(INVESTIGATION OF 393 PATIENTS SEEKING ADMISSION TO A HOSPITAL FOR THE CHRONIC SICK)

BY

C. R. LOWE, M.D., D.P.H.

Lecturer in Public Health, Department of Social Medicine, University of Birmingham

In an investigation of patients in the largest hospital for the chronic sick in the Birmingham region the problem of disposal was considered against the background of recent legislation (Lowe and McKeown, 1949; McKeown and Lowe, 1950). When the need for frequent medical attention and for skilled nursing were used as criteria of suitability for hospital admission it was evident that about three-fifths of the patients could be cared for outside hospital if essential complementary facilities (domestic service, simple nursing, and occasional medical attention) were made available. It was recognized, however, that results based on the present hospital population were unacceptable as an accurate guide to future policy, and this inquiry was undertaken in an attempt to correct the previous estimates. It was hoped that examination of the medical condition and social circumstances of patients seeking admission to hospital would indicate (*a*) the proportions of applicants for whom regional hospital boards and local authorities are respectively responsible, and (*b*) the additional facilities required to meet the obligations of local authorities.

The data were recorded by investigation of all new patients for whom admission to Dudley Road Infirmary† was sought between October 10 and December 22, 1949. Details of social and domestic circumstances were recorded in the home by an almoner within twenty-four hours of the request for admission; medical data were recorded by one of five consultants after examination of the patient either at home or shortly after admission to hospital. With the full social and medical data before him, the consultant in each case finally made a decision in respect of disposal.

During the period of the inquiry there were 393 applications for admission. Thirty-two patients refused to enter the infirmary, still associated in their minds with the nineteenth-century workhouse, and relatives eventually made alternative arrangements for them. Twenty patients died at home before they could be examined, and six were admitted to general hospitals. The analysis which follows is based on the remaining 335 patients (161 men and 174 women) for whom the requisite examinations were completed.

Disposal of the Chronic Sick

Table I gives the disposal suggested for the 335 patients seeking hospital admission. Criteria used were those previously applied to the hospital population at Dudley Road Infirmary.

(*a*) General hospital (40%). Patients who needed skilled nursing and/or medical attention once a week or more frequently. These patients were acutely ill or needed hospital investigation, or were in the terminal stages of malignant disease.

*This research was assisted by a grant from the Birmingham University Students' Social Services Fund.

Parts I, II, and IV appeared in the *British Journal of Social Medicine* for July, 1949, and April and July, 1950, and Part III in the *British Medical Journal* of February 11, 1950.

†Formerly called Western Road Infirmary.

TABLE I.—*Suggested Disposal of 335 Patients Seeking Admission to a Hospital for the Chronic Sick*

	Regional Hospital Board		Local Authority		Total
	(*a*) General Hospital	(*b*) Mental Institution	(*c*) Long-stay Annexe	(*d*) Own Home	
Males ..	74 (46·0%)	11 (6·8%)	48 (29·8%)	28 (17·4%)	161 (100%)
Females ..	62 (35·6%)	23 (13·2%)	31 (17·8%)	58 (33·4%)	174 (100%)
Total ..	136 (40·6%)	34 (10·1%)	79 (23·6%)	86 (25·7%)	335 (100%)

(*b*) Mental institution (10%). Patients who needed personal supervision because of their abnormal mental state.

(*c*) Long-stay annexe (24%). Patients not requiring skilled nursing or weekly medical attention who could not be kept in their own homes.

(*d*) Own home (26%). Patients who could be cared for at home.

As stated above, patients were allocated to the four groups by one of five consultants. To check the consistency of standards the data in each case were later examined by one of the physicians who had not seen the patient, and a second opinion was given in respect of disposal without knowledge of the earlier decision. There was almost complete agreement about patients considered suitable for (*a*) general hospital or (*b*) mental institution, but there were substantial differences of opinion about the division of the remainder between (*c*) long-stay annexe and (*d*) their own home. Table I is based on the first decision—that is, upon the view of the consultant who examined the patient. It may be noted that the differences, though important in relation to the work of local authorities, do not affect the main conclusion, which is that regional hospital boards and local authorities are each responsible for about half the chronic sick for whom admission to hospital is requested.

Patients assigned to each of the four classes are considered separately and in more detail below.

(a) General Hospital

Before accepting the conclusion that some of the chronic sick should be cared for in general hospitals, hospital authorities will no doubt want to be satisfied, first, about the kind of attention needed, and, secondly, that the numbers are such that the responsibility can be discharged without serious embarrassment to their traditional work. Table II classifies the 136 "hospital" patients according to the nature of their requirements: 53% were acutely ill, 29% required investigation as in-patients, and 18% were in the terminal stages of malignant disease.

TABLE II.—*Classification of Patients Suitable for General Hospital*

Diagnosis	Males	Females	Total
Acute illness	43	29	72 (52·9%)
Cerebral thrombosis	9	13	
Cardiac failure	19	5	
Bronchopneumonia	11	2	
Other conditions*	4	9	
Needing investigation	19	20	39 (28·7%)
For carcinoma	9	10	
For other reasons†	10	10	
Terminal stages of malignant disease	12	13	25 (18·4%)
Totals	74	62	136 (100%)

* Acute illness, other conditions: unexplained acute illness (2 cases), acute enteritis (2 cases), leg gangrene, empyema, uraemia, ischio-rectal abscess, acute glaucoma, recent fracture of spine, recent fracture of femur, suppurative parotitis, acute myeloid leukaemia.

† Needing investigation, other reasons: fractured spine, tuberculosis, peripheral neuritis, cerebral syphilis, steatorrhoea, leg ulcer, pleural effusion, etc.

These patients clearly require attention best provided in a general hospital. Acute illness in the elderly patient has of course distinctive features which have made general hospitals reluctant to accept this commitment; for example, 40% of the 136 patients were incontinent. But the fact that incontinence will sometimes respond to treatment is an additional consideration in favour of their admission. The data suggests that numbers will not be formidable if alternative arrangements can be made for the remaining 60% of the patients (considered not to require care in a general hospital), as well as for the swift transfer of patients who neither die nor recover.

(b) Mental Institution

One-tenth of all applications were in respect of patients in need of constant supervision because of their mental condition, and Table III classifies them according to the

TABLE III.—*Classification of Patients Suitable for a Mental Institution*

Diagnosis	Males	Females	Total
Senile dementia (no other pathology)	10	18	28 (82·4%)
Old hemiplegia	1	2	3 (8·8%)
Psychosis	—	2	2 (5·9%)
Other	—	1*	1 (2·9%)
Total	11	23	34 (100%)

* A woman of 82 with a fungating carcinoma of breast and no evidence of secondaries.

diagnosis. Two patients, both women, were psychotics, but most (82%) were demented senile patients for whom no more specific diagnosis was made. More than half of these old people were both bedfast and incontinent; they are typical of the class of patient which places the heaviest nursing burden on existing hospitals for the chronic sick.

A recent Ministry of Health circular to hospital boards (R.H.B. (50) 26) considers some of the difficulties of caring for the aged who are mentally infirm. It suggests that large general hospitals should provide short-stay units for diagnosis and short-term treatment; after a period a few patients may be well enough to return home, a few more may require certification, but most will need alternative accommodation. For these the circular suggests long-stay annexes associated with mental hospitals, with hospitals for the chronic sick, or with general hospitals. The suggestion that these annexes should be within the grounds of mental hospitals is unlikely to be attractive to patients or their relatives, but wherever they are sited the problem of staffing will be formidable, since the care of the aged who are also mentally infirm is among the least attractive of medical and nursing commitments.

(c) Long-stay Annexe

About one-quarter of the cases were considered suitable for admission to a long-stay annexe. Because of their social circumstances these patients could not be kept at home, yet their medical and nursing requirements were not such as would justify admission to a general hospital.

TABLE IV.—*Classification of Patients Suitable for a Long-stay Annexe*

	Males	Females	Total
"Senility" (no pathology)	14	10	24 (30·4%)
Cardiac conditions	13	4	17 (21·5%)
Carcinoma	10	2	12 (15·2%)
Old cerebral thrombosis	6	4	10 (12·6%)
Other conditions*	5	11	16 (20·3%)
Total	48	31	79 (100%)

* Other conditions: 8 with disease of C.N.S. (post-encephalitic Parkinsonism, paralysis agitans, motor neurone disease, disseminated sclerosis, Huntington's chorea); 6 with advanced arthritis; 2 with old fracture of femur.

Table IV classifies them according to their medical condition, and it may be noted that about one-third had no pathological lesion and suffered merely from infirmity associated with advanced age. A few patients had incurable malignant disease, and the remainder were partially incapacitated by other illnesses.

Two questions arise in relation to the suggested disposal. The first is whether the nursing requirements constitute a sufficient reason for admission to hospital. The information in Table V underlines this question, for it shows that

TABLE V.—*Mobility and Continence of Patients Suitable for a Long-stay Annexe*

	Bedfast	Sitting Out of Bed	Ambulant	Total
Continent	26 (32·9%)	12 (15·2%)	18 (22·8%)	56 (70·9%)
Incontinent	17 (21·5%)	2 (2·5%)	4 (5·1%)	23 (29·1%)
Total	43 (54·4%)	14 (17·7%)	22 (27·9%)	79 (100%)

54% were bedfast and 29% incontinent. Clearly such patients need more attention than can be offered in the typical municipal home for the aged; equally clearly they do not belong in the wards of a general hospital.

The second question is whether any of the 79 patients in this group could be cared for at home. This was out of the question in the case of 23 patients who had no home and were living in lodgings, municipal homes, or common lodging houses; in the remaining 56 cases the decision rested on the judgment of the consultant that personal circumstances prohibited home care, even assuming the availability of complementary services.

(d) Own Home

As shown in Table I, roughly one-quarter of all requests for admission were in respect of patients considered suitable for care at home, and Table VI gives particulars of

TABLE VI.—*Classification of Patients Suitable for Care at Home*

	Males	Females	Total
"Senility"	5	20	25 (29·1%)
Cardiac conditions	6	8	14 (16·3%)
Old cerebral thrombosis	8	9	17 (19·8%)
Carcinoma	3	6	9 (10·4%)
Other conditions*	6	15	21 (24·4%)
Total	28	58	86 (100%)

* Other conditions: 10 with advanced disease of C.N.S. (post-encephalitic Parkinsonism, paralysis agitans, disseminated sclerosis, motor neurone disease, unexplained paraplegia); 5 with diabetes; 2 with terminal illness (too ill to move); 4 others—*suprapubic cystotomy*, varicose ulcer, bronchopneumonia (recovering), dermatitis herpetiformis.

their medical condition. From a medical point of view this group is very similar to the previous one, and, since the two have been separated solely on consideration of personal circumstances, it is necessary to examine specific requirements in detail. Information of this kind is provided in Table VII, which gives particulars of the medical, nursing, and domestic assistance needed by these patients.

They need little medical attention: a few (7%) require visiting more than once a week, but the majority (61%) could be supervised by visits once a fortnight, or less often. It seems reasonable, therefore, to suggest that these services are within the compass of the general practitioner.

Skilled nursing is required by 16%, simple nursing by 41%, and no nursing by 43%. It may be recalled that in our investigation of chronic sick in hospital all patients needing skilled nursing were assigned to the hospital group. This was in fact the only reasonable decision where the

TABLE VII.—*Services Required by Patients Suitable for Care at Home*

Medical Supervision

	Daily	More than Once a Week	Weekly	Fortnightly	Monthly	Total
Males	—	1	10	14	3	28

Domestic Help

	All Day	Half-day	2–3 Times Weekly	Not Required	Total
Males	4	3	15	6	28
Females	11	20	15	12	58
Total	15 (17·4%)	23 (26·8%)	30 (34·9%)	18 (20·9%)	86 (100%)

examination was conducted in hospital without detailed knowledge of domestic circumstances, but in the present inquiry, in which most patients were seen at home, it was permissible to be somewhat more flexible. Of the 14 patients who required skilled nursing, six were diabetics having daily insulin injections, five needed care of pressure sores or of varicose ulcers, four were acutely ill, and one required daily attention to a suprapubic cystotomy. It was considered practicable to provide these services through the home nursing service of the local authority. Simple nursing (for 35 patients) comprised washing, dressing, feeding, lifting in and out of bed, with, in the case of bedfast patients, attention to bowels and bladder and prevention of pressure sores. In cases which required no nursing (37 patients), requests for hospital admission were entirely determined by domestic circumstances.

Table VII also indicates that most patients (79%) need some kind of domestic assistance, although only a few (17%) require continuous help. These requirements could be met in part through local provision of hot meals and a laundry service. The investigation exposed deficiencies in such essentials as beds and bed-linen; 22 homes had no bed suitable for an invalid. In 12 cases difficulties were financial in origin, and supplementary funds from the National Assistance Board would have made it possible for the household to deal with its own problem.

Personal Circumstances

Since social circumstances of the chronic sick have a considerable bearing on the question of disposal, information in respect of the patients examined may be considered briefly. Of patients in Dudley Road Infirmary 92% were 60 and over; 88% of the applicants for admission were 60 and over, and 68% were 70 and over (Table VIII). About one-quarter of these old people were living alone or in lodgings, municipal homes, and common lodging houses (Table IX), and additional domiciliary services are therefore unlikely to meet their difficulties.

To maintain a reasonable standard of home care for an invalid a bath and an adequate supply of hot water are essential. Less than one-fifth of the houses visited attained

TABLE VIII.—*Age and Sex Distribution of Patients Investigated*

Age:	30–39	40–49	50–59	60–69	70–79	80–89	90 and Over	Total

† Excludes 29 patients—28 in municipal homes and common lodging houses, 1 no home (admitted from streets).

this standard (Table X), and in many cases (29%) outdoor sanitation was shared with neighbours.

It is difficult to appreciate the degree of squalor and misery that these figures represent, and indeed some of the living conditions were almost unbelievably bad. They indicate that the social problem created by the increasing number of chronic sick extends beyond the difficulty of providing adequate medical and nursing services. If the rising demand for hospital accommodation is to be stemmed, a steady improvement in national housing standards is as important as the provision by local authorities of specific services.

Discussion

The data examined suggest that regional hospital boards and local authorities are responsible for about equal numbers of patients applying for admission to hospitals for the chronic sick. This conclusion rests on two assumptions: (*a*) that regional hospital boards accept only patients who need hospital care or who require supervision because of their abnormal mental state; and (*b*) that local authorities provide for all other patients in their homes or in long-stay annexes.

Since the allocation of responsibility for the long-stay annexe to local authorities may provoke differences of opinion it is necessary to be clear about the kind of patient suggested for admission. About one-quarter of the patients examined required only simple nursing and domestic service, but because of social circumstances could not be cared for at home. They cannot be admitted to the typical municipal home for the aged, which does not provide simple nursing, nor do they need the skilled attention which justifies hospital admission. If hospitals for the chronic

sick continue in their present form, such patients will of course be admitted to them; but if patients are to enter hospital only when they require skilled attention, some alternative to the general hospital or municipal home will be needed. The long-stay annexe is the alternative suggested, and it will be necessary to assign responsibility for it either to regional hospital boards or to local authorities. It is here placed under local authorities only because this seems consistent with Section 21 of the National Assistance Act. A different decision would of course alter the proportions indicated above, and would assign to regional hospital boards three-quarters of the patients applying for admission to hospital.

Summary

The personal circumstances of 393 patients seeking admission to a hospital for the chronic sick were investigated by a social worker; 335 of these were examined by a consultant who considered the problem of disposal in the light of social circumstances and medical requirements. Cases were recommended for care as follows: (*a*) In a general hospital (40%): patients who needed skilled nursing and/or medical attention once a week or more frequently. (*b*) In a mental institution (10%): patients who needed personal supervision because of their abnormal mental state. (*c*) In a long-stay annexe (24%): patients not requiring skilled nursing or weekly medical attention who could not be kept in their own homes. (*d*) At home (26%): patients who could be cared for at home.

If local authorities provide the long-stay annexe they will be responsible for about one-half the patients seeking admission to hospital; if they do not, they will be responsible for about one-quarter—that is, only for patients who could remain at home. According to this decision regional hospital boards must accept one-half or three-quarters respectively in the two cases.

The maintenance of one-quarter of the patients in their own homes requires the provision of domiciliary medical and nursing services, and of a more complete domestic service than is now available.

I am very glad to acknowledge my indebtedness to the five physicians who provided the clinical records: Drs. G. Hearn, F. G. Marson, K. May, L. Nagley, and Professor A. P. Thomson (who suggested the investigation); and to Mrs. E. M. Sagrott, who did most of the work of the social survey with help from the almoners of the Birmingham United Hospitals.

The Brussels Treaty Public Health Committee, set up in application of Article II of the Treaty, as a part of the efforts to be made by the five signatory powers—Belgium, France, Luxembourg, Netherlands, and the United Kingdom—to raise the standard of living of their peoples, held its sixth session in Edinburgh on September 7, 8, and 9, 1950, under the chairmanship of Sir Andrew Davidson, Chief Medical Officer of the Department of Health for Scotland. The committee began the study of the protection of the civil population from the health point of view in time of emergency. In the matter of the health control of sea traffic the committee decided to recommend the five Governments to introduce, from March 1, 1951, onwards, a uniform system which will enable the five countries to be treated as one single territory in this respect, as has been achieved under the uniform system for control of air traffic which has been in operation since February 1, 1950. The committee took note of the very useful results obtained from the visits of health personnel organized in 1949–50, during which period 40 doctors and specialists from the five countries travelled in the other Brussels Treaty countries to learn about current methods as well as the general administrative structure of public health services in those countries.

RADIOLOGICAL AND PATHOLOGICAL CORRELATION OF MILIARY TUBERCULOSIS OF LUNGS IN CHILDREN

WITH SPECIAL REFERENCE TO CHOROIDAL TUBERCLES

BY

J. L. EMERY, M.D., D.C.H.
Pathologist, Children's Hospital, Sheffield

AND

J. LORBER, M.B., M.R.C.P.
Lecturer in Child Health, University of Sheffield

Since the description of the radiological appearance of the lungs in miliary tuberculosis by Klieneberger (1908), Otten (1908), and Presuhn (1908), the diagnosis of this condition during life has become almost exclusively based on radiological findings. As early as 1911 Assmann (1911b) regarded the diagnosis of miliary tuberculosis as a triumph of *x*-ray examination. Most reference books offer no alternative method of diagnosis, and the impression gained is that this method is generally satisfactory. Nevertheless, some books recognize that the disease may be present for weeks before the typical snow-storm appearance develops, and that sometimes there is no radiological evidence of the disease at all (Amberson, 1947; Hill, 1948; Kayne *et al.*, 1948; Nelson, 1948). Similar views are expressed by Axén (1941), Davis (1942), Gratzek (1941), and Rigler (1949). The literature refers to many unexpected necropsy findings of miliary tuberculosis where previous radiographs of the chest were negative (e.g., Baggenstoss *et al.*, 1947; Lincoln, 1947; Löffler and Piotti, 1948; Rigler, 1949; Rubie and Mohun, 1949).

Three previous papers concerning the pathological and radiological correlation of miliary tuberculosis have been noted (Bronson *et al.*, 1934; Steiner, 1937; Chapman and Whorton, 1946). A fourth study correlated clinical and pathological findings, without specifying radiographs as the method of clinical diagnosis (Lewison *et al.*, 1931). These four studies deal almost exclusively with adult material (Table I).

TABLE I.—*Pathological and Radiological Correlation of Miliary Tuberculosis (Previous Work)*

Author	Total Positive at Necropsy	Diagnosed by Radiographs
Bronson *et al.* (1934)	9	5 (56%)
Steiner (1937)	46	22 (48%)
Chapman and Whorton (1946)	63	16 (25%)
		Diagnosed in Life
Lewison *et al.* (1931)	96	75* (78%)

* 9 further cases diagnosed in life did not have miliary tuberculosis at necropsy.

Specific treatment is now available for miliary tuberculosis. The earlier treatment is instituted the better are the results, and early diagnosis is therefore essential. This study is an attempt to investigate the accuracy and speed of the present methods of diagnosis.

Material and Methods

In a consecutive series of necropsies between January, 1947, and August, 1949, the pathological diagnosis of miliary tuberculosis was established in 52 children under 14. Tuberculous meningitis was present in all but two cases. During the same period 11 children died of tuberculous meningitis, but necropsy did not reveal miliary tuberculosis. Radiographs of the chest taken within a fortnight of death were available for examination in all cases.

Interpretation of Radiographs

When a discrepancy between the radiological and post-mortem findings became apparent it was decided to obtain a wider opinion on the *x*-ray appearances. Accordingly the films were referred to an independent panel of two radiologists and two paediatricians.

The assessors were informed that all these deaths were from tuberculosis and were asked to make a radiological diagnosis of the presence, doubtful presence, or absence of miliary tuberculosis. The usual marks of identification had been removed from the films and each assessor was unaware of the others' diagnoses. The reports of the four assessors were analysed, along with those of Dr. Lodge (consultant radiologist to the hospital) and one of us (J. L.). The majority vote was accepted as the diagnosis. Eleven cases came to necropsy after the survey of the assessors was completed. The findings of the assessors, however, had been so consistent that it was regarded as justifiable to take the report of Dr. Lodge and one of us (J. L.) and include the eleven cases in the series. In the analysis of the results four radiologically doubtful cases will be included with those reported as negative, because many children with similar radiographs prove never to have miliary tuberculosis.

Ophthalmoscopy

In all but four children the fundus oculi had been examined for the presence of choroidal tubercles. The examination was carried out by the technique of Illingworth and Wright (1948) in the earlier cases, and under rectal thiopentone anaesthesia later (Lorber, 1950).

Morbid Anatomy of the Lungs (J. L. E.)

Before opening the chest the trachea was clamped in order to minimize collapse of the lungs. Blocks for histological examination were taken from at least one lobe of the lung quite separate from the one containing the primary focus. In many cases the blocks were taken from all lobes.

The criteria for diagnosis of miliary tuberculosis were either (*a*) the presence of macroscopic miliary tubercles throughout the lung at necropsy, or (*b*) the presence of miliary tubercles in sections taken from lobes of the lung not containing the site of primary focus.

The identification of miliary tubercles on histological examination was not difficult, except in some cases in which differentiation was required between small lymph follicles near bronchioles and early tubercles. The identity of a tubercle was not accepted unless it was typical, contained well-developed epithelial-cell foci and areas of necrosis, or was shown to contain acid-fast bacilli.

In several instances miliary tubercles had been found within the lobe containing the primary focus, but were absent in the block from a distal part of the lung. These were excluded from the cases reported here.

The diameters of the tubercles were measured from their extreme edges, using the microscope stage scale. The tubercles were classified according to the size of their majority into three groups: (*a*) less than 0.5 mm., (*b*) 0.5–1 mm., and (*c*) over 1 mm. in diameter. They were also classified according to their type into primarily cellular, necrotic, or fibrous groups. An estimate was made of the concentration of tubercles seen in the pleura and in the cut surface of the lobes and of the numbers of tubercles present per square centimetre of section.

Results

In 12 of the 52 cases miliary tuberculosis was diagnosed radiologically on the last film taken before death. Choroidal tubercles were seen in 10 of the 11 cases examined. At necropsy all showed macroscopic miliary tubercles of the lung, numbering 5 to 20 per cm.², and on histological examination all the tubercles were over 0.5 mm. in diameter, half being over 1 mm.

In the remaining 40 cases miliary tuberculosis was not diagnosed on the last radiograph taken before death. In six cases miliary tuberculosis was diagnosed radiologically at an earlier stage of the disease, but owing to streptomycin therapy was no longer apparent on the final examination. At necropsy macroscopic miliary tuberculosis was present in all of them. In five of these six cases choroidal tubercles had been found. It will be noted, therefore, that of the 17 patients examined in the radiologically positive group 15 had choroidal tubercles.

In 34 children there was never radiological evidence of miliary tuberculosis, yet at necropsy this was seen macroscopically in 23 and microscopically in the remaining 11. Choroidal tubercles were present in 10 of 31 examined—a significantly lower proportion than in those with radiological evidence of miliary tuberculosis. The miliary tubercles in this series varied in number from 1 to 6 per cm.² of section and the majority were 0.5 mm. or less in diameter.

