8.30 p.m.—U. Popular Lecture by Dr. C. O. Stallybrass, D.P.H., Picton Hall. "Epidemics Old and New."

REMUNERATION OF GENERAL PRACTITIONERS

PREPARATION FOR TERMINATION OF CONTRACTS

A Special Conference of Representatives of Local Medical Committees from all parts of Great Britain was held in the Great Hall of B.M.A. House, London, on June 29. The Conference was summoned to receive a report from the General Medical Services Committee on the negotiations with the Ministry of Health regarding the remuneration of general practitioners under the National Health Service Act and to consider recommendations. Dr. W. JOPE (Blantyre, Lanarkshire) presided, and was supported by Dr. E. A. GREGG (Chairman of Council) and Dr. S. WAND (Chairman of General Medical Services Committee).

Opening Statement

Dr. WAND said that a reference to Spens and the global sum would be noted in the report. The Committee had pressed the Government time after time to give some indication of the global figure which might be taken to represent Spens, but had been refused. The Government of course recognized that a pronouncement of the global value required to implement Spens at the 1950 value of money would disclose the betterment factor now being paid, and this might embarrass the Government in other fields. The Committee claimed that the global sum should be continuously adjusted in respect of the number of doctors in the Service and the amount of work done, and it was impossible to adjust something which had not been precisely defined.

When they met the Minister in April it was quite clear that he did not appear to regard Spens as a continuing factor, and indeed he was at some pains to tell them that if the number of doctors should, say, double itself within a certain time, and thereby reduce the work of the individual, it would not be reasonable to pay them the same amount for that reduced amount of work. That, the Committee argued, was quite contrary to the spirit of Spens.

Dr. Wand went on to remind the Conference that what the profession was now getting was 40% betterment. This betterment was a most important factor. It was betterment for which they were fighting. They were still 30% below the 70% betterment which they had claimed two years ago, and indeed now they had to ask whether even that 70% was sufficient. The cost of living and practice expenses had gone up in recent months. In February last Mr. Gaitskell said that if £1 was represented as 100 in 1938 it should now be represented only as 52. This meant that the proper betterment factor to-day would be considerably over 70%.

The Whitley and arbitration machinery was coming into operation. The basis of arbitration through Whitley was being discussed. The other Services included in the N.H.S. were agreed that the proposed arbitration machine was not satisfactory. For instance, the Minister was given the right to refuse arbitration. Another quite important point was the constitution of the arbitration tribunal, to which they took exception. It would be seen from the report that unilateral action by the Minister was feared. Whether that fear was well founded or not the representatives were in a position to determine just as well as the members of the Committee.

The Down-grading of General Practitioners

At the meeting with the Minister on April 3 last the deputation emphasized very strongly the down-grading of general practitioners. The Minister expressed his sympathy and indicated that in the National Health Service if general practice was not attractive enough it would not be in the interests of the Service. There was no doubt that at the Ministry there was now a much larger measure of sympathy with general practitioners than formerly. The Minister had made a request for some information about practice expenses, and when they challenged the net remuneration which was arrived at from a calculation of the gross as set out by the Ministry they did indicate that the practice expense position was a very important factor. Therefore it was not unreasonable in the light of that that the Minister should have asked that practice expenses should be the subject of inquiry. He had then told them that he wanted their co-operation in effecting certain economies in the Service. They pressed him hard that the results of such economies should be applied for the betterment of general-practitioner remuneration, but he could not undertake that that would be done. He did say, however, that, if economies were brought about in one field, any moneys thereby saved would not necessarily revert to the Treasury. The Minister was at great pains to indicate that no cuts had been made in general-practitioner remuneration, but shortly afterwards they did have a "cut" in the shape of the increased tax on petrol which had the effect of reducing their net income, and this impost could not be passed on to others in the same way as business people passed it on to their customers.

As practitioners they had done their best to carry out this Service under great difficulties and in face of enormous demands. It was true that they had had a few improvements—increased mileage allowance, something more for the maternity services, and the Government was now going to pay the 8% for assistants for superannuation purposes. There were certain overall factors to be considered—the wage-freeze policy of the Chancellor, the White Paper on economies, the economic position of the country, and, within the last few days, the new international trouble. But the difficulty at the moment was not the Minister of Health or the Ministry: it was the Treasury and the Chancellor. There was now in the general-practitioner field an excess of incomes at the lower end of the scale, while at the upper end of the scale the single-handed practitioner with a full list could not get to within hundreds of pounds of the amount received by the consultant of the same age even without the merit award. General practitioners were doing a 7-day week and a 24-hour day, and they could be forgiven if they looked with bewilderment upon the pharmacists and dentists whose remuneration had been set out in the White Paper on the cost of the Service. The position was intolerable. When they entered the Service they were told that their lot was to be made easier, but the Government had done nothing to bring that about. Costs had become immeasurably heavier to-day, and some of the burden of work which would otherwise have been carried by the health centre was still carried by doctors' wives. He wished to stress the point that incentive had gone out of the life of the general practitioner. The Minister in his last reply made reference to the fact that normally the Whitley machinery would operate in any dispute. It was for that Conference to make important decisions. They might perhaps say that the latest offer was another example of Government procrastination. On the other hand, they might say that after two years' negotiation the Ministry was not unsympathetic with the G.P.'s case, and they were on the eve of some progress.

Termination of Contracts

Dr. Wand added that withdrawal was the most serious step they could take. It was a step which, if decided upon, must be decided deliberately and with a full knowledge of all its implications. It must be realized that the threat of withdrawal might lead to compulsory arbitration. The idea that withdrawal was a bluff and that a threat was sufficient must be put out of their minds.

"The time has come, without any shadow of doubt, when we must make a decision. We have fought very hard indeed by negotiation to get justice, but our hands are now being forced. We are a unique group of people doing a unique job, and it is high time that the conditions of our work and the difficulties under which we labour should be recognized and that we should be properly rewarded." (Applause.)

Dr. A. B. DAVIES (Walsall) moved:

That the Conference places on record the fact that at no time, either before or since the appointed day, has the remuneration of general practitioners been agreed.

He said that this was merely a statement of fact, but it was essential to inform the public, the Press, and some members of their own profession that they were not fighting for an increase of something which had been agreed, but for a settlement of something which should have been agreed before they came into the Service.

The motion was carried.

Criticism of Negotiations

The following motion was on the agenda in the name of Swansea:

That this Conference expresses strong disapproval of the method by which negotiations have so far been conducted, and suggests that the General Medical Services Committee should invoke the aid of a highly experienced advocate in preparing and presenting the profession's case to the Minister.

Dr. C. H. DAVIES, in moving this on behalf of Swansea, said that he wished to pay his own personal tribute to the Committee, but the fact remained that they had not made any large impression on the Minister. He was not at all surprised that they were unable to cope with the astute minds at the Ministry. All along the Minister had retained the initiative. This report on the remuneration of general practitioners which was before the present Conference was an abject confession of failure. In March, 1949, a conference agreed that the central pool should be increased by some £16m. What had happened about that? Nothing—except that another inquiry was in the offing. There was the utmost discontent among general practitioners at the inadequacy of their remuneration in comparison with other members of the Health Service. So far all that they had had was a little extra mileage allowance and some increase in vaccination fees. He thought the Committee should employ the services of a skilled advocate to assist it.

Dr. W. N. MAPLE (East Sussex) said he was in agreement with the second half of the Swansea motion but not with the first half. He thought they should be content to express their

dissatisfaction at the result of the negotiations but not go witch-hunting.

Dr. J. A. IRELAND (Shropshire) said that this was a motion of no confidence in the Committee. As to the employment of an experienced advocate, that proposal had already been before the Conference and the Representative Body and had been thrown out by both. He reminded practitioners that they had joined the Service voluntarily, not knowing what certain terms and conditions were, and that the Committee had been elected by them. At the present moment, when things were moving slightly in their favour, to pass a vote of no confidence would be absurd. He had seen something of the negotiations which the Committee had undertaken with the Government, and, while he had had a critical mind, he was full of admiration for Dr. Wand and his colleagues, whose procedure in these negotiations had appeared to him wholly admirable.

Dr. A. G. MANLEY (Surrey) spoke in favour of the Swansea motion, which, he said, was not a condemnation of the Committee but only an expression of disapproval at the way they had handled the case.

Dr. H. H. GOODMAN (Newcastle-upon-Tyne) said that he had hoped that the proposers of this motion would have brought forward some constructive criticism as to how they would have conducted the negotiations to better advantage. Such suggestions were singularly absent. They could not find a better advocate than Dr. Wand.

The CHAIRMAN OF COUNCIL (Dr. E. A. Gregg) said that that was not a new resolution. It had been considered and turned down before. He had had the privilege of being associated with negotiations since the days of Brackenbury, and he had heard how their case was presented in those days. He had lived through the stalwart days of Dain, when their case was thoroughly presented. He had lived through some later days [during his own chairmanship of the Committee] when he hoped the case was not inadequately presented, and he had reached the days of Wand. What was wanted in such negotiations was a plain unvarnished statement of the case, backed up with adequate evidence. What they did not want was an attempt by a skilled advocate by rhetoric to try to obtain some result which could not be obtained by plain statement. He begged them not to be led astray into thinking that there was some marvellous power in having a legal advocate. They were not dealing here with twelve jurymen at the Old Bailey; they were dealing with people who had a knowledge of the Service and who, point by point, would be able to stump a skilled advocate as well as they could stump anybody else. What was wanted in these negotiations was a man with a knowledge of practice, able to bring out facts from his own experience and that of his colleagues.

Dr. C. H. DAVIES, in reply, said that the only people who appeared to be satisfied with the Committee were the members of the Committee themselves.

The Swansea motion was lost by an overwhelming majority.

Prolonged Delays

Dr. WAND proceeded to move the first of six recommendations of the Committee:

That the Conference is seriously disturbed at the repeated hold-ups and prolonged delays in the negotiations on general-practitioner remuneration.

An amendment was proposed by Newcastle-upon-Tyne to add the following words to the recommendation: "and calls upon the Minister of Health to state immediately what global sum should be in the central pool to implement the recommendations in the Spens report."

Dr. H. H. GOODMAN, in moving, said that two years after the beginning of the Service it was time the Minister told them what the sum should be. He believed that the Government was "stalling" until after the next General Election. What practitioners asked for was elementary and was not denied to any class of worker in the country. It should be remembered that many new doctors had entered the Service since July, 1948, and the crowded state of the consulting service had led to an increase of those choosing general practice. Some of these would take out the basic £300, and this would diminish the pool and also the number of people on their lists. Unless moneys came into the central pool practitioners would suffer cuts—insidious cuts, not open cuts like those of the dentists. They wanted the central pool to be fixed so that the necessary adjustments could be made in accordance with external changes.

Dr. FRANK GRAY (Committee) said that the meeting would be in sympathy with the spirit of the Newcastle amendment. He would suggest one slight alteration. As it stood at present it was inviting the Minister to take unilateral action and determine what the figure should be. He thought that it should read, "what global sum should in his opinion be in the central pool."

This alteration was accepted by Newcastle, and in that form the Newcastle amendment was carried.

The first recommendation of the Committee was then carried in the following form:

That the Conference is seriously disturbed at the repeated hold-ups and prolonged delays in the negotiations on general practitioners' remuneration and calls upon the Minister of Health to state immediately what global sum should in his opinion be in the central pool to implement the recommendations in the Spens report.

The second recommendation of the Committee was formally moved by Dr. Wand and carried without discussion:

That the Conference deplores the failure of the Minister of Health to give an unqualified assurance that negotiations on general-practitioner remuneration will always be conducted through Whitley machinery.

Preparations for Withdrawal

The recommendation was as follows:

That the Conference instructs the General Medical Services Committee to make preparations for the withdrawal of general medical practitioners from the National Health Service in the event of the Minister failing to give the necessary assurance, sought in the previous resolution, or in the event of the investigations now under consideration not leading to a satisfactory settlement of general-practitioner remuneration.

Dr. WAND, in moving this recommendation, said that the amendments which were down on the agenda following this recommendation suggested a number of different courses of action. In his last reply the Minister had said that normally discussions on disputes on remuneration would be conducted through Whitley machinery. There were a number of alternative actions which might be taken. The Conference might decide to await the results of the inquiry. It might decide that there should be no inquiry and that withdrawal should take place immediately. It might decide to make preparations immediately for withdrawal and fix a date, or to make preparations immediately to withdraw under certain circumstances, such as unilateral action by the Minister, or unreasonable delay in carrying out the inquiry, or dissatisfaction with its results. If these alternatives were adopted power could be given to the Committee to take the necessary action at the appropriate time or another Conference could be called to make the final decision. If they did decide on withdrawal should certain things happen in the future, they must determine both the strategy and the timing. They would bear in mind certain important points. They must be aware of the feeling of their constituents and the necessity for certain preparation, including the giving of three months' notice. They would bear in mind that if they declined to take part in this inquiry there was a risk that the Government might use that as a point against them and make a great deal of capital out of it. But if they decided that withdrawal—or he preferred the words "termination of contract"—in certain circumstances was their policy they had to prepare themselves through their actions at the periphery to march forward united and determined, in good spirit, knowing that any action they took now was a fight for good general practice in the future. This was not a fight for money only; in recent months the question of status had come more and more to the fore.

The "Necessary Steps"

Among several amendments on the paper it was decided to take one by Lancashire:

That this Conference deplores the inadequacy of the remuneration of general practitioners, and considers that a final settlement of such remuneration is overdue. The Conference instructs the General Medical Services Committee to take all necessary steps to prepare for the withdrawal of general practitioners from the Service if the question of remuneration is not settled satisfactorily forthwith.

Dr. A. OWEN, in moving the above, said that they had gone round the "periphery" in Lancashire and had asked some 1,600 members their opinions, and so far 72% had declared their willingness to terminate their contracts.

Dr. C. M. CRAIG (Westmoreland) opposed the Committee's recommendation. He suggested that on this occasion they should concentrate on the question of remuneration and not mix it up with a threatened withdrawal of service.

Dr. A. H. WESTON (Middlesex) considered that the Lancashire amendment was rather woolly. A later amendment in the name of his own area instructed the Committee to make preparations forthwith for the termination of contracts, and that immediate action be taken in the event of the Minister failing to give the necessary assurance without undue delay or in the event of the investigations not leading to a satisfactory settlement. So far the Committee had failed to produce results. It was by results that in future they would be judged. The introduction of the word "forthwith" into the Middlesex amendment meant that preparations should be started now. These preparations included good staff work and a state of readiness at a moment's notice to take action.

Dr. W. H. HAYES (Bristol) said that his committee did not think there was any point in having further negotiations. The only thing left now was the weapon of resignation. He believed that the public had never been more sympathetic than now to the doctors' case. As to the financial state of the country, that was an argument which was always being brought up, but the Government had now told them that the financial prospects were improved, and the T.U.C. was claiming that wages should be unfrozen.

Dr. R. W. MCCONNEL (Buckinghamshire) felt that another Conference should be called to consider the preparations. They must await the results of the inquiry.

Dr. WAND said that in view of the number of amendments and their slight differences in wording he hoped the Chairman would give the meeting an opportunity of deciding the straight question on withdrawal as a clear-cut issue.

The CHAIRMAN said that he was prepared to accept a motion to give the Conference the opportunity of voting clearly on whether there should be immediate withdrawal. It was understood that withdrawal meant three months' notice.

Dr. W. H. HAYES (Bristol) was strongly in favour of withdrawal (three months' notice) now. Any other action would be taken as weakness on their part. Dr. W. D. ANDERSON (Glasgow) said that a resolution that practitioners should place their resignations in the hands of the Committee, to be used unless the Minister was willing fully to implement Spens, with retrospective effect to July, 1948, was carried at a meeting at Glasgow at which 85 practitioners were present, the number in favour of the resolution being 72. Dr. F. E. GOULD (Birmingham) believed that preparations for withdrawal should be made forthwith, but the preparation must include very careful explanation to those practitioners who did not attend meetings of the profession. Dr. H. D. SUTHERLAND (London) said that time must be given for staff work; the next three months would be insufficient.

The CHAIRMAN then put it to the meeting whether notices should be handed in immediately or not, and there was an overwhelming "No." The Lancashire motion already moved was disposed of by a vote to proceed to the next business. The "next business" was part of a motion by Middlesex:

That the Conference instructs the General Medical Services Committee to make preparations forthwith for the withdrawal of general medical practitioners from the National Health Service.

This was moved by Dr. A. H. WESTON (Middlesex), who said that it was a simple direct instruction, attaching no conditions whatever to the preparations for withdrawal.

Dr. O. C. CARTER (Committee) said that, although he was one of the few people present who were not personally affected by the decision, these matters were of such vital importance to the whole profession that the view of every type of practitioner should be put before the Conference. He was not sure that it was to the credit of the profession as a whole that two years after the Act came into force they should be called together to consider such matters as were on the agenda that day. They were as far as ever from getting satisfaction. There were some of them who, after the second plebiscite, did their utmost to persuade practitioners not to accept service, but they were unsuccessful. The result was that practitioners had been split into two unequal groups, a small group outside the Service and a big group inside. Many of those inside the Service had suffered financial hardship, and all had found their status deteriorating. This must be put right at the earliest possible moment. On this matter he was as much a die-hard as ever. The Spens Report, the charter of the general practitioner, had not been implemented. He hoped the Conference would decide on withdrawal from the Service at the proper time.

Preparations "Forthwith"

The Middlesex motion was reworded as follows:

That the Conference instructs the General Medical Services Committee to make preparations forthwith for the termination of contracts by general medical practitioners in the National Health Service.

There voted:

In favour	141
Against	17

The Conference then turned to consider as a single issue the time at which withdrawal should become operative.

Dr. WAND said that fixing the date was always an embarrassment, for one could never anticipate events. He reviewed again the various possible instructions which the Conference might give to the Committee. Dr. A. G. MANLEY (Surrey) asked if they were serious about this question of determining contracts. If they were there was no reason why they should not give a date. Dr. R. HUTCHISON (Lanark) spoke of the feeling of frustration north of the Border. He thought they should put a definite date to their withdrawal. Dr. A. V. RUSSELL (Wolverhampton) said that discontent all over the country had increased very much. He hoped that the Committee, in following their instructions to organize termination of contracts, would also organize an alternative service which they could offer to their patients. Dr. A. MCARTHUR (Oldham) said that if they terminated their contracts they would become again free and independent practitioners, and they would have with their freedom the power of negotiation which they lost in 1948. Dr. S. NOY SCOTT (Devon) spoke against the fixing of a date; a large number of them had no mandate to fix a date. They must await events and have another Conference before doing anything further.

After some further debate it was suggested that the following form of words should follow the part of the Middlesex motion already passed:

and that, if and when it becomes evident that there is no prospect of a satisfactory settlement of the claim, a Conference be called to name a date at which general practitioners shall be advised to end their contracts with executive councils, and that in any case a Conference be called to consider the position in December, 1950, if a satisfactory settlement has not been reached by that time.

These words satisfied Middlesex and Surrey, which had motions on the subject. They were put to the Conference and carried by a full vote.

The Effective Percentage

Dr. J. C. ARTHUR (Gateshead) moved that when resignation of practitioners was called for an 85% adhesion should be specified as necessary before resignations became effective. He believed that if a high figure was specified it would be attained. Dr. BARBARA WOODHOUSE (Middlesex) objected to one area laying down the law for the whole country in this respect. Dr. ARTHUR said that his was a representative area. His committee was simply suggesting a figure which would be likely to encourage the waverers.

The motion was referred to the Committee.

Dr. J. C. MCMASTER (Somerset) moved that preparations for termination of contract should be put in hand at once and

planned in full practical detail, with adequate attention to the public relations aspect. Dr. FRANK GRAY said that the Committee could not make all these preparations; the bigger responsibility rested on the members of the Conference and of local medical committees. It was only at the periphery that any weaknesses could be overcome.

This motion was accepted by the Committee and carried.

A further motion by Gateshead concerning preparations and calling for a clear statement on the availability of the accumulated defence funds and the procedure to be followed by practitioners in the acceptance of patients for treatment in the circumstances then arising was carried. The SECRETARY informed the meeting that the decision of the Conference that day would lead to the operation of the Guild machinery for the first time.

A Middlesex motion instructing the Committee to obtain assurances of support from other branches of the profession was accepted by Dr. WAND in principle as a reference to the Committee.

Dr. W. P. HEDGCOCK (Cambridgeshire) moved that practitioners should be prepared to co-operate with the Minister to ensure economies in the Service if he would undertake to apply the sums saved to the implementation of the Spens Committee's proposals for remuneration of all grades of general practitioners. It was evident that a vast amount of money was being wasted. Dr. WAND pointed out that this was contrary to constitutional procedure regarding expenditure of moneys.

It was agreed to pass to the next business.

The Investigation into Income and Expenses

Dr. WAND then moved the third recommendation of the Committee:

That the Conference, recognizing that an equitable settlement of the remuneration issue may be influenced by early and accurate information on general-practitioner income from National Health Service sources and practice expenses, is willing to participate in the proposed inquiry.

He said the intention was that the two sides together should agree on a method of getting the information and the factors to be determined.

Dr. H. P. SUMNER (Salford) said that the Minister should already have a good idea of what practice expenses were. Dr. B. HALFPENNY (Kent) said that before agreeing to these further investigations an assurance should be sought from the Minister that any disputes on remuneration would be settled through the recognized machinery or referred to arbitration. Dr. R. W. MCCONNEL (Buckinghamshire) felt that any participation in such an investigation should not be conditional on the question of negotiation through Whitley machinery. Dr. H. H. D. SUTHERLAND (London) hoped that the inquiry would not mean another large document which would take much time to study and discuss.

Dr. WAND said he could give an assurance that matters would not be allowed to be unduly protracted.

The recommendation was carried with one dissentient.

Status of the General Practitioner

Dr. J. BAIRD FORRESTER (Glasgow) moved:

That the fundamental requirement to secure a satisfactory status for the general practitioner and to improve the Service is a reduction in the maximum number of patients permitted with an appropriate increase in the capitation fee.

He said that many of the services which the general practitioner was able and qualified to perform had now to be done at the hospital, because the practitioner had not time to cope with them, owing to the trivial matters which of necessity occupied him. In order to enable him to carry out these services the maximum number of patients on the list might be reduced below 4,000, but this should be conditional on the implementation of Spens.

Dr. R. W. MCCONNEL (Buckinghamshire) said they did not want to tie an able man down to a lower standard.

Dr. J. C. ARTHUR (Gateshead) asked by what right Glasgow, because it could not manage 4,000 patients as a maximum, had to say that they could not manage them in Gateshead.

Dr. J. T. MCCUTCHEON (Glasgow) said that what Glasgow wanted was to secure that the work was done under better conditions and with more time for its performance. The motion brought forward by Dr. Forrester had been passed practically unanimously at their meeting. There were many practitioners who could manage a list of 4,000, though they felt on the whole that the average practitioner could not manage that number to the best advantage.

Dr. FRANK GRAY (London) supported Dr. Arthur. It was not a question of the "average doctor." Most of the doctors with a list of 4,000 were better able to manage their practices and give a good service than a large number of those with smaller lists.

Dr. WAND said that the purpose of the Conference was to seek a method of trying to obtain proper remuneration for general practitioners. To pass a resolution of this kind now might be most dangerous. The first thing to do was to get more remuneration. Having done so, the question of distribution would come in. But if they started cutting down the maximum, first by one step and then by another, they would arrive at an equalization of practices and a full-time service.

Dr. FORRESTER said, in reply, that he personally had a list of 4,000, but if it was not for a very efficient assistant he certainly would not be able to cope with it. How could one deal with 100 people in the surgery and give them proper attention?

The Glasgow motion was heavily defeated.

The Increased Burden of Work

Dr. A. B. DAVIES moved a resolution calling upon the Conference once again to stress the greatly increased burden of work experienced by the profession as a result of the introduction of the Act.

The motion was carried.

Dr. WAND at this point moved the fifth recommendation of the Committee:

That, in the opinion of the Conference, one of the greatest dangers confronting general practitioners, and so their patients, is the lowering of the status of the general practitioner since the introduction of the National Health Service.

The motion was carried unanimously.

Dr. H. SOUTHWORTH (Lancashire) moved:

That this Conference regrets to record the lowering of the status of the general practitioner under the National Health Service, and instructs the General Medical Services Committee immediately to take whatever action may be necessary to secure the restoration of the general practitioner to the high and honoured position he held immediately before the introduction of the present Medical Service.

He said that practitioners must have time for study, not only in refresher courses and in the reading of technical books and journals, but time for study of what was going on around them, how they could advise their patients properly about their ailments and learn something about their environment. One patient who came into his surgery told him that that was the first time he had ever sat down in a doctor's surgery. In all his previous visits he had remained standing and had received his certificate or prescription or whatever it might be. They wanted time to see their patients in hospital. If they were to obtain the best results for their patients they must be their friends, and to be anyone's friend took time.

Dr. D. F. HUTCHINSON (Middlesex) said that this motion by Lancashire instructed the Committee to do something they could not possibly do.

Dr. SOUTHWORTH replied that in his view this was the most important motion of the Conference. The other motions were merely administrative instructions.

The motion was carried.

General Practitioners and Hospitals

The last of the Committee's recommendations was as follows:

That the Conference deplores the changing relationship of the general practitioner to the hospital, with particular reference to the insufficiency of general-practitioner beds; to the exclusion of general practitioners from the membership of hospital management committees; to the difficulty of access to special departments; and generally to the position of general practitioners in the administration of hospitals.

Dr. WAND moved this recommendation formally.

Dr. R. W. MCCONNEL (Buckinghamshire) moved as an amendment that it be suggested to local medical committees that they should form joint committees in the area of a regional hospital board, such committees to seek liaison with the board. In his area a co-ordinating committee had made a considerable difference in the attitude of the board to general practice. He strongly recommended other local medical committees to follow the same course of action.

Dr. W. F. HUDSON (Oxfordshire) said that the previous week the Minister had addressed the Association of Hospital Management Committees. At the close of the address he (the present speaker) asked Mr. Bevan whether it was not a fact that there were several regional boards and hospital management committees on which there was no general practitioner, and whether there were not several hospital management committees which attempted to manage their affairs without the assistance of a medical advisory committee. Mr. Bevan's reply, which was somewhat unenlightening, was, "Too many doctors are serving on committees, possibly at the expense of their clinical work." At the same time Mr. Bevan said that it was right that every hospital management committee should have a medical advisory committee. But whenever the Minister was asked to ensure that medical advisory committees were set up he had stubbornly refused to make such committees statutory. In Oxfordshire his attitude was much deprecated.

Dr. F. M. ROSE (Preston) said that if they were going to allow themselves to be ousted from hospitals their status was going to drop, and, in addition, they were likely to lose their clinical skill.

Dr. J. A. IRELAND (Shropshire) said that one aspect of this matter had not been referred to. The present set-up tended to close the avenue of approach for the general practitioner to consultant and specialist status. In the past many general practitioners had qualified as consultants and specialists owing to their attachment to various hospitals.

Dr. WAND said that he approved personally of the Buckinghamshire recommendation. They had taken steps to bring home to the Ministry the position of the general practitioner in relation to the regional hospital boards and hospital management committees, and he believed they had made some progress and that the offending circular might be modified very considerably before the next elections took place. His little doubt about this recommendation went back to the resolution which the Conference had already passed asking the Committee to try to obtain the co-operation of other sections of the profession. These committees would have a relationship with the consultants of the area. There had been set up a Joint Liaison Committee between the General Medical Services and the Consultants and Specialists Committees and he wondered whether this motion should not be referred to that Committee in order that the matter might be taken up there.

Dr. TALBOT ROGERS (Kent) said that it was a very difficult job to be a general practitioner on a regional hospital board, for there were very few people to back up one's point of view. He welcomed the Buckinghamshire suggestion and hoped that it would be carried. He wanted to see every region follow the example of Oxfordshire.

It was agreed to refer the Buckinghamshire motion to the General Medical Services Committee.

Dr. HOWIE WOOD (Isle of Wight) moved an amendment to the Committee's recommendation introducing two fresh clauses. The recommendation with these clauses would read:

That the Conference deplores the changing relationship of the hospital to the general practitioner, with particular reference to the insufficiency of general-practitioner beds, *both general and maternity*; to the exclusion of general practitioners from the membership of hospital management committees; to the difficulty of access to special departments; *to the exclusion of general practitioners from those departments in which they have special experience*; and generally to the position of general practitioners in the administration of hospitals.

The recommendation would thus stress the need for some steps to be taken to secure the admission of the general-practitioner obstetrician to maternity hospitals where he might look after his own cases if he so wished.

This amended form was accepted by Dr. Wand and agreed to by the Conference.

Increase in Hospital Personnel

Dr. A. G. CHAMBERLAIN (Dorset) moved, "That this Conference views with concern the rapid increase in personnel (both medical and lay) in the hospital services and in the resultant cost of such services."

He said that this additional personnel was not replacement but new appointments, and although a certain number of them would be bound to be made in a new Service this state of things was going on too rapidly. In a hospital known to him the medical staff was now two-and-a-half times as great as it used to be, and yet very little more work was done. Every consultant in every hospital he went to seemed now to have one or more young men of registrar status. In addition, there was a perfect army of lay officials, multitudes of technicians—he knew that some of them were needed, but they were not all needed—as well as clerks and other people.

Dr. J. A. PRIDHAM (Committee) hoped the Conference would pass this motion unanimously. The Service was getting out of balance. It was started with the idea of prevention, but all the resources appeared to be applied to the hospital services, which really came in where the preventive services broke down.

Dr. WAND said he was not happy about this resolution at all. Leaving aside the point about the lay personnel, take the reference to medical staffing. The profession were asking that general practitioners should be associated with the hospitals. They were disturbed by the fact that the ranks of general practice might be swollen by registrars who could not find staff appointments. They were concerned with the position of the S.H.M.O.s and their gradings. In his city of Birmingham they had to wait three weeks for an appointment with a physician, and his patients had to wait two years before their children's tonsils and adenoids could be removed. He wondered whether it was their business at that time to make comment on such a matter as was brought forward by the Dorset motion. It would be better discussed at the Representative Meeting, where both parties were concerned.

It was proposed from the body of the Conference, and agreed, to pass to the next business.

Superannuation

Dr. A. G. HOLMAN (Norfolk) moved:

That this Conference considers that the 8% contribution by the Exchequer towards superannuation payments should be payable to general practitioners or their dependants in the case of death or retirement before the required ten years' service has been completed, or, alternatively, that the recent concession by which hospital medical officers are allowed to count their previous service towards the necessary ten years to qualify for pension should be extended to general practitioners from the time when they started National Health Insurance work.

Dr. WAND said that when they discussed superannuation regulations previously to the appointed day the points which were made in the Norfolk resolution were pressed upon the Ministry very strongly, but the Ministry refused to consider them. The Ministry's statement was that the scheme had an actuarial balance, and the actuary whom the profession employed to advise them on that point confirmed that actuarially the scheme was a good one. Therefore if increases were to be made for any particular group it would mean that there would have to be larger payments than the 6 or 8%. They would, of course, take up the point again if the Conference so desired, but he was not very hopeful of success. He suggested that the motion be remitted to the Superannuation and Compensation Committee of the British Medical Association.

It was agreed that this should be done.

Fees for Specialist Services

Dr. C. F. WRIGHT (Reading) moved to instruct the Committee to make representations to the Ministry that general practitioners with acknowledged specialist abilities, who performed

services for patients on their own lists, such services being agreed to be outside the scope of general practice, should be permitted to charge fees for such services.

Dr. WAND said that for two solid years the Committee had been hammering at this question. The regulation was that a doctor could not charge, and that was that. But they had in the meanwhile approached this from another angle. They had a subcommittee which had produced a report on the association of the general practitioner with the hospital, and it was in this approach that he thought they might achieve the object of Reading.

The motion was put to the Conference and lost.

A motion from Brighton asked that the agenda of future Conferences might be published in the *British Medical Journal* for the week immediately preceding the date of the Conference.

Dr. WAND explained that the amendments were necessarily received late, and the democratic machine by which they worked made timing difficult. But they would do their best.

The Conference ended after passing a cordial vote of thanks to the Chairman.

PRESCRIBING IN THE HEALTH SERVICE

NO ABSOLUTE RESTRICTION

In its Second Interim Report the Joint Committee on Prescribing states: "From the outset we were agreed that wherever our discussions might lead us there should be no absolute restriction on the prescribing by a general practitioner of any drug which in his opinion was necessary for the treatment of his patients."

The committee was appointed in 1949 by the Central and Scottish Health Services Councils

"to consider and report from time to time whether it is desirable and practicable to restrict or discourage the prescribing by practitioners giving general medical services under the National Health Service Acts of 1946 and 1947 of (1) drugs and medicines of doubtful value or of unethical character; (2) unnecessarily expensive brands of standard drugs."

The members of the committee are:

Sir Henry Cohen (chairman); Dr. Janet Aitken; Professor Stanley Alstead, Dr. J. A. Brown; Professor E. C. Dodds, F.R.S.; Professor D. M. Dunlop; Dr. F. Gray; Dr. P. Hamill; Mr. J. C. Hanbury, F.R.I.C.; Dr. G. MacFeat; Professor Chassar Moir; Dr. A. Smith Pool; Mr. J. H. Ramsay, Ph.C.; Dr. W. D. D. Small; Sir Henry Souttar; Mr. D. E. Sparshott, M.P.S.; Dr. J. G. Thwaites; Alderman W. J. Tristram, M.P.S.; with, as joint secretaries, Mr. D. Emery and Mr. W. G. Honnor.

Amplifying its statement that there should be no absolute restriction on prescribing, the report states that if the committee were to recommend that certain drugs should not be prescribed by a practitioner he would still be at liberty to prescribe them; or if a list of "approved" drugs were drawn up the practitioner could still prescribe drugs not on this list. But in either case he might have to justify his action to the local medical committee.

The Health Departments provided the committee with a list of several hundred proprietary preparations. Most of them did not differ materially, states the report, from the drugs and preparations included in the *B.P.*, the *B.P.C.*, or the *National Formulary*. "Such proprietary preparations are usually more expensive—often very much more expensive—than standard drugs or preparations of reputed analogous therapeutic effect. There is no medical advantage in prescribing an expensive proprietary brand of a standard drug or preparation, but equally no objection to such prescriptions can be taken on purely medical grounds."

The committee was not unanimous on the desirability of drawing up at this stage lists of proprietary preparations and other drugs which a doctor could or could not prescribe without risk of having to justify his action. A minority thought a list would be resented and that any form of restriction would foster a belief in the public that some drugs, however essential for treatment, could not be obtained in the Health Service. But the majority thought that practitioners would welcome a list, for then they would know what they could prescribe in reasonable quantity without risk of having to justify their action, and they would be in a stronger position to resist the requests of unreasonable patients.

The committee recommended that before imposing any restrictions a letter should be sent to all practitioners stating the committee's views. It is being sent to hospital practitioners as well as general practitioners, and is summarized below.

Though deciding that no attempt should be made to impose restrictions until the effect of the letter had been determined, the committee decided by a majority that the preparation of a list of drugs should start at once. A practicable method would be to compile a list of "approved" drugs which a practitioner would know he could prescribe in reasonable quantity without question.

The committee (with one dissentient) regards it as undesirable that medicinal preparations advertised direct to the public should be prescribable on Form E.C.10. All drugs and preparations described in the *B.P.*, the *B.P.C.*, and the *National Formulary* should be freely prescribable, except those classified as food, toilet preparations, or not drugs for National Health Service purposes by the Definition of Drugs Joint Subcommittee.

Classification of Drugs

The committee decided that proprietary preparations could be conveniently arranged under the following six categories:

(1) New drugs of proved value not yet standard.
(2) Proprietary brands of standard drugs, singly or in combination.
(3) Standard preparations, and new remedies of proved value, in elegant form or vehicle.
(4) Qualitative and/or quantitative modifications in the composition or combination of standard preparations, or new remedies of proved value, which are not accepted as therapeutically superior to preparations included either alone or in combination in the *B.P.*, the *B.P.C.*, or the *National Formulary*.
(5) Preparations not in the *B.P.*, *B.P.C.*, or *National Formulary* which in the committee's view have not been proved of therapeutic value.
(6) Preparations which are a combination of (4) and (5).

Apart from preparations in categories (5) and (6) of the previous paragraph (which consist of, or contain, drugs of doubtful value) the committee has no reason for suggesting on medical grounds that these proprietary preparations should not be freely prescribable in the National Health Service, except when advertised direct to the public. The objection to many of them is that a standard drug of reputed analogous therapeutic effect can be prescribed at less cost, but the committee does not feel that it is a competent body to advise on this question of cost.

The committee recommends that proprietary preparations in category (1) should be freely prescribable, and that preparations in categories (2), (3), and (4), which it regards as not therapeutically superior to standard preparations, should be prescribable subject to (i) their not being designated as foods, toilet preparations, or not drugs for N.H.S. purposes by the Definition of Drugs Joint Subcommittee, (ii) their not being advertised direct to the public (recommended, with one dissentient), and (iii) satisfactory arrangements for price being made between the Health Departments and the manufacturers.

The committee is prepared, if the councils so wish, to continue classifying proprietary preparations referred to it into these six categories. This will be a long process because there are many thousands of such preparations and a therapeutic assessment involves the collection of all relevant information and a study of each preparation individually.

LETTER TO DOCTORS

The letter which the Chief Medical Officer of the Ministry of Health is sending to doctors about the prescribing of expensive proprietary preparations begins by asking for co-operation, since "it is by co-operation, rather than by orders and regulations, that the best results are achieved." After saying that there is no intention of placing any absolute restriction on the prescribing by a general practitioner of any drug which in his opinion is necessary for the treatment of his patients, the letter continues:

"You are probably aware of the fact that rather more than 30% of the cost of medicines supplied to public patients is for proprietary preparations. Of course, it would be wrong to condemn proprietary preparations as a whole; indeed, some of them are of great value in the treatment of patients and have no standard equivalent. There can be no question of asking practitioners not to prescribe proprietary preparations known to be of proved value and for which there is no equivalent substitute.

"There are, however, some proprietary preparations for which there are standard equivalents in the *Pharmacopoeia*, *B.P.C.*, or the *National Formulary* and which are more expensive than the standard preparation. It is in this field that substantial economies could be made without affecting in any way the efficacy of treatment. None of us want the Health Service to cost more than is necessary, and there is reason to believe that a substantial saving could be effected if practitioners would prescribe the standard preparation, wherever it is equivalent to the proprietary.

"The formal suggestion I want to make is that, save in any exceptional case where there is an overriding medical consideration, doctors will seriously consider before ordering one of these proprietary preparations whether the alternative standard drug could not be ordered without detriment to the patient's condition. It will be appreciated that, in many cases, preparations in this group are advertised direct to the public.

"The departments would greatly value the help of the medical profession, while preserving their right to do what they believe to be best in the interests of the patient, in prescribing a standard preparation, where there is such a preparation, and so avoiding unnecessarily expensive prescribing."

Correspondence

Status of General Practice

SIR,—The passing of a second year of National Health Service finds our profession increasingly concerned with its financial and moral status. When Mr. Bevan was induced to accept the Spens standard of remuneration of doctors it seemed that we had finally settled and assured our financial status for at least a decade. At that time our N.H.I. capitation fees were so long overdue for revision that there was little difficulty in obtaining either a united threat of resignation or, within a matter of days, the appropriate response from Mr. Bevan. The present investigations are unlikely to show that our position is as far below accepted standards as in those days. Therein lies our weakness: not only because our case will be harder to make out, but because there will be relatively fewer doctors who are personally interested in taking measures on this occasion which would stand a reasonable chance of proving effective. It looks, therefore, as if questions of our financial status are increasingly going to be left to the discretion of the Minister of Health, just because he has chosen to challenge our right to independent machinery at a time when many of us are too well off to care about either future consequences or a present minority who are already hard hit.

What I have referred to as our "moral" status is in the opinion of many doctors on a steep decline, and to many of them this is causing as much concern as material considerations. There can be little doubt that the status of doctors in the eyes of the public is declining, and in my view this is intimately connected with the fact that our public contacts are so frequently under circumstances that find us collectively or individually interested primarily in securing the shekels. Mr. Bevan is largely responsible for our prolonged fight for our financial rights as a profession, but I doubt if even this is diverting public opinion from the most worthy objects of our calling as much as the increasing revelation by individual doctors of a cash outlook that had hitherto been unsuspected by their patients.

In the past, half the population, and probably the more intelligent and discerning half, used to receive regular medical accounts, which were paid and receipted without any other recognition between doctor and patient that they existed at all. This attitude was not inconsistent on the doctors' part with their rather disinterested appeals for public support in the fight against Mr. Bevan's introduction of the N.H.S. Act. Everyone knew the doctor had to be paid for his work, but his profession had built up for itself a reputation for a sort of service that sought inspiration primarily in the particular nature of his calling.

It has come as a considerable shock to great numbers of people, many of whom are themselves engaged in vocational work, to find that their doctors' service to them was so intimately related to the money they paid him. The butcher and baker called regularly once a week and often were most kind and obliging, but they never were regarded in the same light as the doctor. His was a kindly courteous action which called for quite a different sort of response than was usually afforded tradesmen, however considerate, skilful, or necessary to life they might have been. Now all is suddenly changed. Dear Dr. X no longer looks in for his nice little talk that was such an event each week; and even when emergency arises he does not seem as attentive and concerned as of old. To make matters worse he has said and done a great deal to give the impression that the old Dr. X is still about if you tip him heavily in addition to the already heavy burden of taxation that you thought did at least eliminate doctors' bills.

Personally I have resolutely refused to accept "private" patients and done everything possible (in a practice that was less than half "panel") to make my old private patients realize that our former relationship was not after all a cloak for a cash-and-carry business. I took what I thought was an opportunity to enhance my status, and I am not so far disappointed in the result, even from the financial aspect I neglected. A few really money-minded people are still suspicious, but on the whole I think patients find less cause to question the motives which actuate my personal attention and in many cases cultivate a greater respect for them than hitherto. My previous attitude to general practice has undoubtedly facilitated the change-over in my case, but I think most doctors could do as I have done, and they and their patients would derive immense satisfaction therefrom.

In my opinion this private-patient "racket" is an enormous blunder and is even of doubtful money value. I should like to see someone like Lord Horder collect a body of doctors who would pledge themselves to do all they can to abolish it and lead the profession to a position of even greater respect than it has ever commanded. We are not getting away with the general attempt to blame the patient's sudden change of status on Mr. Bevan. A lot of patients realize already that this change is at least as much due to their doctor's reaction to the N.H.S. as it is to anything in the Act itself.

Finally, if money *were* our ultimate inspiration, the success of our financial negotiations in the long run might well depend on keeping the public in ignorance of the fact. We cannot look for much support from a public who regard our negotiations with Mr. Bevan as merely a mass edition of the doctors' general scramble for more money wherever it can be obtained. The Act has come to stay and private practice almost certainly has not. Let us fight for our rights in the proper place, but at the same time order our personal relationships with patients to take advantage of the Act rather than in such a way as will soon reduce the whole profession to a status considerably below that of Civil Servants.—I am, etc.,

Eye, Suffolk. J. SHACKLETON BAILEY.

SIR,—Why the continuous smearing of the G.P.s? One is frequently reading in and out of the medical journals such sentences as "the *deterioration* that has taken place in standards of general practice since the N.H.S.," and "so-and-so would do a lot to ameliorate the *downward trend* of medicine in general practice that is now taking place." Add to this the suggestions or plans to make the G.P. attend courses yearly or occasionally, presumably in order to fit him for general practice; talks of altering the pregraduate and postgraduate curricula, etc. All these sorts of things put together can only leave the public with the impression that whatever is wrong with the N.H.S. is at the door of the G.P., not forgetting "lack of proper accommodation" for his patients. Now this is all eyewash and there is something very sinister behind it all.

The truth is that the modern G.P. and the older ones with years of experience behind them were never so competent to deal with the ill-health of the nation as they are to-day; and all—and I mean all—the evils of the totalitarian N.H.S. are due to the overloading of the Service with politics and lay administrators. There must be more committees and boards and

councils running the Service than there are doctors, who are actually coping with the situation extraordinarily well, and but for the overwork put in by the G.P.s the Service would have gone phut long ago.

Here I will ask this pertinent question: What body of men in this country or any other would do the amount of overwork that the G.P.s have done and are doing for pre-war rates of pay?—and doing it with little or no hope of getting a post-war rate, most having been robbed of their capital asset. It is about time that the doctors' representatives and the medical journals set about impressing the public that the failures, evils, and frustrations of the N.H.S. have nothing whatever to do with the G.P.s (underpaid) or hospital staff. The semi-breakdown is due to too much laity and to the fact that there were not and are not enough doctors, hospitals, nurses, or domestics to run a total service, and there will not be for many, many years.

Just imagine what would happen if the State said that for a compulsory weekly contribution we could use the transport system when and where to we liked. I wonder if the railway workers would work as well as we have, and as long as we have, for pre-war wages, and I wonder if their representatives would suggest to them courses on how to run railways or suggest that they keep better and brighter stations and waiting-rooms, cleaner buses, etc. You can take it from me the public would be reduced to walking.

What exactly is the matter with the B.M.A.? I can't make out whether it is in love with the Ministry of Health or the Ministry of Health in love with it. Both have been behaving queerly for a long time, and neither committees, nor resolutions, nor curses, nor chaos seem to have the slightest effect. All end in forms, and more committees, and investigations, and pools.—I am, etc.,

St. Osyth, Essex. R. E. CLARKE.

Medical Patenting

SIR,—The position in regard to medical patents is that open publication of the idea is sufficient, unless profit is required. This automatically precludes a valid patent being granted.

In regard to improvements relating to methods of manufacture and initial discoveries, the larger manufacturing chemists have the advantage of experienced research departments. These improvements and ideas are patented with a view to profit. Handing over patents to the National Research Development Corporation only invites competition between the firms and the corporation. The medical inventor may also have to bear the cost of obtaining the initial patent.

The holding by the corporation of the patent may place them in a better position for bargaining over royalties, but little else. The corporation should be of use in developing ideas which are ignored or suppressed by the normal producers and research departments.—I am, etc.,

London, S.W.1. STANLEY HANS.

Training of Nurses

SIR,—The paragraph on "Lectures to Nurses" (*Supplement*, June 10, p. 279) states: "Student nurses are trained chiefly by members of hospital medical staffs." I submit, Sir, that this is not so. Nurses receive their practical instruction, which even medical men must admit is the most important part of their training in the wards, from the ward sisters, some help being given in the class-room by the sister tutor.

The medical staffs certainly give courses of lectures in specialties—e.g., medicine, surgery, etc.—and many medical staff appointed to give lectures to nurses do discuss the work with the tutor and as a result of that discussion give a course of lectures, which, taken with the tutor's nursing lectures in the same subject, make a complete and satisfactory whole. A very great number, however, think it unnecessary to discuss the work with her, and one is forced to listen to medical staff telling nurses how to open an abdomen to perform an appendicectomy, how to do surgery of the palmar surface of the hand, or, at the other extreme, describing simple nursing treatments.

The nurses would fare very badly if their training were left chiefly to the medical staffs of hospitals, who are no more qualified to train nurses than nurses are to train doctors, medicine and nursing being two entirely different arts complementary to each other and, when allied, making a whole.—I am, etc.,

Northwood, Middlesex. G. EVE COLLINGWOOD, Senior Tutor to Mount Vernon School of Nursing.

Co-operation between Health Services

SIR,—The status of the general practitioner is hardly likely to be raised by the inadequate representation given on the very important committee set up by the Central Health Services Council to study co-operation between the services. The smooth running of the scheme depends almost entirely on this co-operation between hospitals, local authorities, and general practitioners. Can this be attained without more advice from workers in the field, who should be on this committee?—I am, etc.,

Stoke, Plymouth. O. LL. LANDER.

Disciplinary Powers of B.M.A.

SIR,—Many members of the B.M.A. will, and all of them should, be grateful to Dr. S. Wray (*Supplement*, June 17, p. 291) for pointing out the implications and possible result of the new Article 11 of the Articles of Association, if it is passed into being. The theoretical position at least will be intolerable.

Although a member for 32 years, I shall resign from the B.M.A. immediately if the new Article 11 comes into operation. Whatever is the B.M.A. thinking of, and who is behind all this?—I am, etc.,

Colchester, Essex. M. C. BREESE.

SIR,—I regard Recommendation C as one of the most obnoxious, authoritarian, and malevolent resolutions that has ever come before the A.R.M. I hope it will be turned down flatly. I shall not continue to be a member if it is passed. I am sure that the Council would act wisely in rejecting it.—I am, etc.,

London, W.9. S. CROWN.

Branch and Division Meetings to be Held

ROCHDALE DIVISION.—At Rochdale Infirmary, Monday, July 10, 8.30 p.m., meeting. Agenda includes consideration of agenda for Annual Representative Meeting, Southport, July 13.

TRADE UNION MEMBERSHIP

The following is a list of local authorities which are understood to require employees to be members of a trade union or other organization:

Metropolitan Borough Councils.—Fulham, Hackney, Poplar.

Non-County Borough Councils.—Dartford.

Urban District Councils.—Denton, Droylsden, Houghton-le-Spring, Huyton-with-Roby.

SUPPLEMENT TO THE
BRITISH MEDICAL JOURNAL
LONDON SATURDAY JULY 15 1950

GOLD MEDAL OF THE ASSOCIATION

PRESENTATION TO DR. JAMIESON

At a meeting arranged by the New Zealand Branch in Auckland University College on the evening of June 5, the Chairman of Council, Dr. E. A. Gregg, presented to James Peter Speid Jamieson, M.D., F.R.A.C.S., the Gold Medal of the Association. This was awarded to him by the Council in recognition of his great services to the Association and to the profession. Mr. E. H. Luke, President of the Branch, was in the chair, and those accompanying him on the platform included the Mayor of Auckland, Sir John Allum, Dr. J. O. Mercer, who is Chairman of the Branch Council, Mr. D. S. Wylie, Mr. F. R. Smale, Chairman of the Auckland Division, and Mr. L. K. Munro, Editor of the *New Zealand Herald*.

After the Mayor had spoken briefly in praise of the profession and of Dr. Jamieson's services to it and to the community, Dr. Gregg addressed the meeting and conveyed to the Branch the warm good wishes of the Association at home. Referring to the National Health Service in Britain, he stressed the importance of a sense of vocation in medical practice and the need for maintaining the professional independence for which Dr. Jamieson had fought so doggedly.

At the conclusion of his speech, before decorating Dr. Jamieson with the medal, Dr. Gregg read the words of the accompanying illuminated testimonial. Dr. Jamieson expressed his thanks in a memorable speech.

"You will readily understand," Dr. Jamieson said, "that it is difficult for one at a moment which, as it were, places a crown on the efforts of a lifetime to fully express his emotion. You will forgive me, then, if I seek thoughts from someone eminent to help me. I recall an impromptu address by the late Sir William Osler to a gathering of recently qualified graduates in the winter of 1906–7. In that he rapidly sketched the geographical line of advance of scientific medicine from its beginning to his own time. He traced it from the island of Cos, through Greece, Sicily, and Asia Minor, to the Arabs. Thence, through them, into Moorish Spain, and from there to Italy. Then from Padua to Leiden and the Low Countries, and into Britain, which still held leadership. He asked a question, 'Where will it be next—West, East, or the Antipodes?' He answered the question himself, thus: 'It is hard to say; but of one thing we may be certain. Athene places her shrine only where there is freedom; and where there is most freedom, there will be made the future developments in scientific medicine.' This saying of this master in medicine has remained with me ever since, and it is to that more than anything that the reference to freedom, in the address with which you have honoured me, is due.

"On the same occasion Osler imparted to us certain precepts for guidance. From those I should like to record this, every word of which he emphasized with the motion of his hand: 'Never allow yourself, on any account whatever, to quarrel with a colleague.' Those things came to me from Osler's lips. Freedom is essential for progress, and harmony is essential in the profession.

"There are in this room many men with whom I have had the honour to work, as of one mind. It was their work that won me this award. There are also here perhaps some whose ways of thought lay differently. It is the greatest pleasure to see them all, whether we agreed or differed, for it marks two things. First, that here we are not compelled to think alike. Unlike some other countries, we still have freedom to think as we believe right. Secondly, that, however we may differ on points, we are completely united in the desire to develop the best medical service for the benefit of everyone.

"It is with much pride, then, tempered by a sense of humility for my own part, that I receive this address and the medal with which you have decorated me, not in the narrow sense of a personal distinction, but as a recognition by the parent body of the spirit of freedom and responsibility in this Branch, which the Association has striven always to foster. I thank you, Dr. Gregg; will you accept through me the filial homage of this Branch to the parent body in Britain?"

Dr. Jamieson, a native of Shetland and a brother of Dr. E. B. Jamieson, the distinguished Edinburgh anatomist, has practised in Nelson for many years. He was chairman of the National Health Insurance Committee of the New Zealand Branch and the acknowledged leader of the profession in the Dominion in the long and difficult but successful struggle to preserve unlimited clinical responsibility for the practitioner. He is a Past-President of the Branch.

After Dr. Jamieson's speech the meeting concluded with a stimulating address, from the point of view of the "consumer," by Mr. L. K. Munro.

TO BRISBANE AND BACK

BY

ANGUS MACRAE, M.A., M.B., Ch.B.
Deputy Secretary

With three Canadian companions and myself, the Chairman of Council had already made sixteen landings before crossing the Equator on the way to Honolulu at 06.30 hours on Tuesday, June 6. There were still ten landings to be made before we would see Heath Row again. The Chairman had visited Brisbane as the Council's delegate to the second British Commonwealth Medical Conference and the seventh Australasian Medical Congress (B.M.A.). He had called at Auckland to present the Gold Medal of the Association to Dr. J. P. S. Jamieson. An account of the Auckland ceremony appears above, so here I shall say only that the speech delivered with controlled emotion by Dr. Jamieson will remain one of the chief memories of a remarkable journey.

A full report of the Commonwealth Conference will be published later. A number of delegates spoke of the spiritual value of this series of meetings. These are high-sounding words, but to witness the spirit of fellowship that pervaded both the formal discussions and the casual conversations was certainly an inspiring experience. Outstanding among the papers read were a fascinating account of the history and work of the Flying Doctor Service and an outline by Sir Earle Page, Australian Commonwealth Minister of Health, of his new conception of a national health scheme, based on a combination of Government aid with nation-wide voluntary insurance.

The Minister proposes to avoid costly Governmental administration by making the financial benefits, which will include Government subsidies, payable through the Friendly Societies. These benefits will constitute a grant-in-aid (up to 90%) towards payment for services received, the doctor being paid on a fee-for-service basis and the patient providing, in addition to his insurance contribution, a small part of the fee.

It was refreshing to find the Minister, without a single accompanying official, making a long journey to Queensland

to expound his proposals and to answer questions about them in an atmosphere of great good will at a meeting of the B.M.A. Federal Council, which decided to accept the scheme in principle.

Cairo and Points East

On the way to Brisbane we called at Cairo, Karachi, Delhi, Bombay, Calcutta, and Singapore. At each of these places, as well as in Australia and New Zealand, we received a welcome of a cordiality that had to be experienced to be believed. In India, Pakistan, and Singapore we visited many impressive hospitals, laboratories, and research institutions. We heard of a proposed new health insurance scheme for industrial workers in India, but both there and in Pakistan the provision of satisfactory medical services in the rural areas seems to be an extraordinarily difficult problem.

Everywhere the hospitality we received was overwhelming, and many delightful social functions were fitted into our crowded days. Here are a few—but only a few—of the things I shall not forget: the wonderful affection and loyalty that bind Australia and New Zealand to the mother country, and the B.M.A. in these Dominions to what they like to call "the parent body"; the Taj Mahal at Agra; the brilliance of the silver crescent moon as we drove through the night from Delhi to Agra; the fortitude of the Chairman of Council, who kept moving throughout ten days in the really hot countries; the comradeship of our fellow-travellers from Canada, Dr. Harris McPhedran, and Dr. and Mrs. T. C. Routley; the towering personality of the Premier of Western Bengal, the Hon. B. C. Roy, F.R.C.S.; the dexterity of the intrepid snake-man who showed us the method of extracting venom from a dangerous reptile; and the treasures in the Egyptian Museum from the tomb of the boy-king, Tutankhamen.

I remember particularly experiments with chopsticks at a marvellous Chinese dinner in Singapore; the blarney of the Chairman of Council when negotiating with a Calcutta vendor of grave demeanour the appropriate deduction to be made from the price of a small ivory elephant by reason of a fractured tusk; the grace and skill of the Indian dancers who demonstrated their art for our delight; the view from Picnic Point, Toowoomba, a beautiful city 2,000 feet above the level of the sea; and the engaging frankness of the handsome Ukrainian head-waitress in Canada, who explained that she had left England because there were "too many other good-looking women" in that country as competitors in the labour market. I recall, too, the uncomplaining resignation of the Chairman of Council when he accepted my suggestion (dictated by extreme shortage of dollars) of a 10-cent ride in a tram during our one-day rest-pause at Honolulu; the splendour of the snow-clad Canadian Rockies; and the loveliness of the more modest hills of home as we flew in over Lamlash to the happiest of landings at Prestwick on a perfect June morning.

One thing more I might add. My most lasting impressions will be of the reality of the British Commonwealth of Nations as a potent force for amity and peace in the world, and of kindness, of very great kindness, at the hands of hospitable people too numerous to be mentioned by name.

ANNUAL MEETING

AMENDED PROGRAMME FOR SECTION OF ANAESTHETICS

Meeting-place: Lecture Theatre, Physics Building.

Tuesday, July 18.—10 a.m., *Paper:* Applied Pharmacology in Anaesthesia for Abdominal Operations, by Dr. STUART C. CULLEN (U.S.A.). 11.30 a.m., *Paper:* Resuscitation of the Newborn, by Dr. G. ORGANE (London), followed by Dr. R. J. MINNITT (Liverpool).