It will be seen, therefore, that miliary tuberculosis was diagnosed radiologically in only 18 of 52 cases established at necropsy. Choroidal tubercles were seen in life in 25 of 48 children examined. Using both methods of diagnosis, 28 of 52 cases were diagnosed correctly during life. These results are summarized in Tables II and III.

TABLE II.—*Pathological and Radiological Correlation of Miliary Tuberculosis (Present Study)*

	No. of Cases	Positive Macroscopically at Necropsy	Positive Microscopically Only
Radiologically positive	12	12	0
Radiologically positive on admission only, not in last radiograph before death	6	6	0
Radiologically negative or doubtful	34	23	11
Total	52	41	11

TABLE III.—*Correlation of Choroidal Tubercles with Miliary Tuberculosis*

	No.	Choroidal Tubercles Present
Radiologically positive at any time	17	15
Radiologically negative or doubtful	31	10
Total cases	48	25 (52%)
Cases dying of tuberculosis without miliary disease	11	0

Discussion

The factors rendering miliary tubercle in the lungs visible on radiographs have been the subject of many experiments and observations. In the opinion of many, the number and size of the tubercles are the major factors responsible (Ott, 1930; Dale, 1932; Rigler, 1949). Achelis and Nunokawa (1910), Ott (1930), and Schinz *et al.* (1939) thought that the appearance is due to superimposition of the shadows cast by many tubercles in the same line of the Roentgen rays, but according to others (Assmann, 1911a; Haudek, 1911; von Dehn and Weinschenk, 1924) the picture obtained represents the individual tubercles lying nearest to the film. Assmann (1911a) *x*-rayed narrow slices

of lung tissue with miliary tuberculosis and these films gave similar appearances to those of the whole lung.

Steiner (1937) held that the histological nature of lesions was more important than their size and number. In his series of 46 cases, the 16 in which epithelioid tubercles without caseation predominated showed no radiological abnormalities. Where, however, central caseation predominated in the tubercles, these produced the characteristic radiological appearance regardless of the size and number of the lesions. Blacklock (1932) divided miliary tubercles into acute and subacute types according to their histological structure, and pointed out that it was the larger subacute type of lesion which gave the typical snowstorm appearance, while the smaller acute lesions may not show at all, unless particularly abundant.

An attempt was made in this study to correlate the histological structure of the tubercles with the radiological diagnosis. No direct relationship was found. Our findings confirm the views of the previous writers that size and numbers matter most. The radiographs were positive when the majority of the tubercles were over 1 mm. in diameter and their number was 5 to 20 per cm.^{2} In the *x*-ray-negative group the tubercles were mostly under 0.5 mm. wide and their numbers ranged from 1 to 6 per cm.^{2}

The frequency with which miliary tuberculosis could not be diagnosed by radiographs in this series is in substantial agreement with the findings of Bronson *et al.* (1934), Steiner (1937), and Chapman and Whorton (1946) (Table I). It must, however, be pointed out that all patients with negative radiographs in this series died of coexistent meningitis. It is therefore possible that if untreated cases survived longer the lesions might have become visible radiologically. It is clear that when miliary tuberculosis can be diagnosed radiologically the disease is already in an advanced stage. For early diagnosis, therefore, other methods are required.

The thorough examination of the fundus oculi is one such method. In this series it gave positive evidence in 25 of 48 cases. Of the clinico-pathological studies mentioned, only Chapman and Whorton (1946) refer to the help that choroidal tubercles may give in the diagnosis, but these were seen in only one of their 63 cases. The incidence of choroidal tubercles in miliary tuberculosis, however, has been discussed by several writers and full references were given by Illingworth and Wright (1948). They found choroidal tubercles in 60% of 42 cases. Choroidal tubercles appear early in the disease, being found at the first or second examination. The same finding also holds true for the 12 positive cases in this series, which were not included in those discussed by Illingworth and Wright. Furthermore, choroidal tubercles at the first examination are often in a stage of development which is thought to denote that they must have been present for at least several weeks. Consequently these cases could have been diagnosed by ophthalmoscopy at an earlier stage of the disease.

Choroidal tubercles were not seen in tuberculous meningitis in which miliary tuberculosis was subsequently excluded by histological examination. This experience agrees with that of Bernard *et al.* (1949), who never found choroidal tubercles in adults suffering from tuberculous meningitis and where miliary tuberculosis was not present at the same time. In a very exceptional case choroidal tubercles may be found in primary tuberculosis, but, as the few children in whom this was observed are still alive, miliary tuberculosis cannot definitely be excluded. Therefore it may be assumed that, if a child's clinical condition is suggestive of miliary tuberculosis, the presence of early choroidal tubercles proves the diagnosis, irrespective of *x*-ray findings or a normal cerebrospinal fluid.

Using the combination of the two most widely accepted methods of diagnosis of miliary tuberculosis, only 27 of 48 cases were diagnosed in life, or little over half the total. This observation suggests that more sensitive methods of diagnosis are required. We have no personal experience with bone-marrow biopsy. This method has been used (Schleicher, 1946) but must be regarded as being in an experimental stage.

Summary

The accuracy and speed of the present methods of diagnosis of miliary tuberculosis in life were analysed. The material consisted of 52 consecutive children with histologically proved miliary tuberculosis of the lung.

Radiographs of the chest taken within 14 days of death were available in all cases. The fundus oculi was examined for choroidal tubercles in 48 children.

Eighteen, or only about one-third of the cases, were diagnosed by *x*-ray examination by a panel of experts. In 25 of 48 cases choroidal tubercles were seen. Altogether 28 of 52 cases were diagnosed in life.

Histological observations suggested that the number and the size of tubercles were the major factors in the production of the diagnostic *x*-ray appearances.

The tubercles were more numerous and larger in the 18 *x*-ray-positive than in the 34 *x*-ray-negative cases. Choroidal tubercles were present in a significantly higher proportion in the former (15 of 17) than in the latter (10 of 31).

Clinical features consistent with miliary tuberculosis and the presence of early choroidal tubercles establish the diagnosis irrespective of the radiological findings.

The present methods of diagnosis of miliary tuberculosis are not sensitive enough.

Our thanks are due to the four assessors: Dr. J. L. Grout, Dr. J. Wilkie, Professor R. S. Illingworth, and Dr. S. A. Doxiadis for their help and interest; to Professor R. S. Illingworth and Dr. T. Colver for permission to study their cases; and to Dr. T. Lodge for his reports on the radiographs.

SULPHONAMIDE SENSITIVITY OF H. INFLUENZAE STRAINS

WITH SPECIAL REFERENCE TO THE COMBINED USE OF ANTIBACTERIAL DRUGS

BY

K. ZINNEMANN, M.D.

(From the Department of Bacteriology, School of Medicine, Leeds)

It is now a commonly acknowledged therapeutic principle, as soon as treatment is begun, to use maximal doses of sulphonamides and of antibiotics to avoid, so far as is possible, the development of drug resistance in the infecting micro-organism. Nevertheless, the incidence of resistant strains has of late been commented upon and reported more frequently.

Haemophilus influenzae (Pfeiffer's bacillus) is sensitive to a comparatively wide range of sulphonamides and antibiotics, but it is also capable of developing strains resistant to the action of some of these drugs. It is therefore a suitable bacterium for the study of the antibacterial action of these preparations, and any theoretical and practical considerations arising from the study of its behaviour and of infections caused by it may be applicable to other pathogenic micro-organisms with a similar range of sensitivity.

Effects of Combination of Antibacterial Drugs

When two antibacterial drugs, each attacking bacterial populations in a different way, are allowed to act on the same bacterial culture the observed increase in the degree of sensitivity is exponential—that is, the effect of two or even more drugs is considerably greater than could be expected from the added values of the effects of each drug separately (Ungar, 1943; Thomas and Hayes, 1947; Mayr-Harting and Katscher, personal communication). This synergistic action is also well marked in strains resistant to penicillin when this antibiotic is combined with one of the sulphonamides (Chain and Duthie, 1945). Another principle involved, along with its bearing on clinical considerations with regard to the development of drug-resistant strains, has been stated very lucidly by Demerec (1948) as follows: "Theoretically, the most effective way of preventing the origin of resistant strains of bacteria is the use in clinical treatment of a mixture of two antibiotics, when such are available, that affect the same pathogen but are independent in their actions. The evidence of independence is that bacterial strains that have developed resistance to one antibiotic are still sensitive to the other, and vice versa. If such a mixture of two antibiotics is used, then only bacteria that are resistant to both can survive the treatment and form . . . resistant strains. Such bacteria would be exceedingly rare." It might be added that they would be rarer still if a third antibacterial drug with similar potency and mutation rate were employed.

Corresponding in vivo and Clinical Observations

American authors have produced *in vivo* experimental evidence showing that combination of the more effective sulphonamides with type-specific rabbit antiserum results not merely in an additive but in a synergistic effect (Pittman, 1942; Alexander and Leidy, 1943).

TABLE I.—*Clinical Results with Treatment of Various Combinations of Sulphonamides, Antiserum, and Antibiotics by Different Authors*

Good therapeutic results have also been reported in larger series of cases treated with penicillin or streptomycin, either alone or in combination with sulphonamides or antiserum (see Table I).

The relapses frequently observed (Alexander, 1943; Zinnemann, 1946) after apparently successful treatment of *H. influenzae* meningitis seem to indicate not only survival of Pfeiffer's bacillus in inaccessible recesses of the cerebrospinal canal but possibly also the development of a strain of higher resistance to the particular form of treatment. Emergence of highly resistant strains in the case of streptomycin-treated patients has been demonstrated conclusively by a number of workers (Birmingham *et al.*, 1946; Alexander *et al.*, 1946b; Smythe, 1948; Roscoe and Gleeson-White, 1948).

At present we have at our disposal four clinically well tried substances attacking *H. influenzae*, each acting in a different way. These are: (1) Type-b-specific *H. influenzae* rabbit antiserum, which enters into an antigen–antibody reaction with the polysaccharides of the bacterial capsule. (2) Sulphonamides. It is claimed that they interfere with the intermediary metabolism of the bacterial cell by blocking the assimilation of para-aminobenzoic acid (Woods, 1940). (3) Penicillin, which acts on growing sensitive bacteria by preventing their multiplication (Garrod, 1945), possibly by blocking the passage of glutamic acid through the cell wall into the bacterial cell (Gale and Taylor, 1947). (4) Streptomycin, the mechanism of which is as yet little understood, but which has a rapid bactericidal action as distinct from the slower bacteriostatic and bactericidal effect of penicillin (Garrod, 1948; Alexander and Leidy, 1949). Another pointer to its possible mode of action is the interference of anaerobic conditions or of reducing agents with the antibacterial action of streptomycin (Bondi *et al.*, 1946). At a later date the newer antibiotics chloramphenicol and "aureomycin" may also be useful. These drugs are reported to evoke a pattern of development of resistance similar to that produced by penicillin (Alexander and Leidy, 1949; Demerec, 1949).

According to the foregoing considerations none of the earlier remedies successfully tried in severe *H. influenzae* infections has become obsolete in consequence of subsequent developments. There is every reason to suppose that the combination of therapeutic doses of sulphonamides, penicillin, and streptomycin—the first administered systemically and the other two both systemically and locally—is able to control any acute *H. influenzae* infection. It will, in the first instance, achieve speedy sterilization

of the affected organs or body fluids—a most useful characteristic of the action of streptomycin—while, secondly, it will at the same time prevent the high rate of drug-resistant strains observed in streptomycin-treated cases. If type-specific *H. influenzae* rabbit antiserum is also used its neutralizing action on the bacterial polysaccharide freely circulating in the blood and present in the cerebrospinal fluid will help the patient more rapidly to overcome a state of toxaemia, while the action of antiserum on the bacterial capsule is likely further to damage the invading micro-organisms. With regard to possible future developments, one has to keep in mind that a marked antagonistic action of some of the newer antibiotics on each other has been demonstrated recently when tested together against certain Gram-negative micro-organisms (Price *et al.*, 1949).

In practice three of the agents available—sulphadiazine, streptomycin, and penicillin or type-specific rabbit antiserum—have already been used simultaneously with good results as judged by the small number of cases (see Table I). Some experimental findings of Alexander and Leidy (1946) seemed to suggest that sulphonamides are incapable of enhancing the bactericidal effect of streptomycin. Potentiation of streptomycin by sulphonamides would not necessarily reveal itself under the experimental conditions used by these authors. This latter interpretation of their findings is supported by later papers recommending the combination of sulphadiazine, streptomycin, and type-specific rabbit antiserum in severe subacute cases and in children under 7 months of age (Alexander and Leidy, 1947, 1949).

Experimental Observations on Sulphonamide Sensitivity

It is likely, therefore, that for some time to come the sulphonamides will still have their value in the treatment of *H. influenzae* infections and in particular in *H. influenzae* meningitis. In view of a number of clinical reports mentioning resistance of some *H. influenzae* strains to one or the other sulphonamide (Pittman, 1942; McIntosh and Drysdale, 1945; Drysdale, McIntosh, and Brodie, 1946; Gottlieb, Forsyth, and Allott, 1947; Thomson, Bruce, and Green, 1947; Martin and Sureau, 1948) it seemed of practical importance to investigate this phenomenon *in vitro* in a greater number of strains than had been examined hitherto. Guyton (1940) had examined two strains for sulphonamide sensitivity, Pittman (1942) had noticed a variation in susceptibility to the same compound in some of six strains tested, and Alexander and Leidy (1943) in their inquiry into the synergistic effect of the various sulphonamides and rabbit antiserum had used only one strain.

Materials

Strains.—A collection of 50 capsulated and 50 non-capsulated strains of *H. influenzae* was investigated. The first group comprised 5 type a strains, 35 type b strains, one type c strain, three type d strains, one type e strain and three strains related to type e, and, finally, two type f strains. The majority of these strains had been isolated from cases of *H. influenzae* meningitis, some were originally found in the nasopharynx of children, the rarer types were stock strains kept for reference purposes, and four type b strains were obtained from the National Collection of Type Cultures. Twenty-four of the non-capsulated strains were isolated from pernasal swabs of children suspected of whooping-cough, two strains from the cerebrospinal fluid of cases of *H. influenzae* meningitis, two strains from antral washings, one from an eye swab, and the remainder from bronchial secretions and sputa.

Medium.—When choosing a nutrient medium in which to test sulphonamide sensitivity attention has to be paid to substances inhibiting the action of sulphonamides and known to be present in most media incorporating peptone. Neutralization of these inhibiting substances can be achieved by treatment with 5% horse blood (Harper and Cawston, 1945; Walker *et al.*, 1947). A Levinthal agar modified with this point in view was used. Ten per cent. oxalated horse blood was added to nutrient broth and incubated overnight at 37° C. On the next day this fresh horse-blood broth was used for making Pittman's (1931) modification of Levinthal agar, which was then poured into plates.

Technique.—The tests of sensitivity to the various sulphonamides were carried out on Levinthal-agar plates in two different ways. (1) By incorporating a suitable concentration of the sulphonamides into Levinthal-agar plates. Seven plates were necessary for each test, one for each sulphonamide, and a maximum of eight inoculations were placed on each plate. In this way seven *H. influenzae* strains and one other control culture—*Staphylococcus aureus* as a rule—could be tested in one experiment. (2) By the punch-plate method. Seven punch-holes in a single Levinthal-agar plate were filled with a solution of the seven different sulphonamides after the plate had been inoculated previously with a suitable dilution—1 in 100 or 1 in 1,000—of a 24-hour Levinthal broth culture of the *H. influenzae* strain under investigation.

The two techniques were applied to the same strains simultaneously, seven *H. influenzae* strains being tested against seven sulphonamides at a time.

The following sulphonamides were tested: sulphanilamide (henceforth abbreviated SA); sulphapyridine (SP); sulphathiazole (ST); sulphadiazine (SD); sulphadimidine, also known as "sulphamezathine" (SMZ); 2-(*p*-aminobenzenesulphamido)-4-methylpyrimidine, also known as sulphamerazine (SMR); and maphenide (MAPH) (4-aminomethylbenzenesulphonamide), also known as "marfanil" or "ambamide." The concentration tested was that corresponding approximately to the concentration obtained in the blood by the usually recommended dosages—that is, 10 mg. per 100 ml. This concentration was adopted for all seven sulphonamides. The readily soluble substances—SA and MAPH—were used as such to prepare solutions, while the more easily soluble sodium salts of the remaining five compounds were employed to make up stock solutions. All solutions were sterilized by filtration.

Results

Table II summarizes the results obtained with 50 capsulated strains tested by incorporating the sulphonamides in the medium. From 10 to 24% of the strains were completely inhibited. The majority of the strains were either markedly or slightly inhibited. One strain, the same in each instance, was resistant to 10 mg. per 100 ml. of all sulphonamides except ST, by which it was inhibited to a marked degree. The considerable number of strains insensitive to both SA and MAPH is remarkable, though perhaps not altogether surprising. There can be no doubt that with this technique ST is the most effective drug.

TABLE II.—*Capsulated Smooth H. influenzae Strains on Modified 10 mg. per 100 ml. Levinthal Agar*

Sulphonamide Tested	Insensitive Strains	Partially Sensitive and Markedly Inhibited Strains	Completely Inhibited Strains
SA	13	32	5
SP	2	41	7
ST	0	38	12
SD	1	39	10
SMZ	1	41	8
SMR	1	41	8
MAPH	13	28	9

SA—sulphanilamide; SP—sulphapyridine; ST—sulphathiazole; SD—sulphadiazine; SMZ—sulphamezathine; SMR—sulphamerazine; MAPH—maphenide.

TABLE III.—*Capsulated Smooth H. influenzae Strains on Modified Levinthal Agar, Punch-plate Method*

Sulphonamide Tested	Insensitive Strains	Partially Sensitive and Markedly Inhibited Strains	Completely Inhibited Strains
SA	37	12	1
SP	6	37	7
ST	3	34	13
SD	4	36	10
SMZ	5	35	10
SMR	4	33	13
MAPH	32	18	0

Table III gives the results obtained with the same strains tested by the punch-plate method. When compared with Table II a general shift is noticeable from right to left. This is particularly evident with strains completely inhibited by SA and MAPH and less so with strains inhibited by the other sulphonamides. However, when the markedly inhibited and partially insensitive strains are considered the shift becomes more pronounced. The obvious interpretation of this shift is that the punch-plate method is less sensitive and therefore less accurate than the method incorporating sulphonamide compounds into the medium. In Table III, as in Table II, ST appears to be the most potent sulphonamide.

TABLE IV.—*Non-capsulated Rough H. influenzae Strains on Modified 10 mg. per 100 ml. Sulphonamide Levinthal Agar*

Sulphonamide Tested	Insensitive Strains	Partially Sensitive and Markedly Inhibited Strains	Completely Inhibited Strains
SA	6	34	10
SP	2	31	17
ST	2	23	25
SD	1	34	15
SMZ	2	37	11
SMR	2	35	13
MAPH	5	32	13

TABLE V.—*Non-capsulated Rough H. influenzae Strains on Modified Levinthal Agar, Punch-plate Method*

Sulphonamide Tested	Insensitive Strains	Partially Sensitive and Markedly Inhibited Strains	Completely Inhibited Strains
SA	32	16	2
SP	6	36	8
ST	3	32	15
SD	4	32	14
SMZ	5	32	13
SMR	5	33	12
MAPH	42	8	0

Tables IV and V show the results obtained when non-capsulated strains are tested with the same techniques. Here, too, ST is the most effective compound, although in this group of strains there are two which are completely insensitive to ST. On the whole, the figures for completely and partially inhibited strains are higher than those obtained with capsulated strains. In other words, more non-capsulated respiratory strains are effectively controlled by sulphonamides than capsulated strains. On clinical grounds it had been suspected earlier that differences in sulphonamide sensitivity might exist between capsulated and non-capsulated strains of *H. influenzae* (Gordon, Woodcock, and Zinnemann, 1944). This suggestion appears now to be confirmed by *in vitro* tests.

In these experiments the same strain was usually resistant to many or all sulphonamides, but occasionally a strain was found which was resistant to only one or two sulphonamides. This resistance, however, is relative in so far as in these tests sensitivity to only one concentration, the one easily attainable in the serum, has been investigated. With few exceptions resistant strains showed some degree of sensitivity to ST. It might seem, therefore, that ST should be the sulphonamide of choice in *H. influenzae* infections. Unfortunately, however, only a small fraction of ST as compared with other sulphonamides appears in the C.S.F. As Table VI shows, the level in the C.S.F. of the sulphonamide least effective with regard to *H. influenzae*—that is, SA—is equal to the blood level, while the level of the most effective sulphonamide *in vitro*—that is, ST—is lowest. In the case of SD, SMZ, and SMR, which are nearly as effective as ST, about half to three-quarters of the blood level is reached in the C.S.F.

TABLE VI.—*Concentrations of the Various Sulphonamides in the C.S.F. in Relation to the Blood Levels*

Sulphonamide	Sulphonamide in C.S.F. as Compared with Blood Level	Authors
SA	Approximately 100%	Marshall *et al.* (1937); Allott (1938)
SP	60–80%	Hobson and MacQuaide (1938); Long and Feinstone (1938)
ST	20–30%	Banks (1941); Andersen and Simesen (1943)
SD	50–80%	Long (1941)
SMZ	60–80%	Kremer *et al.* (1945); Rose *et al.* (1943); Macartney *et al.* (1942)
SMR	50–75%	Hageman *et al.* (1943); Murphy *et al.* (1943)

On the basis of the present investigations it would seem that ST is best suited for *H. influenzae* infections other than meningitis. However, ST should not be dismissed altogether from the treatment of *H. influenzae* meningitis, for this infection is often accompanied by septicaemia (Smith, Wilson, and Hodes, 1946).

When the above facts had become evident it was thought that a combination of the most effective sulphonamides should be tested against a similar series of *H. influenzae* strains. A combination of three sulphonamides is available as "sulphatriad" (S3), and includes 37% ST, 37% SD, and 26% SMR. The original recommendation of this or similar combinations by Frisk *et al.* (1947), Lehr (1947), and Martin and Sureau (1948) was made in order to obtain a higher total blood level and/or to avoid renal complications. As these considerations are of some importance in severe *H. influenzae* meningitis cases receiving maximal doses of sulphonamides over longer periods, the reasons for testing a mixture of sulphonamides seemed to be all the more compelling.

Accordingly a stock solution was made of the sodium salts of ST, SD, and SMR in the proportions in which they are present in commercial S3. The total of sulphonamides of the stock solutions was adjusted to give a final concentration of 10 mg. per 100 ml. This concentration was then tested in the same way and, so far as possible, with the same strains as the seven sulphonamides in the preceding experiments. Nine of the capsulated and eleven of the non-capsulated strains had to be replaced by others, as they had been lost accidentally.

TABLE VII.—*Sensitivity of Capsulated H. influenzae Strains to 10 mg. per 100 ml. of S3 on Modified Levinthal Agar*

Technique of Test	Insensitive Strains	Partially Sensitive and Markedly Inhibited Strains	Completely Inhibited Strains
S3 incorporated in medium	0	27	23
Punch-plate method	3	19	28

TABLE VIII.—*Sensitivity of Non-capsulated Rough H. Influenzae Strains to 10 mg. per 100 ml. of S3 on Modified Levinthal Agar*

Technique of Test	Insensitive Strains	Partially Sensitive and Markedly Inhibited Strains	Completely Inhibited Strains
S3 incorporated in medium	0	23	27
Punch-plate method	0	35	15

The results for capsulated *H. influenzae* strains recorded in Table VII suggest that S3 is at least equal to if not more effective than the single sulphonamides which it contains. In this particular instance the punch-plate method seems a more sensitive test than incorporation of the drug in the medium. No explanation is offered for this phenomenon, which is the opposite of that observed in the preceding series and the one following. The behaviour of non-capsulated strains, as shown in Table VIII, indicates a high degree of sensitivity to S3, no insensitive strain having been encountered by either method of testing. Tables VII and VIII are not strictly comparable to Tables II–V, as not all strains in the two sets of tables are identical. Yet, judging by the width of the zones of inhibition in the series using the punch-plate technique the majority of *H. influenzae* strains, both capsulated and non-capsulated, seem to be more sensitive to S3 than to any of the sulphonamides singly. Here again more non-capsulated strains are sensitive to S3 than capsulated ones.

Discussion

On the one hand, these experiments establish on a broad basis the bactericidal and bacteriostatic action of sulphonamides on *H. influenzae*, thus indicating their usefulness in combined chemotherapy. On the other hand, strains occur which are not inhibited by the standard concentration of SD. In such cases the recommendations of Alexander and Leidy (1943) with regard to SD are not applicable. The results presented here point to the necessity for testing each individual strain isolated from a clinical case for its sensitivity to a standard concentration of 10 mg. per 100 ml. of at least the following sulphonamides: ST, SD, SMZ, SMR, S3, and possibly MAPH. The simplest method is the punch-plate technique. It can be employed quite efficiently for daily routine purposes so long as one keeps in mind that a strain completely insensitive by this method may yet show sensitivity when the sulphonamides are incorporated in the medium and that a repetition of the test with this more complicated technique may therefore be necessary. A further advantage of the punch-plate technique is the ease with which potentially resistant strains can be discovered. Such strains show single colonies of normal size in the area of inhibition surrounding the punch-hole. Subcultures from such colonies yield strains of comparatively high resistance to sulphonamides. This phenomenon has been noticed in several of the strains tested. The observation seems to confirm the theory of progressive selection of *H. influenzae* strains resistant to sulphonamides.

The preparation of modified Levinthal agar may be somewhat difficult in certain circumstances. For this reason chocolate-agar plates prepared for routine purposes with oxalated horse blood were used in parallel with Levinthal-agar plates in all experiments described above in which the punch-plate technique was employed. The readings were as a rule less sensitive than those with the punch-hole technique on Levinthal-agar plates.

Summary

The recent literature on resistance to antibacterial drugs and on the combined use of these drugs has been reviewed.

The sensitivity to the various sulphonamides of 50 capsulated and an equal number of non-capsulated *H. influenzae* strains was tested with two different techniques on modified Levinthal agar.

In a concentration of 10 mg. per 100 ml. sulphathiazole is the most effective drug *in vitro*, almost equalled by sulphadiazine, sulphadimidine, and sulphamerazine. Sulphatriad seems to be more effective than any of its constituent sulphonamides alone.

Non-capsulated strains of *H. influenzae* show a higher *in vitro* sensitivity to sulphonamides than capsulated strains.

Individual strains of *H. influenzae* may be sensitive to the standard concentration of one sulphonamide and resistant to that of others. Strains may occur which are insensitive to the standard concentration of sulphadiazine. It is necessary, therefore, to test each strain from individual clinical cases for sulphonamide sensitivities.

Advantages and disadvantages of the bacteriological techniques employed are discussed and recommendations are made.

It is my pleasant duty to acknowledge generous gifts of drugs from May and Baker, Ltd., Imperial Chemical Industries, Ltd., and R. F. Reed, Ltd. The Medical Information Department of May and Baker, Ltd., was very helpful in finding data and references given in Table VI. Dr. Anna Mayr-Harting kindly discussed some of the genetic aspects with me. Dr. Edith A. Straker, and Drs. Betty Dawson, J. W. Czekalowski, and G. M. Williamson of this department, as well as the National Collection of Type Cultures, very obligingly supplied some of the H. influenzae strains used. I owe thanks to Mr. A. Myers and Mrs. B. Hewitt for the preparation of media used in the experiments.

CHRONIC ADHESIVE SPINAL MENINGITIS ASSOCIATED WITH LUMBAR NAEVUS AND DIMPLE

BY

T. R. SAVAGE, B.M., M.R.C.P.

(From the Hospital for Sick Children, Great Ormond Street)

Chronic meningitis confined to the spinal theca has been described frequently during the last fifty years; it has been known by various synonyms—arachnitis adhesiva circumscripta, arachnoïdite cloisonnée, arachnoid cysts, circumscribed serous spinal meningitis, and chronic spinal meningitis.

The aetiology of the condition is obscure in most cases: Ford (1945) states that it may follow various types of meningitis, spinal analgesia, and, in the opinion of most authorities, trauma to the spine. The reason for this obscurity seems to be that chronic spinal meningitis is usually the end-result of a previously unrecognized inflammatory process, and there is a clearly defined picture in the later stages only, either clinically or at operation or necropsy.

The subject has been reviewed by Horsley (1909), Mauss and Krüger (1918), Elkington (1936), and Rocovich (1947); but these authors do not mention congenital dermal sinuses as an important cause of chronic spinal meningitis. Mallory (1892) described coccygeal sinuses and cysts without meningeal or spinal cord involvement, and discussed their pathogenesis, with particular reference to abnormal foetal development.

Moise (1926) states that the sacro-lumbar region is a common site for developmental anomalies, among which are included congenital dimples, sinuses, cysts, and tumours. These cysts and tumours may be dermoid or epidermoid (List, 1941). There is only occasionally a connexion between the spinal canal and the skin surface. Also there may be instances of spina bifida, with all gradations from an unnoticed spina bifida occulta with no evidence of an external defect to a fusion of the spinal cord with the integument. The cases showing a connexion between the spinal canal and the exterior do not as a rule survive infancy. Moise was the first to report a case of meningitis (*Staphylococcus albus*) secondary to a congenital dermal sinus; there were no symptoms until the age of 18; there was spina bifida and a direct connexion between the skin and the spinal cord, and the patient recovered after laminectomy with drainage.

Ripley and Thompson (1928) described a case of *Staph. albus* meningitis in which a pilonidal sinus was the route of infection. Walker and Bucy (1934) reported seven cases in which a congenital dermal sinus, appearing externally as a small dimple in the midline of the back, had become infected (two with *Staph. albus*); all the cases but one were associated with spina bifida occulta.

Other cases have been recorded by Stammers (1938), Boldrey and Elvidge (1939), List (1941), and Tizard (1950). O'Connell's case (1942), that of a child aged 4, had a lumbosacral port-wine stain and a small central pit extruding sebaceous material on pressure; this was complicated by recurring attacks of meningitis (coliform organisms) from the age of 8 months; the sinus was traced through a lumbar spina bifida to a large intradural abscess lying among the roots of the cauda equina.

Intramedullary abscess of the spinal cord complicating congenital dermal sinuses has been recorded by Kooistra (1942) and Shenkin and others (1944). Mount (1949) has been the first to describe a case with intracranial abscess as a similar complication.

The following case is reported because the causation of the condition and the route of infection raise some interesting problems, and because in several features it resembles previously reported cases, especially that of O'Connell.

Case Report

A girl aged 9 had backache for two weeks in 1947. In February, 1948, she again had severe backache, low in position, with delirium and pyrexia for one week, and was admitted to a hospital near her home.

Her own and her family history revealed nothing relevant. She was pale and thin; the posterior cervical and inguinal lymph nodes were enlarged; and flexion of the left hip with straight leg raising was limited. The white cells numbered 5,000 per c.mm. (neutrophils 39%), the E.S.R. (Wintrobe) was 7 mm. in one hour, and the Mantoux test (1 in 1,000) was negative. Her temperature and pulse became normal within three weeks; she received only sedatives.

In March, 1948, recrudescence of pain in the back and fever led to her readmission to the local hospital. There was limited mobility of the lumbar spine with spasm of the erector spinae. Swelling of joints, nodules, and skin rashes were absent; the white cells numbered 9,000 per c.mm. (neutrophils 50%), the E.S.R. (Wintrobe) was 19 mm. in one hour, the blood Wassermann reaction was negative, and blood culture was negative. Radiography showed spina bifida of the eleventh thoracic, fourth and fifth lumbar, and first sacral vertebrae. A tentative diagnosis of rheumatic fever was then made. She was kept flat in bed for four months and was in hospital for eight months; she was given salicylates and phenobarbitone.

In December, 1948, pain in the back and right lower limb and pyrexia reappeared.

In March, 1949, she was admitted to Great Ormond Street. She was miserable and wasted generally; there was a circular brown pigmented naevus about 2.5 cm. in diameter with a shallow dimple or pit about 3 mm. in diameter over the lumbar spine. Walking was painful and difficult. Sitting with her knees fully flexed was the position she adopted in bed. There was no neck rigidity. In the upper and lower limbs muscular development, tone, and power were poor and impaired equally with the rest of the body and on the two sides. There was no localized wasting; co-ordination was normal. The biceps, supinator, and triceps jerks were absent on the right and present on the left. The abdominal reflexes were present and equal. There was still gross limitation of straight leg raising—to 45 degrees. The right knee-jerk was exaggerated and the left

absent. Both ankle-jerks were absent and the plantar responses were both equivocal. There were no sensory changes or evidence of a sensory level.

Special Investigations

Radiography revealed no abnormality in the skull, lungs, heart outline, and mediastinum.

On March 19 the white cells numbered 12,650 (neutrophils 60%); the E.S.R. was 4 mm. in one hour; agglutinations against *Salmonella typhi, Salm. paratyphi* A and B, all with O and H antigens, and *Brucella abortus* were all negative. A catheter specimen of urine was normal.

On March 21 a lumbar puncture produced a dry tap from 3/4 and 4/5 lumbar spaces, but a faintly cloudy colourless fluid with clot from the 2/3 space; no resting pressure could be read because of crying. Examination of the fluid showed: 42 cells per c.mm. (98% monocytes); no organisms seen; culture sterile; protein, 275 mg. per 100 ml.; sugar, 50 mg. per 100 ml.; insufficient for chlorides; Wassermann reaction negative.

On March 25 a lumbar puncture in all the above spaces resulted in a dry tap. Cisternal puncture gave a slightly turbid colourless fluid with a clot: cells 25 per c.mm.; culture sterile; protein, 150 mg. per 100 ml.; sugar, 56 mg. per 100 ml.; chlorides, 735 mg. per 100 ml. On March 30 a post-nasal swab (for meningogocci) contained a few colonies of *Staph. albus*.

The provisional diagnosis at this time was chronic adhesive arachnoiditis following old meningitis, possibly meningococcal. The patient was transferred to the Atkinson Morley Hospital under Mr. Wylie McKissock for further investigation.

On April 11 a cisternal encephalogram revealed good and normal filling of the ventricular system. Lumbar myelography (1 ml. of "myodil" introduced into the cisterna magna) showed poor filling of the theca, and the appearances suggested an arachnoiditis with block at the level of the second lumbar vertebra (Figs. 1 and 2). With the head down, the theca was filled with air and the existence of spinal block was confirmed.

Mr. Wylie McKissock performed laminectomy of the second, third, and fourth lumbar vertebrae on April 19. The theca was

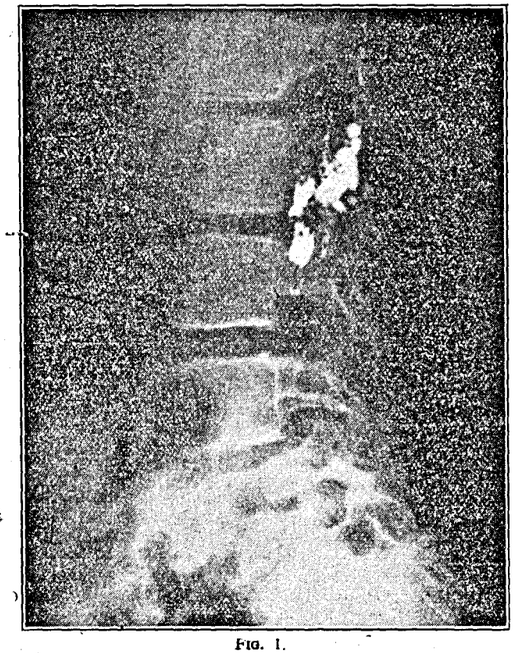

FIG. 1.

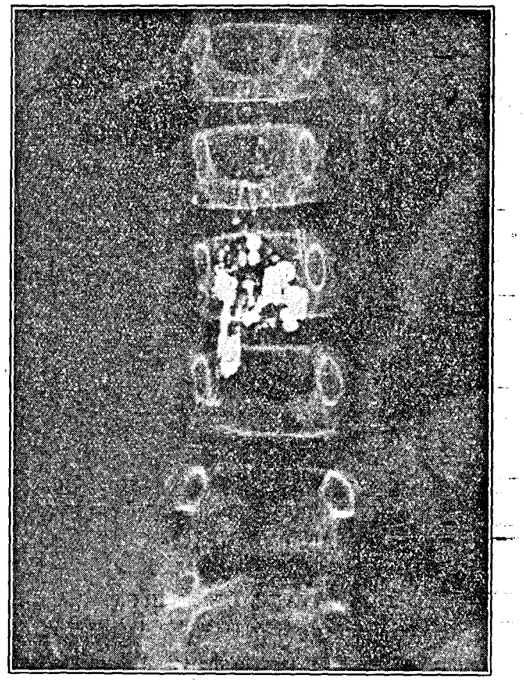

FIG. 2.

tense and bulging and unusually firm to the touch. The dura was found to be particularly thick and adherent to the underlying granulation tissue. The whole subdural space was filled with a mixture of granulation tissue, pus, and fibrous adhesions, in which most of the nerve roots were embedded. The dura was left open and the wound closed in layers over it. No sinus between the skin and spinal theca was found. A light growth of coliform organisms was obtained from a swab at operation.

In the immediate post-operative period penicillin was given four-hourly for three days (total 440,000 units) and streptomycin 4 g. over five days, both by intramuscular injection, and sulphadimidine by mouth for seven days (total 18 g.).

Post-operative Progress

The wound healed by first intention. Full movement in both lower limbs had returned 10 days after operation. The patient was free from pain in the back and legs. There was only occasional urinary incontinence, and the spine remained rather rigid. During the first few weeks the tendon-jerks in the right upper limb returned and equalled those on the left; the left knee-jerk returned and was brisk, the right knee-jerk remained exaggerated; both ankle-jerks could just be elicited; plantar responses were flexor; Rombergism was absent; her gait was normal except for some evidence of apprehension.

From May to September, 1949, she was symptomless except for a discharging sinus near the laminectomy scar. Her nutrition and muscular development improved greatly and she had even learned to swim.

On her fourth admission to hospital on September 26 (Atkinson Morley Hospital), for exploration and excision of the residual sinus, there was very slight weakness of the muscles moving the left knee- and ankle-joints. There was no wasting, and the muscular tone was good. All tendon-jerks were brisk, the right knee-jerk being slightly greater than the left; the plantar responses were flexor. Spinal movements were good and painless; there was no tenderness on pressure over the spine; the gait was normal. Pus was discharging from two small sinuses

in the laminectomy wound and from the small pit in the naevus. Radiography of the lumbar spine showed no myodil residues and no evidence of bone infection. *Staph. aureus* and *Neisseria catarrhalis* were cultured from the sinuses.

On October 4 the sinus was found to extend as deep as the anterior surface of the erector spinae. The wound healed, but discharged again intermittently. Swabs were repeatedly sterile on culture.

On January 24, 1950, the original wound, together with the naevus, was completely excised down to the block of fibrous tissue which covered the open theca; no true granulation tissue was discovered at any point.

During the next six months the sinus in the operation scar discharged intermittently, but the patient's general health was excellent; she remained symptomless and free from pain in the back and lower limbs. In July, 1950, there was a small discharging sinus in the lumbar scar; spinal movements were full except for slight limitation of flexion; straight leg raising was limited to 80 degrees (right and left) by pain in the hamstrings; right hip flexion was slightly weak; the right knee-jerk was very brisk, the left was normal; the right ankle-jerk was absent, the left was present on reinforcement; the plantar responses were flexor; sensation and gait were normal.

Discussion

This case has several features of interest, particularly from the aspect of diagnosis and the mode of infection.

Diagnosis of Site of Lesion.—Negative evidence included absence of a history of trauma and of radiographic signs of vertebral disease, and therefore indicated that the lesion was intradural: absence of involvement of the long tracts excluded an intramedullary lesion. Positive evidence depended chiefly on the presence of bilateral and asymmetrical changes in the tendon reflexes in the upper as well as the lower limbs, showing that spinal nerve roots in the cervical region as well as the cauda equina were involved; also, the existence of spinal block was demonstrated after lumbar puncture and contrast myelography. Spinal block was complete at the level of the second lumbar vertebra and was partial above the lumbar region.

Diagnosis of Nature of Lesion.—The long history of recurring bouts of pyrexia and back pain over more than twelve months strongly suggested an inflammatory process. An equally extensive intradural neoplastic lesion was only likely to be due to "seedling" metastases derived by gravity from an intracranial tumour, but there was no clinical or radiographic evidence of such a space-occupying lesion. Negative serological tests excluded syphilis as a cause.

The appearances at myelography were those of arachnoiditis, but all authorities agree that a pre-operative diagnosis of chronic adhesive spinal meningitis is seldom made, and that clinical distinction from spinal tumour is difficult. Mackay (1939) states that, clinically, such cases differ from those of extramedullary spinal tumour in the evidence of a diffuse disturbance of the spinal cord and roots, such as widely scattered paraesthesiae and pains, irregular and inconstant sensory disturbances, muscular atrophy and large fascicular twitches, painful muscular spasms, a mixture of exaggerated and diminished tendon reflexes, and arrest of iodized oil at multiple levels. There is absence of agreement concerning sensory disturbances, since Beaumont (1950) states that in spinal arachnoiditis the posterior roots are much more likely to be affected than the anterior. It is not clear why the first operation was followed by a return to normal of the upper-limb tendon-jerks; it has been suggested that this was an effect of chemotherapy. There remains the possibility that a dermoid is still present among the roots of the cauda equina.

Mode of Infection.—This is the chief problem of the case. In considering the possible routes by which infection reached the spinal meninges, there was no evidence of septicaemia or a primary infective focus elsewhere, at or before the onset of symptoms. There was no history of a lumbar puncture for diagnosis or spinal analgesia (Kremer, 1945). The presence together of a pigmented naevus with a dimple in the midline over the lumbar spine, spina bifida occulta of the eleventh thoracic, fourth and fifth lumbar, and first sacral vertebrae, and chronic adhesive arachnoiditis suggest that infection may have reached the meninges via a sinus, though such a sinus was not demonstrated at operation. Some support for this claim is provided by the close resemblance to the case described by O'Connell (1942).

I am indebted to Dr. Bernard Schlesinger and Mr. Wylie McKissock for permission to record the case that was under their care. I should like to thank Dr. Schlesinger for his interest and helpful criticism of this report, and Dr. E. J Glynn for his case notes.

The following statement about the prophylactic administration of penicillin in certain cases has been approved by the American Council on Rheumatic Fever of the American Heart Association: "Following dental extractions and removal of tonsils and adenoids, bacteria are frequently present in the blood stream for short periods of time. In rheumatic individuals or in patients with congenital heart disease these bacteria may lodge in the heart valves and cause bacterial endocarditis. Although a variety of bacteria cause this disease, the majority of cases are due to alpha streptococci (*Streptococcus viridans*). Alpha streptococci are usually resistant to sulphonamide drugs. Penicillin is, therefore, recommended for prophylaxis as follows. (1) Except in emergencies operative procedures in rheumatic individuals should be deferred until there is no clinical evidence of rheumatic activity and laboratory tests indicate that the rheumatic process is subsiding. (2) Patients should be free from upper respiratory infection. (3) Minimum dosage of penicillin: (*a*) 300,000 units of aqueous penicillin intramuscularly 30–60 minutes before extraction or operation. (*b*) 300,000 units of procaine penicillin in oil injected intramuscularly at the same time in a different site. Penicillin prophylaxis is not necessary for the extraction of deciduous incisors or bicuspids unless infection of the gum is present. It should be used in the extraction of deciduous molars and all permanent teeth, and for tonsillectomy and adenoidectomy. In most instances it is best to extract one tooth at a time; multiple extractions should be avoided. In cases of extensive gum infection or severe root infections (apical abscesses) it is advisable to give several doses of penicillin starting the day before operation and continuing one or two days thereafter. Women with rheumatic or congenital heart disease should receive penicillin prophylaxis at the time of delivery. It is also recommended for patients requiring gastro-intestinal surgery."

A CASE OF CARDIAC ARREST

VAGAL INHIBITION RELIEVED BY PROCAINE

BY

HENRI L. M. ROUALLE, M.D., F.R.C.S.

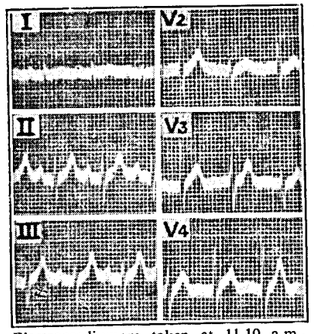
Senior Surgical Registrar, Wellhouse Hospital, Barnet

Cardiac arrest occurs about twice a year in a busy surgical unit (Hamilton Bailey, 1941 ; Lahey and Ruzicka, 1950) ; it may arise quite unexpectedly in any operation or with any form of anaesthetic, and when it occurs very rapid measures must be taken if the patient is to survive. Anoxia lasting for more than 3½ minutes may lead to irreparable cerebral damage, and survival is unlikely if the circulation has been arrested for more than 8¼ minutes (Weinberger, Gibbon, and Gibbon, 1940).

No apology is therefore necessary in reporting a single case, and that ultimately unsuccessful, if the experience thereby obtained will contribute to success in the future.

Case Report

A man aged 48 was admitted on June 12, 1950, on account of a retrosternal goitre causing dysphagia, voice changes, and thyrotoxicosis of eight weeks' duration. He was a nervous patient with exophthalmos and a tachycardia of 140 a minute. His blood pressure was 170/70 mm. Hg ; B.M.R. +37% ; serum cholesterol 220 mg. per 100 ml. An electrocardiogram showed sinus tachycardia only. There was no evidence of cardiac failure.



After two weeks' rest and sedation a course of Lugol's iodine was given in preparation for operation. On July 20 his pulse rate had steadied to 96 a minute and he was considered fit for operation.

Next day potassium bromide and chloral, 30 gr. (2 g.) each, and hyoscine, 1/150 gr. (0.43 mg.), were given at 7 a.m., followed by Lugol's iodine, 30 min. (1.8 ml.) by mouth. At 8.30 a.m. induction was begun smoothly, using gas and oxygen, supplemented by isopropyl chloride, and an endotracheal tube was passed without difficulty. At 8.40 a.m. he was brought into the theatre and lifted on to the operating table: he immediately gave a slight cough and raised his arms, and was then seen to change colour to a grey lividity. His pulse could not be detected.

His head was lowered, and controlled respiration with pure oxygen was begun. An intracardiac injection of 0.5 ml. of 1/1,000 adrenaline was given without effect, and an upper midline abdominal incision was made and infradiaphragmatic cardiac massage started by 8.48 a.m. Control of the heart was unsatisfactory and an antero-posterior incision was made through the diaphragm and three fingers were passed into the pericardial cavity.

The left ventricle was felt to be dilated, flaccid, and inert ; on the other hand, rhythmic rippling movements of the left auricle could be felt at about 160 a minute. Rhythmic compression of the ventricles at 60 to 80 beats a minute, allowing refilling between strokes, was maintained against the sternum without effect. Meanwhile occasional shallow jerky respirations continued ; the pupils remained moderately dilated. Controlled respiration with pure oxygen continued.

At 9.10 a.m. another 1 ml. of adrenaline was injected into the cavity of the right ventricle ; within two minutes the ventricle was felt to pass into a state of systole and a few rippling twitches followed. At 9.20 a.m. 3 ml. of 2% procaine was injected into the cavity of the ventricle: after a delay of about five minutes strong rhythmic contractions quite suddenly returned at about 100 a minute ; these began to weaken after a few minutes, but improved with further massage ; intermittent irregularity and weakening occurred. At 10 a.m. a further injection of 6 ml. of 2% procaine was given. By 10.10 a.m. normal rhythm was restored (see accompanying electrocardiogram). The abdomen was later closed. Respirations returned, but were of a rapid, gasping type, and the lividity persisted. Despite treatment in an oxygen tent, the pulse weakened gradually, and he died at 2.10 p.m. without regaining consciousness.