Wednesday, July 19.—10 a.m., *Papers:* Anaesthesia in the Newborn, by Dr. T. N. P. WILTON (Bristol), followed by Dr. G. JACKSON REES (Liverpool). 2.30 p.m., *Papers:* (1) Some Therapeutic Applications of Nerve Blocks, by Dr. G. C. STEEL (London); (2) Analgesia in Anaesthesia, by Dr. L. RENDELL-BAKER (Cardiff); (3) Sudden Death During Operation due to Undetected Paraganglioma, by Dr. S. B. DARBISHIRE (Ulverston).

AN EXPERIMENT IN GROUP PRACTICE

BY

B. ROSEFIELD, L.R.C.P.&S.I.

Several months before July 5, 1948, a meeting was called to discuss the formation of a non-partnership group practice. A number of neighbouring general practitioners were invited. Eight practitioners attended, and they unanimously agreed to establish a roster system for off-duty hours to include week nights, week-ends, Bank holidays, and annual vacations, as well as absence from practice due to illness. There are now twelve doctors (including three assistants) working in harmony together. The scheme has worked so well that at least two other groups of doctors in the same Metropolitan borough have organized themselves similarly, and other groups are being formed in adjacent boroughs.

Duties

The members of our particular group all live in close proximity to one another in an urban area. The average size of our N.H.S. lists is about 3,250. Three of the members have assistants. All members practise from their own residences, though two have branch surgeries in addition. We meet once a quarter to discuss all matters affecting the group and to draw up the dates for duties for the next twelve weeks.

In a period of twelve weeks each doctor is on duty for five week nights (at average intervals of one night in twelve) and for one week-end. Some prefer to split up the week-end duty in winter, doing Saturday night to Sunday afternoon in one week, and Sunday afternoon to Monday morning another week. Others do the week-end as a whole, and so are free from further week-end duties during that period. Permission was received from the executive council to close Saturday evening surgeries from the beginning of May to the end of September. The duty doctor for that evening is available to deal with all calls.

Each member is supplied with three or four copies of the duty roster. A boldly printed card is hung on the front door each evening at 7 p.m., informing patients where to apply for treatment from the doctor on duty. The card is in a frame with a detachable back, allowing the card to be changed as required. Similar cards are displayed at week-ends. For annual holidays there is a framed printed notice displayed, giving the list of doctors' names, addresses, and consulting hours, and informing patients that they may attend any of the doctors listed while their own practitioner is on vacation. In the evening this card is replaced by the usual card giving the name of the doctor on duty that night.

Constitution

As a result of our experiences in the first year's working of the group practice we drew up a constitution, which all members agreed to support. The rules of the constitution are as follows:

1. *Objects.*—To work in close harmony and co-operation for the mutual benefit of all members of the group.

2. *Membership.*—Open to all doctors approved by the present members of the group.

3. *Chairman.*—Shall be elected annually in rotation from the members.

4. *Tours of Duty.*—Week nights: 7 p.m. to 8 a.m. Week-ends: Summer months, 1 p.m. Saturday to 8 a.m. Monday; winter months, 7 p.m. Saturday to 3 p.m. Sunday, 3 p.m. Sunday to 8 a.m. Monday. Bank holidays: As for winter week-ends.

5. *Requests for Visits.*—The doctor on duty must ensure that someone is available at his premises to receive all messages during his tour of duty.

6. *Fees.*—All fees received may be retained by the duty doctor, unless other arrangements have been made between individual members of the roster.

7. *Transfer of Patients.*—A duty doctor who meets patients of other members for the first time while on duty roster must *not* accept any transfers to his list of such patients.

8. *Illness of Members.*—In the event of sudden illness of any members, the remainder of the group should be prepared to look after the sick members' patients for a period not exceeding one month.

9. *Half-holidays.*—If possible, arrangements should be made between individual members of the group for acceptance of calls up to 7 p.m. If necessary, the duty doctor for that night should be willing to do urgent calls before 7 p.m. A too rigid adherence to hours of duty is not in the spirit of this group.

10. *Annual Vacation.*—Should be taken if possible in summer months, and so avoid excessive strain on group members. It is suggested that, if possible, only two members be away at a time. Members on vacation in winter months should have a locumtenent or assistant to carry on their work.

11. *Continuity of Treatment for Patients.*—Except in an emergency, treatment of patients of absentee doctor should not be handed over from one member to another. Original doctor called in to attend should continue the treatment of the patient as required until return of absentee doctor.

12. *Roster Meetings.*—Shall be called as deemed necessary by the chairman. Two-thirds attendance of members shall constitute a quorum. Decisions taken at roster meetings shall be binding on all members, whether present or absent. The chairman shall have a casting vote.

13. *Assistants.*—Full-time assistants of members, living in the district, should become members of the roster.

14. *Complaints.*—Complaints between members should be referred to the chairman for decision. If the complaint is sufficiently serious, the chairman may call an emergency meeting of the group to decide on all points at issue.

15. *Expenses.*—All expenses incurred in the organization of the group shall be shared equally between the members.

16. *Expulsion from the Group.*—A member may be expelled from the group forthwith if a majority of members decide that he is not contributing adequately to the principles of the group, as laid down in the preceding rules.

Calls

The amount of work to be done has been remarkably light. Week-day evening visits (before midnight) do not average more than four an evening over the year. Night calls (after midnight) are very few. We find that a large number of patients prefer to wait for their own doctor in the morning rather than call in the duty doctor. Week-end work varies considerably. Some doctors have had from fourteen to twenty-four calls to do in one day; others have had six or less. Generally speaking, we never fail to be amazed at the comparatively few calls we have had to do.

Midwifery does not come within the scope of duties in the group.

Benefits of Group Practice

There is little extra work entailed for those working in a group practice. Patients have accepted the scheme without any objections and appreciate the fact that there is always a doctor available for them to call when necessary. The ideal minimum number for a roster would be six doctors. This would allow for a week night and a week-end on duty, in rotation, for each.

The benefits to be gained from a group practice are manifold. The general practitioner has definite hours of leisure and rest, and can go out, when off duty, without fear of recall. The difficulty and expense of obtaining locums for holidays and illness is eliminated. There is a spirit of friendliness and co-operation between colleagues which was noticeably absent before the inception of the N.H.S. Despite the increased work occasioned by the Health Service, we have never had so much time for relaxation.

We cannot speak for rural practitioners, but as a result of our experiences we would urge all urban doctors to endeavour to organize a similar scheme in their own districts. It would be to their own advantage and to that of their patients.

TRADE UNION MEMBERSHIP

The following is a list of local authorities which are understood to require employees to be members of a trade union or other organization:

Metropolitan Borough Councils.—Fulham, Hackney, Poplar.

Non-County Borough Councils.—Dartford.

Urban District Councils.—Denton, Droylsden, Houghton-le-Spring, Huyton-with-Roby.

PAY IN THE ARMED FORCES

DEPUTATION TO MINISTERS

On July 6 a deputation from the B.M.A. was received at the House of Commons by the Minister of Defence (Mr. E. Shinwell), the First Lord of the Admiralty (Viscount Hall), the Secretary of State for War (Mr. John Strachey), and the Secretary of State for Air (Mr. Arthur Henderson). The members of the deputation were Dr. E. A. Gregg (Chairman of Council), Air Vice-Marshal D'Arcy Power (Acting Chairman of the Armed Forces Committee), Surgeon Captain A. Robinson Thomas, R.N.V.R., and Colonel E. C. Linton, accompanied by the Secretary of the Association and other members of the Secretariat.

The deputation expressed concern at the low level of voluntary recruitment to the medical branches of the armed Forces. It drew attention also to the dwindling yield from conscription, due to the fact that a growing proportion of doctors who will qualify in the next five years will have already performed their National Service before starting their medical training. The main reason for the present low rate of voluntary recruitment was stated to be the fact that the terms offered by the armed Forces compared unfavourably with prospects in the National Health Service.

The deputation then referred to the Association's proposals for improvement of pay, which were first laid before the Ministry of Defence in March, 1949 (*Supplement*, April 2, 1949, p. 204), and to the subsequent fruitless discussions, an account of which appeared this year in the *Supplement* of May 20 (p. 223).

In reply, Mr. Shinwell stated that the Ministers were sympathetic with the Association's case. They were as concerned as the deputation at the growing shortage of medical officers. They were not convinced, however, that improvement of pay was necessarily the only answer to this problem. Mr. Shinwell reminded the deputation of the Government's present policy of restraint on personal incomes.

The Minister chided the deputation on the Association's refusal to publish War Office advertisements for civilian specialists at preferential rates of pay. The deputation replied that it was a combination of three things—underpayment in the Service, the ban on retirement, and the importation of civilians at considerably higher rates of pay—which the Association felt could not be tolerated, and asked whether the ban on retirement from the R.A.M.C. was likely to be lifted. Mr. Shinwell stated that it would be difficult to lift the ban under present circumstances.

The Ministers paid a tribute to the work of the medical officers in the three armed Forces and concluded by saying that they would consider the points made by the deputation as quickly as possible.

SERVICE COMMITTEE REGULATIONS

DEPUTIES AND ASSISTANTS

The Minister of Health has made some alterations in the Service Committees and Tribunal Regulations.

The N.H.S. (Service Committees and Tribunal) Amendment Regulations, 1950, provide that a deputy or assistant to a general practitioner in the Health Service shall on application be treated as if he were a party to any service committee proceedings which concern his conduct. The Ministry of Health states that, if the deputy or assistant elects to be treated as if he were a party to the proceedings, the executive council cannot make any recommendation for action against him (including, for example, reprimand). The council's decision under Regulation 6 of the principal regulations can relate only to action against the responsible practitioner. It follows from this that the deputy or assistant will not have a right of appeal.

When the conduct of a deputy or assistant is called in question, this will normally be apparent from the complaint. In such cases a copy of the complaint should be sent to the deputy

or assistant at the same time as it is sent to the principal (or as soon afterwards as the facts become clear), and he should then be asked whether he wishes to be treated as if he were a party to the proceedings. If the deputy or assistant does not become a party, he will still be entitled to be present as a witness on behalf of the respondent.

The new regulations also enable an executive council to establish with the consent of the Minister two or more medical service committees, dental service committees, or pharmaceutical service committees.

CENTRAL HEALTH SERVICES COUNCIL

The Minister has made the following appointments to the Central Health Services Council and Standing Advisory Committees:

Central Health Services Council.—Medical Practitioners: Dr. Janet Aitken; Professor R. Cruickshank; Sir Stewart Duke-Elder; Dr. W. V. Howells; Dr. C. W. Walker. Persons with experience in hospital management: Hon. A. J. P. Howard; Mr. F. S. Stancliffe. Persons with experience in local government: Alderman A. F. Bradbeer; Mrs. Dorothy Thurtle. Dental practitioners: Mr. J. Lauer; Professor R. V. Bradlaw. Registered nurse: Miss C. H. Alexander.

Standing Medical Advisory Committee.—Dr. Janet Aitken; Professor R. Cruickshank; Sir Stewart Duke-Elder; Dr. W. V. Howells; Dr. C. W. Walker.

Standing Dental Advisory Committee.—Mr. C. V. Armitage; Mr. Joseph Lauer.

Standing Ophthalmic Advisory Committee.—Dr. Janet Aitken; Sir Stewart Duke-Elder.

Standing Nursing Advisory Committee.—Miss C. H. Alexander; Dr. Horace Joules; Hon. A. J. P. Howard; Professor R. M. F. Picken; Mr. F. S. Stancliffe.

Standing Maternity and Midwifery Advisory Committee.—Dr. Janet Aitken; Mr. A. W. Bourne; Dr. W. V. Howells; Mrs. Dorothy Thurtle; Dr. C. W. Walker; Councillor W. Onions, J.P.

Standing Mental Health Advisory Committee.—Dr. Denis J. Williams.

Standing Cancer and Radiotherapy Advisory Committee.—Dr. W. V. Howells.

The period of office of these members is until March 31, 1953, except for the following:

Professor R. V. Bradlaw, Mr. C. V. Armitage, and Dr. Horace Joules serve until March 31, 1951, and Dr. Denis Williams until March 31, 1952.

ANAESTHETICS GIVEN BY TRAINEE ASSISTANTS

A circular from the Ministry of Health states that, after consultation with the General Medical Services Committee of the B.M.A., the Minister has decided that it would not be appropriate for an anaesthetic fee to be claimed in respect of the administration of an anaesthetic by a trainee assistant at an operation performed by his principal (or performed by a partner or ordinary assistant of the principal).

The Minister also considers that it would be inappropriate for an anaesthetic fee to be claimed where a trainee assistant acts as an anaesthetist for his principal (or for the partner or ordinary assistant of his principal) in connexion with the provision of maternity medical services.

PATIENTS AND ASSISTANTS

A circular from the Ministry of Health gives guidance to executive councils on the additional number of patients allowed to a doctor in respect of assistants. In respect of a permanent assistant the regulations provide for an increase of up to 2,400 patients. "Permanent assistant" is not defined, but the Minister, after consultation with the General Medical Services Committee of the B.M.A., suggests that, while the facts of each case must be considered on their merits, in general it would be reasonable to regard as a permanent assistant not only a full-time assistant but also an assistant regularly employed part-time for at least one-half of the time that a full-time assistant would normally serve the practice; that in the case of such a part-time assistant it would be reasonable for an executive council to agree that the principal's list might be increased by a proportion of 2,400 approximately equal to the proportion of the time given by the assistant; but that, where the assistant is employed for less than half-time, no increase in his principal's list should be permitted.

When permission is given in future to a doctor to have an increased list in respect of an assistant, the Minister suggests that the permission should be made subject to the doctor's informing the council of any change in the period of service given by that (or any subsequent) assistant, and to review by the council in the event of any such change.

CENTRAL HEALTH SERVICES COUNCIL
FIRST REPORT

Under the National Health Service Act the Central Health Services Council was appointed to advise the Minister of Health on general matters, and in its first report[1] it considers the first 18 months of the Health Service up to December 31, 1949. The report covers only England and Wales, since there is a separate council for Scotland.

Health Centres.—As a result of a recommendation by this committee the council has advised the Minister that the Act should be amended so that doctors in practice at a health centre may, if they wish, treat private patients at the centre. The council has also advised the Minister that, if a new health centre is opened, the appropriate authority should be able to prohibit doctors from opening a surgery in a prescribed area round the centre for a limited period, exceptions being made for death or retirement.

Hospital Administration.—A special committee has been considering the relation between (*a*) the Minister and regional hospital boards; (*b*) regional boards and hospital management committees; and (*c*) management committees and hospitals in their groups; with special reference to the control of finance and staff establishments. The council has advised the Minister to invite the King Edward's Hospital Fund and the Nuffield Trust to undertake a complete unit costing of a small number of representative London and provincial hospitals. An agreed system should be used, and the results subject to a joint report by the two bodies.

Prescribing.—A Joint Subcommittee was set up and included Scottish representatives to give guidance on various aspects of prescribing. The first report—on the distinction between foods and drugs—was summarized in the *Supplement* of May 27 (p. 231), and a second report—on whether there should be any restriction on what could be prescribed under the Health Service—was summarized in the *Supplement* of July 8 (p. 24). The Joint Subcommittee is now considering toilet preparations, disinfectants, and antiseptics. The Minister had been advised that drugs in the experimental stage or in short supply should be treated in three stages:

(*a*) An initial period of investigation during which the value of the drug is being ascertained—e.g., by the Medical Research Council—and no prescribing should take place.

(*b*) A period during which a drug of proved value is in short supply. During this time the drug should be available at designated centres to which patients should be referred or from which supplies could be obtained on application in cases approved by the director of the centre.

(*c*) A period of unlimited supply when any further control is necessary only in the interests of the patient. There should then be complete liberty of prescribing, but it may often be desirable to issue advice on prescribing a drug to general practitioners either through the medical press or by circular letter based, where necessary, on the authority of the Medical Research Council.

Hospital Services

The Pressure on Hospitals.—The council has made the following recommendations to the Minister:

Acute Emergency Cases.—(i) Regional boards, in consultation with the boards of governors, should set up an emergency bed bureau for each appropriate area which would be responsible for the admission of emergency cases from that area. (ii) With each bed bureau there should be associated a senior medical officer, who would have authority to order any hospital within the area to admit emergencies. (iii) No patient reported to the bed bureau as an emergency case should be refused admission to hospital unless the patient had been seen, either at home or at the hospital, by the medical officer concerned or by a responsible officer acting on his behalf. (iv) Records should be kept not only of cases admitted but also of those refused admission.

[1] Report of the Central Health Services Council for the period ending December 31, 1949. H.M.S.O. 1s.

Early Malignant Cases.—Similar action should be taken for early malignant cases where even a short delay in providing treatment would reduce the prospect of recovery.

Non-urgent Cases.—(i) Facilities for minor operations in out-patient departments should be improved. (ii) More patients should be treated in their homes by means of domiciliary visits. (iii) The discharge of post-operative cases to convalescent homes and other places—e.g., vacant wards in hospitals—where they could recuperate should be facilitated. This would allow of a dilution of skilled nursing staff. (iv) Beds should be redistributed among specialties in the light of the review made by regional boards. (v) Some larger urban isolation hospitals should be used for non-infectious cases, especially post-operative recovery and chronic sick; this too would allow of a dilution of skilled nursing staff. (vi) There should be closer liaison on this matter between regional boards and boards of governors, and teaching hospitals should accept a reasonable number of chronic sick patients. (vii) The need for admission to hospital of infectious cases who could often be nursed at home should be reassessed. (viii) The average length of stay of patients could often be shortened by increasing the frequency of specialist visits and by providing more pathological and radiological facilities; patients sometimes occupied beds for several days waiting for their investigation or treatment to be started or their discharge to be authorized. (ix) Improvements in standards of hospital accommodation and of the ratio of nurses to patients should not be made by reducing the numbers of available beds. (x) Advantage should be taken of the services of district nurses and home helps to nurse patients in their homes when possible.

Co-operation Between the Services.—The council has asked the committees concerned not to submit any advice to the Minister for the present, for it proposes to consider during this year what advice should be formulated on this subject.

Work of Standing Advisory Committees

Medical Advisory Committee.—This committee carried out much of the work referred to above. The committee is obtaining information on whether certain methods of contraception are injurious to health and whether doctors should be better informed on methods of contraception.

Ophthalmic Advisory Committee.—The committee has given the following advice to the Minister:

(*a*) That as an interim measure a patient who had been referred to the hospital eye service and found by a hospital ophthalmologist not to need ophthalmic treatment, but only to need glasses which could be supplied through the supplementary ophthalmic services, might be returned to the supplementary ophthalmic services for the supply of those glasses, at the discretion of the hospital ophthalmologist who examined him.

(*b*) That in all other cases where a patient had been referred to the hospital eye service from the supplementary ophthalmic services, the patient should remain within the hospital eye service for any treatment, glasses, or observation necessary.

Nursing Advisory Committee.—The committee was asked by the Minister what would be the most effective procedure for obtaining and collating information regarding approved nursing techniques and for making this information available to hospitals and nurses throughout the National Health Service. It was also asked what techniques ought to be recommended. The committee has given considerable thought to this question and will submit a report this year.

Large-scale recruitment of student nurses by teaching hospitals is said to have had an adverse effect on the recruitment of nurses to hospitals under regional hospital boards. The committee is studying this problem. Costs and methods of dividing general wards into cubicles by means of curtains are also being studied.

Maternity and Midwifery Advisory Committee.—The committee thought it desirable that the attention of medical students should be drawn to the fact that a resident appointment in a maternity unit would normally qualify them for admission to obstetric practices under Part 4 of the Act.

Mental Health Advisory Committee.—The committee is considering the problem of the organization of preventive psychiatry and of the aftercare service by local authorities. An experimental scheme would be welcomed for the boarding out of suitable mental patients, and the committee hopes to report on this later.

Tuberculosis Advisory Committee.—The advice of the medical committee has been sought on a proposal that a proportion of beds in suitable general hospitals should be reserved for cases of tuberculosis. The committee advised the Minister that there should be no general ban on placing infectious tuberculous persons in ordinary employment subject to medical decision in each case and the suitability of the employment. It has also advised him that it would be unwise to train tuberculous persons in making woolly toys or to supply them with materials for such toys.

Cancer and Radiotherapy Advisory Committee.—The committee has recommended to the Minister that the existing facilities for educating general practitioners about the symptoms of cancer should be encouraged and expanded wherever possible, but that it was undesirable at present for any cancer publicity to be carried out directly to the general public, though the latter advice is to be considered further.

C.M.S. SALARIES IN EAST AND CENTRAL AFRICA

The Association's negotiations on Colonial Medical Service salaries with the Colonial Office are beginning to bear fruit. Increased salaries as set forth below have been introduced in Kenya, Tanganyika, and Nyasaland.

Kenya	
Director of Medical Services	£2,050
Deputy Director of Medical Services	£1,800
Assistant Director of Medical Services Assistant Director of Laboratory Services	£1,700
Senior Medical Officer	£1,650
Medical Officer	£865: £865: £935 by £35 to £1,005 (E.B.) by £45 to £1,140 (P.B.) by £45 to £1,320 (E.B.) by £45 to £1,590
Tanganyika	
Director of Medical Services	£2,000
Deputy Director of Medical Services	£1,800
Assistant Director of Medical Services	£1,700
Senior Medical Officer	£1,650
Medical Officer	£865: £865: £935 by £35 to £1,005 (E.B.) by £45 to £1,140 (P.B.) by £45 to £1,320 (E.B.) by £45 to £1,590
Nyasaland	
Director of Medical Services	£1,800
Deputy Director of Medical Services	£1,700
Assistant Director (Health)	£1,675
Senior Medical Officer	£1,650
Medical Officer	£865: £865: £935 by £35 to £1,005 (E.B.) by £45 to £1,140 (P.B.) by £45 to £1,320 (E.B.) by £45 to £1,590

(E.B. = Efficiency Bar; P.B. = Promotion Bar)

Increases on similar lines are under consideration by the Governments of Uganda, Zanzibar, and Northern Rhodesia.

Negotiations in regard to specialists are still in progress.

Correspondence

The J.H.M.O. Grade

SIR,—The time has come for a thorough investigation into the J.H.M.O. grade; enough has been said on behalf of, and in defence of, other grades. There appears to be no specific method by which one is assessed for this inferior grade, and one is left in little doubt as to its being either a "dead end," a "back-water," or a source of cheap labour and exploitation.

The J.H.M.O. is not catered for in relation to clinics, classes, or any form of prescribed training. He has merely to "be," and is looked upon as being nothing more than a medically qualified errand-boy suffering from profound lethargy and mental constipation—the mental defective of medicine. No person or group of persons is interested in his defence, his promotion, his future, or his well-being.

The only action he is allowed to perform, it appears, is to lazily wallow in the quagmire of his own ignorance. He is not supposed to take any responsibility (although it may be thrust upon him), and yet paradoxically in at least one hospital there is a J.H.M.O. at present who is taking over the full duties of a consultant when on holiday.

How is this possible? The J.H.M.O. concerned is of mature age, has been qualified for some years, is keen and progressive, has had plenty of all-round experience, held a senior appointment in one of the Services, and was recently on a short-list of two for a senior-registrar appointment, and has had complete charge of a hospital. So, gentle reader, do not sneer at the J.H.M.O. He may be much better qualified for his job than you: tread warily.

The scheme of grading as it stands stinks and should be scrapped. May I suggest that if we are to be graded it should be as follows: consultants, specialists, and A.M.O.s. We are becoming too class-conscious, and that is bad. Nowadays when doctors meet they immediately inquire as to each other's grading; the salary is quickly assessed (jealousy often occurs in one, or both); then a further inquiry as to any extra qualifications: which brings me to the fact that, if one does not possess the necessary diploma(s) with which British medicine is flooded, then it must follow that one is a dullard and a dolt. We are none the better for having these diplomas, as the individual would still strive to give of his best irrespective of the prize other than having the patient recover quickly, which is the greatest of all rewards. A patient asks to be cured; he doesn't ask about diplomas.

When in Canada recently I was not asked once what my qualifications were, and I was accepted as having at least the same knowledge as themselves. What matters in the North American continent is, Can you work hard? Can you get the results? and it is on these that one obtains the proper rewards, which to me at least is a very sensible attitude.

However, one must have the prescribed diplomas in this country, otherwise one is brainless: what a rotten psychology! We all know of those among us, who for some reason or other are not the possessors of any extra qualifications, whose work and diligence are of the highest order. Are such people to be rewarded with a J.H.M.O. grade, or are they to be graded according to results?

We must all stand firm as the dentists and pharmacists and insist to the last on our rights. We must fight against a system which is out to oppress and suppress us. We must deal properly and expeditiously with such a system whose "brains" has no "association" and in which there are too many "clots."—I am, etc.,

Shotts, Lanarkshire. A. M. BUCHANAN.

SIR,—Dr. J. McGhee (*Supplement*, June 17, p. 292) is surely and rightly pointing out a grievance which has hitherto had very little attention. This grade should combine to get their case adequately represented. Age, experience, and years of service have indeed been ignored. One J.H.M.O. of my acquaintance is over 60 years of age but still a "junior." The B.M.A. when approached on this subject promised to take up our case in the second half of next year together with a number of other inappropriately graded senior practitioners.

I strongly feel that the matter should not rest there. The post of J.H.M.O. is *de facto* a *cul-de-sac* from which there is no escape except by very slender chance, since the possibilities of promotion from this grade are so extremely limited. I therefore suggest that the J.H.M.O.s unite to secure, primarily, regrading, and, pending such regrading, fair and just remuneration as stressed by Dr. McGhee.

To apply the term "junior" to men grey with long and mature experience is not merely inappropriate but detracts from the prestige and dignity of our profession.—I am, etc.,

Birmingham. R. S. HOLZER.

Whitley Machinery

SIR,—Since July, 1948, whenever the mass of frustration and irritation over negotiations threatened to depress the G.P. he always sought comfort in the fact that we had established the right to take our problems to a Whitley Council. He felt that here his case would receive impartial consideration, and if his case could be established as right and just it would be binding on the Government to act accordingly.

The consultants have now had their first meeting of a Whitley Council to consider their problems. May we be told just what happened at that meeting, and did it turn out to be the impartial tribunal which it is supposed to be?

I am one of the profound cynics that believe that in winning the right to take our problems to a Whitley Council we have won but a barren victory, as I do not believe that it will advance our cause, however just. I am prepared to be convinced that I am wrong, but only if we can be told how the first meeting was conducted. I believe we have a right to know.—I am, etc.,

Upminster, Essex. E. ANTHONY.

POINTS FROM LETTERS

One Profession

Mr. A. W. D. COVENTON (Leafield, Oxford) writes: . . . General practice was a fine life for a man, a liberal education, a test of character. What is it now? Something to be avoided, a grind, an imprisonment of the spirit? The elements of specialism lie in general practice. It provides unlimited opportunity for observation, for follow-up, for studying men, women, and children in health and sickness in their own homes, not served up on a plate in hospitals. Away with this dichotomy. Open the gates; make the medical profession one and indivisible. Teach the specialist that he is the assistant of the general practitioner and is privileged in serving. Give the general practitioner opportunity to follow his bent, a ready welcome in any hospital, library, or laboratory in the land which can stimulate and enlarge his knowledge till he too may become a specialist. And warn the patient—that guinea-pig whose guineas are extracted before treatment—that he is in danger of becoming a number in a cage.

Branch and Division Meetings to be Held

SOUTHAMPTON DIVISION.—At Royal South Hants and Southampton Hospital, Wednesday, July 19, 8.30 p.m., special general meeting.

SUPPLEMENT TO THE
BRITISH MEDICAL JOURNAL
LONDON SATURDAY JULY 22 1950

British Medical Association

ANNUAL REPRESENTATIVE MEETING, SOUTHPORT, 1950

The Annual Representative Meeting opened in the Floral Hall, Southport, on Thursday, July 13, and was continued on the following Friday, Saturday, and Monday. The chair was taken by Dr. J. A. Brown (Birmingham), who was supported by the President (Dr. C. W. Curtis Bain), the President-Elect (Sir Henry Cohen), the Chairman of Council (Dr. E. A. Gregg), and the Treasurer (Mr. A. M. A. Moore). The main agenda contained some 267 motions and amendments, almost all of which related to matters contained in or arising from the Annual and Supplementary Reports of Council, published in the *Supplement* of April 22 and 29 and June 10, respectively.

THURSDAY, JULY 13
PRELIMINARY BUSINESS

The meeting opened at 10 a.m.

Mr. J. Ewart Purves (Bromley) moved that each copy of the Minutes of the Representative Meeting should contain a verbatim report, as in *Hansard*, and that this copy be available at Headquarters.

The Chairman of Council said that as there was no reference to the printing of the report he was prepared to accept the proposal on the understanding that the record need not include the more trivial parts of the discussions.

Some discussion took place on the arrangement of the agenda. It was agreed that the Agenda Committee should group motions or amendments which covered substantially the same ground and should have powers to select and mark with an asterisk in the agenda of the meeting one motion or amendment in the group on which discussion should take place.

A time limit for speeches was also considered, and it was agreed on a motion by Burton-on-Trent that a representative should be allowed to speak for seven minutes in moving any resolution, subsequent speakers to be allowed five minutes. Chairmen of committees in introducing reports were allowed 15 minutes.

On the motion of the Chairman of Council the part of the report under "Preliminary," with the exception of paragraph 2, which was postponed for consideration by the Council, was approved.