Electrocardiogram taken at 11.10 a.m., showing return to normal rhythm with marked variations in voltage.

Necropsy showed gross congestion of the upper part of the body, including the brain. The thyroid gland was much enlarged, weighing 4 oz. (113 g.), and completely encircled the trachea and oesophagus. The heart was enlarged, the muscle fibrous and not of good quality ; the only evidence of trauma was a small nick in the postero-inferior surface which had injured the descending branch of the right coronary vessel. About a pint (570 ml.) of blood had escaped into the left pleural sac, which had been opened.

Comment

The cardiac arrest was at the time attributed to failure of a thyrotoxic heart under the added strain of an anaesthetic, but the subsequent sudden restoration of normal rhythm following on the injection of procaine, when prolonged massage and two injections of adrenaline had completely failed, suggests that the immediate cause of the arrest was intense vagal inhibition. According to Fulton (1949), vagal stimulation weakens the force of the heart beat and depresses conduction within the heart, chiefly within the auricles and the A-V node, where it may produce all grades of A-V delay and dissociation. Vagal reflexes may be initiated from nerve endings in the aortic arch and carotid sinus, and also from any part of the respiratory tract from the nose to the trachea. Reid and Brace (1940) have demonstrated electrocardiographically that the insertion of an endotracheal tube under light anaesthesia may produce cardiac irregularities such as extrasystoles, delayed conduction time, and bradycardia, and that this vagal reflex can largely be abolished by atropine.

This case is in many respects similar to that reported by Adams and Hand (1942) in which a patient undergoing lobectomy for bronchiectasis gave three sharp coughs when endotracheal suction was applied: cardiac arrest occurred, and the circulation was kept going manually for 20 minutes. Adrenaline failed to produce any effect, but procaine was given intramuscularly at 15 minutes, and the heart restarted five minutes later, with complete recovery. Success in this case was probably due to the fact that as the thorax was open immediate compression of the heart was carried out and actual arrest of the circulation did not occur. Howkins *et al.* (1946), however, report a case in which the circulation was not established for 11 minutes and extensive cerebral changes were found after death on the twenty-sixth day. Recovery following 25 minutes' arrest relieved by intravenous procaine also occurred in a case quoted by Burstein (1949).

Although it has been customary to give adrenaline on these occasions, its value in complete arrest is doubtful, as there is no evidence that it restarts the heart and it may produce ventricular fibrillation. Lahey and Ruzicka (1950) recommend that a stock dose containing 9.5 ml. of 1% procaine with 0.5 ml. of 1/1,000 adrenaline should be kept ready in the operating theatre. The present case has shown, however, that, despite its dramatic effect, procaine may have no action for about five minutes, during which time severe damage to the brain will occur. Time should therefore not be wasted in awaiting the result of the procaine injection, and cardiac massage should be started at once. Our experience with the above case showed the difficulty of compressing the heart satisfactorily from below the diaphragm, as mentioned by Nicholson (1942), and that the transdiaphragmatic incision carries a risk of injury to the heart. Unless the abdomen be already open, Lahey and Ruzicka recommend a direct transthoracic approach through the fourth interspace, dividing the fourth and fifth costal cartilages. Lahey and Eversole (1950) suggest that a disconnected needle be passed through the fourth interspace into the ventricle as soon as the pulse becomes imperceptible ; if no movement be observable, or begins after the needle prick, the case is one of true cardiac arrest and not momentary inhibition as may occur following accidental pressure on the carotid sinus ; the procaine–adrenaline mixture is then injected in two instalments of 5 ml. each, and if there is no response within 30 seconds cardiac massage should be started at once. Lahey and Ruzicka report 46% of complete recoveries in 15 cases ; Hamilton Bailey had only four survivors of 40 cases, though the heart restarted in 13 ; and Barber and Madden (1945) reported 48 recoveries in 143 cases

Summary

A case of cardiac arrest is reported in which complete asystole persisted for 45 minutes despite cardiac massage and adrenaline, but normal rhythm was restored after two intracardiac injections of procaine, though the patient survived for only four hours. The immediate use of procaine, injected into the heart in preference to or with adrenaline, is suggested, but in view of its delayed action cardiac massage should be performed at once so that there is no interruption of the cerebral circulation.

I wish to acknowledge the counsel and assistance given at a time of stress by Dr. John Elam and Mr. Alan Small, to whom I am also indebted for permission to publish this report.

A conference was held on July 14 at Salford, Lancashire, under the auspices of the public health department, to consider the better co-ordination of home and hospital services in the sphere of mental health. The conference was attended by local medical and nursing staff, social workers, and local government councillors. The Mayor of Salford, Alderman Frank Cowin, was in the chair. Dr. J. Bierer (Institute of Social Psychiatry, London) described his experience of day hospitals and therapeutic social clubs in the home management of psychotic patients. He had found day hospitals valuable for those who had spent many years in mental hospitals but were now at home, for patients who had undergone prefrontal leucotomy, for those discharged from hospital for after-treatment or unimproved, and at times to help delinquents in their return to society. A number of other speakers contributed to the conference.

Medical Memoranda

Acute Myocardial Infarction following Tetraethylammonium Chloride Therapy

Since Acheson and Moe (1945) drew attention to the autonomic ganglion blocking effect of the tetraethylammonium ion, preparations of this drug have been increasingly used in the investigation and treatment of hypertension and peripheral vascular disease. Lyons *et al.* (1947) confirm the usefulness of the drug in this respect and also record two cases in which intravenous administration dramatically relieved the pain of acute myocardial infarction. Lindgren and Frisk (1948) treated three cases of angina pectoris with tetraethylammonium bromide : this was followed by severe anginal attacks in two cases and by acute myocardial infarction in one. They conclude that the drug should be used with caution in angina pectoris and hypertension with marked arteriosclerosis. Below are reported three cases of occlusive arteriosclerosis of the lower limbs in which tetraethylammonium therapy was followed by acute myocardial infarction.

Case Reports

Case 1.—A man aged 41 was admitted to hospital on October 24, 1948, with a complaint of pain in both calves which came on after walking 50–100 yards (46–92 metres) and which disappeared on rest. He had also suffered from coldness of the feet for some years. No dyspnoea was present, nor did he complain of chest pain. His pulse was 70 a minute and regular, and the vessel wall was not palpable. The heart sounds were good, with no murmurs and a normal *x*-ray shadow. His blood pressure was 125/85 mm. Hg. Urinary investigation was negative. Both feet were cold and slightly congested, and ankle pulses were absent. His right great toe became increasingly discoloured. Right lumbar ganglionectomy was carried out on March 1, 1949, but no improvement followed. On March 30 the right lower limb was amputated because of spreading gangrene. Tetraethylammonium chloride, 6 ml. (7.5 mg. per kg.) twice daily by intramuscular injection, was started on July 14 and continued for five days. On July 30 6 ml. daily was given. On August 2 he had a sudden attack of pain in the neck and shoulders spreading to the chest, with dyspnoea. An electrocardiogram showed changes compatible with posterior myocardial infarction. *X*-ray examination revealed consolidation of the bases of both lungs. His blood pressure was 120/70 mm. Hg.

Case 2.—A man aged 71 complained in June, 1949, of pain in his calves after walking 60–70 yards (55–64 metres), with occasional slight breathlessness on exertion and mild precordial pain. These symptoms occurred only on exercise and were relieved by rest. His pulse was 80 a minute and regular ; the vessel wall was just palpable. The heart sounds were poor, without murmurs, and his blood pressure was 170/110 mm. Hg. Tetraethylammonium chloride, 2 ml. (3 mg. per kg.), was administered intravenously followed by 5 ml. (7.5 mg. per kg.) by the same route seven days later. Five days after the latter dose the patient suffered a severe attack of dyspnoea, precordial pain radiating to the finger-tips, and he was very restless. During the following two days signs of pericarditis developed and he died on the sixth day from congestive cardiac failure. (As this patient was treated at home no electrocardiographic confirmation exists, but the clinical picture was typical.)

Case 3.—A man aged 49 was admitted to hospital on June 14, 1949, with a complaint of pain in the calves after walking 50 yards (46 metres). This pain disappeared with rest. His feet were cold and congested, and the ankle pulses were absent.

The heart sounds were good, there were no murmurs, and the heart shadow was normal. His pulse was 74 a minute ; the vessel wall was not palpable. His blood pressure was 140/85 mm. Hg. Urinary investigations revealed nothing abnormal. On July 31 tetraethylammonium chloride, 6 ml. (8.5 mg. per kg.) twice daily by intramuscular injection, was started. On August 5 he had a sudden attack of dyspnoea, substernal pain radiating to the arms, diminished right respiratory movement, and poor air entry on the right side. *X*-ray examination showed slight elevation of the diaphragm. His blood pressure was 100/70 mm. Hg. An electrocardiogram showed changes consistent with posterior myocardial infarction.

Although the possibility of coincidence cannot be excluded, it is thought that in these cases tetraethylammonium therapy was at least a contributory cause of the acute cardiac lesions. Great care should be exercised in the use of this drug in any patient showing evidence of arteriosclerosis even in the absence of hypertension or marked cardiac symptoms.

I wish to thank Mr. J. Dunbar, surgeon, Glasgow Royal Infirmary, for permission to publish these cases.

Sudden Death after Spontaneous Pneumothorax

Death in cases of spontaneous pneumothorax occurring in otherwise healthy persons is a rare event. A search of the literature has revealed no case similar to the one recorded below.

In this general medical charge (50 beds) of the Royal Infirmary, Edinburgh, from November, 1941, to January, 1950, there have been 12 cases of spontaneous pneumothorax with only one death. Of these 12 cases nine occurred in otherwise healthy males, two were associated with active pulmonary tuberculosis, and one case was of pyopneumothorax, a sequel to lobar pneumonia. One case developed a haemopneumothorax and there was an additional case of haemopneumothorax due to fractured ribs, both of these recovered. Pneumothorax also occurred in a case of bronchial neoplasm following bronchoscopy.

CASE REPORT

A railway engine driver aged 30 was admitted to the Royal Infirmary, Edinburgh, under the charge of Dr. T. R. R. Todd. He gave a history that in the morning of the previous day he experienced a sudden severe pain over the left lower chest, radiating to the left shoulder and associated with increasing dyspnoea. The episode occurred while painting his house. He went to bed, but his symptoms persisted and he vomited in the evening. His doctor thought he had a gross pleural effusion. Symptoms persisted unchanged overnight and he was admitted to hospital the next day.

He gave no previous history of serious illness and had served for 6½ years in the Army, being demobilized early in 1946 in Medical Grade I. His relatives stated that he had had a mild dry morning cough for the past few months and thought he had become thinner about the face recently. Several weeks previously he had complained of slight pain off and on in the left mid-zone of the chest anteriorly but had not sought medical advice. There was no family history suggestive of tuberculosis.

On admission he was seen to be well nourished, pale but not anaemic, perspiring, anxious, and dyspnoeic. His temperature was 97.8° F. (36.5° C.); his pulse was 102 a minute and regular but of poor volume. Both pulses were synchronous. His blood pressure was 118/78. His respiratory rate was 28 a minute and rather shallow. The chest showed markedly diminished movement on the left side with some displacement of the trachea to the right. The percussion note was hyperresonant all over the left lung and the breath sounds were absent on that side, being vesicular over the right lung with no accompaniments. Vocal resonance and fremitus were diminished to absent on the left side. The coin sign was present over the left chest.

The apex beat was not palpable, the left border of the heart was percussed just to the left of the sternum, the right border being percussible 2 in. (5 cm.) to the right of the midline. The heart sounds were closed in all areas and not unduly soft. No abnormality was detected elsewhere.

A diagnosis of spontaneous pneumothorax was made, and in view of the displacement of the mediastinum, the previous severe dyspnoea, and the dullness of the left chest detected by his own doctor on the previous day, though not confirmed by us, it was thought that a degree of tension had been present.

Air aspiration was considered, but as he seemed to be improving this was temporarily postponed. During the evening he became more comfortable (temperature 96.4° F. (35.8° C.), pulse 84, respirations 28), and, although still dyspnoeic, he slept most of the time. About 9 p.m. he turned over quietly on to his left side and died within two minutes, apparently from cardiac failure. The percussion note over the right lung had not altered.

Post-mortem examination was unfortunately refused. It was thought that a sudden mediastinal swing had occurred with possibly torsion of the great vessels at the base of the heart.

COMMENT

In this case the evidence does not suggest underlying pulmonary disease. From the falling pulse rate and the patient's appearance haemopneumothorax was not thought to be present. There was no evidence of bilateral pneumothorax, and, as no alteration of the percussion note was detected over the right lung immediately after death, this is not thought to have occurred as a sudden terminal event. On similar grounds mediastinal emphysema was excluded.

As already mentioned, from the severity of the symptoms and the clinical findings before admission tension pneumothorax was diagnosed ; but in view of the general improvement, the falling pulse rate, and the maintenance of blood pressure it was thought that the tension had diminished and was decreasing further on admission. For this reason air aspiration was not performed, because of the risk of reopening the valvular fistula in the lung. In reviewing the case it is possible that had this been done his life might have been saved.

The other point arising out of this case is that it is advisable in nursing such cases to keep them in the orthopnoeic position and to prevent them turning on to the affected side.

In the absence of a post-mortem examination the possibility of tuberculosis cannot be excluded, but the history and findings do not suggest this. Certainly there was no clinically detectable lesion on the right side.

I wish to thank Dr. T. R. R. Todd for permission to publish this case and also for helpful criticism and advice.

J. W. BUCHANAN, M.A., M.D., M.R C.P.Ed.,
Senior Medical Registrar, Royal Infirmary, Edinburgh.

Caldecote Hall, at Nuneaton, Warwickshire, announces that it is still open for patients. Since the resident medical superintendent, Dr. A. E. Carver, died three months ago there has been an impression that the Hall is closed. In fact a fully qualified nursing sister is in charge and the Hall is being regularly visited by a medical man until a resident medical superintendent is appointed.

Reviews

EAR, NOSE, AND THROAT

Common Diseases of the Ear, Nose, and Throat. By Philip Reading, M.S.(Lond.), F.R.C.S. (Pp. 288 ; 2 coloured plates and 37 text figures. £1 1s.) London: J. and A. Churchill. 1950.

This book is designed for students and newly qualified practitioners. Since the subject, which is a large one, is compressed into 270 pages, it is inevitable that anatomical descriptions are reduced to the minimum, but they are adequate. An inevitable result of compression, too, is that the author makes many dogmatic statements, but for the student that is no bad thing. Only emergency operations are discussed in detail. Of these, tracheotomy and its difficulties are clearly described and illustrated.

Nearly one-third of the book is on diseases of the ear ; the anatomical description is novel and arresting. But one statement about the temporal bone is misleading : the petrous is said to run towards the foramen magnum instead of the foramen lacerum medium. Acute infections of the middle ear are explained well and the bacteriology and pathology are clearly set out. It would be sounder to consider pain rather than deafness as the cardinal symptom, and there should be more emphasis on adequate and early administration of antibiotics and chemotherapy. Indeed, it would be helpful if the last chapter, which is on this subject, were placed early in the book. The coloured illustrations of the tympanic membrane are admirable. The important symptom of facial paralysis is not given its due prominence. After chemotherapy its occurrence may be the only symptom of mastoid involvement, and this ought to be in the practitioner's mind. Again, the author should point out that pain referred to the ear from teeth is always from the lower jaw. Advice on the treatment of acute otitis media and on detecting complications when treatment has failed is very good.

Subsequent chapters on mastoiditis and its treatment are also sound, as is the advice on meatitis. The author discusses vertigo fully, and by means of an ingenious diagram and its explanation shows the effects of loss of labyrinthine function. The caloric test of the function might well have been given first place to the exclusion of the rotatory and galvanic tests ; the fistula test or sign would come more appropriately in the chapter on chronic suppurative otitis media. Not everyone will agree that a dead labyrinth is best treated by radical mastoidectomy supplemented by labyrinthotomy. To decide on the type of deafness, tuning-fork tests are described. (Throughout Rinne is, in error, given an acute accent on the "e.") The voice is preferred to the audiometer for deciding the degree of deafness, but surely this almost universally used apparatus might have been allowed a few lines. Many will take exception to the statement that perception of the upper tones is progressively lost after the age of 21 ; experience disproves it. The chapters on the nose and paranasal sinuses offer excellent guidance to the practitioner.

There is a good chapter on intracranial infections resulting from suppuration in the ear or nasal sinuses ; the paths of infection are clearly described. The author gives a succinct account of the cerebrospinal fluid. Cerebral abscess and thrombosis of the cerebral sinuses are described well, and the treatment of these conditions is admirably set out. The chapters on the larynx are also good, the anatomy being clarified by a diagram, though another illustration might mislead because of a slight error in the placing of the "pointer" to the pyriform fossa. The functions of the larynx and their disorders are well described, as are its diseases and the results of inhaling foreign bodies. The account of tracheotomy is clear, and the detailed description of the aftercare of the patient will be useful to the inexperienced. A section follows on the throat and its ulceration and inflammation. It is well written, and the author emphasizes the importance of swabs in cases where the pathology is in doubt. The indications for tonsillectomy are well set out and conservative, though the anaesthetist will not agree with the opinion that pre-anaesthetics should not be given to children. The short chapter on deglutition and dysphagia must be read closely, for the author has omitted nothing, but has a few words to say on every condition. Lastly, there is a chapter on new growths of the upper respiratory tract ; again a few words only are devoted to each part, but they convey the essential facts.

W. M. MOLLISON.

RESEARCH METHODS

Methods in Medical Research. Volume 2. Julius H. Comroe, jun., Editor-in-Chief. (Pp. 361. $6.50.) Chicago: The Year Book Publishers, Inc.

The Americans have a great respect for methodology, and it is possible to take a degree in the methods, as distinct from the content, of a science. The Germans, who were great scientists before the Americans, frankly said, "Die Technik ist alles." In England we have too deep an affection for the amateur and the garret scientist to believe methodology is everything, and the story of penicillin has confirmed us in our respect for the divine spark. Let us hope that we have learnt the lesson that we need both the spark and the technique. Routine procedures are well described in books, but not so the latest methods of research. Editors of journals and periodicals are more interested in the results of experiments than the technique, and research procedures often undergo a continuous evolution.

For this reason a group of American workers has begun publication of a series of volumes entitled "Methods of Research." This second volume contains three sections—methods of study of bacterial viruses, by Mark H. Adams ; pulmonary function tests, by Julius H. Comroe ; and the assay of hormone secretions, by Eleanor H. Venning. This odd mixture seems unavoidable, and all one can do is to commend the articles to workers in the different fields with the information that they appear to be well done. The Year Book Publishers seem to have a valuable technique of their own which enables them to publish the "hot dope," as the Americans call it, in an incredibly short time and at a price which would be reasonable but for devaluation.

L. J. WITTS.

THE ACTION OF DIGITALIS

Digitalis and Other Cardiotonic Drugs. By Eli Rodin Movitt, M.D. Second edition. (Pp. 245 ; illustrated. £2 5s.) New York: Oxford University Press. London: Geoffrey Cumberlege. 1950.

During the last few years the action of digitalis has aroused fresh interest in several directions. The work of McMichael and Sharpey-Schafer has suggested that "digoxin" exerts its effect not directly on the heart but by a vascular action whereby the pressure in the right auricle is reduced. In the second edition of his book Dr. Movitt discusses their work, but shows that others, notably Stead and also Bloomfield, who have employed the same technique of right-heart

catheterization have obtained different results, which indicate that digitalis improves the cardiac output by an action on the heart itself.

In the treatment of congestive failure, Gold and his colleagues recommend first of all the use of mercurial diuretics and salt restriction. They say that these agents alone control the congestive failure in many patients who do not respond to digitalis. Dr. Movitt considers that Gold's view—that in such patients the use of digitalis is of little importance—is an extreme one, though he admits that in many cases digitalis is ineffective when the rhythm is normal. It is interesting to note this general agreement that, with a normal rhythm, digitalis is often without action. This was the view of Mackenzie and Lewis, who accordingly reserved digitalis for cases of fibrillation. Only a few years ago, however, they were considered to be out of date.

In discussing the part played by the vagus in bringing about the slowing which follows digitalis administration the author quotes the work of Porter, who believed that failure to demonstrate the vagus effect was due to the use of doses of atropine which were too small. The same point was shown by Lewis and his colleagues in 1922, though it is now overlooked.

The chief criticism, indeed, which is to be made of this book is that it contains only five references to the work of Lewis. It seems a pity that the careful studies he made should now receive so little attention. Perhaps he wrote too much.

J. H. BURN.

MEDICAL THERAPEUTICS FOR STUDENTS

Aids to Medical Treatment. By T. H. Crozier, B.Sc., M.D., D.P.H., F.R.C.P. 2nd edition. (Pp. 439. 7s. 6d.) London: Baillière, Tindall and Cox. 1950.

The second edition of this representative of the "Aids" series, written by Dr. Crozier and a team of contributors recruited from his colleagues in Belfast, has grown to a volume of 439 pages. This increase in bulk, although it may depress the student who is intent on hasty revision, rightly indicates the growing complexity of medical therapeutics. The difficulty of divorcing discussion of treatment from that of diagnosis is apparent in many textbooks of therapeutics; Dr. Crozier has avoided this pitfall. His descriptions of treatment contain the minimum of clinical details; they are complete, readable, and properly dogmatic. The book can be recommended as an accurate and full account of medical therapeutics to-day, and it will provide the student with more than he needs for his final examination. It is unfortunate that the first word of Chapter I should have been mis-spelt.

R. BODLEY SCOTT.

THE SOCIAL WORKER

Social Work in the Current Scene. Selected Papers, 76th Annual Meeting, National Conference of Social Work, Cleveland, Ohio, June 12–17, 1949. (Pp. 392. £1 18s.) New York: Columbia University Press. London: Geoffrey Cumberlege. 1950.

In this volume is published a selection of the papers delivered at the last Annual Meeting of the National Conference of Social Work. The papers included in the book comprise only a small proportion of those presented and are arranged in three sections—philosophy, programme, and practice—of which by far the largest is that on programme. This emphasis is perhaps typical of the whole attitude of the majority of the papers: even those which appear in other sections deal more with hopes than with facts and realities.

It has been commonly observed in much of the social work practised in America, as in many other countries, including Britain, that the social worker's attitude to the people among whom he practises is, consciously or unconsciously, condescending. Implicit in most of the papers in this book is the attitude that the conflicts experienced by individuals are due to some fault in them, that the social worker has the key which enables him to "adjust" them to society, and that he stands outside society and acts as guide, philosopher, and friend to the poor and the disabled, who, poor things, are incapable of managing their own affairs and need to be taught better. Although a number of the papers dutifully mention the fact that environment produces many of these conflicts or that the individual should have some rights, few go on to elaborate on the part which the social worker should play in the fight for a better environment. The elaboration is almost entirely on the role of the social worker in "treating" the individual or the family.

There are exceptions to this attitude in some of the papers, exceptions not only in the pious hopes they express but also in the underlying approach to the subject. In particular, Alva Myrdal discusses society's responsibilities towards children and poses a programme for child welfare which is comprehensive and realistic.

LILLI STEIN.

BOOKS RECEIVED

Review is not precluded by notice here of books recently received

The National Health Service. By R. Ormrod, M.A., B.M., B.Ch., and H. Walker. (Pp. 641. 27s. 6d.) London: Butterworth. 1950.

Pathologische Histologie. By M. Borst. 4th ed. (Pp. 539. M. 94.50.) Berlin: Springer. 1950.

Die Wirkungseinheit des Lebens. By L. Seitz. (Pp. 500. M. 30.) Berlin: Urban and Schwarzenberg. 1950.

Spezielle Chirurgische Diagnostik. By F. de Quervain. Edited by K. Lenggenhager. 10th ed. (Pp. 767. M. 75.) Berlin: Springer. 1950.

Lehrbuch der Kinderheilkunde. By R. Degkwitz and others. Edited by E. Rominger. 4th and 5th editions. (Pp. 971. M. 49.80.) Berlin: Springer. 1950.