Dr. J. B. Miller, Vice-President

The Chairman of Council moved that Dr. J. B. Miller, of Bishopbriggs, Lanarkshire, a former chairman of the Representative Body, be elected a Vice-president of the Association. He said that he made this proposal with the very greatest pleasure and referred to the outstanding services which Dr. Miller had rendered to the Association.

Dr. Miller was at this point called to the platform, representatives rising and applauding, and the motion was carried unanimously.

The Chairman of Council further said that there was no honour which could be done to Dr. Miller which he did not completely and heartily deserve.

Dr. Miller said that when he was elected Chairman of the Representative Body he stated that it was the greatest honour to which any general practitioner could look forward. He still thought so, but it was also a very great honour to be made a vice-president of this great Association. For the last 30 years he had been trained to learn a little about the work of the Association, which indeed had been the principal interest in his life. Now he felt that he could take a back seat. He thanked them not only for their kind reception but for the way in which the representatives had enabled him to carry through those trying and tempestuous years when he was Chairman. (Applause.)

THE AUTONOMOUS BODIES

The Chairman of Council moved approval of the report of Council under "Relationship of Autonomous Bodies to the Association."

Dr. J. C. Wishart (Bromley) moved to confirm the composition and status of the two autonomous committees as defined in the Supplementary Report in respect of the year 1950–1, but to declare that the autonomous powers of these committees, in so far as they derived from the Representative Body, required to be specifically renewed by successive Annual Representative Meetings. In doing so he said that they had always looked to the Representative Body as the parliament of the Association. They believed that the decisions taken by the Representative Body were those that mattered. His Division had learnt with dismay of the powers handed over to the autonomous bodies which were not responsible either to the Council or to the Representative Meeting. This caused many discussions in the Divisions and also in the Representative Body itself, and they were told by the chairman of one of the autonomous bodies that all their discussions were useless and that the function of that particular meeting of the Representative Body was only to impress the rubber stamp of approval. This was a serious position. The Representative Body was jealous of its powers. It was quite obvious from the report that the Council were not entirely happy about the position. His committee was prepared to accept the report on the constitution and functions of the autonomous committees, but it felt that the Council should retain some control, and accordingly it asked for the autonomy of these committees to be specifically reviewed at each annual meeting.

The Chairman of Council said that this was a subject that naturally caused a good deal of vague anxiety. He gave the meeting credit for having read the report. There were all sorts of possibilities, difficulties, and dangers which might be conjured up in their minds, but he put it to the meeting that it would be an extremely unwise thing at this stage to take precipitate action. The Council was keeping an eye on the problem, and he took no exception to the Bromley phrase "in so far as they derived from the Representative Body." But it was just as well not to pass this motion, because they did not want to limit themselves as to the action they had to take. He thought therefore that they might usefully pass to the next business. ("No.") By passing such a motion they might easily do more harm than good. The position in regard to this matter was under closest possible observation all the time.

Dr. J. A. Gorsky (Council) said that while he appreciated the arguments just put forward by the Chairman he still viewed the situation with some anxiety. They were at the moment employees, whether they liked to be or not, of a rather troublesome individual at the Ministry of Health whose power enabled him to by-pass the Council. While he approved of the report issued by the committee of which he is a member he still felt that this matter must be under the supervision of the Representative Body. Neither the Representative Body nor the Council were ever consulted about the payment of the staff side of the Whitley Council. For this and other reasons he felt that the Bromley motion should be passed. There was nothing in it which was objectionable.

Mr. H. H. Langston (Winchester) said that autonomy might become autocracy. It might lead to division and dissension within the profession. The Minister had shown more than once that he was aware of the old maxim "Divide and Rule." In the consultants and specialists field he thought the exercise of autonomy did give rise to grave disquiet. On the Joint Committee the Central Consultants and Specialists Committee had only six representatives and that Joint Committee was now a constituent part of the staff side of the Whitley Council. He wondered whether the Representative Body had envisaged that a body over which it had so little control should be the negotiating authority for consultants and specialists.

Autonomy had these dangers, and freedom of action might be abused. This Representative Body must guard its mandate jealously. The only safeguard was that the question of autonomy be re-examined freely.

Dr. R. W. McConnel (Buckinghamshire) expressed the opinion that the Council had acted wisely in asking that the matter should be deferred. The members had asked for evolution in the case of the National Health Service, and he would suggest that the matter under discussion now should be allowed to evolve. The General Medical Services Committee had become a partly autonomous body; the Representative Body knew that last year and gave the Committee power to act on its own. There might be a danger of the Committee becoming a stronger body than the Council, but the matter could be discussed again in three years' time.

CIVIC WELCOME

At this point the Mayor of Southport (Lieutenant-Colonel R. Fleetwood Hesketh) attended to convey a welcome to the Association. He said that he regarded it as a great privilege to welcome the Association, not only because it was one of the most distinguished bodies in the country but also because it was very largely due to the medical profession that Southport existed at all. It was owing to the recommendations of doctors in the latter part of the eighteenth century, when for the first time they took the view that the sea was a cure for all ills, that people were induced to visit this part of the coast of England.

He wished to extend a special welcome to those who had come from overseas, and he hoped that their visit to this country would be both interesting and enjoyable.

He hoped that the Association's meeting in Southport would be a success and that those who were there would repeat their visit in the near future.

The Chairman, in thanking the Mayor for his cordial welcome, said that he knew that the Mayor and his council had taken very considerable pains to make the Association's visit to Southport a great success, and he was quite sure, judging by the arrangements which the members had already seen, that that object would be achieved.

The Mayor then withdrew.

THE AUTONOMOUS BODIES

(Discussion continued)

Dr. W. D. Anderson (Glasgow), in speaking in support of the Council's motion, said that his Branch approved of the position of autonomy which the General Medical Services Committee held, in which the Committee reported to the Council of the British Medical Association and any decision that was not in accordance with the policy of the Association could be referred back by the Council to the General Medical Services Committee.

Before the inception of the new Service, the specialists in Glasgow had an inter-hospital committee which represented all specialists in the area, and when it was suggested that regional consultants and specialists committees should be formed this inter-hospital committee wished to form a committee independent of the British Medical Association, but it was persuaded not to do that because its representatives were informed, at a Branch Council meeting to which they were invited, about the autonomy possessed by the General Medical Services Committee and were told that the specialists and consultants could have the same autonomy. At first they did not wish to have any general practitioners on their committee, but now they had been persuaded to have two.

Dr. Frank Gray (Council) suggested that the representatives should ask themselves whether the amendment was wise and whether it was necessary. There was no doubt that the Representative Body had the power in question and could exercise it, and it had shown that it was not unwilling to exercise it. To state that it had that power would imply, he submitted, a doubt of its possession of it.

As to whether the amendment was wise, he would point out that the situation was new in one respect and old in another. The Insurance Acts Committee had had autonomy for years and no one questioned it, but on the consultants' side the situation was a new one. That might be an illogical development, but he did not need to remind the representatives of the troubles which might have arisen had it not been for the wholly illogical act of statesmanship, the appointment of the Joint Committee.

He would suggest that, now there was an arrangement in existence which had prevented troubles arising, the Representative Body should be content to let that arrangement continue, knowing that it could review the position in a year's time if it wished to do so. He felt sure that in three years' time the Representative Body would be satisfied that it had an arrangement which preserved all its power but did not clog it with unnecessary detail.

He submitted that the amendment was unnecessary and that the Representative Body would be wise to pass to the next business.

Dr. R. Hale-White (Marylebone) thought that the issue before the meeting was simply whether the existing arrangement should be reviewed by the Representative Body annually or whether it should be left to the discretion of the Representative Body to say whether it should be reviewed annually or not. The present was a time of extremely rapid change, and he felt that the situation must be reviewed by the Representative Body every year if the Representative Body was to continue to mean anything at all. He entirely agreed with what Dr. Gorsky and Mr. Langston had said.

Dr. K. C. Bailey (West Somerset), in supporting the amendment, said that there were so many cross-sections in the profession that if they were all going to be split into their own groups and put their own cause first the profession would be divided much more than it had been in the past. He felt it was necessary that the Representative Body should have the final word and that the Council should be able, if any contentious matter arose, to advise the various committees on the possible harm that might be done.

He would point out that the amendment only asked that the Representative Body should have the power to review the situation at the end of each year. It was better to have a specific time laid down for the review, and he thought that three years was too long an interval.

Dr. D. F. Hutchinson (Council) asked the Representative Body to reject the amendment. He knew from experience, he said, that both Committees were working extremely well, and he thought it was wrong to upset anything which was working so well, especially as the matter could be reviewed by the Representative Body at any time.

Dr. Wishart, in replying to the discussion on the amendment, drew attention to the very careful wording of the amendment and said that the operative part was "the autonomous powers of these committees, in so far as they derive from the

Representative Body." It had been suggested that because things were working well they should be left as they were and evolution allowed to take place, but he wanted the Representative Body to control the evolution.

The Bromley amendment was carried, and the report of Council under this heading, as amended by Bromley, was carried.

THE WAR MEMORIAL

Dr. H. Guy Dain (chairman of the War Memorial Committee), in moving approval of that part of the report, said that the Council, acting on the instructions given by the Representative Body at its last meeting, had proceeded with the preparation of the war memorial and had taken expert artistic advice on the subject. The Representative Body had decided that the memorial should take the form of a fountain in the forecourt at Headquarters, and a design for this had been prepared and could be seen by the representatives at the present meeting. The opinion had been expressed by some members that the memorial should take a form that would be of use to the living, and it was proposed to meet that point of view by founding scholarships for the dependants of those who had given their lives in the war. Substantial subscriptions had already been received for the memorial, some of them being earmarked for one or other part of the memorial; the Committee preferred that the subscriptions should not be earmarked, but subscribers could earmark them if they wished.

The design of the permanent memorial was by Mr. James Woodford, R.A., and had been selected after very careful consideration by experts in the artistic world. There was a central fountain which represented resurgence after the war, and there were figures symbolizing service and sacrifice. He thought it was a very worthy memorial to the members of the Association who had made the supreme sacrifice in the war.

It was also proposed to have a roll of honour on which the names of the members who gave their lives would be inscribed and which would be kept in a case in a room at Headquarters, the pages being turned day by day. It was proposed to add the names of medical sons of members of the Association who had not joined the Association at the time of their death and the names of other medical men who were not members of the Association, these names being put into a separate list from that of the Association members.

With a membership of some 60,000, the contributions to the memorial ought to be sufficient to provide not only the fountain which he had described but also a considerable sum of money to be spent on the living, as had been suggested.

Dr. T. F. Tierney (Marylebone) thought that some indication should be given to members of the Association of the amount that they should subscribe for the memorial. He would suggest that it should be two guineas.

Dr. E. C. Warner (Marylebone) deprecated the proposal to have two separate lists in the roll of honour, and said that he thought the making of a distinction between those who were and those who were not members of the Association would be unworthy of the Association.

Mr. G. J. Alexander (Edinburgh City) moved that the dedicatory inscription be so worded as to include not only members of the Association but all other British medical men and women who lost their lives in the recent war. In putting forward this motion, he said, the Edinburgh Division had in mind a number of young doctors who very shortly after graduation joined the Forces and had not become members of the Association. Many of these young men were the sons of doctors who were members of the Association, and he thought it might be assumed that they would have become members of the Association. It was felt that to exclude their names from the inscription on the memorial would cause dissatisfaction and distress. As the British Medical Association was the only representative of the medical profession as a whole, his Division thought that the inscription on the memorial should be so worded as to include all British medical men and women who lost their lives in the war.

Dr. W. Radcliffe (North-East Essex) thought that the design of the memorial should be considered very carefully, and it should be remembered that anatomy was the foundation of good sculpture. The design which was chosen should not be one which in fifty or a hundred years' time would be regretted. He suggested that the design which had been chosen by the Committee should not be accepted by the Representative Body but should be referred back to the Council.

Dr. G. O. Barber (Mid-Essex) said that the figures in the proposed design did not appeal to a number of the members who had seen them, and he thought that many who had not yet seen them would be horrified by the way in which the human form had been distorted. The artistic appreciation of the human form was a fashion, and a fashion which changed quite rapidly, but the human form itself did not change.

Dr. Dain, referring to the Edinburgh motion, said he hoped that it would not be proceeded with in its present form, because it was not proposed to put on the memorial the names of the doctors who lost their lives in the war; they would be inscribed in the roll of honour, which would be in the form of a memorial book.

Mr. Alexander said that, in view of what Dr. Dain had said, his Division would not press for its motion to be carried in the present wording. The object which the members of the Division had in mind was to avoid any distinction between members and non-members of the Association on the memorial.

The Edinburgh motion was carried.

Dr. Dain said it was possible to enter in the roll of honour the names of all doctors who made the supreme sacrifice during the war, without any distinction between members and non-members of the Association. (Applause.)

He would welcome the help of any member of the Association in deciding on the most appropriate inscription to be placed on the memorial itself. It should not be long, but it should indicate the object of the memorial.

He hoped the Representative Body would not delay the matter but would allow it to go forward now. The design was an artistic one and was suitable for the site on which the memorial was to be placed, and, as the sculptor proceeded with the figures in stone, there would be an opportunity of inspecting them to see that they were anatomically correct.

Dr. J. A. Ireland (Shropshire and Mid-Wales) said that in the opinion of a great many people, including the late President of the Royal Academy, modern art was a passing phase. He hoped that the design of the figures would be referred back to the Council to be reconsidered.

Dr. H. B. Muir (Fife) said that the figures on the memorial represented nothing which appealed to him, and he found them repellent. He was one of those who strongly objected to the form of the memorial that had been decided upon, and if the design of the memorial was unsatisfactory he felt that its whole object was defeated.

Dr. Dain said he hoped that the design would not be referred back to the Council unless the Council was given authority to proceed with it after it had been re-examined, as otherwise it would mean a delay until the next meeting of the Representative Body. He would remind the members that the form of the figures could be modified whilst the sculptor was working on them.

Dr. D. L. S. Johnston (Halifax (with Todmorden)) moved that the Representative Body should defer a decision on the matter until Saturday morning, so that all the representatives would have time to see them before a decision was taken.

This was agreed.

MEDICAL FILMS

Dr. R. P. Liston, chairman of the Film Committee, moved approval of the report under "Medical Films." He said that it was obvious that increasing interest was being shown in medical films, judging by the applications they were receiving. The B.M.A. film "Infections of the Hand" had been well received by those who had seen it already. It would have its first public showing next week in Liverpool. It was being shown also at the International Film Congress at Lausanne in August.

The Association had accepted an invitation to send a delegate to the International Medical Conference (Film Section) at

Verona at the end of the present month. This would do something more to enhance the standing of the Association overseas.

The report was adopted.

NATIONAL HEALTH SERVICE ACTS

Dr. R. Hale-White (Marylebone) moved:

That this meeting reaffirms its readiness to co-operate with the authorities in building up an efficient and smooth-working National Health Service, but deeply regrets that all efforts in this direction during the past three years have been frustrated by the cavalier treatment accorded to its representatives in their conversations and negotiations with the Minister.

He said that the public might have got the impression that the profession was against any kind of National Health Service, but that was not so, and they felt in Marylebone that it should be put on record that the profession continued its willingness to build up an efficient and smooth-working Service. But he was none the less critical. He recalled some remarks by Mr. Bevan in the issue of the *British Medical Journal* on July 3, 1948, and he asked that the Minister's assurances then given should be viewed in the light of after events. In the two years since those words were written they might well feel that the Minister had "plumbed the depths of insincerity" and they might also feel that they had the right to expect something better of a Minister of the Crown. For his own part he did not believe that the Minister had ever the slightest intention of co-operation once he got the doctors in the "bag." In fact he did not believe that the Minister knew how to co-operate; it was not in his make-up. The method of dictation by the Minister and subservience by the profession had been tried for two years—two years too long—and in fact it had failed, as they all knew it would. Among doctors, especially general practitioners, it had produced distrust and cynicism.

The Marylebone motion was carried by an overwhelming vote, apparently unanimously.

Mr. H. H. Langston (Winchester) moved:

That this meeting considers the time long overdue when the Association should formulate a detailed programme of reforms the profession desires to be adopted in relation to the National Health Service and instructs the Council to draw up such a list forthwith for submission to and discussion by Branches and Divisions.

He said that the accusation was not infrequently levelled at the profession that it did not know its own mind nor what it wanted and that one section wanted one thing and another section something different. Even more strongly did some members of the profession accuse the Association of not knowing its own mind. Much of that criticism was purely destructive and made by those who seldom took the trouble to help formulate the policy. But there was much of it also which deserved very serious consideration. It should clearly be stated that to whatever degree the National Health Service had or had not been a success, and whatever benefit it might have brought to the public, the Service was being undertaken by a medical profession which was frustrated, overworked, tired, and disillusioned. There was great dissatisfaction in all branches in various degrees, but perhaps this was greatest among general practitioners.

He thought also that it should be stressed that this dissatisfaction did not arise purely from financial causes. Before anything else it arose from a sense of frustration. Their administrators did not seem able to understand or appreciate that a man, if he was to do his proper work, must have a certain clinical freedom and access to diagnostic facilities. What sort of men were they going to get in 10 or 20 years' time if the present situation continued? Yet this Association had not yet published any detailed programme of reform which they could present to the Government or the public with the whole weight of the profession behind it. He was aware that the Council did set up an Amending Acts Committee—a body which never properly functioned. They in the Winchester Division felt it was necessary for the Council to get down to the formulation of a detailed programme with the full support of the autonomous bodies and their co-operation. These suggestions should then be sent down to the Divisions for discussion and after being considered by the Council brought before the Representative Body. He thought this was a matter of urgency and one of the most important functions the Council had now before it.

Dr. R. Kelson Ford (Chelsea and Fulham) said that about two years ago the Minister of Health stated at a meeting that he expected that the new Service would have growing pains. They as medical men knew something of the significance of growing pains. They knew that these were evidence of one of the most crippling diseases of the organism. Some of its symptoms were exhibited now in the National Health Service. If these symptoms continued and the underlying disease was allowed to develop it might very well be irremediable. He spoke in particular of the situation in hospitals and of the frustration to which general practitioners were subject, also of the added expenses of practice, and the difficulties which arose in the public health field. He doubted whether the nation could afford a really efficient Service on the lines on which it was at present run. The Winchester motion ought to be implemented by calling for a scheme of rehabilitation in the National Health Service.

Dr. A. V. Russell (Council) said that it was essential that they should formulate their ideas as to how this deplorable scheme could be saved from utter disaster. He would like to take the meeting back to May, 1948, when they were induced, very much against their will, to enter this Service on the understanding that once they entered it they would be able to shape it to their own desires and make it into a Service of which they could be proud. The late Chairman of Council (Dr. Dain) told them that they were assured of amending legislation to meet their complaints and to put right anomalies, and largely on that understanding they agreed to come in. The Amending Acts Committee was formed. They did not know what its activities were, but they did know that at the time the Council were discussing the situation the Amending Act, which they were assured would not be tabled without prior consultation, was actually tabled in the House of Commons without any consultation with them at all. The Amending Act certainly included measures to prevent full-time salaried State services, and it embodied some minor amendments which did not alter the main position at all. It was more than time that they should put forward their suggestions as to how this intolerable situation could be put right.

By and large it was they who were working the Service who knew best how it should be worked. One of the things which might be considered forthwith was the curtailment of the overriding powers of the Minister. (The time limit prevented the speaker from concluding his argument.)

Dr. T. W. Morgan (Kingston-on-Thames) said that he came to them as a general practitioner and asked them to give their unqualified support to this Winchester motion. They were asked during their visits and in their surgeries what constructive proposals they as an Association had put forward, and they had to reply that there was no specific policy yet laid down. They had waited for two years. A number of points should be considered. One of these was the opportunity for general practitioners to partake in the ancillary services. The general trend at the moment was to send up their patients to hospitals for investigation, whereas if the practitioner could be given pathological and *x*-ray reports it would add greatly to the usefulness and interest of his practice.

From the point of view of the administration of the Service there should be a greater representation of general practitioners on both advisory and executive bodies. They had to face a sense of frustration which general practitioners experienced as a result of this policy. He urged that a really constructive programme be placed before the Branches and Divisions. Everybody should have some say in the formulation of constructive criticism.

Dr. J. C. Arthur (Council) said that he did not think they were any more satisfied with the consultant service than with the general-practitioner service, or that the public was satisfied. On the hospital side his patients were seriously concerned over the fact that they had to pay two and a half times as much for private beds as they paid before.

Perhaps they did not realize the enormous burden of bureaucracy with which the Service was being saddled. He gave some instances of the extravagance of lay administration. He begged for a clear statement—one which should be not merely bits and pieces—of what they thought was wrong in the whole set-up from top to bottom.

Several other speakers intimated their desire to address the meeting, but a motion was proposed and carried that the question be now put.

Mr. Langston, in reply, emphasized one point that what was required was that the Association should hammer out through its machinery a policy of reform endorsed by the whole profession and supported by sound arguments, and thought that such a policy should be given the widest publicity.

The Winchester motion was carried, amid applause, without a dissentient.

The Amending Acts Committee

Dr. H. Barbara Woodhouse (Harrow) moved that an Amending Acts Committee be constituted as a standing committee of the Association. She said that the National Health Service "child" was born on "the wrong side of the blanket." They need not perhaps be surprised that it was not altogether a normal infant. Such a child must call for the attention of the best "specialists" that could be employed. In order that the health services might be got into a healthy condition it would be necessary to correct one by one the abnormalities, and for this purpose she suggested that an Amending Acts Committee be constituted.

Dr. R. Cove-Smith (Marylebone) thought it was a pity that the Amending Acts Committee was ever allowed to sink into oblivion. He hoped this motion would be supported. There was a great tendency at present, when they were being almost snowed under by delegated legislation, for material to slip through unobserved. The new Committee would hold a watching brief.

Dr. H. Alexander (Wandsworth) also supported the motion. It was imperative that the Amending Acts Committee should be revived. There had been one Amending Act which had contained certain concessions, but there were many more points to be considered. The Government machine had increased tremendously and had now become overriding and top-heavy, with the result that legislation flowed from the various Ministries at a rate with which the overworked House of Commons could not keep pace. It was of paramount importance that every one of the regulations which were laid on the table of the House and eventually became law should be scrutinized. That would be one of the most important functions of the new Committee.

Dr. H. H. D. Sutherland (Kensington and Hammersmith) imagined that the meeting would have no objection to this being made a standing committee and carrying full responsibilities. It would have important duties in consultation with the Council and the Representative Body and the autonomous bodies.

Dr. R. M. S. McConaghey (Torquay) considered they had too many committees already and that this motion was covered by the Winchester motion already passed.

Dr. E. C. Warner (Marylebone) supported the motion. He asked the meeting to bear in mind the overwhelming powers of the Ministry. The Minister himself had said, when discussing the question of anaesthesia in childbirth, that there was nothing that he himself could not do by exercising his dictatorial powers. The enormous powers possessed by regional hospital boards and hospital management committees must also be remembered.

He believed that there was a great deal of support for some change in the Act from Labour Members of Parliament. A Labour Member had said to him that he thought the present Act could be put right only by another Act altogether.

Dr. J. A. Gorsky (Council) supported the motion. The Act, he said, was top-heavy and in fact unworkable, and it would be necessary very soon to have a complete Amending Act altogether. There was a precedent for it in Parliament. In 1923 the Law of Property Act was passed, which the lawyers found was unworkable. In the following year it was amended and still proved to be unworkable. Later still another Act was passed.

The Chairman of Council said that they were all in sympathy with the object of this motion. The previous committee of this kind had to gather together various points for presentation when the Amending Bill was introduced. It was not true to say that it had died from neglect. It was not a policy-forming committee; policy would be shaped by various committees concerned with different parts of the Act. A standing committee was different from other committees and some such action as suggested would in all probability be the action adopted by the Council. The meeting itself had already passed the Winchester motion, and he thought it would be better if the idea behind this Harrow resolution were referred to the Council so that at the moment when the result of the Winchester motion would be available the appropriate action might be taken.

Dr. Woodhouse, in reply, said that it had been objected that the Winchester motion had been carried and covered the same ground. But the first work of the proposed Amending Acts Committee would be to implement the Winchester motion. It was most important that this work should be started at once and carried through to the end. The ground could not be covered in one Amending Act.

The Harrow motion to reconstitute the Amending Acts Committee as a standing committee was carried, and it was further agreed that membership should include, in addition to the principal officers of the Association *ex officio*, the chairmen of the General Medical Services, Central Consultants and Specialists, and Public Health Committees, four members elected by the Representative Body, and four by the Council.

GENERAL MEDICAL SERVICES

The Position of General Practitioners

Dr. S. Wand, chairman of the General Medical Services Committee, presented the report of Council under this heading. In doing so he repeated in great part the statement he made at the recent Conference of Local Medical Committees, reported in the *Supplement* of July 8 (p. 18), and he drew attention to the resolutions passed by that Conference which he hoped the Representative Meeting would endorse. He emphasized certain special points which had arisen in the discussions with the Minister. What practitioners were asking for was not extra money but a determination of their remuneration as it should have been on the appointed day. The Minister had made it clear at their last interview that he did not regard Spens as necessarily a continuing factor. They had always been aware of the possibility of unilateral action on the part of the Minister, having in mind such action by him in the case of pharmacists, dentists, and ophthalmic practitioners. The betterment factor, or cost-of-living bonus, which they had requested should be 70%, was at present only about 40%, but 70% was now too low, and it should be nearer 100%. On the question of the downgrading of the general practitioner the Minister had expressed a good deal of sympathy; the trouble at the moment was with the Treasury and the Chancellor.

What was the financial position of general practitioners to-day? According to the Doctor's Remuneration Tables prepared by the Government, at the lower end of the scale 36.4% were earning under £1,000 a year net. The time it took to qualify as a doctor, the cost of education, and the fact that he did not earn money until he was 23 or 24 years of age must all be taken into account. At the upper end of the scale the general practitioner compared badly with the specialist. The whole general-practitioner group was lower than the specialist group. One Sunday paper worked out that the Service cost £9 5s. 6d. a year for each person. But the general practitioner's share was about 2½d. a week—equal to a little more than one cigarette, or one cigarette and a match! In these days of attractive specialisms it was more than ever necessary that there should be a first-class general-practitioner service, but, as it was, frustrated men were filling the ranks of general practice, and the number was likely to be increased by registrars who wanted to get into consultant practice and for whom there were no places. This being the case, the effect on the Service would be very serious.

Doctors nevertheless were trying loyally to carry out their fullest responsibilities whatever the demands might be, but, should it become evident that there was no prospect of a satisfactory settlement of the claim, steps would be taken to organize termination of contracts. (Applause.) He wanted to make it clear that withdrawal of service did not mean that they stopped giving advice and treatment to their patients. It meant only that they ended their contracts with the Minister, which might mean compulsory arbitration. The Conference was to meet in December, or it would meet earlier if in the meantime unilateral action was taken by the Minister.

"We have tried our best to act fairly to get justice. We have no design to make political capital. Our purpose is to get a fair deal for general practitioners. But now the time seems to have come when we must have a showdown. We cannot allow things to go on in this indeterminate manner. We are, after all, a unique body of people. We are doing a unique job of work, and that work includes hardships and difficulties and responsibilities for us and our families such as are shared by no other section of the community. It is time that that was properly recognized and rewarded. If we have to come to a fight I want to emphasize the need for unity. Let it be remembered that without a satisfied general-practitioner service there are bound to be reactions, and it is the patients who will suffer. I ask this meeting to endorse and fortify the resolutions of the Special Conference, and to that end I propose the following resolution:

"That this Representative Meeting endorses the resolutions (on remuneration and on status of the general practitioner) of the Special Conference of Local Medical Committees held on June 29, 1950, and pledges its support."

There was prolonged applause at the end of Dr. Wand's speech.

The Proposed Inquiry

Dr. C. P. Wallace (Guildford) said that he would like to support Dr. Wand's proposal, which included the suggestion of withdrawing in certain circumstances. He was well aware that, to use Dr. Wand's own words in the *Supplement* of July 8 (p. 18), withdrawal was the most serious step that could be taken, and it was a step which, if decided upon, must be decided upon deliberately and with a full knowledge of its implications. He thought it would help the meeting if the Chairman of Council could give a general assurance that during the past year such arrangements had been made as would enable doctors to withdraw at very short notice.

Commenting on Dr. Wand's statement, he thought it was reasonable for the Minister to ask for an inquiry with regard to the expenses of general practitioners, but it was also a fact that it was most unreasonable for him to ask for that inquiry at the present juncture. The Minister had had two years in which to discover what those expenses were. The subject of general practitioners' expenses had been investigated by the Spens Committee, and in the intervening years those expenses had increased very considerably. For instance, the cost of domestic help had increased by 225%, the capital value of the doctor's motor-car had increased by 200% or 250%, and the expense of obtaining and maintaining a house had increased by about 220%. He did not agree that adequate remuneration for doctors could be provided only by effecting economies in the Service.

Dr. W. N. Leak (Mid-Cheshire) suggested that the Representative Body's appreciation of the work which had been done by Dr. Wand and his colleagues should be entered in the Minutes. (Applause.)

Some doctors felt that there was a certain amount of indignity in pressing for an increase in remuneration at the present time, but he would point out that the Minister had given a definite promise to the Association about matters which could be proved statistically, such as the cost of living, and if he could not be held to his promise about matters which could be proved statistically it would be hopeless for the Association to expect to hold him to his promise about status or anything of that kind which concerned the profession.

Dr. A. V. Russell (Council) pointed out that what was being asked for was not an increase in remuneration. The remuneration of general practitioners had never been agreed. They were receiving at the moment an inadequate interim payment, and they were asking for the Spens Report to be implemented. They were asking for their rights and not for a rise.

The resolution "That this Representative Meeting endorses the following resolutions of the Conference of Local Medical Committees and pledges its support" was carried with one dissentient. These resolutions, on remuneration and status, were published in the *Supplement* of July 8.

Whitley Machinery and Compulsory Arbitration

Dr. J. M. Marshall (Tunbridge Wells) moved that participation in the investigation into general-practitioner income from N.H.S. sources and practice expenses should be made conditional upon a satisfactory assurance that remuneration would always be a matter for negotiation through Whitley machinery and that, in the event of disagreement, either party should have the right to refer the matter to arbitration.

Dr. A. C. E. Breach (Bromley) thought that it was important to clarify the position about Whitley machinery and compulsory arbitration. He himself believed Whitley machinery to be basically machinery for discussion and, if possible, agreement between employer and employee, and he did not think that a Whitley Council had power to enforce a settlement upon either party. If there was to be such a power new machinery would have to be set up with authority to enforce its decisions on both parties. As to the practicability of that, he thought that the public would consider it quite reasonable for the medical profession to claim the right to refer disputes between themselves and their employers to arbitration. As Dr. Wand had pointed out, the medical profession was unique in that it had voluntarily set aside the right to form a trade union and to use the principal weapon of the trade union, and in return it asked the Government for the right to refer disputes to arbitration.

The Secretary (Dr. Charles Hill) said he would try to make clear the position with regard to arbitration. As Dr. Breach had said, Whitley machinery was purely voluntary, and at the present time it did not include any provision for arbitration. There was, however, an arbitration agreement which was under discussion. Section 13 of the Amending Act laid down a form of inquiry or arbitration, the essence of which was that the Minister's consent was necessary before a matter went to arbitration, though there was the possibility that the Minister of Labour would refer a dispute to a court of inquiry and not arbitration in certain circumstances.

There was, however, a provision which was in no way affected by the Amending Act or by any Whitley agreement —namely, the provision in the Conditions of Employment Order of 1940 dealing with the National Arbitration Tribunal, and for practical purposes that was the only form of arbitration for medical practitioners at the present time. It would exist in law from the moment that the general practitioners as a whole gave notice of withdrawal or termination of contract, and it meant that when a dispute existed—i.e., at the moment of resignation—the matter must be referred to the Minister of Labour, and within the next 21 days the Minister would decide what action to take. He might decide, in the absence of voluntary machinery, to refer the matter to compulsory arbitration. If he did general practitioners would be required to accept compulsory arbitration and not to proceed with the withdrawal of service until that arbitration was completed, and they would be bound to accept the result. If, on the other hand, at the end of 21 days the Minister had not acted, general practitioners would be free in law to proceed to withdraw and to take such action as they chose. Therefore their position was, in relation to the motions which the Representative Body had endorsed, that from the moment of the mass resignation they might find that the Minister of Labour had referred the matter to compulsory arbitration. They could not proceed to withdraw without giving notice to the Minister of Labour and giving him the opportunity, if he chose (and personally he thought the Minister would so choose), to proceed to compulsory arbitration.

Dr. J. A. Gorsky (Council) called attention to a resolution which had been carried unanimously at the last Annual Representative Meeting, to the effect that, as the Minister of Health had withdrawn the assurances and undertakings repeatedly given to the profession on the question of arbitration in the event of a dispute, the Representative Body demanded that effective action should be taken forthwith to insist that arbitration machinery should be set up and that the demand for arbitration by the profession should not be subject to the Minister's veto. He would add to that to-day "not even the Government's veto of prerogative."

Dr. Marshall suggested that the motion by Tunbridge Wells should be referred to the Council to be put before the appropriate committee, and this was agreed.

An Independent Court of Arbitration

Dr. C. P. Wallace (Guildford) moved that the meeting should press the Minister of Health to agree to the appointment of an independent Court of Arbitration to which appeal could be made in the event of disagreement concerning the remuneration of practitioners, and that such Court should be established without delay.

Since the coming into force of the National Health Service Act, he said, the whole position of the profession had changed. Previous to July 5, 1948, only a small percentage of the profession were employed directly or indirectly by the State, whereas now about 90% were employed by the State and were dependent on the State for their daily bread, and he could not see how they could escape from a position of serfdom unless they secured independent arbitration. He thought that the meeting should assert in no uncertain way its demand for an independent court of arbitration, and the public should know that the reason why the profession was threatening withdrawal was that it had been denied independent arbitration between the Minister and the profession.

Dr. Wand, in opposing the motion, said that, in the light of what he had pointed out to the meeting, he could not envisage an independent court of inquiry or arbitration being set up at the moment. Such a motion would embarrass those who were carrying out negotiations for general practitioners, because it would tie them down to the exact way in which they were to proceed. They were fully determined to obtain fair and honest arbitration in its fullest sense, with no overriding influence. He hoped that the motion would be withdrawn or, failing that, rejected.

Dr. Breach said he could not understand why Dr. Wand did not wish this vital issue to be discussed by the meeting. The members were concerned to obtain proper terms of service, which to many of them resolved itself into a question of payment. How could they possibly decide on a certain drastic course of action, such as the withdrawal of service, in support of any particular figure, when the value of money was changing from week to week? Surely the sensible thing to do was to set up a court of arbitration which would have power to enforce an impartial decision on both parties. Dr. Hill had not dealt with the question of the setting up by Parliament of a court specifically designed to resolve disputes between doctors and the Minister to which either party could appeal. Such a court, by virtue of its being set up by Parliament, must have power to enforce its decisions, and it was this kind of court that was required.

Dr. Gorsky (Council) endorsed the remarks made by Dr. Breach and said he hoped that the meeting would support the motion by Guildford. In a leading article on arbitration in the *Manchester Guardian* of July 8 last year it was stated that there was a good deal of substance in the doctors' contention and that it did not apply only to themselves; with the spread of public services there was a strong case for reconsidering the method of settling differences in which the Minister was a party to the dispute as well as the judge.

The medical profession wanted an independent court of arbitration, and he believed that if they asked for it they would obtain it.

Dr. J. C. Arthur (Gateshead) said he had had a good deal of experience of negotiation, and he believed there was only one thing which the Ministry understood—namely, the big stick. He would rather go to the Ministry with the resignations of 90% of practitioners in his pocket than go to any arbitration tribunal. The Spens Committee was the arbitration tribunal which fixed the position of the doctor, not necessarily by any given figure but by a position in the social scale in this country. Doctors were considered by many other professions to be not badly paid, and if they put their case before an independent arbitration tribunal on which there were, for instance, school masters, those members of the tribunal might not be very sympathetic towards even the implementing of the Spens award. If the medical profession tied itself to compulsory arbitration it would be putting itself into a dangerous position and might lose all that it had gained by the Spens report. What the medical profession should do was to see that the Spens report was fully implemented.

Dr. A. Beauchamp (Birmingham) hoped that the meeting would reject the motion, because the operative word was "independent." Some of the representatives might remember the result of the last independent court of arbitration, with which none of them were satisfied.

Dr. W. Jope (Council), speaking as one of those who from time to time accompanied Dr. Wand to the Ministry to discuss terms and conditions of service, expressed the hope that the Representative Body would not tie their hands.

Dr. H. H. D. Sutherland (Kensington and Hammersmith), in opposing the motion, said that so far as he knew there was no independent compulsory court of arbitration available and none that would cover the position of the doctors. They were not envisaging a dispute that would result in a strike in the usual sense of the word, as it was understood by the present Government and the people of this country, and he therefore hoped that the Representative Body would not do anything which might act as a boomerang and come back on them when, under the present arrangements, their negotiators were able to see the opening of the door.

The meeting agreed that the question be now put.

Dr. Wallace, in replying to the debate on the Guildford motion, said he could not understand why the Association's negotiators should object to the suggestion that the profession would be prepared to accept an independent court of arbitration. The meeting, in passing the motion, would not be in any way tying their hands in their negotiations, nor would it be in any way expressing disappointment at or disapproval of the results of the negotiations up to date. The members might well do so, but they were conscious of the fact that Dr. Wand and his team had been doing their best. His Division felt that, in view of the suggestion of withdrawal of service, it was absolutely necessary that the Representative Body should put on record its willingness to accept an independent arbitration court.

Dr. F. E. Gould (Birmingham) asked whether, if the members agreed to an independent court of arbitration being appointed, they would lose their right to give notice to terminate their contracts.

The Chairman said he thought that would be so.

The motion by Guildford to press the Minister for an independent court of arbitration was lost by a large majority.

Compensation

A motion by Tunbridge Wells was on the agenda relating to the prolonged delays in the negotiations on compensation for general practitioners. The mover said that it was put forward with a view to eliciting a statement on the compensation question.

Dr. Wand said that the Compensation Committee had been busy during the whole year, and had nearly completed its part of the job. There had been a number of appeals, two of which had been taken to the courts for adjudication, and the decision was in favour of the Compensation Committee's point of view in both cases. It was hoped that all these matters would be dealt with by the end of the year. The cases that now came forward were more difficult than formerly. At the last committee meeting over an hour was spent on one case.

The Tunbridge Wells motion was withdrawn.

Petrol and the Mileage Fund

Dr. J. T. McGlasson (Dumfries and Galloway) moved:

That in view of the increased expense to the doctor due to the rise in the price of petrol there should be an increase in remuneration.

This motion was the result of a unanimous decision of a meeting of his Branch—a Branch in which the great majority of the doctors were rural or semi-rural, and practically all were dependent on mileage payments to supplement their incomes. They felt that the additional mileage grant was now quite insufficient. There had been a considerable increase in the amount of work, in the cost of cars, and, since last May, an increase in the cost of petrol. The extra cost of petrol to the practitioners in his district was roughly £70 a year—equivalent to 100 capitation fees.

Dr. Wand said that the day after the Budget they made representations to the Ministry on this subject, and they had been to the Treasury and the Ministry back and forth rather like a shuttlecock. The pool had been diminished by the amount of this tax to the extent of getting on for half a million a year. It was particularly hard on the rural practitioner who had to cover a large mileage for a small number of patients. The Minister was being asked to receive a deputation to consider ways of putting back the money which had been lost to the pool. It was very important to watch the terms of the forthcoming inquiry so that this addition to practice expenses might be fully taken into account.

The resolution was carried unanimously.

Mr. J. C. McMaster (West Somerset) moved, and it was agreed, that in view of the considerable advances in the price of petrol the sum of £2m. for mileage was inadequate and should be increased.

Dr. H. L. Taylor (Newcastle-upon-Tyne) said that his Division felt that there was great inequality in the proportion of mileage allowance for various districts, and he urged that before there was any alteration in the distribution of mileage money there should be a comprehensive survey of the country as a whole.

Dr. Frank Gray (Council) said that although not a rural practitioner he was a member of the Rural Practitioners Subcommittee. The old system of distribution of mileage as between the different counties was thoroughly inequitable. The Conference had asked for that distribution to be revised, and there was an interim scheme which would in his judgment give a much fairer distribution. The complete survey for which Newcastle was asking was a long process which would take 18 months or more. But in the interim if mileage was to be distributed differently money must be taken from areas which had had more than their fair share and passed to areas which had had too little. He hoped the Newcastle motion would be turned down, and the existing scheme be allowed to take its course, particularly as those who would benefit would be those who had had the roughest deal in the past.

Dr. J. A. Ireland (Shropshire and Mid-Wales) said that executive councils should have power to distribute as and how they considered equitable among practitioners entitled to mileage. The allocation as given to-day was vastly more equitable than the old system. He did not want anyone to go away with the idea that they had "lost money." If they had less money it meant that they had been receiving more than they were entitled to in the past.

Dr. Wand said that this redistribution involved £91,000 out of £2m.—that is, 5% of the total pool. The new distribution would remedy present inequalities. These inequalities had gone on for long enough.

The Newcastle motion was withdrawn.

Dr. Enid A. Hughes (West Denbigh and Flint) moved that the mileage grant should take into account the increased cost of travelling in a mountainous as compared with a flat area.

It was agreed to refer this to the Council.

Dr. N. G. Lindsay (Harrogate) was of opinion that the sum allocated for mileage to rural practitioners was inadequate and took insufficient cognizance of the time spent on travelling. He pressed for an early statement on the effect on individual rural practitioners of the proposed re-allocation of the global sum.

Dr. Wand said that it was an interesting fact that out of the Doctors' Remuneration Tables there emerged the very definite point that the net annual remuneration of doctors in receipt of mileage payments exceeded that of doctors who were not in receipt of such payments. Doctors in rural areas should remember that even urban practitioners spent a certain amount of time in travelling. He hoped that before passing any such resolution as Harrogate had in mind they would await the results of the fact-finding inquiry of the Mileage Commission. Another point which rural practitioners should bear in mind was that their town colleagues were more subject to the impeding effect of fogs and traffic blocks.

A Harrogate motion on the subject was withdrawn.

Dr. R. B. Allen (Consett (with Hexham)) urged that mileage payments in maternity cases should be paid from the same source as maternity fees, and should not be a first or any other charge on the central mileage fund. The mileage fund should not be raided for this purpose.

Dr. Wand pointed out that this would include mileage for maternity cases, and they must not go back on their bargain.

The motion in favour of the course indicated by Dr. Allen was lost.

Dr. L. N. Jackson (Exeter) asked the meeting to express the opinion that rural mileage in maternity cases was entirely inadequate. A maternity case seven miles away might involve a dozen visits, for which the total mileage payment was 12s., or 1s. a visit.

Dr. D. M. Hughes (South-West Wales) and Dr. H. B. Muir (Fife) continued the discussion. Dr. W. Jope (Council) said that in Scotland it was agreed to allocate this money to executive councils to use at their discretion.

Dr. Wand said that they had had discussions in the Rural Practitioners Subcommittee and their opinion was that the mileage should be paid at the figure at present indicated. He hoped that in view of the discussions which had taken place Exeter and other Divisions with similar motions would all agree to have them referred to the Council, which would look at the matter again.

Exeter, however, asked that its motion that rural mileage in maternity cases was entirely inadequate might be put to the meeting, and on a show of hands it was lost.

The meeting adjourned at 5.30 p.m.

FRIDAY, JULY 14

The Annual Representative Meeting resumed at 9.30 a.m.

GENERAL MEDICAL SERVICES

Rural Mileage

Dr. Enid A. Hughes (West Denbigh and Flint) moved that mileage for maternity cases should be calculated from the distance between a practitioner's residence and the place where the patient was confined, instead of the place where the patient resided.

This was agreed to, as was a further motion by Shropshire drawing attention to the injustice towards a rural practitioner who could not claim maternity benefit mileage for a patient confined at a cottage hospital or nursing home in a "closed" area at some distance from the patient's or the doctor's residence.

Dental Anaesthetic Fees

Dr. R. M. S. McConaghey (Torquay) moved that the Minister be informed that the recent cut of 10% in the fee for dental anaesthetics had been made without previous consultation with the medical profession and that it was unacceptable to the profession and that the Minister be asked to restore it forthwith. He said that this cut in remuneration was made by a Minister who was said to be "sympathetic" to the profession; he wondered what would happen with a Minister who was not sympathetic. It seemed to him that this was a shadow of things to come.

Dr. H. F. Hiscocks (South-east Essex) said that some members of the profession had been asked whether the Minister recognized that doctors gave anaesthetics for dentists. Of course he did; doctors were specifically referred to in the schedule of fees, and on the prescribed form there was a place for the doctor's name to be filled in if the fee was over a certain amount. They were not concerned with the rights and wrongs of the dentists' "cut," though they might all have their views on its justification. But the fact that this involved doctors' anaesthetic fees at the same time seemed to have been ignored. The doctor got his full fee in the majority of cases from the dentist simply because the dentist was kind enough to pay him. It was a humiliating position for the doctor and one which was quite wrong in principle. He hoped the General Medical Services Committee would take up this case with the Ministry forthwith.

Dr. Wand said that this matter had already been taken up with the Ministry, and the line the Committee had taken was that this was a fee for medical work and should be paid as such and that there should be an *ad hoc* payment for each administration irrespective of the number of teeth extracted. They were now awaiting a reply from the Ministry; he was not too optimistic about that reply, but the matter would be pursued vigorously.

The Torquay motion was carried.

Classification of Areas

Dr. J. C. Arthur (Gateshead) moved that in view of the completely unrealistic standards adopted by the Medical Practices Committee in classifying certain areas as under-doctored the meeting strongly supported the General Medical Services Committee in its protest to the Ministry. This matter as to what constituted an under-doctored area should be considered very carefully by the Committee.

The motion was carried.

Medical Service Subcommittees

Dr. A. M. Maiden (Lincoln) moved to press the Ministry of Health to amend the regulations so that a doctor was notified in every case immediately a patient laid a complaint against him, and not, as now, as soon as reasonable after the Chairman of the Medical Service Subcommittee ruled that there was a prima facie case. There was some ambiguity about the regulations, resulting in a certain amount of hardship to the doctor. The doctor in many cases did not hear about a complaint until three months had elapsed. One complaint within his knowledge was made on March 25. The first notice the doctor had of it was on June 14, and he was notified later that an inquiry would take place on July 27. The doctor should be notified immediately of any complaint, frivolous or otherwise; or, alternatively, a directive might be sent by the Ministry whereby this ambiguity in the regulations would be cleared up.

Dr. Wand said that they had made representations to the Ministry for a number of changes in the regulations under the Medical Service Committee procedure. The time-lag had caused a great deal of dissatisfaction. The point had been raised with the Ministry and legal advice had been taken. The Ministry were unwilling to alter the regulations, but they had put up a draft handbook for consideration with a view to helping the chairmen of these committees. This handbook his committee had not considered completely. On the general subject of these regulations—they were put out in 1948, and the profession had now some right to say that after they had been working for two years it was desirable to look into the matter and show where changes could be made in the light of experience.

Dr. A. C. E. Breach (Bromley) moved that there be substituted for the principal part of the Lincoln resolution the following words: "that the Ministry of Health be pressed to amend the regulations in consultation with the Council of the B.M.A. and that the Council be requested to undertake at once a full investigation of the status, composition, procedure, and functioning of the Tribunal and Medical Service Committees, to hear evidence, to ask legal advice, and to publish a report before the end of the year."

Dr. Breach said that up to ten years ago the common people of this country were confident in their birthright of freedom, and rightly so, for they knew that there stood between them and the whims of the political executive a bench of judges who were no respecters of persons. The judges were still there, but during the past ten years Parliament had devised means of short-circuiting the administration of the law. Over a wide field it had set up a system of tribunals endowed with powers comparable to those previously resting with the courts alone. It was their duty as citizens to view these changes critically when they tended to threaten the liberties of the subject.

These tribunals, which had become a popular expedient with the politicians, constituted a danger to the freedom of justice. As compared with a court of law, the medical tribunal was in the extraordinary position of hearing only one type of case, a complaint from the "consumer" against the "supplier." The process could never be reversed. The defendant, always a professional man, stood to lose everything if he was held to be at fault. If he was exonerated he did not even recover costs. The appellant, however unjustifiable his complaint, might not even be rebuked. The composition of the tribunal was also significant. The members were not salaried like judges. They were remunerated by fees for their services and had no security of tenure. If a medical member did not interpret the official wish satisfactorily it would be competent for the Minister to select other members of the medical panel to serve in future. Another factor which might well prejudice the independence of the members was that they received circulars from the Ministry explaining the official view of the law. Finally, when one realized that from such tribunals the only appeal was to the Ministry it was apparent how far we had wandered in these few short years from the well-beaten paths of British justice.

If these tribunals were to be tolerated certain drastic reforms must be sought. Rules of evidence must be carefully laid down by the court and strictly followed. Appeals to a superior court must be allowed on questions of law. The decision of the tribunal must be unanimous. The tribunal should give a reasoned decision. Medical members to the tribunal should be appointed by the profession and should be given security of tenure with a retainer. The law should be laid down by the superior court, not by the Government department concerned. The tribunal should be empowered to censure the plaintiff and impose substantial costs as a deterrent from frivolous and malicious mischief-making. As it was with the tribunals, so it was at an even more amateurish level with the Medical Service Committees.

Such was the position in which as a profession they had let themselves be placed. The need to find a remedy was urgent indeed and deserved close attention. It might be that informed opinion would conclude that these committees were so potentially mischievous that the only remedy was to abolish them entirely. If that was indeed the solution then it was up to the profession to see that by united action they obtained the necessary amendment of the present law.

Dr. Robert Forbes (Council), in supporting the amendment by Bromley, said that the Representative Body would remember that last year it had devoted a considerable amount of time to the subject with which the amendment dealt, and since then Dr. Dain and a committee associated with him had examined the problem and made certain proposals which they intended to put before the Ministry with a view to the revision of the procedure of Medical Service Committees. Those committees were of growing importance and of growing significance to every individual practitioner engaged in the Service. There was a considerable amount of concern about their procedure and their powers, and there was ample room for improvement to protect the respondent practitioner. All the committees did not observe the regulations, and there were occasions when the practitioner was placed at a serious disadvantage. It was therefore felt that a further examination of the situation would be justified, and the Bromley amendment would enable further, fuller, and even more constructive submissions to be made for the improvement of the Medical Service Committee and its procedure.

Dr. J. A. Gorsky (Council) said the danger was that the tribunals were administrative and therefore were not bound by law to give reasons for their decisions. They did not publish their decisions, so it was not possible to know when there was a miscarriage of justice, and no case was stated by an administrative tribunal before the High Court of Justice. The matter was now in the hands of the legislature, because a

Bill dealing with it had been introduced into the House of Lords by Lord Samuel. The matter was an important one not only for doctors but for all professional men and women, and if the members of the Representative Body wished to strike a blow for the liberty of the subject they should support the Bromley amendment.

Dr. J. C. Arthur (Gateshead), in supporting the amendment, said that in the report of the General Medical Services Committee a time limit was fixed for lodging complaints and a time limit was fixed for the report of the appropriate committee to the Executive Council, but nothing was said about any time limit for the appropriate committee holding its inquiry on the complaint. It was the time which elapsed between the lodging of the complaint and the holding of the inquiry which was so particularly trying to the doctor concerned, and that time was sometimes as long as five or even six months. There could be no adequate reason for such a delay in any circumstances, and this was a matter which should be rectified as soon as possible. The whole matter was receiving very full consideration by the General Medical Services Committee, which he was told would shortly report upon it to the Council of the Association. He thought that the most expeditious and efficient way of dealing with the whole matter might be to refer the Gateshead motion and the other motions on the subject to the General Medical Services Committee.

Dr. Breach, in replying to the discussion on the Bromley amendment, said that in view of the authoritative support which the amendment had received he was confident that the importance of the subject with which it dealt was fully realized.

The Bromley amendment was carried with one dissentient and was also carried as the substantive motion.

Change of Doctor

Dr. Wand, in moving the paragraphs of the report concerning change of doctor (paras. 32 and 193), said that the Ministry had accepted the proposal that a patient must give notice to the executive council in order to change his doctor and that such notice would become effective at the end of two weeks. The notice would be valid for one month only. Change by consent would continue.

Dr. C. W. Walker (Cambridge and Huntingdon) moved:

That this meeting is of opinion (*a*) that the present arrangements whereby a patient may change his doctor without notice is satisfactory, and (*b*) that a return to the practice under the National Health Insurance Act is not desirable.

He said that the members in Cambridge had found that the new arrangement whereby a patient could change at any time was more satisfactory than the old N.H.I. regulation that the patient had to obtain the signature of his old doctor—a procedure which was considered by the patient to be an obstacle to change. The choice of doctor should not only be free but should be seen to be free, and that cut the ground from under most complaints. Moreover, the members in Cambridge very much disliked the idea of treating a patient who would prefer to be treated by someone else but had not the courage to say so.

Dr. D. L. Gullick (East Herts), in supporting the amendment, said that the relationship between doctor and patient was essentially one of confidence, and if confidence was lost on either side it was better that the relationship should be broken. It therefore followed that no obstacle should be placed in the way of severance. Under the old system, if a patient asked his doctor to sign his card for transfer there would be very few occasions on which the doctor would be disinclined to do so, so that to revert to the old system would simply mean another form for doctors to sign.

Dr. A. M. Maiden (Lincoln), in opposing the amendment, said that it had been found in eight local medical committee areas in the East Midlands that a certain abuse crept in when patients knew that they had a right to change their doctor at any time. For instance, a patient might ask her doctor for cod-liver oil for her baby, and, if the doctor thought the baby did not require it and, being a man of integrity, refused it, the patient would go to a neighbouring surgery and ask the doctor there to put her name on his list, and he might give her the cod-liver oil. There was a certain drift of patients to the lists of doctors who gave way to patients, and it was felt in his Division that this abuse could be prevented only by the giving of notice before a change was made.

Dr. A. G. Chamberlain (Dorset) said he did not think the abuse to which Dr. Maiden had referred was very prevalent. There would always be some disgruntled patients. The members in Dorset did not want to have a patient on their lists for even a day after the patient wanted to make a change, and they preferred the system under which patients could change whenever they wished to do so, without notice. He therefore supported the amendment.

Dr. S. Smith (Tower Hamlets), in speaking against the amendment, said that there was a small minority of patients who abused their rights, and the new regulations were framed with a view to putting an obstacle in the way of those patients. He had had one patient who came to him from another doctor and who, he subsequently discovered, had changed her doctor three times in the course of a year and had made unreasonable requests to all of them.

Dr. H. H. D. Sutherland (Kensington and Hammersmith) hoped that the meeting would reject the amendment and support the proposal that 14 days' notice of change should be given, as he thought that was the best compromise that could be achieved.

Dr. Doris Odlum (Bournemouth) expressed the opinion that the matter of status was at issue. Patients nowadays had the idea that doctors were at their beck and call and could be pushed around as they chose, and the fact that they could change their doctor so easily strengthened their idea that doctors were people of no importance. That was a very sound reason, she thought, for making it rather more difficult for patients to change their doctor. She agreed that doctors did not want to have on their lists anyone who was unwilling to be there, but that was not quite the point; the point was that the easy change lowered the doctors' status. She therefore supported the proposal that 14 days' notice of change should be given.

The Chairman of Council said that the representatives should not lose sight of the fact that the ease with which a patient could transfer from one doctor to another provided a way of escape from a complaint against the doctor which might otherwise be made. It was better that a dissatisfied patient should be able to change his doctor easily than that he should adopt the expedient of becoming troublesome and making a frivolous complaint against his doctor, thereby causing the doctor a great deal of trouble. He remained a firm believer in free choice at any moment, even though there were many troubles associated with it.

Dr. J. Bleakley (Belfast), in opposing the amendment, said that the new proposal did not in any way interfere with free choice of doctor; it merely introduced a little sand into the works to make it difficult for busybodies to go round collecting cards and giving them to a doctor who had been over-generous to them. In Northern Ireland 14 days' notice was not specified, but a patient who wished to change his doctor had to send a form to the board, which was the equivalent of the executive council in this country, to obtain permission to transfer. That did not delay change very much, but it made it a little more difficult. The members in Northern Ireland felt that this was only a small beginning, leading to the larger issue of the reintroduction of penal and disciplinary measures against patients, which they felt to be absolutely necessary.

Dr. J. A. Pridham (Dorset) said that doctors were always protesting about regulations and wanting their freedom and to go back to private practice, one of the characteristics of which was that a patient could change his doctor at any time; but now doctors wanted to put an obstacle in the way of that. It seemed to him that they were speaking with two voices. He wished to emphasize strongly what the Chairman of Council had so wisely said.

The representatives should realize that by putting sand in the machinery they were favouring the older practitioners, as against the young men who were trying to build up practices or who had just come out of the Forces. The more difficult it was made for a patient to change his doctor the more the man in an established practice would be assisted.

The new regulation would be inviting patients to put pen to paper and make a complaint, and he thought it would therefore be distinctly unwise.

Dr. R. B. Allen (Consett (with Hexham)) said there were black sheep among patients, and there were also black sheep in the medical profession. He deprecated doctors tying themselves up once again in red tape. They should be careful in accepting a transfer from another doctor and find out the reason for the change. He strongly supported the amendment.

Dr. F. E. Gould (Birmingham) pointed out that one of the conditions which the Association had managed to establish at the inception of the new Service was free choice of patient by doctor and free choice of doctor by patient; as the regulations stood at the present moment the patient had the right to change his doctor at any time, but the doctor had not the same right to get rid of a patient; he had to give at least one week's notice. He thought there was a great deal to be said in favour of the old system, under which the doctor could sign part "C" of the medical card and request his patient to find another doctor immediately.

Dr. Frank Gray (Council) submitted that the proposed change of procedure was in the interests of the patients themselves and the community. If a patient really wished to change his doctor he could either ask the doctor for his consent, which was not likely to be refused, or write to the executive council. It was much better for the patient to have to take time to think again than for him to be able to rush off to another doctor whenever he liked. He would never find a perfect doctor, and second thoughts were often best. The proposed change of procedure would not involve any real interference with the patient's freedom of choice.