An Atlas of Amputations (Henry Kimpton, 1949; £7), by Dr. D. B. Slocum, is well produced and illustrated, and the information is clearly set out. Written from the American point of view, it is not suitable for general use in Britain, but should find a place as a reference book in libraries. The discussion on surgical aspects is good, but some of the technique described differs from that in Britain. The author sets out the lengths of stumps—that is, ideal stumps—in inches, but patients differ in height, and they may be children. Indeed, he does not mention the special needs of child amputees. The section on complications of amputated stumps is sound, but little reference is made to the correct way to bandage stumps, though some complications that may result from incorrect bandaging are commented on. The discussion on the mechanics of the gait of the normal subject and the amputee is one of the best features of the book, and worth studying by all who work with amputees. The section on prostheses, which is fully illustrated, is devoted only to American types. Modern British artificial arms with quickly detachable appliances are considered to be in advance of those illustrated here. There is a good section on the methods of physical medicine in the treatment of the lower limbs, though again there is little reference to the importance of correctly bandaging each type of amputated stump.

SATURDAY SEPTEMBER 23 1950

CONGENITAL HEART DISEASE

The newer methods of investigation of congenital heart disease, particularly cardiac catheterization and angiocardiography, have given valuable help in establishing the exact nature of the malformation. Many physicians familiar with the results of these investigations have the impression that the ordinary methods of clinical examination and of radiology of the heart have been largely superseded by these newer techniques and that a diagnosis can be made only with their aid. In the St. Cyres Lecture, published in this and last week's issues of the *Journal*, Dr. Paul Wood has demonstrated convincingly how the information gained by cardiac catheterization and, to a lesser extent, by angiocardiography may be used to increase the accuracy of clinical diagnosis through a better understanding of the physical signs elicited at the bedside. The emphasis he places on clinical signs is especially valuable at the present time in view of the tendency to rely more and more on the results of elaborate instrumental investigations.

In most of the common types of congenital heart lesion, with the exception of the ventricular septal defect, Wood's description of the clinical, catheter, and angiocardiographic findings is in general agreement with other published work. The diagnosis of a ventricular septal defect is usually based on the presence of a loud systolic murmur often associated with a thrill at the lower left sternal border without any other signs of heart disease, but only four of Wood's twenty-four cases would fit in with this description. In the others, in addition to the typical Roger murmur and thrill there was a thrusting left ventricular type of impulse and increased pulsation on the outflow tract of the right ventricle and pulmonary artery. A functional mitral diastolic murmur was present in most of the severe cases, and the radiological appearance was identical with that seen in a patent ductus arteriosus—with left ventricular enlargement, a prominent pulmonary artery, and increased pulmonary vascular markings. Selzer[1] reviewed the post-mortem findings in 92 cases of ventricular defect and reported that the size of the right ventricle and pulmonary artery bore a direct relationship to the size of the defect, and that since the defect was usually a small one there was often very little change in the size of the heart or the pulmonary artery. It seems likely that the majority of the cases Wood has described had a medium-sized or large defect, and the number of such cases may have been disproportionately big in his series. Clinical experience and necropsy findings suggest that the classical description of the "maladie de Roger" adequately covers the majority of cases of ventricular septal defect. Death from cardiac failure occurred in only 15% of Selzer's cases, and, since the risk of death from bacterial endocarditis is now a small one, a ventricular septal defect should still be considered a relatively benign lesion compatible with many years of active life. Brock's[2] demonstration of the successful treatment of pulmonary stenosis by pulmonary valvulotomy has emphasized the need for accurate diagnosis of this condition. It has become evident that pulmonary stenosis is not the rarity Taussig[3] stated it to be, so that Wood's detailed description of the various types of pulmonary stenosis is particularly welcome. In mild cases pulmonary stenosis may cause no symptoms and need no treatment, whereas the severe case should be benefited by surgery.

The value of angiocardiography as an aid to diagnosis is well shown in some of the illustrations accompanying Wood's paper. The technique of injection which has been most commonly used in this country is that described by Robb and Steinburg.[4] Recent technical developments with the *x*-ray camera in Scandinavia have shown that it is possible to obtain 12 pictures per second simultaneously in two planes, and it is probable that additional information about the heart action in health and disease will be obtained with this method. For routine use the simpler mechanical film-changing devices enabling pictures to be taken at one-second intervals give valuable information, particularly in cyanotic congenital heart disease. Campbell and Hills,[5] reporting their findings in 50 such cases investigated by angiocardiography, obtained clear evidence of the right-to-left shunt and overriding of the aorta in all cases with the tetralogy of Fallot. Direct demonstration of the actual pulmonary stenosis proved to be difficult because of the variable shape of the outflow tract of the right ventricle. Early filling of the pulmonary artery may occur in the presence of pulmonary stenosis, but later films showed no steady increase in the density of the lung fields. Similar findings in cyanotic congenital heart disease have been described by Zinsser and Kendrick.[6] They found angiocardiography to be less helpful than cardiac catheterization in patients with

uncomplicated septal defects or a patent ductus arteriosus when the shunt is from left to right, although occasionally the sudden rise of pressure in the right auricle after the injection would cause a temporary reversal of the shunt through an atrial septal defect. Re-circulation of the dye through the right heart in this type of case was difficult to demonstrate, since some of the "diodrast" was often held up in the vein used for injection and might reach the heart at the time when re-circulation was likely to be occurring.

In cases of coarctation of the aorta or patent ductus arteriosus it is difficult sometimes to obtain satisfactory pictures of the aorta, because dilution of the bolus of diodrast in its passage through the right heart and lungs has occurred. Injection into the pulmonary artery through a cardiac catheter may overcome this difficulty, but the length and narrow bore of the catheter slow the speed of injection so that poor-contrast films may still be obtained. Direct injection into the arch of the aorta gives better results, and this has been carried out either by inserting a needle into the ascending aorta or by retrograde arterial catheterization. Burford, Carson, and Scott[7] have carried out direct aortography on 23 patients, using the left common carotid artery. Temporary occlusion of the artery distal to the point of injection prevented the dye passing directly into the cerebral circulation, and no complications were observed in any of their patients. They were able to demonstrate the detailed anatomy of the aorta and the exact site and extent of the stricture in patients with coarctation after injection of 20 ml. of dye. A patent ductus arteriosus could also be outlined, and this might be of help in differentiating those patients with an aortic septal defect or rupture of an aneurysm of the sinus of Valsalva into the pulmonary artery; in such cases clinical examination and the use of the cardiac catheter may give identical results. Fatti and Gilroy[8] have approached the same problem from a different direction: they inspected the arch of the aorta and the gap between it and the pulmonary artery with a thoracoscope. After induction of a small pneumothorax with 400–500 ml. of air they inserted the thoracoscope anteriorly into the second left interspace in the midclavicular line and obtained a satisfactory view. They were able to inspect the site of a coarctation and to demonstrate the presence of a patent ductus, while in one patient the pressure in the pulmonary artery was measured by needle puncture under direct vision.

Many patients with congenital heart disease are now treated surgically, and though the diagnosis of the malformation is usually possible by routine methods of examination the purpose of all these special investigations is to provide accurate details of the anatomy of the defect. The task of the surgeon is thus made less difficult.

COLCHICINE IN THE CHEMOTHERAPY OF CANCER

Colchicine, which was mentioned last week in the leading article about a secret remedy for cancer,[1] is a mitotic poison which has been much used in research as a chemotherapeutic agent for cancer. This alkaloid, which is extracted from the autumn crocus, is probably the most powerful "radiomimetic" drug known—that is, it reproduces the cellular changes induced in cells by *x* rays. Even at dilutions of 1 in 100,000,000 it can bring about the typical mitotic arrest at the metaphase stage. Microscopically, areas of a tissue treated with colchicine will sometimes show more cells in arrested division than in the resting state. Ludford,[2] who has ably reviewed the literature on this subject, examined the mode of action of colchicine on tissues grown *in vitro* and observed that the drug does not differentiate between embryonic and neoplastic tissue, which are equally sensitive to its mitosis-arresting activity. Other chemical and physical agents can inhibit mitosis, but, Ludford wrote, "colchicine is unique in that it does not arrest the initial phase of division but brings the process to a standstill at the metaphase in a remarkably wide range of concentrations." There is little evidence that colchicine stimulates mitosis as well as blocking it at metaphase, and, indeed, it has been reported that in high dilution it slows down the rate at which cells enter the mitotic cycle. Macroscopically, the most obvious effect of the drug on a tumour is to induce haemorrhage of the kind also caused by polysaccharide fractions of bacterial filtrates—for instance, from *Serratia marcescens*. Even in minute amounts, of the order of 0.1 μ, these cause necrosis and haemorrhage.[3] The similarity of the effects of colchicine and bacterial filtrates is close enough to have suggested that they inhibit tumour growth by the same mechanism—by attacking the sensitive cells of the capillary system of a rapidly growing tumour. One of the principal conditions of chemotherapy is maximal injury to tumour cells with minimal effect on normal tissue, and the use of colchicine appeared promising when examination by dark-ground illumination showed little alteration in the mitochondria and in the cytoplasmic granulation, indicating that the metabolic mechanism had escaped injury. Ludford found that mitosis could be blocked with dilutions of colchicine far below that required for metabolic disturbance: in one experiment a thousandth of the concentration needed for metabolic effect sufficed to arrest mitosis.

Amoroso[4] was one of the first to try the effect of colchicine on tumours in animals. He found that transplantable mouse carcinoma No. 63 responded by complete regression, and he successfully treated a carcinoma of the buccal mucous membrane in a dog. Among other early experiments with colchicine in animals the regression of multiple skin tumours in a mare has been recorded, and also of the Shope rabbit papilloma after the injection of a few milligrammes of the drug. In the latter case the treatment induced immunity to further infection by the virus. Colchicine has been used with success in experiments on the regression of a lymphoid tumour of the C3H strain of mice and on the Flexner–Jobling rat carcinoma. Ludford, after studying 17 different strains of transplantable tumours and 47 spontaneous mammary carcinomas, concluded that the lethal and chemotherapeutic doses are close to one another and that soft, highly cellular, rapidly growing tumours are the most responsive, the reaction of slow-growing tumours being negligible. In a detailed investigation[5] of the factors determining the action of colchicine on tumour growth he used a rapidly growing carcinosarcoma of the Strong A strain of mice. The transplants were treated with a 1 in 10,000 solution of the alkaloid, the total dose of 0.7 mg. being divided and spread over a few hours. The injections were repeated on the 26th and 35th day. After a sudden decline in the size of the tumour grafts growth was resumed, and on the 50th day after transplantation the experimental tumours were the same size as the controls on the 30th day. A spindle-celled sarcoma growing in Strong A mice was treated with a total of 0.154 mg. of colchicine. Two out of three tumours regressed completely. Nevertheless Ludford considers such success exceptional, the more typical result with colchicine being regression followed by recurrence. Among other factors which influence the effect of colchicine, he found that young adult mice are more resistant to the toxic action of the drug than very young or old mice, and that tumour regression is more obvious in strain A mice than in C57 mice. The results of treatment of mice bearing carcinoma 63—a soft, highly cellular tumour with a large number of mitotic figures—was to produce total regression in 5 mice out of 10. Three died of toxic effects, and the tumours of 2 continued to grow. The tumours which regressed showed extensive haemorrhage, just as in the case of tumours treated by bacterial filtrates. It has been suggested that the haemorrhage may be caused by pressure exerted on the newly formed capillaries by the tumour cells, which become swollen after colchicine treatment. Bass and Probet[6] in the U.S.A. recently reported the satisfactory treatment with colchicine of C3H hybrid mice bearing lymphosarcoma, the drug being given in doses of 0.5–0.75 mg. per kg. of body weight daily for 2 to 23 days. The regressions, expressed as fractions, were 8 out of 10 mice, 4/9, 12/20, and 10/28 in different experiments. The mice whose tumours regressed were observed for five months; immunity lasted at least 173 days after the original transplantation.

Although there is a close parallel between the nucleotoxic action of colchicine and of *x* rays—for instance, in the acquired tolerance of tumour cells to the drug and the acquired radio-resistance of tumours which were previously radio-sensitive—yet there are certain differences in the toxic effects on the nuclear chromatin. Colchicine is much more specific in its action on the nuclear structures. Ludford states that one of the outstanding difficulties in the colchicine treatment of tumours is the lack of cell-type specificity. Tests with the aim of supplementing the action of colchicine with radiotherapy have been, on the whole, without success. Several workers have investigated the action of colchicine in the treatment of cancer in man, but it was found that the drug caused very unpleasant symptoms, and sometimes death from colchicine poisoning. One woman was treated with colchicine combined with *x* rays for an adenomedullary carcinoma of the breast. The tumour at first shrank to a third of its original size, but then rapidly began to grow again, with fatal results. Another patient with an anaplastic carcinoma of the neck reacted in much the same way; the central portion of the tumour necrosed, but the peripheral layers grew with increasing speed.

Seed, Slaughter, and Limarzi,[7] after investigating the action of colchicine on human subjects and on laboratory animals, concluded that, "although the rapidly growing cancer cells are much more susceptible to the poison, the concomitant general toxic effect is much too great to expect any curative effect."

THE TREATMENT OF VOMITING

In the opening pages of this issue we publish the paper on the antihistamine compounds which Professor J. H. Burn read at the Annual Meeting of the B.M.A. in Liverpool. In his lucid review of the pharmacological action of this interesting group of drugs Professor Burn refers to a substance named "dramamine" which was introduced last year in the U.S.A. for the prevention and cure of seasickness. Those who were present at the Liverpool meeting also had the benefit of hearing Dr. Leslie Gay, of Baltimore, describe his original work with this drug.[1] Little attention has been given to its composition, but it is in fact a combination of "benadryl" with theophylline (into which a chlorine atom has been introduced). Both benadryl and dramamine are said to relieve the nausea and vomiting of pregnancy. Finch[2] believed that the success he had with benadryl was adequate proof that this symptom complex was an allergic reaction. The investigation of the

efficacy of dramamine in controlling morning sickness was carried out by Gay and Carliner,[3] who had done the original work on seasickness with this drug during an Atlantic crossing on a U.S. Army transport.[4] Forty-three pregnant women who had suffered for 4–6 weeks and had been treated unsuccessfully with various other remedies were given dramamine: 31 were completely relieved in three hours. Each patient continued to take 100 mg. of the drug three times daily: ten of them relapsed when a placebo was substituted, but recovered again when dramamine was resumed.

Beeler and his colleagues[5] have tested dramamine in irradiation sickness. The similarity between the lassitude, nausea and vomiting, anorexia, and malaise in motion and irradiation sickness suggested the trial. Eighty-two patients were treated and compared with 23 who received a placebo. Vomiting ceased in 65 of those given dramamine, but in only 3 of those given the placebo. The best results were obtained when 100 mg. of dramamine was given ½–1 hour before irradiation and repeated twice after irradiation, at 90 and 270 minutes. Campbell[6] found another use for dramamine—in the prevention of nausea and vomiting due to disorders of the vestibular apparatus, such as Ménière's disease, and after the fenestration operation for otosclerosis. Twenty-eight patients were given the drug after undergoing the fenestration operation, and all of them were relieved "to a large extent." Some could leave their beds on the day after operation, could drink freely and take soft food. Dramamine was given only on the day of operation and the following day, but there was no recurrence of vertigo and nausea when it was discontinued.

All the foregoing observations carry the suggestion that dramamine has properties unlike those of any other drug and that it alone can give relief in these conditions. None of the authors apparently thought of comparing dramamine with hyoscine, which was found by Holling, McArdle, and Trotter[7] during the war to be the best remedy for seasickness. Hyoscine of course is a cheap drug, but Chinn and Oberst[8] have recently brought it into the limelight as a competitor to the more expensive proprietary remedies. Working at the U.S.A.F. School of Aviation Medicine at Randolph Field, they have shown that benadryl and dramamine have an almost equal protective effect against airsickness, but that hyoscine is appreciably better. Thirty per cent. of those taking benadryl vomited, and 28.7% of those taking dramamine, but of those taking hyoscine only 19.3% vomited. It is a reasonable conclusion from this that on present evidence, in all the forms of sickness which have been considered—vomiting of pregnancy, irradiation sickness, sickness after labyrinth operations, and different forms of motion sickness—hyoscine is the best as it is certainly by far the cheapest remedy. It is also much less likely to cause drowsiness or confusion.

EARLY DIAGNOSIS OF MILIARY TUBERCULOSIS

It is now well known that early diagnosis of miliary tuberculosis is vital if treatment with streptomycin is to be successful. Unfortunately early diagnosis is not easy. The symptoms are indefinite and in no way pathognomonic of the disease: the insidious onset of malaise, disinclination for exertion, lassitude, and anorexia could be associated with many other conditions. What is needed is a greater awareness of the possibility of miliary tuberculosis when those symptoms arise without any other explanation, especially in a child and when the tuberculin test is known to be positive. The simple tuberculin-jelly test should be used more often in general practice, but the skin should be prepared in the way described by Pointon Dick.[1] A negative jelly test, though not entirely excluding tuberculosis, goes a long way towards doing so, while vague indefinite symptoms of ill-health in a child who gives a positive result to the test are highly suspicious of tuberculosis and are sufficient grounds for sending him to hospital for investigation. It would help the practitioner if the tuberculosis officer or chest physician would let him know when a child in his practice is found to be a contact of a patient with tuberculosis or to have a positive tuberculin reaction. It is not the general practitioner's responsibility to make a confident diagnosis of miliary tuberculosis but rather to bear the possibility of the condition in mind and, when suspicious, to send the child for specialist investigation.

The early diagnosis of miliary tuberculosis is not easy for the specialist, even when he is able to carry out all the usual investigations. A negative tuberculin test, first with 0.1 mg. and then with 1 mg. of old tuberculin, is only very rarely found in miliary tuberculosis in spite of the relative anergy to tuberculin which it is known to cause. The one definite physical sign on which to base a confident diagnosis of miliary tuberculosis is the presence of choroidal tubercles. Illingworth and Wright have described their appearance and characteristics in this *Journal*.[2] Careful search revealed their presence in 70 out of 114 cases (61%) of proved miliary tuberculosis. Only in very exceptional cases can choroidal tubercles be found in tuberculous patients without miliary spread,[3] but their absence clearly does not exclude miliary tuberculosis. Elsewhere in this issue Drs. J. L. Emery and J. Lorber point out how difficult it is to make an early diagnosis on radiological evidence. By correlating the *x*-ray appearances with the results of pathological examination of the lungs of 52 children these workers showed that there was no *x*-ray evidence of miliary tuberculosis at any stage of the disease in 34 of the children (65%), while at necropsy they found macroscopic miliary tubercles in 23 and microscopic ones in the remaining 11. In another six children, who had received streptomycin treatment, the last radiograph, taken within two weeks of death, showed no miliary lesions, though the diagnosis had been made on previous radiographical evidence; macroscopic miliary tubercles were found at necropsy in all six. In only 12 (23%) did the last *x*-ray examination before death reveal miliary lesions. It is clear that *x*-ray examination cannot be relied upon for the early diagnosis of miliary tuberculosis. This must depend on clinical judgment, the result of the tuberculin reaction, a reasoned assessment of the symptoms, a careful search for choroidal tubercles, and radiological examination of the chest, repeated when necessary.

FRACTURE OF THE NECK OF THE FEMUR

In the lifetime of some of us, true, or so-called intracapsular, fracture of the neck of the femur—typically seen in old women—has passed through three phases. First came the phase of fatalism, with the supposition that such fractures never unite by bone—a phase of negligible or ineffective treatment. Next came the period of hopefulness, of which Whitman was the pioneer with his reduction of the fracture and plaster immobilization in an extreme position—a procedure which sometimes led to union of the fracture but was a severe test of the patient's endurance. Indeed, it provided an ordeal which many of the elderly and aged failed to survive. The introduction of skeletal fixation of the accurately reduced fracture—the third phase, of which Smith-Petersen was the brilliant pioneer—promoted union by proper immobilization. Technical improvements by Sven Johansson and others have made the operation relatively trivial for the patient, and it is life-saving in its early restoration of his comfort and mobility. In fact this operation has been so effective in saving life and restoring function that a new problem has arisen—namely, the frequent avascular necrosis of the femoral head. The dead head is replaced gradually by "creeping substitution." While this is in progress the structure is weakened, and the stress of weight-bearing, restored by effective treatment, may end in collapse of the head and consequent disorganization of the joint. There is no proved and practicable method of preventing this frequent calamity, which may occur as late as five years after fracture.

The surgeon's first anxiety must be the preservation of life in the aged victim of a severe and shocking injury. To this end many surgeons, perhaps most, would regard internal fixation of the fracture not only as necessary but as urgently necessary immediately primary shock is ended. On the other hand, these patients, though they withstand plaster immobilization so poorly, do well sitting up in a much-tilted bed with light-weight traction on the broken limb. Thus a feeble patient's fitness for operation may be greatly improved by a few days' delay with expert medical and nursing attention. Without these he will assuredly succumb. Whatever the policy about very early operation, the importance of early activity is incontestible in old people: they should sit out within a few days of operation, and early standing and walking should be encouraged. Often the flame of life burns so low in the aged that the least disturbance must extinguish it. Such patients cannot be expected to survive a disaster like a fractured femur; their days are already numbered. Not only are there patients in whom the general condition must forbid operation, but there are those in whom the softness of the bone—from osteoporosis or from Paget's disease—would doom it to failure. Fortunately there are some fractures of the femoral neck which require little or no local treatment—so-called abduction fractures, in which the head is impacted on to the upper angle of the stump.

Few conditions make a more insistent demand for good team-work than fracture of the femoral neck in the elderly. First-aid worker, general practitioner, surgeon, physician, anaesthetist, radiologist and radiographers, pathologist and, perhaps more than any, nurses have all an important part to play.

TREATMENT OF CARDIAC ARREST

So infrequently do instances of cardiac arrest on the operating table occur in the hands of any one surgeon that it is all the more important that new information should be brought to general attention. The drama of such incidents is heightened by the fact that if the circulation is not maintained fatal cerebral damage will inevitably occur within a very short time. Clinical experience suggests that if the cerebral circulation is interrupted for more than three and a half minutes chances of recovery are remote, and from this it naturally follows that immediate cardiac massage is the most important single method of treatment, combined of course with adequate ventilation of the lungs. Physiologists, in working with animals, have had much experience of cardiac arrest: this is usually due to excess anaesthetic, and in these circumstances immediate intracardiac administration of adrenaline almost always restarts the heart, though cardiac massage may also be necessary. In man, however, sudden cardiac arrest is more likely to be due to the onset of ventricular fibrillation, and various predisposing circumstances have been considered, among which may be mentioned the use of some of the gaseous anaesthetics, vagal inhibition of the heart, and cardiac disease. In the case of cardiac arrhythmias—produced, for instance, by cyclopropane—it is quite certain that the administration of adrenaline is harmful and may precipitate ventricular fibrillation, even though in the normal heart this drug will increase the strength and frequency of the beat. For this reason substances such as quinidine and local anaesthetics, which have been known since the work of Kochmann and Daels[1] in 1908 to reduce the irritability of the myocardium, have been tried in instances of sudden cardiac arrest. As reported by Mr. H. L. M. Roualle on another page, procaine may be administered intravenously or, if the heart is exposed, by topical application, and it has been found of real value according to Beck,[2] Lahey and Ruzicka,[3] and Burstein.[4] An adequate intravenous dose seems to be 100 mg. of procaine for an adult patient under general anaesthesia. Much more experience is required with this remedy, but because of the seriousness of the condition every new method should be given a fair trial. This cannot be done unless the procaine is ready to hand in the emergency equipment reserved for such incidents.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

CHEMOTHERAPY—IV. THE NEWER ANTIBIOTICS

BY

LAWRENCE P. GARROD, M.D., F.R.C.P.

Bacteriologist, St. Bartholomew's Hospital; Professor of Bacteriology, University of London

A world-wide search for further antibiotics has now been in progress for nearly ten years. It has been far more extensive and systematic in the U.S.A. than anywhere else, and it is therefore not surprising that all its results of outstanding value are American monopolies. This survey has ranged over the whole plant kingdom, and interesting substances with antibacterial properties have been recovered from such things as algae, toadstools, bananas, and hops. They have also been found in many species of bacteria, some of them pathogenic. Despite this profusion and variety, properties such as to qualify antibiotics as chemotherapeutic agents are almost confined to those derived from the following three sources.

Higher Fungi.—Penicillia and *Aspergilli* in particular are frequent producers of antibiotics, but almost all of these other than penicillin itself are toxic, and no other is a suitable chemotherapeutic agent.

Actinomycetes.—These are the source of streptomycin, discovered in 1944, and of "aureomycin" and "chloromycetin," which have been known since 1948. These two are much the most important of the newer discoveries, and form the main subject of this article. Terramycin was first described only a few months ago, and its potentialities are still largely unexplored, but it is of similar nature to the two foregoing. Neomycin seems likely to prove too toxic for therapeutic use.

Bacilli.—This name is used in its generic sense, denoting Gram-positive sporogenous aerobes. These are the source of tyrothricin (originally "gramicidin"), now recognized as suitable only for local application, and of the polymyxins (including "aerosporin"), subtilin, bacitracin, ayfivin, licheniformin, and other substances which have been extensively studied and found to possess marked chemotherapeutic activity, susceptible organisms including many species of Gram-negative bacillus and in some cases the tubercle bacillus. Their disadvantage is a strong tendency to produce renal tubular degeneration, resulting in albuminuria and sometimes anuria. It is not yet certain how far this risk can be minimized or whether it may sometimes be justifiable to take it in order to deal with a serious and otherwise resistant infection.

Aureomycin and Chloromycetin

Except in a few research centres, these antibiotics are at present obtainable in this country only from Ministry of Health supply depots and are employed for the treatment of a few specified diseases in which their use is most strongly indicated. It is to be hoped that in time they will be more freely available; in the meantime this account of them may seem a little out of place in a "refresher course." However, it is written to complete a series and partly in anticipation of the future.

Aureomycin, derived from *Streptomyces aureofaciens*, so named from its golden yellow colour, is manufactured by Lederle & Co. The mould from which it is obtained is incidentally a valuable growth-stimulant for pigs and poultry. Chloromycetin (Parke, Davis & Co.) was originally obtained from *Streptomyces venezuelae*, but has now been synthesized. The synthetic product is that now marketed under the alternative name "chloramphenicol." These two antibiotics have many properties in common, notably their pharmacological behaviour, which differs from that of penicillin or streptomycin, with the result that they are administered in a different way.

Administration

It is fortunate that neither has to be administered by injection, since chloromycetin has much too low a solubility, and aureomycin hydrochloride, besides being none too soluble, forms a strongly acid solution which causes serious damage and severe pain when injected intramuscularly. (A form of aureomycin suitable for intravenous injection is available in the U.S.A. although not yet in England.) These difficulties are more or less unimportant, since both drugs exert their full effect when given by mouth, and the fact that the patient has merely to swallow capsules instead of submitting to injections is their most obvious advantage.

Capsules of either contain 250 mg., and two, three, or four may be given three or four times a day. Absorption is comparatively slow and incomplete, since both drugs have a marked effect on the intestinal flora. This is to a great extent suppressed, and the stools become almost odourless. Owing to slow absorption, the drug persists in the blood for as long as 12 hours or more after a single dose, and frequent administration is therefore unnecessary. Aureomycin also reaches the cerebrospinal fluid, and has been used successfully in meningitis. The intrathecal administration of either is out of the question. Both are excreted in the urine in fairly high concentration, though only a fraction of the dose administered can be thus accounted for.

Toxic Effects.—No serious toxic effects are known. Aureomycin has hitherto been apt to cause nausea, with or without vomiting, and diarrhoea in a minority of patients, but a more highly purified product now coming into use is said to obviate even this minor disadvantage. Chloromycetin is apt to cause only anorexia and dryness of the mouth.

Mode of Action.—Whereas penicillin and streptomycin are both bactericidal, aureomycin and chloromycetin are purely bacteriostatic in their action. The viable count of susceptible bacteria exposed to them *in vitro* under conditions favouring growth remains almost constant for many hours. Whatever the nature of this effect, it is apparently not one from which bacteria can learn to escape. A moderate and temporary increase in resistance to chloromycetin has occasionally been observed in some species, but even less evidence of any capacity on the part of bacteria to develop resistance has been observed in studies of aureomycin. It appears therefore that habituation, an ever-present threat to the usefulness of streptomycin, is not likely to impair that of either of these drugs, whether in the treatment of individual cases or by the general propagation of resistant strains.

General Indications.—These two antibiotics have a wide range of activity, overlapping that of penicillin and other chemotherapeutic agents to a considerable extent. It is by no means all-embracing: neither drug has any useful action on the tubercle bacillus, nor has chloromycetin on the spirochaete of syphilis or on the clostridia. Generally speaking, chloromycetin is the more effective against Gram-negative species, and aureomycin against Gram-positive. For the present, both drugs are likely to be used only in infections resistant to other forms of treatment, and the more important of these have now to be specified. Pride of place has to be given, not to any bacterial infection, but to rickettsial and certain virus diseases, the conquest of which is much the most notable achievement of these drugs.

Indications for Chloromycetin

Rickettsial Infections.—It is a staggering fact that all forms of typhus are now fully and easily amenable to chemotherapy. The story of the therapeutic trial of chloromycetin in scrub typhus in Malaya is now well known. Laboratory studies having shown that the drug possessed marked anti-rickettsial activity, a small supply was taken to Malaya and tried in cases of scrub typhus, with results so dramatic that from the first they left no room for doubt. A disease normally lasting a fortnight or more and having a far from negligible mortality could regularly be terminated in about 48 hours by administering only a few grammes of the drug. Small doses would also prevent the disease in subjects deliberately exposed to it. Similar curative effects are now known to be obtainable in epidemic typhus, murine typhus, and Rocky Mountain spotted fever. Aureomycin is also known to be effective in these three infections and in Q fever, the latter, incidentally, being the only rickettsial infection known to exist in the British Isles. Its recent recognition here suggests the possibility that more cases may come to light and provide a new though presumably restricted field of usefulness for this drug.

Typhoid Fever.—The action of chloromycetin in this disease is also unequivocal, if less dramatic, and the indication for it is imperative. There is a lag of about 48 hours before the treatment produces abatement of fever, and administration has to be continued for over a week if relapse is to be prevented. Bacteriaemia is regularly abolished, but the organism is not eliminated from the intestine, and the persistence of a carrier state is unfortunately not prevented. Severe cases of paratyphoid should also be treated with chloromycetin, as may other varieties of salmonella infection, including the acute enteritis caused by members of the food-poisoning group. Aureomycin, although possessing an *in vitro* activity against *Salm. typhi* not far removed from that of chloromycetin, has a disappointing and inconstant effect on typhoid fever. In this it behaves like streptomycin, both illustrating the fact that *in vitro* is not an invariable guarantee of *in vivo* activity.

Undulant Fever.—Chloromycetin has not been as extensively used as aureomycin in this disease, but the evidence, so far as it goes, is that their effects are similar, if not indistinguishable. Fever is terminated within a few days, and provided dosage is adequate and treatment continued long enough—usually 10 to 14 days—cure may be permanent. Relapse, if it occurs, responds to further treatment.

Other Indications.—Chloromycetin has been used successfully as a urinary antiseptic, despite the fact that a large proportion of it is excreted in an inactive form. Most organisms found in the urine are fully susceptible to it. Notable exceptions are *Ps. pyocyanea*, which is usually very resistant, and *Proteus vulgaris*, which is moderately so. It does not seem to be necessary to control the reaction of the urine in order to favour its effect. The drug will also cure gonorrhoea, with the advantage that, since it has little action on *Treponema pallidum*, there is no risk of masking syphilis. Other conditions in which its possible usefulness remains to be more fully explored are whooping-cough, cholera, and bacillary dysentery.

Indications for Aureomycin

As already stated, aureomycin is known to share the efficacy of chloromycetin in most rickettsial infections.

Virus Diseases.—There is unequivocal evidence of the efficacy of aureomycin in three virus diseases—primar atypical pneumonia, psittacosis, and lymphogranulom venereum—and the drug is definitely indicated in thes conditions. To what extent chloromycetin can replace for these purposes is not yet known: primary atvpic pneumonia is said to respond to both, though some ev dence suggests that aureomycin is preferable. It is als claimed that aureomycin can cut short an attack of herpe zoster, but this remains to be proved by further experience These are the only virus diseases, except perhaps trachoma at present known to be influenced. There is certainly n action on poliomyelitis or on influenza or the commor cold.

Undulant Fever.—As already stated, both antibiotics ar effective remedies for this disease, and aureomycin has been used the more extensively, proving its worth in infectio due to both *Br. abortus* and *Br. melitensis.*

Pneumonia.—It has repeatedly been emphasized b American authors that aureomycin is effective in al forms of pneumonia, whether due to pneumococci, strepto cocci, or staphylococci, to Gram-negative bacilli such as *H. influenzae* or *Bact. friedländeri*, or to the viruses of primary atypical pneumonia or psittacosis. The results in pneumococcal pneumonia have been found to equal those obtainable with penicillin. This all-embracing activity makes it possible to treat the disease successfully without even taking the trouble to discover its cause. When no facilities exist for doing so, this will of course be an inestimable advantage, and it seems likely that when aureomycin becomes freely available it will become standard treatment for pneumonia in general practice.

Staphylococcal Infections.—Aureomycin is the answer to the increasingly serious problem of penicillin-resistant staphylococcal infections. Some authorities in America take the view that aureomycin should be given from the first in staphylococcal septicaemia and other severe infections, pending an estimation of the sensitivity of the organism to penicillin. If this proves to be normal, then penicillin can be continued alone. The drug may now be obtained for such cases in this country if penicillin resistance has been confirmed, provided that the patient is in hospital.

Venereal Diseases.—Aureomycin is unique in having a therapeutic effect in all common forms of venereal disease. It will cure gonorrhoea; it has a pronounced effect in syphilis, though its relative value in various forms of this disease remains to be determined; as already mentioned, it is effective in lymphogranuloma venereum; and, finally, it will cure non-specific urethritis.

Urinary-tract Infections.—On account of its wide range of activity, and the simplicity of its administration, aureomycin is probably the most commonly used urinary antiseptic in the U.S.A. at the present time. The drug is so

freely available that it can be used routinely without first trying older remedies. The only common infections resistant to it, as to chloromycetin, are those due to *Ps. pyocyanea* and, to a less extent, *Proteus vulgaris*. So long as scarcity persists with us, a sensible policy would be to treat any coccal infection, at least in the first place, with penicillin, and to reserve aureomycin for coliform infections (other than the two mentioned) which have proved resistant both to sulphonamides and to streptomycin. Aureomycin is excreted unchanged in the urine, which it renders acid, a condition favouring its activity. It is not clear how short a period of treatment will suffice, but four days at the rate of 3 g. daily is certainly enough in some cases. Nor is it yet clear how its merits for this purpose compare with those of chloromycetin. In my limited experience, one case of *Bact. aerogenes* infection was cured with aureomycin when chloromycetin had failed.

Miscellaneous Indications.—According to some American authorities, aureomycin is the most effective of the antibiotics in the treatment of general peritonitis. It is recommended that the initial doses be given intravenously. There is reason to believe that it will be effective in spirochaetal infections other than syphilis, such as relapsing fever and Weil's disease. Its effect in amoebic dysentery, accidentally observed when it was administered for another condition, has now been extensively confirmed, though it does not seem to have been shown to be actually superior to that of emetine. The claim that aureomycin acts in infectious mononucleosis remains to be substantiated.

Neither of the new antibiotics has much scope as a local application, but aureomycin borate has been successfully used in this way in various forms of conjunctivitis.

Conclusion

It will be evident from this account that aureomycin is the most widely useful of all the antibiotics, though chloromycetin is its equal in some conditions, and in one at least (typhoid fever) its superior. Chloromycetin is now being manufactured in this country, whereas for the present at least aureomycin and terramycin, for which there is likely also to be a large demand, have to be paid for in dollars. We are in a strange situation when international economic considerations have to be given weight in therapeutic policy, but it seems at present an inescapable duty to prefer chloromycetin to either of the others when it will serve equally, or even nearly, as well.

THE PROTECTION OF LABORATORY ANIMALS

[BY A SPECIAL CORRESPONDENT]

A document has been received from Major C. W. Hume, director of the Universities Federation for Animal Welfare, entitled "First Draft for a Model Act for the Protection of Laboratory Animals." The covering note explains that the ultimate purpose of this draft is to enable U.F.A.W. to help inquirers from abroad who desire to promote such legislation in their own countries. Those in favour of legislation regulating the use of animals for experiment—and few who have experience in this country of the Cruelty to Animals Act of 1876 can doubt its value—will applaud Major Hume's intention, however much they may be driven to deplore the form which it takes.

Seventy-four years' experience in this country of an Act which was introduced following a Royal Commission, and which has been the subject of a prolonged and critical study by a second Royal Commission, has shown that the very delicate subject of animal experiments is capable of administrative control, provided the administration is wise, faithful, and not shackled by pettifogging statutory requirements. In so far as our present Act falls short of the ideal at which it aims, it is largely because its framers strove to crystallize in terms appropriate to 1876 ideas which were inevitably subject to change and development. For instance, the elaborate certificate system has proved a redundant safeguard of little value, the function for which it was designed having been usurped by the administration. The statute, however, requires that this machinery shall still operate, and the time of presidents and professors is taken up with scrutinizing and signing documents which are later checked at the Home Office; as often as not they are found wanting in some technical detail and have to be returned to the applicant to start their journey all over again.

The "Pain Condition"

The working of the present Act revolves round the so-called "pain condition," which accurately expresses the views of the second Royal Commission on Vivisection (1906–12) about the maximum amount of pain which in the pursuit of knowledge it was reasonable or justifiable to inflict on animals. It can be confidently asserted that this pain condition is rigidly observed. The obligation placed by it on the Home Office inspectors to order the destruction of animals which in their opinion are suffering unduly has not been called into action in recent years, and it must be emphatically stated that this, so far from being an indictment of inspectors, is a tribute to the conscientiousness of licensees and the sound sense of their colleagues.

In framing or administering an Act of this kind the guiding principle must be to relate the maximum amount of pain which it is permissible to inflict on animals for the acquisition of knowledge to that which public opinion tolerates in other pursuits. And since public opinion may vary from decade to decade allowance for this must be inherent in such an Act. Major Hume's draft is lengthy, specific to such a degree as to be unworkable, and inflexible, yet it still leaves unsolved many of the ambiguities of the Act of 1876. Moreover, the fact that many of his implications are scientifically unsound cannot be overlooked. To give but one example, he suggests that "the passage of a continuous electric current through the brain shall not be deemed to produce anaesthesia unless its path, amperage, and wave-form shall conform to requirements to be determined by the Minister in the light of experimental investigation." What can this mean if it does not imply that the Minister is to set up an advisory body to determine the path, amperage, and wave-form required to produce anaesthesia in all types of animal liable or likely to be the subject of experiment? One could add other examples, but to do so might suggest that this draft is capable of amendment and revision. This is not so. A wider knowledge of the administrative problems involved, of animals, and of scientists whose work demands the use of animals, is necessary to one who would tackle this problem usefully.

The draft suggests the setting up of a board of control to advise the Minister. This board "shall comprise persons who are competent to provide as wide an understanding as may be practicable of research in the sciences ancillary to medicine, persons with experience in veterinary practice, and persons who have been active in discouraging cruelty to animals." These three qualifications may presumably be mutually exclusive, so that we have the possibility of a board of control including persons who have been active in discouraging cruelty to animals but have no understanding of scientific matters—a dangerous situation.

What Is an Experiment?

Major Hume's Act proposes to regulate every "experiment" on a living animal, by which is meant "any test which is carried out on a living animal for a purpose other than veterinary diagnosis and is capable of causing suffering to, or interfering with, the normal health, comfort, or bodily or mental processes of the said animal, and includes *inter alia* any such test used for the purpose of biological assay." As an attempt at the admittedly difficult task of defining the term "experiment" this is remarkable only for the number of questions which it begs. But it is made quite clear later on that a licence shall be required even in experiments in which no pain or discomfort is caused. The implications of this affect every human activity in which animals have any part.

Although this draft falls far short of what might have been expected, it is only fair to point to its recognition of the fact that in one way at least the Act of 1876 is unduly restrictive. This is in the absolute prohibition of experiments, even on the anaesthetized, non-recovering animal, designed for the attainment of manual skill. Such a prohibition serves no useful purpose: indeed, it may well operate, from the animal as well as the human standpoint, in the reverse sense from that which was intended.

Major Hume remarks in his covering note that he takes personal responsibility for the views implied in this draft, but, since the document emanates from the headquarters of U.F.A.W., this organization may presumably be held to give it support. Were such an Act, or anything resembling it, to come into force in any country, animal experiments would for all practical purposes be brought to an end in that country. Alternatively, the Act would become a dead letter. To promote such legislation would therefore be a grave disservice to research and consequently to the whole community.

WORK OF W.H.O.

The World Health Organization celebrated its second birthday as a specialized agency of the United Nations on September 1, 1950, and took the occasion to summarize its work. To date 74 countries have ratified its constitution, although China, Albania, Bulgaria, the Byelorussian S.S.R., Czechoslovakia, Hungary, Rumania, the U.S.S.R., the Ukrainian S.S.R., and Poland are no longer participating. Southern Rhodesia has recently been admitted to W.H.O. as an associate member. While all countries benefit indirectly from the wide range of W.H.O.'s activities, well over half of them have been given direct assistance in one form or another in improving their health services. Projects of various kinds involving some 50 member States are at present under way.

Through regional offices already established—in New Delhi for South-east Asia, Alexandria for the Eastern Mediterranean, and Washington for the Americas (Pan-American Sanitary Bureau)—W.H.O. is able to give direct assistance to countries in meeting urgent health needs. Europe and the Western Pacific region are served through temporary offices located in Geneva and Hong Kong respectively. Within the framework of efforts to improve total health services, special emphasis is being given to malaria, tuberculosis, venereal diseases, environmental sanitation, maternal and child health, and nutrition. Meanwhile, all countries benefit from such overall services as the standardization of biological substances (penicillin, vitamins, etc.), the unification of pharmacopoeias, notifications of epidemics, international research on certain diseases, etc.

Some of the major projects which W.H.O. is carrying out at present through consultants, teachings, or demonstrations are:

Intensive malaria control demonstrations, with D.D.T.-spraying, in countries of South-east Asia and the Eastern Mediterranean. Seven training and demonstration teams are now at work in India, Pakistan, Thailand, and Afghanistan, with an advisory unit in Iran. W.H.O. also led a very successful antimalaria campaign among Arab refugees from Palestine.

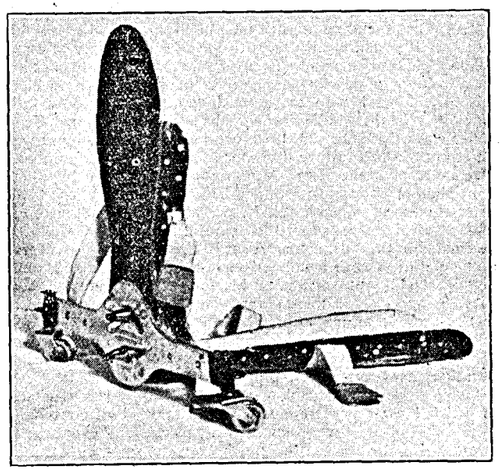
Establishing of international training centres for tuberculosis control where doctors from several countries can study advances in this field. The first two centres have been established in Turkey and El Salvador. Others will follow in Pakistan, Burma, Ceylon, Thailand, and East Pakistan.

Demonstrations of the control of syphilis and yaws with penicillin treatment in countries of South-east Asia and in Haiti. W.H.O. specialists are working in regions where up to 85% of the population are found to have yaws and 50% syphilis.

Creation of the first international anaesthesiology centre in Copenhagen, where 21 W.H.O. Fellows from Northern and Central Europe are able to study modern methods of anaesthesia.

Publication of some 15 types of technical publications and scientific works.

Advice on the establishment of prenatal clinics, health education, modern obstetrics, paediatrics, and other subjects relating to the health of mothers and children. Some 15 countries have thus far received such assistance.



Supplementing these direct services, W.H.O. is organizing seminars grouping specialists from several countries in the hope of promoting useful exchange of scientific information, and perfecting the training of medical personnel. With the same objective in view W.H.O. is granting fellowships in specialized fields. Since September 1, 1948, nearly 500 fellowships have been awarded to people from over 30 countries.

W.H.O. is always ready to render emergency services as required. A supply of typhus vaccines was flown to Afghanistan recently when an epidemic threatened to assume dangerous proportions. Plans are now being made to send assistance to Korea. Epidemics were avoided when medical supplies were flown to the scene of two of the most violent earthquakes in the last few years—in Ecuador and Peru.

Preparations and Appliances

FOOT SPLINT

Mr. H. PETTY, F.R.C.S., consulting orthopaedic surgeon, Harrogate and Ripon Group of Hospitals, writes: I have designed the splint here illustrated primarily for use in the post-operative treatment of the vitallium cup arthroplasty. It enables the foot to be kept at right angles, and the amount of rotation of the

lower limb can be varied from full internal rotation to full external rotation, or it can be kept in the neutral position if desired, by means of the wing nut at the end of the splint.

Two very light castor wheels are attached to the base, which enable the splint to rest or move on a horizontal skating board. This foot-piece has been found extremely useful after many other orthopaedic procedures. It is very light, being constructed of duralumin, and was made for me by Messrs. A. Vizard, Ltd., Great George Street, Leeds, 1.

Sheffield Regional Hospital Board is to acquire Cannon Hall, Cawthorne, near Barnsley, for a mental hospital. The estate comprises 3,000 acres, of which the board proposes to acquire the hall, containing 32 rooms, outbuildings, garden and home farm, and some 270 acres of parkland. The new hospital will serve a population of 184,000 in the Barnsley area.

Correspondence

Distinction Awards

SIR,—During the course of the last week the chairman of the Distinction Awards Committee, Lord Moran, has addressed six meetings in the North-west Metropolitan Region. These meetings were arranged by the secretaries of certain management committees, and in the notices sent out it was stated that "Lord Moran . . . would like to have an opportunity of talking to consultants and explaining what is being done about distinction awards." The consultants concerned were invited to go to any of the six meetings which was most convenient to them.

I am informed that in the course of the various meetings Lord Moran asked those present to elect a single representative for each of several areas so that subcommittees could be formed which would send in their recommendations to the Distinction Awards Committee. Lord Moran said that a substantial proportion of these awards had already been earmarked and that the various subcommittees he was now forming would assist his own committee in making the remaining awards. The chairman of the Distinction Awards Committee also emphasized that there was now little time left in which to make these recommendations, and said that the work would have to be completed by the middle of October.

During one of the above meetings, at which I was not present and which was attended only by 4 of the 40 or so consultants in my own area, I was elected to one of the proposed subcommittees. While having no wish to burden your readers with my personal views on the distinction awards I feel that the above facts should be brought to their notice, and the following observations seem justifiable. First, the notices sent out to consultants contained no hint of the fact that Lord Moran was intending to delegate his responsibilities in this fashion. It would clearly seem to have been his duty to make this fact plain beforehand. Even so, one may seriously question the propriety of electing area representatives in this fashion. Secondly, Lord Moran emphasized that there was now little time left. In that he has been chairman of the Awards Committee since December 23, 1948, one may, perhaps, inquire why we are now asked to take decisions of so great importance with such indecent haste. Lord Moran could have made his intentions plain many months ago, and he might then have asked the staffs of non-teaching hospitals, or the area consultant committees, to give this matter their careful attention. Thirdly, as chairman of the Distinction Awards Committee, Lord Moran is (temporarily) both a salaried servant of the State and, more important still, the servant of his fellow consultants. Those who do approve of these awards are entitled to ask for as just as possible a method of selection.