Dr. J. G. Thwaites (Brighton) thought it was quite clear that all the representatives wished to maintain the patient's freedom to change his doctor whenever he wished to do so. Reference had been made to the state of affairs in private practice, but he would submit that there were certain courtesies which had to be observed then, and surely an effort should be made to preserve those courtesies under the new Health Service. There was no harm whatever in having a slight delay which would remind the patient that there were these courtesies to be observed. Moreover, the delay would give a doctor time to get into touch with the doctor to whom his patient was transferring and to give him some information, good or bad, about the patient if he wished to do so. He hoped that the amendment would be rejected.

Dr. J. C. Arthur (Gateshead) also opposed the amendment. The new procedure, he said, was one of the most helpful things that the medical profession had obtained from the Minister since the National Health Service Act had come into force. The Minister had refused it at first, saying that the patient under the Service must be as free as a private patient, but he had lost sight of the fact that the private patient had to pay both doctors. Under the present arrangement a patient could go to four doctors in a day and get expensive drugs from all of them, and pour them all down the sink if he did not like the taste of them.

Dr. Wand said he thought that most of the representatives who had spoken in favour of the new proposals were urban practitioners, whilst those who had spoken against them were chiefly doctors engaged in rural or semi-rural practice. There was a difference in the conditions of practice in the two types of area. There was a more floating population in the urban areas, and he thought that was a factor which influenced the opinion of the speakers. (Cries of dissent.) Abuses were taking place, and the number of changes to-day were several hundred per cent. more than those in pre-1948 days. The small alteration effected in the new procedure would have a salutary effect in the case of many of the abuses, and it was a very simple compromise between the two extremes. He hoped the meeting would reject the amendment.

Dr. Walker, in replying to the discussion on the amendment, said that his own practice was an urban one. Abuses of the system by the doctor would not be avoided by injuring the patient, and there were other ways of improving the integrity of doctors. Abuse by the patient sometimes occurred, but there was a very simple method of restraining that abuse, quite apart from regulations. If a doctor, before accepting the patient of another doctor, used the telephone he would easily find out whether that patient was a desirable person or not. He could not too strongly emphasize the fact that all regulations were bad because they were sure to be unfair to someone. Regulations were necessary, but they must be reduced to the minimum. The regulation that 14 days' notice of change of doctor must be given must avoid a certain amount of abuse, but someone would suffer unfairly through it. That raised the question of principle, and he was one of those who believed that if doctors could maintain their principles their status would look after itself.

The Cambridge and Huntingdon amendment, declaring the present arrangements for change of doctor satisfactory, was lost by a considerable majority.

Frivolous and Unjustified Emergency Calls

An amendment by Plymouth, requesting the Council to add the words "trades unions" to the organizations to be embraced in a publicity campaign (para. 33 of Annual Report), was accepted.

Dr. J. W. McCarthy (Hendon) moved to urge the Council to take further steps to have the regulations amended to provide the practitioner with a right in appropriate cases to lodge a complaint against a patient on his list who made frivolous or vexatious demands upon his services.

He thought it might be said that a doctor should take such a patient off his list, but the capitation fee was too low to permit a doctor to lose many of his patients. It was only in a few cases that a doctor would complain of patients, but it would be a deterrent to patients being unreasonable in their demands if it was stated on the card that the doctor had the right to make complaints.

Dr. Frank Gray (Council) said that in every walk of life the great majority of people acted reasonably, but in almost every walk of life there had to be disciplinary machinery to deal with the small minority. There was no such machinery in the case of the patients of doctors in the National Health Service, and the Minister by his persistent refusal to establish this machinery was encouraging them to behave in an unruly manner. He hoped that the meeting would pass the motion by Hendon, which asked for the same powers to be used against the troublesome patient as against the troublesome doctor.

Dr. D. M. Hughes (South-west Wales), in opposing the motion, said he thought it would result in doctors suffering a further loss of status. They could deal with the problem themselves by "telling off" patients when necessary. Some patients made frivolous calls, but it must be borne in mind that there were frivolous mentalities in the medical profession, and if such doctors were allowed to make silly complaints against patients the result would be a grand slanging match, in which the doctors would be the losers in the long run and which would result in a further drop in the status of doctors.

Dr. Robert Forbes (Council) pointed out that the proposal put forward in the motion had already been made to the Ministry by the General Medical Services Committee and that the Ministry had not received it favourably. He thought that the Representative Body should give some expression of opinion which would fortify the Committee in the views which it had already expressed, so that it might be more likely to get something done to deter patients from making frivolous and vexatious demands on doctors. It was not contemplated that practitioners would often make complaints against patients, but it was contemplated that they would feel much happier if they had the power to do so. He therefore hoped that the Hendon motion would be carried.

Dr. H. H. Goodman (Newcastle-upon-Tyne) strongly supported the motion. It was wrong to allow a patient to complain against a doctor and to deny the doctor an equal right.

Mr. A. Dickson Wright (Marylebone) thought that some deterrent for this class of patient should be thought out. He wanted something more subtle and clever than was suggested in the Hendon motion.

Dr. E. G. Smallbone (South Essex) spoke against the motion.

The Hendon motion, urging the Council to take further steps to have the regulations amended to provide the practitioner with the right to lodge a complaint against a patient for frivolous or vexatious demands, was carried.

The Question of Penalty

Dr. A. M. Maiden (Lincoln) moved to ask the Association to take all steps to persuade the Minister to institute some machinery whereby a doctor could lay a complaint against a patient, and to impose some penalty on the patient if his conduct was deemed unreasonable. He said that this differed from the Hendon motion only in calling for some penalty. He gave a number of examples of inconsiderateness on the part of patients.

Dr. H. Barbara Woodhouse (Harrow) gave other examples of inconsiderateness. She suggested that patients be required to pay a small mileage fee for each unjustified call.

Dr. G. D. Bolsover (Oxford) said that all of them who were in practice could give a wealth of instances of vexatious calls. Nevertheless, he was opposed to this motion because he felt it would be impracticable. What penalties could be imposed? He doubted whether any body before which a patient could be brought would be in a position to assess or impose a fine. All this would be of no benefit to the doctor, and his relations with his patient would be destroyed.

A representative suggested, amid laughter, that a patient's medical card might be endorsed in the same way as a car-driving licence.

Dr. A. Barker (East Kent) asked the meeting to reject this idea of a penalty. They could very well impose their own penalties. If a patient called them out to some distance and then the case was found to be entirely frivolous, why should they not say, "I am sorry, Mrs. Jones, but you will have to come to my surgery for the medicine and I am afraid I cannot take you back"?

Dr. J. A. Ireland (Shropshire and Mid-Wales) said that having passed the Hendon motion it would be ridiculous not to call for any penalty at all.

The Lincoln motion was declared carried.

General Practitioners and Hospital Committees

Dr. W. N. Leak (Mid-Cheshire), on behalf of Preston, moved:

That this meeting views with the gravest concern recent action taken by regional hospital boards to exclude general practitioners from membership of hospital management committees. It instructs Council to take appropriate action to maintain and improve general-practitioner representation on hospital boards and management committees.

Dr. Leak said that he brought forward this proposal because it was in his area of Cheshire that the case referred to occurred. He gave an outline of the case, which had been the subject of correspondence in the *Manchester Guardian* and elsewhere. It concerned the action of the Liverpool Hospital Board. As a result of correspondence with the Ministry he thought that some advantage had now been gained, thanks to the publicity which this case had received.

Dr. T. Rowland Hill (Marylebone) moved that the phrase should run, ". . . general practitioners *and consultants*." He said that there was too much separation between the consultant and the general practitioner. This could do only harm to both of them. He saw no reason why the General Medical Services Committee should not make some reference to consultants as well as general practitioners. In this matter of representation on hospital boards they had everything to lose by separating the two branches of the profession and everything to gain by marching together. The consultants would be enthusiastically behind the general practitioners in asking for a general increase in the representation on regional hospital boards. But it was important they should leave no suspicion of a division between them.

Mr. A. Dickson Wright (Marylebone) supported the amendment. The consultants were in a minority in that meeting, but it was always a fair meeting and prepared to listen to the point of view of other people. In the case of his own hospital he had been on practically every committee before the Act, and now he was not on any committee at all. They had been frustrated and opposed on all sides. He felt that this motion as originally worded and confined to general practitioners might lead to division, and to add the phrase "and consultants" was surely not asking for too much.

Dr. F. M. Rose (Preston) said that it was a little unfortunate that the position should be obscured by the reference to consultants. They had wanted in this motion to bring forward the principal issue. The circular from the Ministry of Health issued last November of which they complained was directed not against consultants but against general practitioners. He thought that every hospital management committee and every regional board should have one general practitioner. Of course it was agreed that the consultants also should have adequate representation, but he did not think the present motion should be watered down.

Dr. Rowland Hill (Marylebone) said that he did not want to leave a suspicion that there was any disunity in this matter as between general practitioners and consultants.

Dr. R. W. Rae (North Staffordshire) urged that the resolution be passed in the form originally proposed and that the reference to consultants be the subject of a later resolution.

Dr. Frank Gray (Council) said that as the Amending Bill was going through the House of Commons Mr. Bevan was told that he had got his Health Service in three separate sections and was asked what measures he proposed for co-ordinating them. He then said that it was the users of the Service—that is to say, the doctors—who would co-ordinate them. The three sections tended to develop separately without such co-ordination, and the proposal now made was to ensure that that did not go further. He hoped it was appreciated that they were not asking for this as a privilege but as a duty. General practitioners were heavily burdened already, and this was going to add to their burden; but they accepted it because they were convinced that it was essential that there should be one health service and not three health services.

Dr. H. N. Gregg (Coventry) urged that general practitioners and consultants must stand together on this question. He spoke as a general practitioner who was on a hospital management committee.

Dr. S. Wand (Chairman of the General Medical Services Committee) said that strong representations had been made to the Ministry on these lines and it had been made clear that general-practitioner representation must not be at the expense of the consultant. They had been promised a circular letter, and he believed that much of the ill effect would be eliminated when that circular letter was issued.

After some further discussion the motion by Preston was put to the meeting in the following form:

That this meeting views with the gravest concern recent action taken by regional hospital boards to exclude general practitioners and other doctors from membership of the hospital management committees.

This was carried by a unanimous vote.

Medical Advisory Committees

Mr. J. H. Mayer (Tunbridge Wells) moved:

That this meeting considers that adequate representation of both specialists and general practitioners on all regional hospital boards and hospital management committees is essential for the good of the hospital service, and deplores both the present inadequate representation and the tendency further to diminish this representation.

He said that the debate on the previous motion made it necessary to say very little, but this motion emphasized the need for combined action by all branches of the profession in the administration of the hospitals.

Mr. A. Lawrence Abel (Marylebone) said that nothing had been forthcoming on the question of how the general-practitioner representation should be chosen. It was very important to watch these elections to the various committees. He moved to insert the words "by election or nomination by the profession"; also he would like all types of hospital included.

Dr. Rowland Hill pointed out that the Ministry had substituted the word "consultants" for the word "specialists," and technically there were no specialists.

Mr. R. L. Newell (Chairman of the Central Consultants and Specialists Committee) said that this motion raised very serious issues and he strongly supported Mr. Abel's amendment. Suggestions had been made in certain quarters that doctors should be excluded from management committees. Nothing could be more disastrous to the Service than to exclude them from some part of the management of the hospitals. He referred to a report in the *Daily Telegraph* on June 21 of the meeting of the Association of Hospital and Welfare Administrators at Southend in which it was stated that chief administrative officers wanted Mr. Bevan to withdraw from doctors and dentists the right to be members of hospital committees. There was an attempt to exclude medical men from regional boards, but how could this Service be run unless the boards had advice from all sections of the medical profession?

Mr. J. T. Rice Edwards (Monmouthshire) spoke of the importance of having elected—not appointed—members of these boards.

Dr. W. N. Leak (Mid-Cheshire) said that it was quite time that the Minister acted reasonably in this matter and accepted the nominations put forward.

Dr. F. M. Rose (Preston) said that he would have liked a firm statement from the consultants that each regional board and management committee should have one general practitioner. In his view those nominated by local authorities, whether doctors or not, should be regarded as lay people and general-practitioner representation should be separate.

Miss Gladys M. Sandes (Marylebone) considered that there was a great drive to put hospital and medical staffs entirely under lay administrative control.

Dr. J. M. Gibson (Public Health Service) proposed a further amendment to bring in the words "all sections of the medical profession." This was a matter which concerned also medical officers of health.

Dr. C. Metcalfe Brown (Council) urged that they should do nothing as an Association which would convey the slightest suggestion that there was any lack of unity. He supported most heartily the representation on these bodies of the general practitioner and consultant, but there was undoubtedly a place also for the public health officer.

The Chairman of Council said that to use the expression "all sections of the medical profession" would leave opportunity for a very wide interpretation, bringing in orthopaedists, ophthalmic surgeons, and others. All the sections into which the profession was divided might claim representation. Whatever might be the appeal of the National Health Service, he thought they should get some other expression rather than "all sections of the medical profession."

Dr. J. Stanley Thomas (Stratford) referred to the case of teaching hospitals, where there were consultants in very large numbers. The election of a general practitioner was surely of importance and should be urged.

Mr. Lawrence Abel said that he was in sympathy with the request of the public health officers and was ready to agree to the modification of the resolution to include the phrase "and, where applicable, medical officers of health."

The resolution was then put to the meeting and carried in the following form: "That this meeting considers that adequate representation, by election or nomination by the profession, of consultants, general practitioners, and, where applicable, medical officers of health on all regional hospital boards and hospital management committees is essential for the good of the hospital service, and deplores both the present inadequate representation and the tendency further to diminish this representation."

Dr. G. H. Barendt (Southampton) moved:

That it is of the utmost importance that general practitioners be represented on every regional hospital board and that at least one be elected to the medical advisory committee of every hospital management committee.

They as general practitioners should work in the closest possible harmony with consultants, who were in effect their partners.

Certain amendments to this motion were put forward, and after some brief discussion, the hour for luncheon adjournment having arrived, the Chairman adjourned the meeting in order that in the interval the motion might be straightened out.

When the discussion on the motion was resumed there were more amendments.

Dr. W. Smith (Greenwich and Deptford) moved that the motion read as follows: "That it is of the utmost importance that each hospital medical staff advisory committee be approached to secure representation of general practitioners." He said that general practitioners on such committees could and did serve many useful purposes. They made for a proper co-ordination of the work of the hospital. Medical advisory committees were among the most important committees on which they as medical men could sit.

Dr. C. F. Mayne (Plymouth) said that a certain amount of misapprehension existed concerning these committees. In his own clinical area they had made a definite liaison between the clinical medical advisory committee and the local executive council through the local medical committee. The local medical committee had nominated a general practitioner to serve on the advisory committee, and in its turn the advisory committee appointed a member representative of hospital medical staffs to serve on the local medical committee. The arrangement worked well, and the same thing could be done in all areas. He believed that machinery already existed for the purpose.

Mr. C. Hope Carlton (Westminster and Holborn) said that during the last two years he had spent much time sitting on three group medical advisory committees. The medical advisory committee was such a keystone in the building up of the hospital service that it must not be disregarded. Hospitals were suffering now from a diminution of *esprit de corps*. The reason for this was the policy of the Government, which was to exalt the group at the expense of the individual hospital.

In practice two types of committee functioned in London. One was elected by the consultants of the group of hospitals, who might come from 20 different institutions of the most different types. The other was the advisory committee, which was regarded by the hospital management committee as a sub-committee of that body, with a member of the management committee as its chairman. He thought the motion now before the meeting was tinkering with the subject. The Minister should be called upon to lay down the status, procedure, and powers of these bodies.

Mr. J. C. McMaster (West Somerset) said that he was by no means clear what was meant by the medical advisory committee. In the South-western Region hospitals had medical staff committees, not medical advisory committees. A region was divided into clinical areas and each clinical area had a clinical advisory committee. This was not statutory but it had the blessing of the regional board, and it seemed to him that that was the one on which the general practitioner should be represented.

More amendments were proposed, but Dr. H. Guy Dain, who was temporarily filling the chair for the meeting, suggested that all the amendments meant much the same thing and that the form of words now before the meeting might very well be adopted.

The motion in the following form—

That it is of the utmost importance that each hospital medical staff advisory committee be approached to secure representation of general practitioners.

—was carried and passed on to the General Medical Services Committee for its information and action.

On the motion of Dr. Rowland Hill (Marylebone) a recommendation was carried that the Minister should instruct hospital medical committees to recognize and employ local medical committees as advisory bodies in relation to general practitioners and their work.

Dr. Dain said that the meeting would wish to congratulate Sir Henry Cohen, President-Elect of the Association, Dr. Gregg, the Chairman of Council, and Dr. C. O. Stallybrass, chairman of the Liverpool Local Executive Committee, on the honorary

degrees which had been recently conferred upon them by the University of Liverpool. (Applause.)

Refresher Courses

Dr. W. Woolley (Bristol) moved to urge the Minister of Health to amend the regulations governing grants for refresher courses in order that full-time assistants might be eligible for grants. He said that the Minister had been approached by the directors of postgraduate study asking him to change his regulations in order to allow assistants to have grants. They in Bristol felt that the more people who tackled the Minister on any problem the more likely they would be to obtain a result. It might be said that assistants were normally men who had been qualified for only a short time and therefore were not in need of refresher courses. But there were quite a number of men who had been qualified for several years and still remained assistants. Why should there be that differentiation between principal and assistant? If he himself as a principal could obtain a grant, why not his assistant?

Dr. S. Wand indicated his readiness to accept this motion.

Dr. H. S. Howie Wood (Isle of Wight) moved that week-end refresher courses organized by London teaching hospitals should also rank for grant to the practitioner. They should be recognized in exactly the same way as those organized by the Ministry of Health.

It was agreed that this resolution be referred to Council.

Vaccination and Immunization

Dr. O. B. Lean (Northamptonshire) moved that the agreement reached on the fees for vaccination and immunization was not satisfactory in that no fee had been agreed for reports on re-vaccinations which were unsuccessful. His Division felt that this agreement was yet another example of "too little and too late." The general practitioner had always been written down. It would have been better to revise the terms of the agreement with some improvement. He hoped there would be an end of general practitioners waiting for crumbs from the rich man's table.

Dr. Wand said that this re-vaccination problem was rather new. It came forward particularly in the recent epidemic of smallpox at Glasgow. When the terms were agreed by the committee they had in mind a re-vaccination of infants. Now they had the case of the adult who had been vaccinated in infancy and was re-vaccinated and it did not "take." He thought most of them would feel that in the majority of such cases re-vaccination was unnecessary. On that issue they would take it back to the Ministry, point out the anomaly, and see what could be done about it.

The Minister's Undertakings

Dr. R. Cove-Smith (Marylebone) moved that the meeting call upon the Minister to make good his undertaking to adjust the remuneration of urban and rural practitioners in accordance with the recommendations of the Spens Committee, to provide suitable health centres, and to organize adequate clerical assistance for practitioners. This motion was a reminder of how many things still required fulfilment. The figures for practitioners' remuneration had not yet been agreed by the Minister. What other profession would go on working for two years continuously without having their salary properly adjusted? On the question of health centres it was realized that this was a difficult problem at the moment, but there was a possibility of the adaptation of present buildings to this end. The greatest need was for diagnostic centres. These would increase the confidence and morale of the practitioner and would be of great benefit to the patient by giving him the possibility of a more rapid diagnosis, and it would ease the strain on out-patient departments. As to organized clerical assistance, at present doctors' wives were co-opted as "full-time receptionists" on behalf of Mr. Bevan. The Minister should be reminded again and again of his unfulfilled promises.

Dr. G. O. Barber (Mid-Essex) moved to add the words "and press local authorities to provide accommodation for group practices." All over the country there were groups of general practitioners who had taken the bull by the horns and had acquired or rented existing premises and had altered them so as to provide good consulting-rooms, and had arranged rosters for night duty and week-ends. There were other doctors who wished to do the same, but were afraid of the initial capital outlay. This amendment would place the obligation on local authorities to provide such premises in which four or six doctors could be in one consulting block.

Dr. Cove-Smith accepted this addition to his motion.

The Chairman of Council said that he was completely in sympathy with the object behind this resolution, but he had a certain overhanging anxiety on this mode of presenting the issue. In certain large towns there were people connected with the public life of the town who were anxious to press for the hurried setting up of centres which they described as health centres, and who would almost advocate taking over any place they could get. It would be a thousand pities if as a result of pressure brought to bear upon local authorities a number of pseudo-health centres were set up under the guise of helping group practice. Having ventilated the subject it might be wise to allow the Council to deal with the matter and to see that it was presented in such a way that the unfavourable results he had suggested did not arise.

Dr. G. Priestman (Bradford) thought the starting-point of diagnostic centres was a good one, and he hoped the matter would be referred to Council for consideration. Dr. A. C. E. Breach (Bromley) was a little chary of the words which Mid-Essex proposed should be added.

The motion as amended was carried.

On the report under "General Medical Services" as a whole, Dr. E. B. Smith (Nottingham), referring to the paragraph relating to the medical examination of claimants to unemployment benefit, said that he noticed that for the additional work or responsibility entailed there was no reference to fees. It was time that the tendency of Government departments to accept the services of general practitioners without fee should cease.

Dr. Wand said that the paragraph to which attention was called was just an intimation of the fact that the Minister had given a more definite instruction that this consultation with the general practitioner should take place. The doctor had not got to fill in a form or afford any information he did not think necessary.

The Chairman of Council said it was only fair and right that the meeting should realize that with regard to these examinations, which were conducted by examining officers on behalf of the Ministry of Labour, when the form was sent to the doctor giving him the opportunity, if he so wished, to make some communication on it to be laid before the examining officer, he was entitled, if he asked for it, to a copy of the examining officer's report.

Dr. W. A. Hyslop (Leeds) raised the question of the dispensing capitation fee, and Dr. Wand said that the Rural Practitioners Subcommittee was at present making an investigation on this and cognate matters.

Dr. Wand also stated that an addition had been made to the pensions and insurance scheme. It had been possible to negotiate a scheme of pensions for their employees such as their dispensers and secretaries. It was possible to provide for them at a very reasonable annual payment. It had been embarrassing, being eligible for superannuation themselves, to find that there was no scheme for their employees.

The General Practitioner's Burdens

Mr. A. Lawrence Abel (Marylebone) moved:

That this meeting believes that the future of medicine is being placed in jeopardy by the fact that many general practitioners are suffering from overstrain and financial worry and are deprived of any cause for pride and satisfaction in their work.

General practitioners, he said, had inadequate time for the proper examination of patients. He had lately asked many doctors who had brought cases, "How often do you have time to examine a patient?" Some of them replied, "You don't know how we have to run our practices." One of them said that he saw 80, and another 120, patients in a couple of hours. Many doctors told him they thought they were becoming sorting agents for sending cases to hospital, and the patients came back from hospital as cases rather than as patients.

Dr. Wand said that they had expressed many sentiments regarding the quality of their work, and the danger to that quality, because of the burden and frustration placed upon them. He had been struck by the fact during that Representative Meeting that every speaker who had suggested some improvement had been applauded. Every doctor in the country was concerned with only one thing regarding his profession, and that was to do better and better doctoring, and to be given more opportunities to that end. He could not see how a resolution of the kind that Marylebone had proposed would help, and he thought it might be best to proceed to the next business.

Dr. D. M. Hughes (South-west Wales) said that it was not true that the vast majority of doctors did not examine their patients. He supposed that the trend to-day was to examine them less than used to be done, but this deterioration in the standard of general practice did not take place when the National Health Service came into being; it had begun to occur long before that. He thought that general practitioners should make a point of carrying out what examinations they thought fit and doing essential treatment. If the surgery lasted for a couple of hours longer the patients would realize that the doctor was concerned with the genuine need of his patients, and those who had come to the surgery frivolously would become tired of waiting and would leave.

The meeting agreed to proceed to the next business.

Dr. W. M. Knox (Glasgow) moved:

That a fundamental requirement to secure a satisfactory status for the general practitioner, and thus to improve the Service, is a reduction in the maximum number of patients permitted with a corresponding increase, if necessary, in the capitation fee to implement Spens.

There was no doubt, he said, that there was a vast amount of overwork on the part of the general practitioner, and the motion was designed to put forward a remedy for that. The motion had been debated recently at the Special Conference of Local Medical Committees and had then been rejected, chiefly on the ground that, as the conference had been called to deal very largely with the question of increased remuneration, the motion was not strictly relevant, but he did not think that was a true reading of the situation.

As a member of the Spens Committee he could assure the Representative Body that it was never envisaged by any member of that committee that the basis of remuneration of the general practitioner should necessitate gross overwork. One of the important paragraphs of the Spens report was, in his opinion, a short one which stated that when the new Service was introduced the general practitioner must have time for reading, study, and recreation. At the moment, if a doctor was to earn a reasonable income he had no time for any of those things. His remuneration, so far as the Minister was concerned, was obviously based on the maximum amount of work that could be done under the Act and not on a reasonable amount of work. The solution of the problem lay in a curtailment of the maximum number of patients which a practitioner was allowed to take, together with an increase in the capitation fee, in order to implement the findings of the Spens Committee and to bring about the spread that was envisaged by that committee. In that way there would be a redistribution of the work, an improvement of conditions for the junior members of the profession, and an easement for the senior members, who were now overworked.

He was fully in agreement with the view that the general practitioner should have access to hospitals and should take part in the management of hospitals and in the work of the regional hospital boards; but how was it possible for a doctor who was working at full pressure all day to carry out such duties? The general practitioner should have to do only a reasonable amount of work to make a reasonable income and should have time for study and recreation; in his opinion the only way in which that state of affairs could be brought about was by a reduction in the number of his patients.

Dr. W. Fulton (Glasgow), in supporting the motion, said he thought that the only way in which general practitioners could regain their status and standing in the eyes of their specialist colleagues and the public was to do their work better, and they could do it better if they had more time to devote to it. One point which might appeal to the Minister was that if the general practitioner did better work there would be fewer patients sent to hospital, so that hospital costs would be reduced. Some specialists said that patients were being sent to hospital who could have been quite easily diagnosed in another five minutes by the general practitioner. The improvement of the Service was a matter which was very dear to the heart of the Minister, and from that point of view the proposal might appeal to him.

Dr. Wand said he hoped that the question of a reduction in the maximum number of patients would be left over for the present. If persisted in, it might eventually mean such a levelling out that the profession would be forced into the position of a salaried service, with all the disadvantages that would bring to the patient. He hoped that the Representative Meeting would concentrate upon the remuneration issue as put forward on the previous day and not deal with anything else until that matter was satisfactorily settled. He hoped therefore that the meeting would not force the hands of the Committee in a way which might react disadvantageously on the main issue.

The meeting agreed to pass to the next business by 200 votes to 100 (the bare two-thirds majority required).

Provision of Diagnostic Facilities

Dr. F. M. Rose (Preston) moved that the Representative Body reiterate its demand for the provision of *x*-ray and laboratory facilities directly available to the general practitioner, either in hospital or elsewhere. This proposal, he said, was not a new one. It had been the policy of the Association for several years, yet regional hospital boards had circularized hospital management committees in their areas stating that the policy of the boards was that these departments in hospitals should be kept closed. Some of the hospital management committees had been more enlightened than their boards and had maintained open departments. The closing of the departments was in fact ineffective, because the cases which would have been referred direct were sent in a circuitous way through consultative clinics and reached the department some 10 weeks later.

It had been stated that in many areas the departments could not stand the strain if they were open to the general practitioner, but if the work that went through an *x*-ray department was analysed it would be found that the general-practitioner work was probably not more than 10% of the total work done, and in the case of the laboratories the proportion was probably only about 8%.

It was felt that if the general practitioner was to continue to maintain his present high standards he should have the services in question directly at his disposal, so that he could investigate a case thoroughly before deciding what he should do with it. He was the man in charge of the case, and he should not be forced into an unwanted consultation just because he could not get pathological or *x*-ray facilities otherwise. It was in the interests of consultants that there should be in their area general practitioners who took an interest in the clinical problems which were presented to them and who could examine a case and offer a reasonable opinion about the diagnosis. They could do a large amount of the work which was at present burdening the out-patient departments.

Dr. Ff. Roberts (Cambridge and Huntingdon), speaking as the senior radiologist of a hospital, said that last October the Local Medical Committee applied for *x*-ray and laboratory facilities to the medical committee of the hospital, and that committee, without consulting him, said that the diagnostic *x*-ray department was not large enough for general practitioners to send their patients there as a general rule but that the matter might be considered when the department was enlarged. He protested against that decision being made without his having been consulted, but his protest was completely ignored. Although he went to see the chairman of the medical committee on the subject the committee refused to alter its decision. He then wrote to the Minister of Health, who put him into touch with Sir John Charles, but in spite of repeated assurances that steps would be taken in the matter nothing had yet been done. Apparently the answer to the question

whether the Minister wanted patients to have treatment promptly was that he did not care about the patients; he only cared about whether the Service appeared to his supporters to be working satisfactorily. Dr. Roberts amused the meeting greatly with his account of the prolonged correspondence on the case.

The Preston motion was carried unanimously.