Under the circumstances of my own election to one of these subcommittees I have thought it my duty to attend on the first occasion, as I was given only six days' notice of the first meeting. Since any defection on my part would leave the area in which I work unrepresented, I have notified all consultants in this area of the circumstances of my election. As representative of this same area on the North-west Metropolitan Regional Consultants Committee I have, however, called a meeting of all those concerned to discuss this subject and, if they so wish, to elect a representative in proper fashion. This meeting will take place in a few days, and I have made it clear that I must then resign from this Awards Subcommittee, whose task I consider as distasteful as its formation was irregular.

You, Sir, in your editorials and correspondence columns have published various views on the distinction awards, and I do not wish to enlarge on this subject now. I find myself in complete sympathy with those ideas which have been expressed in such eloquent and masterly fashion by Dr. F. M. R. Walshe, and I regret that our profession has suffered so seriously from lack of wise leadership in these difficult times. While members of the public and our general-practitioner colleagues watch our undignified scramble for these pensionable additions to the basic salary, I shall prefer to stick to my old-fashioned belief that the only true award for distinction is distinction.—I am, etc.,

Radlett, Herts. REGINALD S. MURLEY.

A Secret Remedy for Cancer

SIR,—I have no wish to reply to the personal comment on myself, and the Editor of *Picture Post* has asked me not to answer the abuse of the paper. I beg to take the factual points you make one by one and answer them in detail. (See *Journal*, September 16, p. 663.)

I am glad that you recognize with me that the Presbyterian Hospital is "in good standing." This supports my acceptance of details drawn from the hospital case histories and the official reports of the "Tumor Therapy Committee." I agree that the work is "entirely experimental." We stated that. But if the American committee did not feel the work done justified further investigation they would scarcely offer to set up a clinic in the Presbyterian Hospital for continued research on a larger scale as recently as July 31. These offers were made both directly to Rees Evans and to a lawyer of the highest repute. Mr. Rees Evans did not receive a single penny for his ten months' work in America, nor has he ever taken up any of the many commercial offers made to him, in spite of money difficulties.

You state that the Tumor Therapy Committee "evidently refused" to go further with the trial of Mr. Rees Evans's treatment "unless he agreed to divulge the composition of his drug to the Food and Drug Administration." I have already shown that this is untrue. The document on which you base your statement was signed during the investigations, which were then continued for several months. Attempts were made to dissuade Rees Evans from returning to England up to the very last moment.

You ask, "What is the evidence?" but have not tried to examine the data given you, except to pick out a few detailed points from the American experiment. This evidence falls into two parts, first the American experiment and then the statistical analysis of the British cases. You completely ignore this lengthy discussion of 100 of the British cases, extending over 30 years.

The point you raise about the biopsies is somewhat mysterious. We clearly pointed out that in two cases no biopsies were seen. As you know, Louise Gund had no biopsy, and the biopsy of Dr. Reilly was never seen, although his case was accepted as being biopsied on his own undertaking as a physican, a clear description of the findings being given. If there is another case that was not biopsied, then three leading members of the committee misinformed me. I do not believe this.

At the same time Rees Evans never received any proper account of the organization of the research, nor the research agreement he was led to believe would await him on his arrival. It is not surprising, therefore, that he would not commit himself until this was done. It can be stated now that he will give up his formulae quite willingly when an authoritative inquiry is really set up with all the proper safeguards to see that his claims are fairly treated.

You refer to the case of Rausch. He has suffered for some time from kidney trouble, and this is mentioned in the report submitted by the committee to the Federal Drug Administration (from which report this term "white kidney stones" was taken). It was not suspected of being cancerous and was not treated by Rees Evans. It is not clear whether this operation is for cancer, and we have asked for a full report on this point, preferring not to rely on an obscurely worded cable.

The case reported as dying is, I presume, Mrs. Barker. She was classified as terminal and, as you say in your comment, was only considered by us as a partial success. I think we were justified.

Your treatment of the early Cardigan cases, which have little to do with the report on David Rees Evans's work we presented, is, to say the least, ridiculous. One case only is mentioned—the only mention of an English case at all—I know of 43. You compare two photographs taken nearly 50 years apart, draw conclusions from them, and then proceed to repeat the old rote "zinc chloride" and "caustic," based on this alone, coupled with a most vague account of an analysis. The substances used by the old people and by Rees Evans are different, although they contain many of the same ingredients. If you had read my report you would have found accounts of tests for acidity, and a discussion of the possibility that a caustic is being used. Caustic corrodes: Rees Evans's fluids do not. When placed on the tenderest flesh, they do not eat into the healthy tissue. They can all be drunk safely.

This brings me to a further comment from America—that they contain tannic acid. Of course they do, as all herbal mixtures do. But the mixtures themselves are not acid. They are neutral and only become slightly acid after being kept for some time. All this is reported in my technical memorandum.

As for the colchicine: it was reported as cortisone when I was in America. Again I discussed this in my longer report. With regard to the convulsions, it is certainly odd that Miss Barrington (the case referred to) had a further convulsion two weeks after all Rees Evans's treatment had stopped. Other complaints, such as aphasia, gastro-intestinal symptoms, and muscular spasms, were either not recorded or, if they were, are not clearly correlated to any treatment of Rees Evans. Again this is discussed in the longer report, where it is pointed out that the much larger body of British evidence does not bear the matter out. When over a hundred cases are being considered, it would be expected that some account of such reactions would come to our notice from the patients themselves, let alone from medical sources. It should be borne in mind that the majority of these cases had appalling medical histories.

Your last point about disclosure I have already answered. It will be done when justice is done by the setting up of a fair and proper inquiry. Rees Evans will stand by its results, and, though it will take long and arduous work to obtain those results, I think we have justified our case in calling for it.

We have sent you a full report and we have offered to show you the vast mass of information in our files, yet you have neither examined the report nor asked for further information from us. I should like to repeat this invitation, and I hope that this time you will accept it.—I am, etc.,

London, E.C.4. DEREK WRAGGE MORLEY.

*** Our only comment on Mr. Morley's letter is that disclosure of the constituents of a secret remedy would bring an end to speculation.—ED., *B.M.J.*

SIR,—Referring to the article on cancer treatment which has appeared in a popular illustrated paper, may I as a trained pathologist be allowed to say that the microscopical examination of excised tissues, without clinical examination and observation over a period of time, may prove misleading—a remark that could be illustrated by several cogent examples? Under the cross-heading, "What the Microscope Showed," on page 33, considerable stress is placed on the selective killing of the cancer cells by the proliferation of connective tissue. Admittedly this does occur in the scirrhotic cancers of the very aged and can be considered as an attempt of the body to deal with cancer cells. The possible fallacy consists in obtaining a biopsy from a portion that is not active or has undergone radiological treatment—for example, in the centre of the tumour, as illustrated on page 41.

This is, however, a subject which can be left to others to discuss—attention can be focused on the assertions on page 33 where the experiments on 13 mice and 26 chickens are mentioned. Six of the untreated mice died within a week. "All the six treated mice lived for several months, and one was alive . . . nearly seven months after the first treatment. The thirteenth mouse, which had two large growths, survived for over two weeks under treatment." One might have preferred to learn about the size of the tumours and the particular type of neoplasm. Probably it was the usual mammary epithelial cancer of the mouse. What was the size of the growth on death?

The experiments on three-day-old chickens also lack definition, but it can be assumed that a "Rous virus" was employed; this is most active, so that, if only 6 out of 24 developed a growth, something must have been different from ordinary laboratory practice, where a 98% take is usual. In these important animal experiments it is not mentioned whether the treatment was external or internal—or perhaps a combination of both. Animal experiments are important, because it is not only possible to obtain reliable percentage figures but to compare the malignancy of various cancerous strains.—I am, etc.,

Little Shelford. H. P. BAYON.

Training for General Practice

SIR,—Surely Dr. Johnson's article (August 26, p. 493) is a condemnation of Dr. Johnson rather than Bart's. It is not conceivable that a man is unable to find interesting if not absorbing lecturers in one of the medical colleges of London University, and should he fail here I think that his prospect of succeeding elsewhere must be small where often there is only one teacher in a particular subject. I find that the teachers are not only pleased but anxious to see students from other colleges at their ward rounds and lectures.

Probably the best criticism of London University medical education is the continuing tendency to divorce medical students from those of other faculties. This cloistering may be desirable from the viewpoint of the transition from natural to medical sciences; but I can see no good reason why there should not be inter-college university residences (preferably in Bloomsbury) for all students rather than halls of residence provided by individual colleges.

It is not the duty of London University to provide a gradual transition for students from other universities; and I believe that Cambridge arranges a very excellent course in the long vacation term for their students, such that it would be an insult to make these students proceed to a similar course in London.

Finally, since Dr. Johnson was so obviously a fish out of water it would have been preferable had he found out how they taught at Bart's, and then if he decided it was what he wanted to proceed to gain admission rather than criticize a school because it failed to provide what he wanted. In view of the large number of excellent teachers I think this system has the advantages of a well-designed uniform course, combined with the original Italian idea of a university, that a student should be taught those subjects in which he is most interested by the teacher of his choice.—I am, etc.,

London, S.W.1. JOHN PRICE.

SIR,—I have read Dr. Donald McI. Johnson's article (August 26, p. 493) with interest and amazement. I went from Cambridge to Bart's at the same time as he did, and was trained in the same way—or shall I say was offered the same training? Whereas Dr. Johnson considers that he acquired his knowledge from books and surgical out-patients, I believe that as a student I learnt very little from books and nearly all I did learn was from wards and out-patients. I agree with him that the special departments were overcrowded. In my opinion insufficient emphasis is put on the importance of the "specials" for general practice. I was glad of the opportunity later on to supplement my knowledge of these departments even though I did see what I could at Bart's. It is so interesting to me to find that two of us found our clinical training so different. Dr. Johnson received "a mental shock." I found the whole period fascinating. There were many juniors—chief assistants—willing to help the struggling student. My most serious criticism is that there were far too many of us.—I am, etc.,

Bungay, Suffolk. P. G. LEVICK.

SIR,—After reading the article by Dr. Donald Johnson (August 26, p. 493) in which he gives his views on Bart's in 1924 I found a photograph of the residents in November, 1926. Of the 18 men in it, one died in 1928 and two I have lost touch with. The activities of the remaining 15 are as follows: a consulting pathologist, professor of paediatrics, Nuffield professor of orthopaedics, consulting anaesthetist, advising physician to May & Baker, E.N.T. consultant, consulting ophthalmic surgeon, consulting physician, superintendent of T.B. sanatorium, consulting gynaecologist, editor *B.M.J.*, and four of us are reasonably competent general practitioners.

Surely this is not a bad result for such allegedly poor training?—I am, etc.,

Twickenham. M. G. FITZGERALD.

SIR,—All doctors in practice, whether as specialists or as general practitioners, have memories of their student days. It is quite interesting to observe that these recollections vary depending upon how long ago the particular doctor was a student. Student days are an entity in themselves. The perspective varies with time. For example, a student does not always understand quite how his particular stage of training will help him in his future career. Later the newly qualified practitioner finds himself faced with practical problems with which he may not be able to cope. He may think that he ought to be able to do so. This is usually the first mistake.

The blunt fact of the matter is that practical problems can usually be assessed in simple practical terms. The proper assessment of simple facts is something that only comes with time. How very often are simple clinical matters resolved into two or three straightforward alternatives. The choice can be made only from a broad pattern of experience. Dr. Donald Johnson in his very interesting article (August 26, p. 493) refers to an evening emergency call. The context suggests that he expected to reach a correct conclusion. As a newly qualified man he expected to be correct. I humbly suggest that this was a mistake. The newly qualified practitioner may expect a good deal from himself. The general public do not expect great wisdom from a young man who has not had great experience. The public have a great respect for academic training. Experience is also necessary. Both experience and detailed academic training are required. There is no substitute for either.

I submit that it would be quite wrong to modify the present system of academic training, carried out in the main by specialists. The student receiving instruction in a hospital ward cannot be compared with an apprentice in a trade. Nevertheless, like an apprentice, there are many practical wrinkles which he must know. These can only be learnt slowly—namely, in practice of some sort or in hospital, which means working with the other doctors and dealing with patients away from their homes. If the practice is in a domestic field the patient is then visited at home and the newly qualified doctor may feel that he is intruding into a way of life that he possibly never knew existed.

I think it is the process of learning how the other half lives which is so startling. No amount of modification in the student's career will give him much information in this respect. On the other hand there is just so much of value in this experience, and I feel sure that it would then be correct for the doctor with growing experience to resume his association with specialists. The greatest fault in the system is that very often the general practitioner never takes up systematic instruction again. The average G.P. finds that, when he is ready to turn again to the hospital environment to refresh his theoretical knowledge, the claims of general practice upon his time and his attention have crowded out his life to such an extent that a material alteration in his way of life is, if not impossible, certainly improbable.

In considering the clinical training of the general practitioner it would be as well for critics to remember that nearly all theory has been elucidated in the first instance by practical experiment. Even the greatest scientific discoveries underlying clean-cut things were discovered and worked out in the first place by painstaking trial and error. This has been so even when the work has been conducted by a brilliant scientist. Any process of education is a mixture of theory and practice. I feel sure that it is the function of medical education to present the theory. It is the duty of the student to digest the theory and put it into practice. The ability to reproduce academic theory at examination times, in order formally to pass an examination, is of limited significance. What the newly qualified doctor does with his theory matters a great deal. No amount of alteration of medical education will influence this much.

—I am, etc.,

Scarborough. NOEL J. JACKSON.

SIR,—I feel sure that most Bart's men—especially those of us who qualified 25 years ago—will feel grateful to Dr. W. A. Bellamy for his letter (*Journal*, September 9, p. 623) in defence of his teachers. Unless my memory serves me falsely, the educational number of the *Journal* for 1925 reads somewhat as follows: "Most of you will eventually find your way into G.P. Do not expect to make a fortune. The most important thing is that you will be your own master, and be free to lead a full and interesting life." What now is our judgment upon this prophecy of a quarter of a century ago? But why this flight into the dim and distant past? Is it that we now in our dislike of the present and our fear of the future are turning in desperation to the past? That in our anxiety state we are trying to blame the "unimpeachable" for the unhappy state into which our own shortcomings have brought us? It would be better instead for us to plan for the future with more vigour, so that we may return to the way of life our masters prepared us for.—I am, etc.,

Leigh-on-Sea. THOMAS REES.

Chlorinated Swimming-pools and Poliomyelitis

SIR,—The letter from Mr. R. Ogier Ward in your issue of September 9 (p. 625) implies that chlorinated water in swimming-pools is dangerous and more likely to induce infection by the virus of poliomyelitis than prevent it. Is he arguing on sound lines? He believes that a nasal irritation may be set up by chlorinated water, which is no doubt true, as also may be conjunctivitis in certain persons and in certain concentrations of chlorine. I would argue that such irritations may cause transient discomfort, but unless the irritation is permanent or chronic (which is not the case from periodic visits to a swimming-pool) it is not harmful but may even be beneficial. Most of the proprietary gargles, for instance, either ordered by a medical man or more frequently purchased by the credulous public from the chemist's counter, are useless as bactericidal agents. What they do is to act as physical agents for the removal of mucus and debris and, secondly and more important, to irritate mucous membranes with which they come in contact and so *stimulate the further production of mucus*. This artificially stimulated mucus is poured out and, being bactericidal itself, helps to wash away recently implanted bacteria. I contend, therefore, that chlorinated swimming-bath water by intermittent or transient irritation of mucous membranes and by encouraging the flow of mucus does more good than harm, and does not "invite disaster."—I am, etc.,

Shrewsbury. A. D. SYMONS.

SIR,—I was very interested to read the communication on the above subject by Mr. R. O. Ward (September 9, p. 625), but feel that his experience with modern swimming-pools has been rather unfortunate. For some years now I have been associated with swimming-pools and swimmers, and, while I agree with Mr. Ward that one does from time to time meet with over-chlorinated swimming-pools, such occasions are fortunately uncommon. Disease of the ear, nose, and sinuses is one of the "occupational diseases" of swimming, but can be prevented to a large extent by not swimming when a coryza is present. If one indulges in swimming or diving during these circumstances, the mechanical action of the water may wash infection into the sinuses or middle ear. I feel convinced that the action is mechanical rather than chemical, because sinusitis and otitis media are more commonly seen in divers and back-crawl swimmers, where gravity and centrifugal force may play a greater part, than in free-style or breast-stroke swimmers.

Recently I examined 60 of Britain's leading performers, many of whom spend two to four hours per day swimming in order to reach the required standard necessary to achieve international honours. In only one case did I find evidence of otitis media—a healed drumhead. On the other hand, I found chronic otitis media to be common amongst divers of many nations during the 1948 Olympic Games. I have gone carefully into the records, and, so far as I can discover, only one case of poliomyelitis has occurred in a first-class British swimmer. That case was, tragically, fatal, and did not occur in this country but during a swimming meeting abroad, in an open-air pool.—I am, etc.,

Heswall, Cheshire. NOEL BLEASDALE,
Hon. Medical Officer,
English Amateur Swimming Association.

Osteoarthritis

SIR,—I have read with interest the letter from Mr. Franklyn Stonham (September 9, p. 629) on my paper on osteoarthritis in the refresher course (June 17, p. 1415), but he appears to have overlooked the context in parts and the fact that the refresher course is for busy general practitioners and not for surgeons. Since he criticizes my view that trauma is an important cause of osteoarthritis, in case I might be mistaken I have looked up Pemberton and Osgood, Cecil, Comroe, and Copeman, and find that they all regard trauma, especially of minor type as I point out, as being of importance, so I err in good company. It is my experience that massage is helpful and that muscle spasm is generally protective against the pain which is a feature of osteoarthritis. Since the paper was designed purely for the general practitioner details of operative methods were purposely omitted, and I said that if surgery is undertaken the earlier the better, but it is for the surgeon to determine the form it should take. This observation also covers manipulation under anaesthesia, which in my view should be undertaken only by an orthopaedic surgeon, and even then I have seen undesirable results. Exercises without weight-bearing and under instruction furnish the only form of manipulation that should be undertaken in general practice except in very exceptional circumstances. I therefore see no reason for withdrawing or modifying anything I said in the paper, which is based on nearly 50 years' close study of arthritic conditions.—I am, etc.,

Buxton. CHARLES W. BUCKLEY.

Treatment of Warts

SIR,—I was interested in the question in your issue of September 2 (p. 584) about wart weed, since I have just finished a thesis on warts and happen to have the relevant literature available.

Wart weed is a name which is used loosely to refer to a variety of plants, including the greater celandine (*Chelidonium majus*) and the sun spurge (*Euphorbia helioscopia*). The use of the milky juice of the spurges for the cure of warts is an old remedy, and is quoted by Cockayne in his compilation of Anglo-Saxon medicine. Modern references are to be found in two short articles by Michon[1] and Hissard.[2] Countrymen continue to use such plant juices not only, I believe, because countrymen are conservative, but because they have rid themselves of warts by these means.

The mechanism of cure in warts is always a difficult matter to assess. Warts are notoriously open to the influence of suggestion, and the darling remedy of one doctor is the despair of another. But there is one treatment which stands out above all the rest, and that is the use of podophyllin in condylomata acuminata (which are warts of the genital region). This remedy, which originated in folk medicine, depends on the interference with mitosis caused by podophyllotoxin, a portion of the resin of podophyllum. Podophyllin does not work well in common warts, which are more protected from contact with local applications by their structure and thick horny covering.

The resins of podophyllum and euphorbia have in common an irritant action. *Euphorbia peplus*, the petty spurge, known locally as "milk-weed," is in my experience a cause of contact dermatitis in gardeners; and according to Martindale *Euphorbia resinifera* is used as a vesicant by veterinary surgeons.

I believe, therefore, that the action of euphorbia resins on warts would be worth investigation. Patients and doctors would welcome an alternative to the present painful regime of freezing or frying, with the certainty of some degree of scarring to follow.—I am, etc.,

Cambridge. ALAN LYELL.

Acute Toxic Jaundice

SIR,—This case appears to be worth recording because it seems probable that the patient's jaundice and skin condition were caused by the administration of para-aminosalicylic acid (P.A.S.), as there was no case of infective hepatitis in the ward at the time.

A nurse aged 21 reported sick on March 6 with pain in her right chest with cough and sputum. She was found to have a pleural rub over the lower part of her right chest and loud rhonchi audible over the right base. Her blood sedimentation rate was 17 mm. in one hour; her sputum contained tubercle bacilli; the rectal temperature was raised to 100° F. (37.8° C.) in the evening. Her radiograph showed a density in the right middle zone spreading out from the hilus with a cavity in it.

A right artificial pneumothorax was commenced on March 19. On March 25 she was given P.A.S., 2 g. three times per day, slowly increased to 12 g. daily. She had a total of 163 g. up to the time when it was discontinued on April 13. It was stopped because she had vomited several times on April 10 and the vomiting persisted, and on April 13 she developed an urticarial rash. This rash, although quite trivial at first, became very alarming and spread over her whole body, was urticarial in some parts and morbilliform in others. Her face became swollen, her eyes could be opened only with difficulty, and her ankles and legs became swollen.

On April 16 she developed jaundice. Her stools were clay-coloured, her urine contained bile and a slight trace of albumin. The conjunctivae were yellow, but the jaundice was never very marked. It persisted for approximately 10 days. During this time her temperature rose steadily and for 10 days ranged between 101°–104° F. (38.3°–40° C.), and was on three occasions 105° F. (40.6° C.).

Her mental condition was never disturbed and she was always rational, but she was exceedingly difficult to rouse and would not take either food or drink, and towards the end of the 10 days when she was acutely ill had to be catheterized because of retention of urine. This retention persisted for five days. Her symptoms then began to abate, her temperature came down, her skin desquamated profusely in large dry scales in parts, and after approximately one week in this state her mental apathy disappeared and she again took an interest in her surroundings and rapidly became normal in this respect.

The artificial pneumothorax was maintained throughout her illness and is still quite satisfactory.

—I am, etc.,

Newcastle-upon-Tyne. GEORGE HURRELL.

Cortisone and Psychoses

SIR,—Despite much research into the role of cortisone in the human body, the significance of the psychological effects of the adreno-corticoids seems not to have been fully realized. *Par excellence*, the psychoses are "stress" diseases; they are precipitated by mental, physical, or physiological stresses. Once the stress disease is precipitated apathy results; the psychotic becomes hyporeactive to stimuli. This well-known phenomenon has been attributed to autonomic imbalance. The known physiological actions of cortisone show a more than coincidental resemblance to the biochemical findings peculiar to psychotics. Whether the causation of the psychoses can be explained along the lines of Selye's theories on adaptation and the biochemics of cortisone remains to be seen. The biochemically orientated psychiatrist will, however, see here a new vista, and one which should, without delay, be critically investigated.
—I am, etc.,

Cork, Eire. ROBERT A. MACCARTHY.

Optimism in Mental Hospitals

SIR,—The tone of the annotation under this heading (*Journal*, September 2, p. 568) suggests the advertisement of a sensational "psychological" film rather than a serious professional comment. The good results obtained by the newer methods of physical treatment in selected cases of mental disorder are of course well known, and I have had frequent occasion to appreciate the skill and success with which they are employed in the Crichton Royal itself and elsewhere. But the charge of "hopelessness, lethargy, and cynicism" brought comprehensively against mental hospital practice of "20 or even 15 years ago" makes one wonder how many mental hospitals, if any, the writer of the article had personally inspected at that time, with sufficient knowledge to give his opinions any value. It does not seem to have occurred to him that hopeless and lethargic cynics could never have produced and tested and developed the methods of treatment over which he now so exuberantly rejoices, and would not even have bothered themselves to look at the methods if presented to them ready-made. His jubilation about discharge rates is very difficult to understand. Patients may be discharged from hospitals in various states of health and for many different reasons. They may be recovered, improved, not improved, refusing treatment, incurable, unsuitable, moribund, or dead, but the writer of the article seems to imply that he would also be prepared, and even proud, to discharge patients whose continued presence would have an unfavourable effect on the hospital statistics. "Discharge rate" has no useful meaning unless related over a

period to various other factors, such as the recovery rate, the number of subsequent readmissions or relapses and, particularly, the type of case to which admission is granted or refused. Any mental hospital could easily, though shamefully, have a discharge rate of 100% by simply shutting its doors and its eyes to all applicants whose condition was such that they would need asylum, in the original and best sense of the term, for an indefinite period or for life. The writer's "optimism" has apparently blinded him to the fact that there are, and will continue to be, many such patients, or perhaps he does not greatly care what happens to them so long as they are not allowed to spoil the statistics. The real value of a "discharge rate" might perhaps be determined with fair accuracy by the relatives and practitioners who have to live with and care for the patients during the months or years after discharge, but such persons are apt to be regrettably uninterested in statistics.