Dr. H. H. D. Sutherland (Kensington and Hammersmith) moved:

That where facilities are not already available, and as a temporary measure, this meeting is of opinion that for a satisfactory medical service it is essential that centres should be established to provide the general practitioner with such ancillary aids to diagnosis and treatment as pathological laboratories, *x*-ray facilities, and a physiotherapeutic department.

General practitioners, he said, could not go on waiting from six to nine months for these facilities, which were required for ordinary cases such as the tuberculous patient, the pregnant woman, the man who sustained an apparently simple injury at work, and so forth. There were a number of places where this work could be done for general practitioners. For instance, a retired pathologist who still had his own laboratory could do it, and in the larger towns there were various places other than hospitals where it could be carried out.

Dr. T. F. Tierney (Marylebone) said that he was a radiologist on the staff of four hospitals, and if he wished to take patients from general practitioners nobody could prevent him doing so. At the largest of the four hospitals, which was a teaching hospital, he did not accept cases from general practitioners unless they were referred to him personally, because the department could not cope with any more work than it was at present doing. He was sure he was speaking for the majority of hospital radiologists when he said that they were anxious to take cases direct from general practitioners, and he did not think that the hospital authorities would stand in their way; but they did not possess the facilities for dealing with the cases.

Dr. H. Barbara Woodhouse (Harrow) said that a general practitioner in Harrow, who for many years had had his own *x*-ray plant and had done radiological work, had written to various authorities, six months before the inception of the National Health Service, to find out how his equipment could be used under the Service. Although he was told that the equipment was good and adequate, he was also told that a place could not be found for him in the Service. It therefore did not appear to be a fact that there were not enough radiologists or equipment for the work to be done.

Dr. S. Smith (Tower Hamlets) said that in his Division a series of clinical meetings had been held, one of which had taken place at the local hospital, and during the course of that meeting the general practitioners and pathologists discussed the question of facilities, as a result of which both the laboratory and the *x*-ray department were thrown open to general practitioners, who were given direct access to them. It seemed to him that a good deal could be done by friendly chats between the local divisional secretary or the local medical committee and the hospitals concerned.

Dr. W. Smith (Greenwich and Deptford), speaking as a pathologist, said he would welcome general practitioners having access to pathological laboratories, but at the present time there were many hospitals which had not adequate pathological facilities even for their in-patients, who, he would suggest, must be given priority. Last year the Representative Body had agreed that the use of such facilities should be extended as they became available, and additional facilities were becoming available every month.

Dr. D. M. Hughes (South-west Wales) said that in 1940 the Ministry of Health established a laboratory in a county town nine miles away from where he lived, and it had been of so much help and interest to the general practitioners in the district and had helped them to raise their standards of practice so much that he thought such facilities should be extended. He strongly supported the suggestion that wherever these were available general practitioners should be encouraged to make use of them.

Dr. Sutherland said that although the Ministry had set up its laboratories they were not sufficiently on the spot to cope with all the work, and there were facilities elsewhere—e.g., men who had their own *x*-ray plant—which were not used. This proposal of Kensington and Hammersmith was designed to bring out the "little ships" when the "big ships" were very fully burdened.

The motion was carried.

A motion by Trowbridge asking that until there was a great improvement in facilities the proposed elaborate routine examinations of hospital nursing and domestic staff should not be carried out was negatived.

Anaesthetics in Midwifery

Dr. P. A. McCallum (Torquay) asked the Council to press for an alteration in the Ministry ruling that one anaesthetic fee should be payable for one confinement. The Ministry rule was an example of the Civil Service mind. The judgment of the doctor in these cases should surely be trusted.

The motion was carried.

Obstetric Beds

Dr. Watney Roe (Chelsea and Fulham) moved that the Ministry be asked to instruct hospital boards to arrange for obstetric beds in maternity homes and hospital wings to be placed at the disposal of general practitioners where none were now available. If Manchester could do this, why not London? The beds he was asking for were general-practitioner beds, entirely separate from those under the gynaecologist or obstetric specialist. General practitioners were asking only for the return of patients who had been taken from them.

The motion was supported by Dr. I. G. Innes (East Yorkshire), who related some experiences in the East Riding, and Dr. A. C. E. Breach (Bromley), who proposed the addition of the words "in adequate number," which was accepted.

Dr. H. S. Howie Wood (Isle of Wight) called attention to the fall in incomes of general practitioners brought about by the increasing number of expectant mothers who entered hospitals where they would not be attended by doctors of their own choice. One of the questions to which great importance was to be attached was the status of the general-practitioner obstetrician. Surely such a man should be recognized as able to conduct confinements in approved nursing-homes or maternity blocks in a hospital. In his area it was proposed to start a training school for midwives, and apparently one of the conditions was that all the births in the Isle of Wight attended by these women should be conducted in maternity blocks of hospitals. Practitioners who were to be excluded from having their cases in these beds were naturally perturbed.

The motion was carried.

Superannuation Contributions

Dr. A. G. Holman (East Norfolk) asked the meeting to express the opinion that the 8% contribution by the Ministry towards superannuation payments should be payable to general practitioners or their dependants in the case of retirement or death before the requisite 10 years' service had been completed, and that the recent concession whereby hospital medical officers were allowed to count their previous service towards the necessary 10 years to qualify for pension should be extended to general practitioners from the time when they started National Health Insurance work. A similar motion was brought before the recent Conference of Local Medical Committees, and Dr. Wand had said that the scheme was actuarially sound. It was certainly actuarially profitable for the Government.

Dr. Wand said that actuarial advice had been taken throughout the whole of the negotiations on superannuation, and they were assured that the scheme was actuarially sound. Certain improvements in the scheme had been obtained since it was first put forward. At the Special Conference he had given an undertaking that he would look into the matter even further to see if yet other improvements could not be made. Dr. Holman was well aware that he had given that assurance, and when he gave such an assurance he meant what he said.

Dr. E. C. Warner (Marylebone) said that a certain concession had been given to consultants in this respect, and it seemed only fair that a similar concession should be given to those in general practice.

Dr. Holman said that the fact that he brought forward this motion again at the present meeting did not in any way mean that he doubted Dr. Wand's undertaking.

The motion was carried.

Medical Benevolence

In moving approval of the portion of the Council's report under this heading Dr. Janet K. Aitken (Council) said that the details of the moneys received were given in the report. It was 25 years since the B.M.A. Charities Trust Fund was established. In its first year it allocated £45; last year the amount was £4,250.

This part of the report was approved.

Elections

During the day it was announced that Dr. J. A. Brown had been elected Chairman of the Representative Body without a contest, and that after a contest Dr. S. Wand had been elected Deputy Chairman.

The meeting adjourned at 5.30 p.m.

SATURDAY, JULY 15

The Representative Meeting opened at 10 a.m., a meeting of Council having been held at 9 a.m.

The War Memorial

The debate on the Association's war memorial, adjourned from Thursday, was resumed.

Dr. W. Radcliffe (North-east Essex), in moving that the design of the memorial be referred back to the Council, said that until the representatives saw the model on Thursday few people had seen the design which had been approved by the Council. The Representative Meeting last year had given the Council permission to hold a competition for the design, to appoint assessors, and to initiate an appeal. Why had there been no illustration of the design in the *British Medical Journal*? It should be remembered that the widows, mothers, and children of the men to be commemorated would make pilgrimages to the memorial for many years to come and that the design was one which they would consider worthy. He thought that the memorial would be greatly improved by some flowers, which would introduce colour into the courtyard.

Dr. H. S. Howie Wood (Isle of Wight), in supporting reference back, said he was sure the representatives would agree that it was essential that the design of the memorial should be non-controversial.

Dr. W. E. Dornan (Sheffield), in opposing the motion, said that anatomy might not change but fashions in the human form certainly did. He thought that the general effect of the proposed design, as viewed through the gates, was most pleasing.

Dr. J. B. W. Rowe (Harrow) said that he liked the lay-out of the design but he did not like the figures, and he supported reference back as far as the figures were concerned.

So far as the inscription was concerned, for which Dr. Dain had invited suggestions, he noticed that there was room for only 68 letters, so the inscription would have to be very short, and he would like to suggest that it should be taken from the writings of some medical poet, such as the late Poet Laureate, Dr. Robert Bridges.

Dr. J. R. M. Sangster (Lewisham), in opposing reference back, said that so far the Association had a clean record in artistic matters. The Epstein figures on the Association's old building in the Strand were no disgrace to the Association and were still examined with interest by serious students. All art was modern art in its time, and all serious art was modern art. Mr. Woodford had done his best to interpret the Association's wishes and should, he suggested, be asked to proceed with the work.

Dr. Dain, in replying to the discussion, reminded the Representative Body that at its meeting last year it had decided that the memorial should take the form of a fountain and had given the Council authority to engage experts as assessors. The Council had done so, and, on the advice of those experts, had selected three sculptors of repute to send in designs. After carefully considering the three designs, the assessors had unanimously recommended that the design by Mr. Woodford should be accepted, and the Committee had accepted the assessors' report and presented it to the Council, which had approved it. Mr. Woodford was quite ready to receive suggestions with regard to the figures, and some such suggestions had already been made to him. Some criticisms had been made about the anatomical accuracy of the figures, but he had been assured by some experts on the subject that there were no anatomical distortions in the figures as presented. He might mention, in conclusion, that the appeal for funds for the memorial had been issued only a week ago and that £3,000 had been received by last Wednesday.

The reference back was lost by a large majority and the report was approved.

GENERAL MEDICAL SERVICES (RESUMED)

National Formulary

Dr. W. Radcliffe (North-east Essex) moved that the approximate cost of each prescription in the *National Formulary* should be printed in future editions or in a supplement to the present edition. The object of this, he said, was to try to effect an economy in the cost of the drug bill by teaching the young men leaving hospital and, more important still, those still in hospital, and reminding other members of the profession, of the cost of the various prescriptions and drugs in the *National Formulary*.

Dr. A. B. Davies (Walsall and Lichfield) said that there had undoubtedly been a vast increase in the number of prescriptions under the National Health Service Act, and he suggested that at least some of the responsibility for this rested on the Minister, who at the inception of the new Service had promised the public that the sky should be the limit. The three main causes of excessive cost in prescribing were to be found in the quantities prescribed, the frequency of prescribing, and the use of proprietaries. At the last meeting of the Representative Body there had been much criticism of the new *Formulary*, and it had been said that because of its inadequacies there was a necessary call for the prescribing of proprietaries. The Formulary Committee was now endeavouring to reduce the cost of prescribing by introducing a complete range of pleasant flavourings, colourings, and blendings, and it was hoped that when the new *Formulary* was issued in May, 1951, doctors would make greater use of it.

There was already material—the green book which was issued by the Ministry from time to time, the *Formulary* itself, and a list of drugs which had been issued—which practitioners could use in scrutinizing their cost of prescribing. He would suggest that the motion should be referred to the General Medical Services Committee, so that that Committee could in turn delegate the matter to a new subcommittee which was to be set up to examine prescribing.

Dr. S. Wand said that he would accept the motion as a reference to Council. It was a new and interesting suggestion and therefore needed careful consideration.

Dr. Radcliffe agreed that the motion should be referred to the Council.

Provision of Medicine for Private Patients

Dr. H. H. Goodman (Newcastle-upon-Tyne) moved:

That, in the opinion of this meeting, private patients are entitled to free medicines and appliances.

His Division, he said, considered that this matter was so important for the survival and resuscitation of private practice that it should continue to be pressed upon the Minister. It was surely wrong to deprive a certain section of the community of something for which they had paid, and private patients paid just as much as anyone else by way of contribu-

tions and more than others by way of taxation. The real reason why private patients were not allowed free medicines and appliances was that the Government was afraid to allow private practice to compete on equal terms with the National Health Service.

An amendment by Bournemouth to add the following words to the motion, "and this meeting instructs the Council to continue its efforts to get this principle accepted and implemented by the Government," was accepted by Newcastle, and the motion, as amended, was carried.

Certificates from Other than Medical Practitioners

Dr. J. A. Gorsky (Westminster and Holborn) asked the meeting to express its disquiet at the absolute power possessed by the determining authority under Section 43 (3) of the National Insurance Act, 1946, and Clause 2 (1) of S.I. 1948, No. 1175, to accept certificates or other evidence of incapacity for work for sickness benefit claims from persons other than registered medical practitioners. He declared that such procedure did not allow for safeguards against abuse, lowered the status of medical practitioners, and was inconsistent with Section 37 of the Medical Act, 1858.

It would, he said, be a tragedy not only for the profession but also for the nation which it served if the public were left with the impression that, once the matter of remuneration was settled, all would be well with the National Health Service. The medical profession was threatened with encroachments on the ethical and professional freedom of its members and could not tolerate any further degradation of medicine into a State monopoly.

Unqualified persons were permitted to sign certificates entitling people to sickness pay out of National Insurance funds. If this was permitted and allowed to continue, it would be impossible to tell where the process would end. There would seem to be nothing to prevent anyone putting up a brass plate and calling himself an osteopath, a chiropractor, or a Christian Science practitioner and selling certificates to any insured person who wanted to enjoy a period of paid idleness. He had in his possession a card issued by an institute which set out a list of conditions "successfully treated at the institute," including rheumatism, fibrositis, sciatica, obesity, migraine, and high and low blood pressure, and which stated: "Certificates under the Health Service are obtainable for sick benefit."

General practitioners had lost their liberty because they had relaxed their vigilance, and it was vital now that they should strengthen their vigilance if they wished to retain what they had left and to recover what they had lost of their professional liberty.

Section 37 of the Medical Act, 1858, stated that no certificate required by any Act from any physician, surgeon, licentiate in medicine and surgery, or other medical practitioner, is valid unless the person signing the certificate is a registered medical practitioner. That section had not been repealed in the Ninth Schedule of the National Insurance Act, 1946, and therefore any certificate for the purpose of claiming sickness benefit must be given by a registered medical practitioner. Section 2 (1) of S.I. 1948, No. 1175, said that every person claiming sickness benefit must furnish evidence of incapacity in respect of the days for which the claim was made, by means of a certificate given by a registered medical practitioner "or by such other means as the determining authority may accept as sufficient in the circumstances of any particular case or class of cases." The Minister had given power to the officials who constituted "the determining authority" to accept evidence from persons other than registered medical practitioners for the purpose of obtaining sickness benefits, and, as that was repugnant to the wording of Section 37 of the Medical Act of 1858, the Minister was acting *ultra vires*.

Medical registration conferred on doctors a status with which were associated privileges and rights, but those rights imposed a correlative duty or obligation. A breach of those duties or obligations might bring them before the General Medical Council or the Medical Services Committee. It was of paramount importance to those who did the routine work of the medical profession to demand that their status should be safeguarded and not lowered to the standards of unorthodox practice. They could not tolerate with complacency a seemingly trivial unfairness or allow it to go unredressed, for the greatest tyranny had the smallest beginnings.

Did a registered medical practitioner lose his or her medical registration on becoming a Minister of the Crown? If not, was the Minister of National Insurance covering unregistered medical practitioners?

Dr. J. T. Baldwin (Lothians) said that complaints might be lodged against medical practitioners by various persons, including the Minister of National Insurance, in respect of irregular certification, and he believed that those complaints could be lodged only against medical practitioners whose names were on the lists of the local medical committees. It would appear, therefore, that an unregistered practitioner could not have a complaint lodged against him and was not subject to the procedure of the Medical Services Committee, and if he was unqualified he was not subject to the jurisdiction of the General Medical Council. Therefore it would seem that an unregistered practitioner, and particularly an unqualified practitioner, could continue to issue certificates without the possibility of any penalty being imposed upon him. That was an intolerable situation, and the meeting should therefore support the motion by Westminster and Holborn.

Dr. Wand reminded the representatives that the present position had existed since the beginning of National Health Insurance. (Cries of "Shame.") It had always been the right of patients to provide any evidence of incapacity that they chose and for the authority paying out the money—formerly the approved societies and now the Minister—to satisfy itself that the evidence was sufficient. Patients might choose to obtain medical advice from properly qualified medical practitioners or they might choose to obtain it elsewhere. The Ministry of National Insurance could accept the evidence received, it could refer a case to the regional medical officer, or it could decide to accept evidence from other quarters. He asked the representatives to consider the implications carefully before voting on the motion.

Dr. Gorsky, in reply, said he would like to point out that the money in question was public money and that before 1948 the Ministry of Health controlled all insurance, but now there was another Minister for it. Dr. Summerskill had said in the House: "I have no authority to issue directions to these determining authorities." The determining authorities had absolute power to accept the certificates. The only person who could refer a case to the regional medical officer under Section 43 was the determining authority, not the Minister of National Insurance. He did not object to complete freedom, but he objected to the freedom which enabled an unqualified practitioner to advertise for patients and to sell certificates.

The Westminster and Holborn motion was carried by a large majority.

THE ASSOCIATION OVERSEAS

Mr. J. L. Gilks (Zanzibar) moved the report under "Overseas." He referred to the work of the Association in securing new salary scales for colonial medical officers. He said also that the Council had continued to take an active interest in the affairs of the overseas Branches. Early in the year one of the Assistant Secretaries (Dr. Grey Turner) paid a very successful visit to the West Indian Branches, and an immediate result had been that the Council had called a meeting of all the Caribbean Branches to take place next year, and was sending one of its elder statesmen, Dr. Dain, to preside over it. He was being accompanied by Dr. H. B. Morgan, a member of Council for the Caribbean Branches.

A number of representatives from Overseas Branches then briefly addressed the meeting.

Dr. Douglas J. Thomas (Victoria) said that he spoke for all the States in the Commonwealth of Australia. Last December the Association fought and won an action in the High Court of Australia which prevented the then Government from enforcing their "free medicine" scheme, because that scheme contained some element of civil conscription.

Dr. J. E. O'N. Gillespie brought the greetings of the Cyprus Branch. They were very grateful for the improvements that the Colonial Medical Service effected as a result of the Association's work.

Dr. A. G. Davies (Tanganyika) said that their problems in East Africa were really the same as those in this country. "The conditions which you get in England and the standards you build up become ultimately our conditions and standards."

Dr. M. A. Gabriel-Jayamaha, a past president of the Malayan Branch of the B.M.A., brought the greetings of his Branch.

Dr. J. R. Gregory (Kenya), in a humorous speech, gave his impressions of the Representative Meeting as it struck a looker-on. There appeared to be a great deal of muddled thinking, which resulted in muddled publicity. Many speakers had been at great pains to explain that their only point of view was that of the patient, but their subsequent words seemed to belie that. They certainly succeeded in creating a wrong impression to judge by the headlines in some papers. That day's heading in one paper was "Frivolous Calls." Speaking as a private practitioner he could say that frivolous calls were in no way a monopoly of State medicine. He thought that they were talking too much about the falling status of the general practitioner. Never in the history of mankind had a people been better looked after by more highly educated men. The public read only the headlines and got the wrong impression. (Applause.)

Dr. O. A. Diethelm (New South Wales) spoke gratefully of the reception he had had in this country. One thing which impressed him was the almost complete unanimity of the profession. There was almost complete unanimity in the profession in Australia against an Act of the Government—the proposed National Insurance Act which was brought forward by the last Australian Ministry.

Mr. V. G. Griffiths (Malta) and Dr. A. C. Fisher (Northern Rhodesia) conveyed the greetings of their constituencies. Dr. Fisher said how much the *British Medical Journal* was appreciated in Northern Rhodesia. They looked forward with every mail to its coming.

Mr. A. Eisdell Moore, President of the New Zealand Branch, expressed his sense of gratitude to the parent body for the help it had afforded in that distant Dominion. He also expressed appreciation of the conferment of the Gold Medal on Dr. J. P. S. Jamieson, who had been a leader in New Zealand in the protest they had put up against the introduction of socialized medicine.

Mr. R. T. S. Goodchild brought the greetings of the Uganda Branch. They considered themselves an integral part of the British Medical Association, and they had recently had a visit from a very good ambassador of the parent body, Dr. Grey Turner, an Assistant Secretary.

The last of the overseas delegates to speak was Dr. P. T. O'Farrell, of Eire, who said how deeply the close association of the Irish Medical Association and the B.M.A. was appreciated.

The report under "Overseas" was adopted.

GENERAL MEDICAL SERVICES (RESUMED)

Distribution of Moneys in the Service

Dr. J. L. McCallum (Westminster and Holborn) moved to express the dissatisfaction of the meeting with the present distribution of moneys voted by Parliament for the National Health Service as between hospital and general-practitioner services, and to urge that as a matter of policy for the promotion of the better health of the nation the Minister should devote a greater proportion to the front-line services and less to the services at the base. He said that this was not an attack on their colleagues in hospitals. It was, however, an attack on a Minister who prided himself on his administrative ability. They knew in the Association that what was wrong with the Service was its division into three parts, each competing for the money available. General practitioners were called by the Minister one pressure group within the whole structure of the Health Service. Of the total money expended on the Service the general practitioner received not more than 10%—a quite inadequate proportion in view of the work he did.

Dr. H. G. Dowler (Gloucestershire) said that the long-term requirement was to induce a better attitude towards general practice among medical students and their younger colleagues. The short-term requirement was surely an economic one. If more money was spent on general-practitioner services there should be shorter lists, more doctors in practice, and better work done. Unless something was done soon to improve the general-practitioner part of the Service it would be too late.

Dr. H. F. Moffit (North Glamorgan and Brecknock) supported the motion, which he thought went to the root of the matter. The National Health Service was out of balance. They wanted to get the balance put right. The Minister did not realize the quiet and efficient work of the general practitioner. He had a bias towards the more spectacular work of the hospitals.

Dr. Wand said that the Representative Body would realize that this was a very difficult problem, and he hoped that a final decision would not be reached without the fullest consideration in committee. He asked that the motion be referred to the Council. While it came under "General Medical Services" in the agenda the consultants and specialists ought to have something to say about it.

The motion to refer the Westminster and Holborn resolution to Council was lost and the motion was carried.

Negotiations with the Ministry

Dr. R. B. Allen (Consett (with Hexham)) moved that some attempt should be made to do away with the veil of secrecy which was habitually drawn over the negotiations with the Ministry of Health. Divisions wanted to have some information from Headquarters. He thought that Dr. Wand might consider making a confidential periodical statement for the information of their secretaries or members.

Dr. A. Barker (East Kent) opposed the Hexham motion, which he said suggested a lack of confidence in the General Medical Services Committee. They did not want to prejudice negotiations by premature disclosures.

Dr. Wand claimed that his committee had taken the profession into its confidence at every possible stage. The profession had been informed of all that had been done in negotiation. The effect of such a motion would be to make negotiations with a Government body absolutely impossible.

Dr. T. Rowland Hill (Marylebone), speaking as a member of the Joint Committee, did not feel really hostile to this motion. The Joint Committee at its last meeting had resolved to make public as frequently as possible a full report of the work it was undertaking.

Dr. S. Noy Scott (Plymouth) said that this complaint about secrecy came from members who never attended their Division meetings. It was impossible and often unwise to put everything in print.

Dr. Allen offered to withdraw the Consett (with Hexham) motion, but the meeting would not permit him to do so, and on a show of hands it was heavily lost.

A Question of Names

Dr. P. W. F. McIlvenna (Reading) moved that the title of the Committee be altered to the "General Practitioners' Committee," and that the Conference of Local Medical Committees be called the "Conference of General Practitioners." He held that this would make for more cohesion and would identify the general practitioner more closely with its work.

Dr. Wand pointed out that the committee did not represent all general practitioners, some of whom were outside the N.H.S., and their interests were looked after by the Private Practices Committee. The reason for the title "General Medical Services" was because that was the heading of the appropriate section in the Act.

After a brief discussion both motions were lost by a very large majority.

Dr. R. M. S. McConaghey (Torquay) moved:

That the Conference of Local Medical Committees be called the Conference of General Practitioners, and that, in view of the important part now played by such committees in moulding the future of general medical practice, every endeavour be made both centrally and locally to stimulate interest in, and to secure the election of suitable candidates to, local medical committees.

He said that in some areas practitioners had been given no opportunity of discussing Local Medical Committee work. The utmost information was necessary if there was to be a united profession.

This was carried as a recommendation to Council.

CONSULTANTS AND SPECIALISTS

Mr. R. L. Newell (chairman of the Central Consultants and Specialists Committee) introduced the report of Council under this heading.

He said that when he presented this report last year at Harrogate the terms and conditions for consultants had not been approved. There were many difficult outstanding items. The Joint Committee had entered into lengthy discussions with the Ministry and eventually decided that the necessary safeguards had been obtained. They advised that consultants on hospital staffs should sign permanent contracts. The reasons why they came to this conclusion were fully set out in this part of the Annual Report. He thought it was a wise decision of the Joint Committee, but they were still considering and discussing outstanding points with the Ministry. During the year they had appointed an executive committee which had done some extremely good work under the chairmanship of Dr. Rowland Hill. If the formation of the Central Consultants Committee had had only one effect, that of making the consultants attend the Annual Representative Meeting, it had proved its usefulness. Mr. Lawrence Abel had said at the representatives' dinner the other night that the autonomous bodies should act with the B.M.A. in all questions of major policy, and with that he was in full agreement. He regarded the relationship of the autonomous bodies to the B.M.A. in the light of a "Commonwealth of the British Medical Association."

Grading of Hospital Medical Staff

Dr. J. C. Wishart (Bromley) moved:

That this meeting is not satisfied with the composition of the former Grading Committees. Too many mistakes have been made. It recommends that another body, including general practitioners, be set up forthwith to re-hear appeals with a view to rectifying existing anomalies.

He gave instances of anomalies of grading, but said it was not in order to air grievances that this motion had been brought forward. Bromley hoped that the committee would use its influence to set up future grading committees on a better basis. They should press for the setting up of an independent body to hear appeals.

Dr. T. Rowland Hill (Marylebone) moved to add certain words:

"and urges the Central Consultants and Specialists Committee to take all possible steps to ensure that the promised review of grading is carried out in agreement with it upon methods and personnel."

He gave one example of mis-grading—that of a surgeon who had been for many years in general practice in a big South Coast town. The fact that he had been in general practice was the one thing that weighed against him. A very large proportion of the surgery of this country had been done by men in general practice. This particular man had been surgeon on the staff of his local hospital for 30 years and senior surgeon for five years. But he was still graded as "S.H.M.O." Yet he had referred to him by so-called consultants cases that the consultants themselves could not deal with. When the speaker tackled a member of the Grading Committee on this subject the answer was, "Oh, but he is a general practitioner and gets a lot as a general practitioner, so he does not need the money."

The amendment was further supported by Dr. L. A. Gibbons (Reigate), who said that a pathologist in his group was a specialist of 20 years' standing but was graded as "S.H.M.O." and his appeal was not allowed.

The Chairman suggested that it would be wise to leave out any reference to individual cases of mis-grading; they did not really help the matter at all.

Mr. J. C. McMaster (West Somerset) referred to the way in which some grading committees had discharged the duties entrusted to them. He thought that it constituted one of the most discreditable episodes in the history of their profession. A number of the original injustices were corrected on appeal, but many more were not, and many appeals were dismissed in a very arbitrary manner. Not only that, but a requested personal interview was often not accorded to the appellant. There was no evidence of any change of heart in recent months.

Dr. H. S. Howie Wood (Isle of Wight) said that the general-practitioner specialist in many instances had been let down. He realized this, because he had felt the bump. When the original applications were asked for he was invited to submit instances from his colleagues and he did so, but these were disregarded. The personal interview in many cases was asked for and not granted, and the appeals were turned down. He held strongly that they should ask for a review of all cases from the very beginning, even if the persons concerned were graded, not "S.H.M.O.," but were part-time specialists who had been graded "J.H.M.O." or "G.P."

The Chairman said that he was informed by the mover that the motion was intended to cover all grading.

Dr. J. B. Tilley (Newcastle-upon-Tyne) said that, with all deference to the Chairman, he would like to quote one individual case. In his Division there was a doctor who was working in the teaching hospital for the board of governors in the capacity of consultant. That same doctor worked in the hospitals of the regional hospital board in a similar capacity. Yet he had been graded "S.H.M.O."

Mr. A. Dickson Wright (Marylebone) said that this grading had been done regionally, and therefore there was a great lack of uniformity. Appeals had also been heard regionally with discordant results. When they approached the Minister in 1951 they should take a wide view on this subject and try to increase the number of specialist jobs so that there would be more vacancies for this vast army of men who were looking for work.

The Bromley motion was carried in the following form:

That this meeting is not satisfied with the composition of the former grading committees. Too many mistakes have been made. It recommends that another body, including general practitioners, be set up forthwith to re-hear appeals with a view to rectifying existing anomalies, and urges the Central Consultants and Specialists Committee to take all possible steps to ensure that the promised review of gradings is carried out in agreement with it upon the methods and personnel.

A rider by Worcester and Bromsgrove was carried in order to place beyond all shadow of doubt the fact that both general practitioners and specialists would be included in the review of grading.

S.H.M.O. Grading

Dr. K. C. Bailey (West Somerset) moved that the whole grade of S.H.M.O. should be discontinued at once and all advertisements in the *Journal* for posts in this grade should cease. He said that people had been graded not according to their personal merits but according to the convenience of the Service. This meeting was in the Floral Hall, but he could offer no bouquets to Mr. Newell or the Council for their dealings over the S.H.M.O.s.

Dr. M. Westwood (Gloucestershire) opposed the motion to abolish the grade. It had been a very useful grade and a link between the specialist and the general practitioner. He did not deny that some people had been put in the grade improperly, but on the other hand many of those who had been working in small hospitals in the past had been put in this grade and had been able to carry on very useful work.

Mr. Newell asked the mover to withdraw this motion. They were cognizant of the difficulties of the grading, about which they had been in constant consultation with the Ministry. They had almost reached conclusions following which there would be a great diminution in this class of position, and he hoped that when the report was published it would meet with general agreement.

Dr. Bailey could not agree to withdraw the resolution. He had in mind their colleagues who had been disgracefully treated.

The motion received little support and was negatived.

A motion in the name of Worcester and Bromsgrove drew attention to the electorate of regional committees. The electorate proposed consists of members of hospital medical staffs graded as consultants and S.H.M.O.s. Worcester wished to add the words "and general practitioners working in hospitals according to the terms of service." Dr. T. Rowland Hill opposed the addition of these words on the grounds of constitutional correctness, but promised that the Consultants and Specialists Committee would give consideration to this group. The motion was referred to Council.

Prospects for Specialists

Mr. Weldon Watts (Newcastle-upon-Tyne) asked the Council to consider urgently the future position of trainee specialists in view of the few specialist appointments available. Registrars of all grades were necessary in hospitals, especially in teaching hospitals, and if the registrar understood that there was no possibility of becoming a specialist it would bring about a rapid drop in numbers, and it would be difficult for hospitals to replace the registrars they lost. One expedient would be to create posts of the nature of hospital medical officers which surplus trainee specialists might take. Another possibility would be in the use of general-practitioner specialists. Registrars should know what their prospects were.

Mr. R. L. Newell said that the problem was partly due to the use of the term "trainee specialist." The whole Service became flooded with a very large number of registrars, who thought they had got on the first rung of the ladder. In this country a short time ago there were 5,000 registrars, with, possibly, 200 posts falling vacant each year. They might with advantage revert to the older terms of "R.S.O." and "R.M.O.," which would not necessarily imply a specialist appointment.

Dr. C. F. Mayne (Plymouth), in supporting the motion, referred to the hopeless position of many of the senior registrars in non-teaching hospitals.

The Newcastle motion on the subject was carried.

A further motion by West Somerset drew attention to the plight of many qualified senior registrars and instructed the Council to approach the Minister on their behalf.

Dr. T. F. Tierney (Marylebone) said that such a motion was too general in its terms. It should be worded in such a way as to discriminate between trainee radiologists and pathologists on the one hand and supernumerary registrars on the other. There were no supernumerary registrars in radiology.

Dr. J. M. C. Gill (Aberdeen and Kincardine Counties (with Orkney and Shetland)) said that in his area there were 75 specialists with 65 trainee specialists, and 300 general practitioners with only 10 general-practitioner trainees.

Mr. Newell said that he would willingly take this motion to his committee, but there were no data at the moment on which to work. It would be tragic to see these senior registrars turned off their hospitals without any alternative form of employment. Many of them were men of 30 or 40 with families.

The motion was referred to Council.

Dr. G. J. Meikle (Worcester and Bromsgrove) suggested that for a proportion of their period of office—say six months—senior registrars should be seconded to a peripheral hospital. At the peripheral hospital they would have a chance of showing the stuff of which they were made.

Dr. R. Cove-Smith (Marylebone) understood that the Minister had stated that he would be favourable to such interchange.

Mr. Newell said that his committee had already proposed such interchange between the hospitals in the region, but he would not care to tie the proposal down to a period of six months.

This motion also was referred to Council.

A motion by Worcester and Bromsgrove was agreed to urging that the arrangement concerning the apportionment of superannuation of general-practitioner specialists in partnership (para. 65 (*b*) of Annual Report) should be retrospective to July 5, 1948. Another motion from the same Division which was accepted was that medical records of hospital patients should be made available only to the Ministry of National Insurance with the knowledge of the consultant in charge of the case.

Medical Superintendents

Dr. E. C. Dawson (Derby, with West Derbyshire) moved that, if the agreed scale of remuneration for medical superintendents was not implemented in view of economy measures, alternative suggestions be prepared by the Council to make such an agreement operative in accordance with the accepted policy of the Association prior to acceptance of terms of service by consultants and specialists.

The Derby Division was concerned, he said, with a group of medical superintendents who did not come under the heading of consultants and specialists and had no opportunity to obtain consultant status. They were chiefly medical superintendents of the smaller hospitals, who had had to undertake a variety of work, and there were some in the larger general hospitals whose work had been mainly administrative. At the meeting of the Representative Body last year a motion had been passed to the effect that there should be a definite scale of remuneration for medical superintendents and that it should be £1,500 to £2,500 per annum, and that range had later been accepted by the Consultants and Specialists Committee; but when later on the terms of service of consultants and specialists were discussed with the Ministry it had been decided that the rate of remuneration for superintendents of general hospitals could be settled later. Then the economy cut had been introduced, and there had been a notice from the Ministry that no further increase of remuneration could be considered. His Division now considered that ways and means should be found of implementing the scale which had been agreed.

Mr. Newell, in supporting the motion, said that the Consultants and Specialists Committee had strongly represented the position of the medical superintendent to the Ministry. The question of their remuneration had now been referred, as were all questions of remuneration, to the Whitley Council. The proposals on the subject were now being considered by a subcommittee of Committee D, on which there would be direct representatives of medical superintendents.

Dr. F. Lishman (Bishop Auckland (with Durham)), in supporting the motion, said that the status of the medical superintendent had been definitely lowered by his being paid at the same rate as a secretary or assistant secretary for that part of the time when he administered the hospital. Good medical administrators were in short supply, and they should be paid rather more than those who were carrying out clinical duties.

The motion was carried.

Dr. R. B. Allen (Consett (with Hexham)), to cries of "Agreed," moved "That this meeting reaffirms its belief in the superiority of medical over lay administrators of hospitals." It was, he said, the long-term policy of the Ministry to take all administrative power and authority from the medical staffs of hospitals, and the Ministry was rapidly tending to achieve this by the appointment of lay administrators and by freezing out medical superintendents by underpaying them. A parallel case was to be found in the public health service, where town clerks and clerks of councils had been doing all they could to undermine the administrative authority of the medical officer of health. A medical superintendent was the only person who was capable of running a hospital in a proper way and the only person who was able to co-ordinate and fuse the requirements of the various departments. Moreover, he was the only person who, when it came to cutting down expenses, knew what was necessary and what could be dispensed with. The staffs of hospitals and the professional members of hospital management committees should see that medical superintendents were replaced when vacancies occurred. The loss of professional status involved in the continued advance of the Ministry's policy must be fought strenuously for the sake of the profession as a whole and particularly for the sake of those whose work lay within the hospital service.

Dr. T. Rowland Hill (Marylebone), in moving that the words "and that the influence of clinicians upon hospital administration shall be preserved" be added to the motion, said that the issue was a much wider one than that of the lay administrative officer *versus* the medical administrative officer. It was the issue of lay dominance *versus* medical dominance in hospitals. The greatest hospitals in the past had always been guided in their administrative policy by the advice of their clinicians, and that should continue. There was a danger now of its being submerged and the clinician's having no voice at all in medical administration or medical policy.

Dr. Allen agreed to the proposed words being added to the Hexham motion.

Dr. N. Strang (South Shields) thought that most of the representatives must have seen the effect on hospital administration of the medical superintendent being pushed out. The internal disruption of harmony which was seen in some hospitals was admitted by the various sections of the staff to be entirely due to the lay administration which had taken the place of the previous medical administration.

The motion as amended was carried.

Domiciliary Consultation Arrangements

Dr. S. J. Firth (Brighton) moved "That the quota system of domiciliary visits for consultants be abolished, on the ground that it operates against free choice of consultant by both patient and general practitioner."

The present quota system, he said, was bad for the patient, for the general practitioner, and for the consultant. Before the National Health Service came into operation general practitioners could have the services of any consultant they liked as often as they liked. Under the present system, long before the end of a quota period, the best consultants had used up their quota, and the general practitioner had either to get somebody in whom he had less confidence or ask the consultant of his choice to pay a domiciliary visit free. General practitioners did not like to ask consultants to do that, and he was sure that if the quota system was abolished they would get better service for their patients.

Dr. K. C. Bailey (West Somerset) moved as an amendment that the words "on the ground that it operates against free choice of consultant by both patient and general practitioner" be omitted and the following words substituted: "and that whole-time consultants continue to be readily available, as otherwise the free choice of consultants by both patient and general practitioner is impeded."

This amendment, he said, was intended to clarify the position of whole-time consultants. The consultants and specialists felt that the whole-time consultant should be called in only in the absence of any part-time consultant, and that was a disadvantage to the clinician who was interested in his work and wished to see his cases from the onset.

Dr. Doris Odlum (Bournemouth), in supporting the amendment, said she had never approved of the suggestion that the whole-time consultant should be put at the bottom of the list of consultants sent to general practitioners and that the general practitioner should not call in a whole-time consultant so long as a part-time consultant was available. That might mean that the best consultant for a case was not called in. She was in favour of the abolition of the quota system, but she was also in favour of equality of opportunity and calling in the best man for a case.

Dr. H. Barbara Woodhouse (Harrow) also supported the amendment. The medical practitioners in her area had not yet received a list with instructions as to whom they should call in and whom they should not call in, but they felt a certain amount of restriction owing to the fact that whole-time salaried consultants received no payment for the extra work entailed by domiciliary visits.

Mr. A. Lawrence Abel (Marylebone), in opposing the amendment, said it had been pointed out to consultants that they would be much better off financially from the income-tax point of view if they elected to do 9½/11 sessions instead of 11/11, as the Ministry had now given them permission to do. The amendment, he thought, meant something quite different from the Brighton motion. The consultants who were employed whole-time had already got their whole time filled up and had no time for doing domiciliary work in any event. The amendment was, he considered, a red herring drawn across the track of the motion, and it would lead to a full-time State salaried service in the lifetime of the present generation.

Mr. J. C. McMaster (West Somerset) said that Mr. Abel had not explained what was to happen to the whole-time consultant who had applied to become part-time on 9½ sessions and had been refused. What was he to do? If the Association did not approve of whole-time appointments, why did it countenance the reception of advertisements for whole-time appointments?

Mr. Newell said the Ministry had agreed that wherever practicable a whole-time consultant could apply for a part-time position, and in the area of his own regional board three people had so applied, and their applications had been granted.

The West Somerset amendment was lost, and the Brighton motion was carried.

Additional Whole-time Posts

Mr. H. H. Langston (Winchester) moved the following amendment to para. 69 of the Annual Report: "and that this meeting strongly disapproves of the practice of certain boards in refusing to grant consultants who were in whole-time employment before the appointed day the right to transfer to part-time appointments, and considers this contrary to the Ministry's assurance that it was not its intention to place difficulties in the way of private practice."

This amendment, he said, was a vitally important one. In spite of the Ministry's assurance the regional boards were in fact refusing the applications of whole-time consultants to transfer to part-time work. At the last meeting of one regional board part-time consultants were criticized, and the remark was made that "this pseudo-part-time employment, where a man is getting the best of both worlds, is one of the greatest sources of increasing expense in the National Health Service." The chairman of the board stated that the board's medical advisory committee had recommended that consultants should be allowed to change from whole-time to part-time status, but that the board was reconsidering the granting of that permission.

He submitted that consultants had the right to choose whether they would be whole-time or part-time.

Mr. Newell accepted the amendment, and it was carried.

Hospital Advisory Committees

Dr. T. Rowland Hill (Marylebone) moved:

That this meeting recommends that the traditional practice of the hospital boards being advised in all medical matters by an advisory committee composed of members of their own hospital staff should be perpetuated.

This matter, he said, was a very important one to the consultants. The system to which reference was made in the motion had produced a good spirit in the hospitals and was responsible for much of the vital growth of British medicine, and out of it had grown the conception of the consultant. The Minister and his officials had not shown hostility towards this practice, but they had displayed a complete ignorance of it; and in the negotiations with the Ministry it had not been possible to obtain more than a partial recognition of the system.

An amendment that the advisory committee should be strengthened by some general practitioners and public health medical officers in appropriate cases was accepted, and with this addition the motion was carried.

Hospital Out-patient Departments

Dr. A. Brown (Cambridge and Huntingdon) moved:

That this meeting considers that every effort should be made to restrict hospital out-patient departments to consultant work. The patients should be returned to the general practitioner at the earliest opportunity, except where he is unable to provide essential treatment.

It would be agreed, he said, that the general practitioner was primarily responsible for the patient, and when he sent the patient to hospital he did so for one of two reasons—to obtain a second opinion or to have some special investigation carried out. The time lag which took place in getting appointments for these patients increased the work of the general practitioner, because while the patient was waiting he had to be seen many times by the general practitioner. If patients were returned to the general practitioner at the earliest opportunity the new patients could be seen much earlier, and he thought that this should be done in all cases where the general practitioner could give the patient the necessary treatment.

Dr. R. M. S. McConaghey (Torquay), in opposing the motion, said it would mean that, if a general practitioner referred a case of whitlow to the hospital for opening, the patient would be returned to the general practitioner as soon as the whitlow had been opened, and he would do the dressings. He thought that when a general practitioner referred a patient to the consultant at a hospital he should say whether he wanted an opinion only or whether he wanted an opinion and treatment.

Dr. W. N. Leak (Mid-Cheshire) said that the authorities of the Merseyside Hospital Scheme had informed all their people within the last few months that they had now increased the benefits so that every patient who was attending an out-patient department and was off work would get an extra payment. That was an inducement to people to attend the out-patient department instead of seeing their own doctor, and he thought the Association should do its utmost to stop this kind of thing.

Dr. H. H. D. Sutherland (Kensington and Hammersmith) said that forms were issued by the Association to cover the case in which a doctor sent his patient to a hospital and asked for a special investigation, and the patient was returned to him except when in-patient or special out-patient treatment was needed. Those forms were still available.

Dr. Brown, in replying to the discussion, said that general practitioners in Cambridgeshire treated cases of whitlow themselves and did not send them to hospital. They sent patients to hospital only for a second opinion or for investigation or treatment which they could not carry out in their surgeries.

The motion was carried.

Private Patients in Hospital

Dr. P. J. Gibbons (Liverpool), in moving "That this meeting draws the attention of the Ministry to the excessive charges for private patients in hospitals and considers that steps should be taken to review these charges in accordance with the promise of the Minister," said that when medical practitioners entered the National Health Service two years ago they did so in the belief that private practice would form an integral part of the Service, but that position had been gradually undermined by the policy of the Ministry. The cost of beds for private patients in hospital had been increased to such an extent that it was almost impossible for any except the most wealthy people to have private treatment in hospital. A definite charge should be fixed, to apply to all private beds in hospitals, and that charge should be a moderate one.

Dr. H. W. Harvey (Marylebone), in supporting the motion, said that many patients who would formerly have had private beds in hospitals now had to go into the public wards. He had twice had to take them out of the public ward, not because they objected to being there but because they could not sleep without being given more opiates than was good for them.

The motion was carried.

Payment by Patients for Hospital Maintenance

Dr. H. Barbara Woodhouse (Harrow) moved to instruct the Council to make strong representations to the Minister through their negotiating body, with a view to instituting payments by hospital patients for their board up to £1 per week.

The course suggested in the motion, she said, would effect a very substantial economy in the National Health Service. In her own area there were very few people who could not pay £1 a week for their board in their own homes, and if patients in hospital were asked to pay only 10s. a week for their board it would mean a saving of £500 a week, or £26,000 a year, in a hospital with 1,000 beds. The National Health Service was widely advertised as a free health service, but it had never been advertised as a free hotel service. The present system created gross anomalies. It had been argued that if a bread-winner had to go into hospital and drew only his insurance pay it would create great hardship if he had to pay for his board in hospital, but if he had an attack of tonsillitis and was nursed at home he had to pay for his board there.

Mr. Newell said that the concern of the medical profession was with the medical running of hospitals, and he did not think that the proposal made in the motion was one which concerned the Representative Body.

The meeting agreed to pass to the next business.

Mileage Fees to Specialists

Mr. Weldon Watts (Newcastle-upon-Tyne) moved to urge the Central Consultants and Specialists Committee to press for an increase in the mileage fees paid to specialists in the National Health Service. He pointed out that if a specialist did less than 3,000 to 4,000 miles in a year he got 7½d. a mile, and if he did more than that he got about £1 a week plus 3½d. a mile. If a specialist did a big mileage, as many of them did, perhaps 11,000 or 12,000 miles, the £50 a year worked out at only 3,000 miles, and they were getting about 4d. a mile for the whole of their consultant work. This was very inadequate, and, moreover, the question of income tax entered into the matter, as the income tax authorities said that the consultant was being paid for his car expenses. If a consultant worked under the Ministry of Pensions and not in the National Health Service he got 1s. a mile.

Mr. Newell accepted the motion, and it was carried.

The Trainee Specialist

Dr. J. O. McDonagh (Perth) moved:

That this meeting considers that the trainee-specialist should undertake at least one year in general practice (*a*) to make him more fitted to train future general practitioners and (*b*) to give him a wider outlook on his own specialty and on medicine in general.

The representatives, he said, would have noticed that in the report on the training of tuberculosis specialists in the *British Medical Journal* it was suggested that a year in general practice should be part of the training. General practice was now becoming almost a specialty itself. It was often said that the general practitioners were the front line of medicine, and it was felt that these men in the front line were being trained by people who had no idea of the conditions in the front line. The trainee-specialist, although he would like to do a little general practice, dare not do so, because he was afraid of losing contact and being passed over. He thought that a certain number of trainee-specialists, after they had sampled general practice, would choose to remain in it.

The subject dealt with in the motion was a rather big one for the Representative Body to discuss now, and he would be quite content if it was referred to the Council for consideration by the appropriate committee.

Dr. J. W. Taylor (Aberdeen and Kincardine Counties (with Orkney and Shetland)), in supporting the motion, said that a knowledge of the problems of the general practitioner would enable the trainee-specialist better to assess what could be done and what could not be done in the patient's own home. It had been his own intention to become a specialist, but war service had intervened and for one reason and another he had gone into general practice, and now he would not change. There were many benefits in general practice, and he thought that if all graduates who intended to become specialists had a year in general practice many would remain in it. Those who did not do so would gain, from their year in general practice, a much wider outlook on medicine in general and the patient in particular.

It was agreed that the motion should be referred to the Council.

General Practitioner Staffs of Cottage Hospitals

Dr. H. S. Howie Wood (Isle of Wight) moved: "That this meeting is of opinion that where a certain proportion of beds

in a cottage hospital are allocated to the charge of consultants no corresponding decrease in the £25 per occupied bed payments should occur."

He said that in the case of a cottage hospital in his area the general practitioners had been asked to hand over some of their beds to the care of the consultants and they had agreed to do this, but a little later on they had been informed that the £25 per bed annual payment would not apply in future to those beds over which the consultants had control. He did not know whether that was general throughout the country or was only a local ruling. It certainly would not improve the relationship between general practitioners and consultants.

Mr. Newell pointed out that the staff fund of £25 per average occupied bed had been created to remunerate the general practitioner for attendance at the cottage hospital on patients other than his own. The general practitioners had no duties or responsibilities towards the patients in the beds which were reserved for the use of consultants, and it would therefore be very difficult to argue that those beds should be taken into account in the assessing of the staff fund.

Dr. G. Catherine Evans (East Kent), in supporting the motion, said that in the case of the beds reserved for the use of consultants it was the general practitioner who attended the patient in the middle of the night when necessary and who went to see the patient day after day and on Sundays, whilst the consultant visited the patient only once a week or once a fortnight. Surely the general practitioner should be paid for that work.

Dr. Howie Wood said that, although Mr. Newell was technically correct in saying that the payment of £25 was intended to remunerate the general practitioner for attendance on patients other than his own, he did not think anyone could seriously contend that the services which the general practitioner rendered to his own patients in a cottage hospital did not form part of the ground for the payment of the £25. At one cottage hospital in his area the general practitioners had resolutely refused to give up their beds until they had received an assurance that no difference would be made to the £25 per bed payment. It was only fair to state that the regional hospital board liaison officer had hinted that it might be possible, by the proposing of additional duties and something along the lines of non-resident house-surgeon posts, for some additional money to come to the staff at some future date, which would go far to make up for the 50% cut in their bed fund. On the question of principle, it seemed entirely wrong that the general practitioners, who were in fact doing an honorary house-surgeon's work and dealing with all emergencies in the absence of the consultant, should be deprived of their remuneration simply through a change in the control of the beds.

The motion was carried.

Worcester and Bromsgrove proposed an annual conference of group medical committees. Mr. Newell said that his committee was considering this question. The calling of large meetings was not to be undertaken without consideration. The proposal was referred to Council.

Attention to Maternity Cases at Hospital

Dr. Alice E. N. Gilby (Westminster and Holborn) moved:

That this meeting deplores the lack of attention and the failure to accept responsibility by some hospitals in the treatment of early complications and mishaps arising in cases that they have accepted for confinement including antenatal care. This lack of attention is manifested in particular by the tendency to refer these cases back to the general practitioner for treatment.

These patients had booked their confinements at hospital, but if there was anything wrong in the earlier stages they were frequently referred back to their own doctor for treatment. This puzzled the patients. The hospitals booked confinements, and yet refused admission to the patients for the mishaps of pregnancy.

Dr. C. Warner (Liverpool), as a general-practitioner member of the Liverpool Obstetric Advisory Committee, said that it has been his job to try to retain maternity work in the hands of general practitioners, and therefore he asked that this motion be thrown out. They had already passed a motion asking that patients should be returned from out-patient departments to general practitioners as soon as possible. If they were going to detach themselves from all responsibility for their patients from the moment they were sent to hospital they were wasting their time in talking about status. The fact that he sent his patient to hospital did not, as he saw it, absolve him from responsibility for that patient.

Dr. Marguerite G. Sheldon (Birmingham) also opposed the motion, which was lost.

"Sub-consultants"

Dr. G. Catherine Evans (East Kent) moved that a new committee be formed parallel to the Central Consultants and Specialists Committee to represent the interests of "sub-consultants"—that is to say, S.H.M.O.s and those medical superintendents not classified as consultants. She pointed out that the chances of a sub-consultant getting on to the regional or central consultants committee were negligible. True, he or she might be co-opted on to the regional body, but no co-opted member could gain access to the central body. She also pointed out how numerous the sub-consultants were; the previous week two-thirds of the advertisements in the *British Medical Journal* related to sub-consultants. Adequate provision should be made for their representation.

Dr. A. Smith (Lanarkshire) said that this proposal for a new committee was one of the quaintest that had ever come before the Representative Body. He was certain that the people concerned would get representation through the Central Consultants and Specialists Committee far better than through splinter bodies. The very word "sub-consultant" was wrong. How would a doctor like to be described as a "sub-practitioner"?

Mr. Newell said that in his committee they had done their best to represent this section, which they hoped would be a diminishing section. They had given representation to registrars, also to medical superintendents. He deprecated the further formation of committees, and hoped the representation of this as of other groups would be left in the hands of his committee.

The motion was lost by a large majority, but the proposer was loudly applauded for her sprightly advocacy.

Plans Relating to Hospitals

Dr. W. Smith (Greenwich and Deptford) had a motion deploring the regional hospital board plans by which few general hospitals are to remain complete entities. The new plan of the regional board envisaged the cutting up of what were complete hospitals into bits and pieces, so that at one place there would be all the gynaecological patients, at another the surgical and dental, and at another, perhaps a few miles away, the medical cases. What was going to be the position if they had a medical case which required surgical treatment and then possibly became a gynaecological emergency? Such cases would have to be moved from place to place instead of being treated throughout in the same building. They were told that the reason for this policy was that small groups of beds for any specialty were uneconomic, and that unless there were a reasonable number of beds for a unit it was an impracticable position in present circumstances, also that the training of registrars became an impossibility. In Greenwich and Deptford they did not believe this to be true, and they were alarmed that this sort of arrangement should have been forced upon them. It became a question of patients *versus* planning. Were they to go in for an organization which was neat from an administrative point of view or to be able to treat their patients under one roof, thus ensuring a better and perhaps swifter result? Recently in his area a case of haematemesis occurred in a medical bed in a 500-bed hospital, and no surgeon was available because there were in that hospital no surgical beds.

The motion was carried.

THE GENERAL PRACTITIONER AND THE HOSPITAL

The interim report of Council under the heading "The General Practitioner and Hospital Work" was received, and the recommendation was moved calling for the retention of the smaller general-practitioner and cottage hospital for general practitioners, with the setting aside of certain wards in district hospitals, the setting up of clinical assistantships and of part-time registrar type appointments, with other proposals. The full text of the recommendation was set out in the *Supplement* of April 22, p. 145. In moving, Mr. A. Staveley Gough, Chairman of the Committee on the General Practitioner and Hospital Work, said that it was a fact that a large number of hospitals in this country were first bujlt by the energies of general practitioners, sometimes with their own money, and often through the help of their grateful patients. They were in fact general-practitioner hospitals. It was true that these hospitals had become upgraded and were no longer general-practitioner hospitals, in some instances rightly so. But this proved that the general-practitioner hospital was necessary. It was necessary to prevent among doctors a feeling of frustration. In many cases the general practitioner was able to continue the treatment of his patient in a serious illness, and would get much professional comfort thereby, but the reason he could not do so was the housing problem. He mentioned the case of a simple ulcer. The general practitioner, with the diagnostic facilities which should be available to him, was able to make a diagnosis and to set in motion treatment without referring such cases to special departments, but he was unable commonly to ensure for that patient the essential rest, freedom from domestic worries, and the certain amount of supervision required in order that the patient might learn the routine in his own home. When one considered young students to-day coming out of hospital, with their modern training, depending almost as much, if not more, upon ancillary methods of diagnosis than upon their clinical acumen, it was evident that many of them within five years of entering general practice would be frustrated and would be saying to themselves, "I am only here to act as a sorter." Older men, of course, had learned to compensate.

They were asking for the restitution to general practitioners of the hospitals of which they had been dispossessed, but more important still they were asking for additional accommodation in district hospitals in the larger towns. In the smaller towns, on the whole, they found a better average of general practice, but as soon as they got into the industrial areas surrounding the general hospitals the question of general practice was apt to become subordinated to certification and hospital sorting, to the detriment of general practice itself, without any reproach to the practitioners concerned.

The second part of the report was a question of how the general practitioner could be integrated into hospital practice more widely than in a general-practitioner hospital. They had to watch most closely lest a man with great ability, but facing financial difficulty, when he left hospital practice and entered general practice found the door of special practice completely closed to him. For that reason the Committee was proposing clinical assistantships. Many general practitioners would welcome a chance of taking a special appointment in hospital. These jobs would be held in rotation and would provide post-graduate education of the finest type for quite a number of general practitioners.

In the third part of the motion they had another problem. This recognized the difficulty of the supernumerary registrar grade. There was a growing call for appointments of this type or kind. Then it was recognized among the registrars that to-day there would be many who could not be absorbed in full-time consultant work. It would be wrong to suggest that all of them should go into general practice. It could be said that there were plenty of regions where part-time consultants having the necessary experience would fulfil the need for hospitals in many areas which depended in the main on registrar service, backed up by the occasional help of consultants. Finally they asked that all hospitals should welcome the attendance of general practitioners for the purpose of consultations, ward rounds, clinical and scientific meetings, and inclusion in hospital teams. (Applause.)

Dr. Frank Gray (Council) moved an amendment to the part of the recommendation which read "Whenever possible clinical assistantships should be set up. . . ." His amendment was that instead of "whenever possible" the words "for educational purposes" should be used. The verbal alteration was slight, but the principle behind it was of fundamental importance. The meeting had been concerned a great deal with the question of status. General practice was itself a specialty of no less status than any other branch of medicine. For educational purposes the general practitioner might wish to do one of two things: he might wish to exchange his specialty, in whole or in part, for another branch of the profession, and in rural areas, as had been indicated, this might indeed be a very desirable thing, or he might wish to have the best form of postgraduate instruction in one particular specialty for his own purposes as a general practitioner. These objects were quite appropriate, but in no circumstances must it be allowed to go forth that the general practitioner was of a status equivalent to that of clinical assistant or any comparable grade in hospitals. Nothing could be more disastrous than to say that every form of hospital practice was higher than general practice. That position must never be accepted. He would add that the best men were required for general practice, and it was not to be regarded as "promotion" if the general practitioner went into another branch of medicine. While they welcomed these clinical assistantships they were for a specific purpose and must not be allowed to prejudice the status of the general practitioner.

Mr. Gough said that while he believed that there was no derogation of the general practitioner in the original recommendation he was prepared to accept this amendment, having in mind that this was an interim report and still subject to final conclusions. He agreed to the words which indicated that the proposed clinical facilities were an educational facility, which was what in fact they were.

The recommendation as finally adopted was as follows:

A. That the smaller general-practitioner and cottage hospital should be retained by the general practitioner and, in addition, that certain wards in the district hospitals should be set aside for the treatment of patients by general practitioners.

B. That, for educational purposes, clinical assistantships should be set up (1) allowing for periods of approximately two years at least in any particular specialty; (2) allowing for short periods in two or three specialist departments.