The writer's general outlook is such that when he describes the need for certification as "mournful" one might be inclined to question the extent of his personal experience of cases in which that need existed, but he presumably means that certification is always to be mourned, not on the patient's account, but because it spoils the statistics. Whatever the success of new techniques in treatment, if "bare figures . . . in cold statistical form" are to become idols, and if the proper (though unpublished) motto for a mental hospital comes to be "Get well or get out," psychiatry will soon lose its soul, and the most brilliant statistics will not save it.—I am, etc.,

Glasgow. DAVID YELLOWLEES.

Foetal Pathology and Vitamin A

SIR,—Although at variance with his argument, I am in agreement with Dr. Bicknell (September 2, p. 576) that your leading article (August 12, p. 404) has not done justice to the extensive literature dealing with congenital abnormalities caused by experimental vitamin-A deprivation. Unfortunately all these experiments were carried out on animals, mainly rats. In every kind of animal experiment the application of the results to man is difficult, but in this special instance it seems nearly impossible.

In about 75% of the offspring of female rats kept on a vitamin-A-deficient diet[1] the young showed multiple ocular changes, the commonest of which was a fibrous retrolenticular membrane in place of the vitreous body; other abnormalities were colobomas, eversion of the retina, rudimentary development of the iris, of the ocular chambers, of the cornea and conjunctiva. In the same experiment abnormalities of the genito-urinary tract were found approximately in the same frequency,[2] like fused or horseshoe kidneys, undescended testes, absence of seminal vesicles, bulbo-urethral glands, vagina, etc. Furthermore, abnormalities of the heart and aortic arch,[3 4] mainly septal defects, retardation of myocardial development, absence of pulmonary vessels, open duct, etc., were present in about 44% of the offspring but in none of the controls. Animal experiments, however, do not always produce such uniform results. Thus in another series of rats kept on a vitamin-A-deficient diet congenital diaphragmatic hernia was produced in 18.9% of the young, but the incidence of this malformation in the offspring of another strain of rats kept under the same experimental conditions was only 0.9%.[4]

These animal experiments as well as the prenatal rubella syndrome[6] show clearly, as you, Sir, also emphasize, that genetic factors alone cannot always be invoked for the causation of these abnormalities. As some of the malformations caused by German measles during pregnancy are similar to those caused by vitamin A deprivation in rats, Bicknell is tempted to suggest that rubella acts on the human foetus by lowering the vitamin-A level in the maternal blood. This may be so; but whilst in the offspring of vitamin-A-deficient rats interventricular septum defect was the most frequent cardiac maldevelopment and patent ductus arteriosus one of the rarest, in three post-mortem examinations on the rubella syndrome all three infants had patent ducts, but interventricular septal defect was found only in one.[7] Moreover, in the rat experiments nearly all structures of the eye were involved, with the notable exception of the lens[3]; in the prenatal rubella syndrome the congenital cataract of the lens is the leading symptom. The severity of the rubella infection appears to be only of minor importance. Warkany[8] describes an infant with cataracts and congenital heart disease (p. 45) whose mother was unaware that she had been ill during her pregnancy. Two of her children had, however, German measles during the second month of pregnancy. He assumes that the mother had a symptomless infection and suggests a virus injury to the capillaries (which eventually may lead to nutritional disturbances affecting the foetus). This nutritional disturbance might consist of lowering of the maternal blood-vitamin-A level, as Bicknell suggests, only it appears strange that different structures of the same organs are involved in rats and man. Another point in need of clarification is this: it is suggested that nearly 100% of the mothers contracting German measles during the first two months of pregnancy have infants with congenital abnormalities.[9] Therefore it has to be assumed that the organogenic period during which these anomalies are produced lasts for several weeks. Even severe fevers do not, however, as a rule depress the vitamin A to an abnormally low level for several weeks; rubella on the other hand seems to produce congenital defects even if it is so mild as to pass unnoticed. In the light of these facts it seems more likely that the foetal damage is caused by direct virus action and not by the low vitamin-A level.

The following example further demonstrates the difficulty of the application of animal experiments to man. As already mentioned, the commonest congenital abnormality found in the offspring of rats kept on vitamin-A-deficient diet was a fibrous retrolenticular membrane, which was tentatively considered similar to retrolental fibroplasia occurring in man. During the recent International Congress of Ophthalmology[10] reference was made to the rapid increase in incidence of this congenital disease in the U.S.A. since 1943. It was estimated that a premature baby with a birth weight of less than 4 lb. has a 1:14 chance of being afflicted by congenital blindness from this disease. It was, however, found[11] that the limiting level of vitamin A producing the retrolental fibrous mass in rats was less than 16% of the normal, a deficiency which is unlikely to occur in pregnant American women.

Although I disagree with Bicknell's reasoning, I should like nevertheless to applaud his suggestion to give additional vitamin A to pregnant women contracting German measles. I would even go further and say that every pregnant woman suffering from any severe infection or febrile disease during the first trimester should be given additional vitamin A.—I am, etc.,

Radiation in the Shoe Shop

SIR,—I would strongly endorse the views expressed in your leading article of September 2 (p. 565) that it might be wiser to discontinue the use of shoe-fitting *x*-ray fluoroscopes. Your remark that "points of pressure on the fleshy parts probably escape detection in any case" is, if I may say so, an understatement. I recently had occasion to use one of these fluoroscopes in a shoe shop when pressed to do so by the assistant. Immediately on exposing my foot to the *x* rays I noticed a loose nail lying horizontally in the centre of the sole of one shoe, and I pointed this out to the shop assistant, who was looking through her observation opening. She declared she could not detect the nail, but subsequently consented to remove it when I showed her the location on the shoe. I think one needs no further comment on the lack of value of the *x*-ray examination in fitting my foot. (The ectopic nail would have given early evidence of its presence.)

Last month I saw in a newspaper a picture of Christmas crackers being subjected to fluoroscopic examination to ensure that each cracker contained its toy or trinket. The worker was situated in front of a screen with quite a large-sized aperture which showed a row of crackers visible at one time, and it was stated that any unfilled cracker was removed. It would be interesting to know the dose of radiation received by this worker in a week.

The number of patients in hospitals and outside referred for *x*-ray examination or treatment is now so considerable that the dose of *x* rays received by the population as a whole is probably by no means negligible. We should advise that this dose be not increased unnecessarily in the factories and shops where *x*-ray installations and examinations may be made without medical advice or control.—I am, etc.,

London, W.C.1. PHYLLIS WADE.

Amalgamation of Radiological Societies

SIR,—I was impressed by the points raised by Dr. A. R. Thomas in his letter (August 26, p. 530). There are certainly four different bodies concerned with the interests of radiologists, and the British Institute of Radiology in addition has a large representation from physicists and from manufacturers of *x*-ray apparatus. There is an additional point of considerable importance that Dr. Thomas has not mentioned. All these bodies are concerned with the interests of diagnostic radiologists and radiotherapists. Before the war a very large proportion of radiologists were expected to undertake both diagnosis and therapy, and both these subjects were considered as one specialty. To-day the position is quite different and there is no more similarity between the diagnostic and therapeutic sections of our specialty than there is between, say, that of a gynaecologist and an orthopaedic surgeon. Surely the time has come when we should face up to these facts. The subscriptions of several of these bodies have risen considerably, largely owing to printing costs, and I think it would be desirable if each section produced its own journal at suitable intervals. Would it be possible for the organizers of the International Congress of Radiology to produce a full questionary to all concerned? Personally I would welcome one society confined entirely to each section, linked closely with the B.M.A.—I am, etc.,

Ipswich. C. H. C. DALTON.

Threats to General Hospitals

SIR,—Mr. John Howkins in his letter (July 22, p. 219) is quite right. The threat to the integrity of St. John's Hospital, Lewisham, is not an isolated example. In one hospital with which I am acquainted it was rumoured that the obstetrical department would be moved from the main hospital to another building altogether. This dismemberment of general hospitals, thus robbing them of the benefits of specialized departments, can only be a retrograde step, as Mr. Howkins says. Whilst on the surface it would appear that the isolation of specialized departments in separate self-contained hospitals is good planning, it encourages over-specialization. In the long run this can only be detrimental to the patient, for it is the disease rather than the patient which becomes the object of treatment. This aspect of medicine has recently been emphasized by Sir Henry Cohen (July 22, p. 179). It is to be hoped that this dismemberment of general hospitals will not be proceeded with, as they are undoubtedly the mainstay of the hospital service.—I am, etc.,

London, W.1. H. H. FOURACRE BARNS.

Kitchen Hygiene

SIR,—I read with interest your leading article on kitchen hygiene in the *Journal* of September 9, p. 613, and also the article by Drs. E. L. M. Millar and M. Pownall, "Food-poisoning in Sheffield in 1949" (*Journal*, September 2, p. 551). I have given considerable thought to the subject since reading the two articles and wonder if the following suggestions might be of value in reducing the incidence of hand-borne infections.

1. All food-handlers in restaurant kitchens should be provided with surgical-type rubber gloves made with specially long cuffs and supplied by the health department of the local authority concerned.
2. The kitchen workers should be taught to wash their hands on coming to work and should then put on the gloves and keep them on while handling food, cutlery, dishes, etc.
3. After finishing work the hands should be well washed with the gloves still on and then the gloves should be drawn off inside-out and placed to soak overnight in "dettol" solution or some other antiseptic.
4. It should be the responsibility of the local medical officer of health or a specially appointed borough food hygiene officer to instruct workers in the use of the gloves and, by frequent visits to catering establishments, enforce their use and issue replacements when necessary.
5. Personnel should be encouraged to believe that the wearing of gloves is also in their own interest (e.g., to protect their hands from detergents used in washing-up water).

I think the above suggestions would be of some help in the prevention of food-poisoning, because they would prevent contamination of food by minor, and often unnoticed, septic abrasions on hands; and gloves are far more easily cleansed than the human skin and have no nicks in them, like fingernail creases, in which dirt and therefore bacteria can collect.

I realize that the cost of the above measures might prove a serious obstacle to their application, but this would be countered by the saving in man-hours from the reduction in food-poisoning illness if the measures proved effective.—I am, etc.,

Chingford, E.4. W. K. SLACK.

Psychological Polemics

SIR,—Dr. E. Glover states (*Journal*, September 2, p. 576) that "Jungian theory is completely incompatible with Freudian theory" and that this is "a fact which Jung himself would not be inclined to deny." Jung has, in fact, denied it. In the first of his *Two Essays on Analytical Psychology* (trans. Baynes, 1928) he maintains that the theories of Adler and Freud are both "in a large measure correct" (p. 39), that the theoretical differences between them reflect the contrasted personalities of their originators (p. 41), and that the two approaches can be reconciled by the "standpoint superordinate to both," described in the subsequent chapters. In these Freud's views are given due place. For instance, Jung says, "In the treatment of a young extravert it is always advisable, indispensable indeed, to take full account of the Freudian standpoint," (p. 62). Elsewhere he has written (*Modern Man in Search of a Soul*, trans. Dell and Baynes, 1933, p. 134), "I am no opponent of Freud's; I am merely presented in that light by his own short-sightedness and that of his pupils."—I am, etc.,

London, N.W.3. DERRICK S. TROUTON.

Silicosis in Rhodesia

SIR,—In *Venture* (the journal of the Fabian Colonial Bureau) at page 7 of Volume 2, No. 6, dated July, 1950, occurs the following passage.

"In Northern Rhodesia one may note, with mixed feelings, the opening of the permanent headquarters of the silicosis bureau at Kitwe in the copperbelt, which will deal with upwards of 40,000 people a year afflicted in the lungs by rock particles from the mines."

The many medical men and others who are interested in pneumoconiosis should know that it is quite untrue that upwards of 40,000 cases of silicosis attributable to work in Northern Rhodesia mines are seen annually by the bureau, of which I have the honour to be chairman. About 40,000 persons are seen annually by the bureau at the routine examinations prescribed by law before engagement, and thereafter annually. Since the first discovery of silicosis in Northern Rhodesia mines in 1943 up to December 31, 1949, the total cases of silicosis discovered number 280 (Europeans 133; Africans 147), and among that number were no fewer than 133 (Europeans 117, Africans 16) whose silicosis was attributable, at least in part, to mining elsewhere than in Northern Rhodesia.—I am, etc.,

N. Rhodesia. JOHN F. C. HASLAM.

Radical Cure of Hernia

SIR,—Like King Charles's head, the radical cure of hernia is never long absent from the columns of the medical press (see *Journal*, September 9, p. 625), and apparently the search still goes on for something even thinner and more useless than the transversalis fascia. Surely the strongest and most efficient tissue in this region is the external oblique. If this is cut for some half an inch in the direction of the umbilicus, and pleated up by each stitch taking two or three bites, it can be sutured to Poupart's ligament as quite a thick bar. The lower flap of the external oblique, which should be left as long as possible, is then sutured over the upper flap. For direct hernia I put the upper flap below the cord, and in 15 or 20 years I have never seen a recurrence, though I was anxious to see one to find out, if possible, why it happened. The lower flap, it will be found, leaves a little of the cord exposed at the lower end, but gives

no trouble. For an ordinary indirect hernia it is quite satisfactory to put both layers in front of the cord, and I can recall only one recurrence in this method.

The two main points are the cutting of the external oblique and freeing it to get a good inch excess of tendon and then pleating it to form a thick bar of tissue. The conjoint tendon is sutured as in the ordinary Bassini operation.—I am, etc.,

Milford-on-Sea, Hants. H. J. NIGHTINGALE.

No Diagnosis without Clinical Investigation

SIR,—Up to the present the results of several million chest examinations by mass radiography have been returned to the Ministry of Health and the figures published by them. The abnormal cases are classified into diseases, the most important classification being that of active pulmonary tuberculosis. Unfortunately, no criterion has been set as to when this diagnosis should be made and included in the returns. Some units accept this classification immediately they find a suspicious soft upper zone lesion. Other units await the result of a first chest clinic investigation, when sputum tests, B.S.R., etc., have been performed. Here, again, the results are not altogether satisfactory, for I have myself had apparently soft lesions returned as inactive by a chest clinic; three months later a positive sputum is discovered and the result is altered. By this time, however, it has been classified in the Ministry returns as an inactive case. In addition to this, the length of time which chest clinics follow the apparently soft radiological lesions, with no definite symptoms, appears to vary considerably. I have found that some clinics will write these cases off after the preliminary investigation, and then find that they are returned later as sputum-positive cases with symptoms.

I would like to make a plea that a diagnosis of active pulmonary tuberculosis should never be made in mass radiography returns until after a full chest clinic investigation, and that the apparently soft radiological lesions in young persons with no symptoms or sputum should not be returned to us labelled inactive unless the subjects have been kept under observation for at least six months by the chest clinics. Furthermore, there should be a minimum follow-up period for these cases of at least two years. By this means we should have a uniform standard throughout the country, both as regards mass radiography findings and the chest clinic follow-up of early cases discovered.—I am, etc.,

Coventry. A. GORDON EVANS.

POINTS FROM LETTERS

Over-population

Dr. W. R. E. HARRISON (Buxted, Sussex) writes: When will men awake to the menace of over-population? Not until the "experts" stop confusing the issue with stories of land ripe for development from which science will be able to squeeze more and yet more food. The fact is that preventive medicine has suddenly disrupted the age-old plan of Nature. Infant mortality has been cut, epidemic diseases are on the way out, local famine can be stalled by dumping food from the air. Grand! But these happen to be the very sanctions which Nature was wont to use to mould her varied species and to keep her individuals fit. So what? Either prevention must devise man-made controls at least as effective as the old ones of Nature, or else Nature will be compelled to come back on us with cataclysmic action. And the longer the disequilibrium is allowed to grow, the bigger the jolt to put it right. Now, preventive medicine must, *a priori*, go hand in hand with politics, which may well be the reason why prevention has come to think exclusively in terms of *quantity* and has got itself bogged down in "welfare," leaving the harder, politically taboo side of the balance sheet—namely, birth control—in the hands of private enterprise, where inevitably it must lead to dysgenic breeding. Thus "progress" in our time has become the record of man's destruction of the world's bounty. Land is worked to desert; water everywhere polluted; towns turned into built-up areas: the lower animals, the so-called vermin, regarding us as the universal enemy. All this to what purpose? So that *Homo sapiens* may one day cover the face of the globe to the thickness of standing room only. And the remedy for this madness? Well, obviously there is no single panacea, but, for a beginning, suppose science and politics were to grow a bit more humble, recognizing the undoubted truth that man is a part only of Nature, and not the whole works.

Obituary

W. J. DILLING, M.B.

Dr. D. J. Browne writes: News of Professor W. J. Dilling's death (*Journal*, September 2, p. 579) brings sadness to his old students at the Liverpool medical school. One will always remember his lectures, fluently delivered as he paced the room. Pure pharmacology was never a dry subject in his hands. He could prevent the memorizing of doses from becoming dull, and his description of the actions of drugs such as strychnine, opium, and alcohol is still fresh in our memory. While he was dean of the medical faculty there existed a happy atmosphere of friendliness: interviewing the dean was certainly not an ordeal. Even the viva voce was robbed of its terrors in his presence. He was liberal in the extreme, and will be remembered as a university professor in the old tradition whose attitude to education and examinations was not strenuous as it is to-day. Because of our mutual interest in music I was in a position to see how greatly he influenced music culture in the university. The university music society owes its existence to him, and the orchestra was allowed to practise in the pharmacology department—the non-medical students blaming the odours of drugs for faulty intonation. Visiting artists to Liverpool often gave recitals at the Students Union. Even Sir Thomas Beecham was beguiled by Professor Dilling. And it was due to him that in Liverpool we have the finest concert hall in the country, the Philharmonic Hall. As chairman Dilling drove hard and spurred on the Philharmonic Society, the hall being finished just before the outbreak of the last war. The memory of his charming personality will live long in Liverpool.

Dr. JAMES CARRUTHERS YOUNG died at his home in Edgbaston on August 12 at the age of 62. He was educated at the Royal Grammar School, Newcastle-upon-Tyne, and at Durham University. He graduated M.B., B.S. in 1910, proceeding M.D., M.S. in 1914. In the years before the first world war he held four house appointments in the Royal Victoria Infirmary, Newcastle. When war broke out Young was already a special reserve lieutenant in the R.A.M.C. He was wounded in Gallipoli, twice mentioned in dispatches, and decorated with the Military Cross in France in 1917. After holding positions as surgeon-specialist and commandant of military hospitals he was released from the Army in April, 1919. By this time his interest in psychological medicine had been aroused, and he took a psychiatric post at Leytonstone and so passed into practical psychiatry. At one time or another he was resident physician at Bowden House, Harrow, and at Kenlow, Fife, physician to the Tavistock Clinic, and honorary medical psychologist to the Maida Vale Hospital. He also worked at the National Hospital, Queen Square, and did endocrine research at the Lister Institute. He was chairman of the Medical Society of Individual Psychology from 1933 to 1935. More recently he had been working as a specialist neuro-psychiatrist for the Ministry of Pensions at Birmingham.

Dr. H. Crichton-Miller writes: Dr. J. C. Young was one of the men who prove exceptions to the rule that a rolling stone gathers no moss. During the years between the wars he gathered experience in many fields of psychiatry. In 1921 he spent four months in Zurich undergoing a personal analysis with Jung. In his Continental travels he met Freud and Adler, In America he studied under Foster Kennedy, Adolf Meyer, Macphie Campbell, and elsewhere. But he still thirsted for further psychiatric experience, so he returned to Vienna in 1932 and studied under Bauer, Marburg, and Adler. His writings were numerous on dream psychology, analytic psychology, and recent advances in psychotherapy. He contributed many papers

to the Medical Society of Individual Psychology, and one entitled "An Experiment at Fontainebleau" he read before the British Psychological Medical Section. This was a great turning point in his philosophy. At Fontainebleau Ouspenski and Guirdjeff established what was popularly known as the "School of Forest Philosophy." "Jimmy" Young was one of the first to go there. It was soon after his arrival that Katherine Mansfield joined the group—against all medical advice, for she should have been in a sanatorium. Young told me that it took him exactly three weeks to "come out of the hypnosis." Many of us would like to have been free to browse in so many pastures, but, when all had been seen, consumed, and digested, Jimmy Young remained the same cheerful, lovable, and, withal, mercurial person who graduated at Durham 40 years ago.

Dr. WILLIAM THOMAS HILLIER, for 25 years clinical pathologist at the Birmingham General Hospital, died in Birmingham on August 18 aged 74. He was the son of Dr. James Hillier, of Ramsgate, and was educated at Taunton School. He studied medicine at the Middlesex Hospital and qualified in 1899, taking the D.P.H. in 1901. At first he turned his thoughts to surgery, but after he decided that this was not his bent he was appointed assistant to the director of the clinical laboratories at the Middlesex Hospital and pathologist to the Queen Elizabeth Hospital, Hackney Road. He was one of the first clinical pathologists in the country, and during the 20 years he was a student and pathologist at the Middlesex Hospital he won the enduring affection and respect of many men who afterwards became well known in medicine, surgery, and pathology. He had a great love of the sea and of natural history, and he spent many holidays working at the marine biological stations at Plymouth and elsewhere. He enlisted in the volunteer branch of the Royal Navy as a seaman, and, though he was a qualified doctor, he was content to serve as a petty officer. In the first world war he was captured when fighting with the Naval Brigade in the defence of Antwerp. However, he worked as a doctor in the prisoner-of-war camps, where, strangely enough, he obtained by dissection and microscopy a remarkable knowledge of the herring, which constituted the principal article of food at his camp. Hillier was awarded the O.B.E. as a result of his war service. In 1920 he became clinical pathologist at the Birmingham General Hospital, a post which he held until his retirement in 1946. Neat in appearance, pleasant and friendly in manner, and contented in disposition, he sought no personal advancement. He did not aspire to profound scientific learning, but by instinct he was a naturalist. Every week-end he walked long distances in the country, for he loved the countryside and its lore. He aided his friend, A. R. Thompson, in producing two books, *Nature by Night* and *Nature by Day*. He was a gentle man, and he showed that happiness of mind and greatness of soul are not necessarily accompanied by personal ambition.—H. W. F.

Dr. CEDRIC BAXTER, chairman of the Liverpool Local Medical Committee, died on August 22. He studied medicine at Liverpool University after having first entered upon a legal career. He graduated M.B., Ch.B. in 1925 and went into practice in Liverpool. Baxter took a keen interest in local medical affairs, and became prominent in the life of the city after his election to the Local Medical and Panel Committee about 20 years ago. He was a member of the Liverpool Insurance Committee for many years, and was its chairman when the functions of insurance committees ceased in July, 1948. In 1943 he was elected a member of the Insurance Acts Committee, and when the National Health Service came into operation he became a member of the General Medical Services Committee, and served upon this until his death. He was co-opted a member of the Lancashire Medical Committee upon his election to the central committee. A member of the Liverpool Executive Council from its inception, Dr. Baxter was elected chairman of the Local Medical Committee this year. He served upon the Public Relations Committee of the British Medical Association from 1947 to 1949. He was a prominent layman in the Roman Catholic Church, being honoured in 1932 when the Pope appointed him to be a Privy Chamberlain of the Cape and Sword.

V. T. T. writes: As a friend of 45 years' standing might I pay tribute to "Ceddie" Baxter? His natural kindliness and generosity gained him a wide circle of friends and the affectionate gratitude of his patients in the large practice founded by his father 75 years ago, and subsequently run by Ceddie and his surviving brother Cecil. As a young man he was a keen footballer and cricketer, and an amateur actor with the polish of a professional. He possessed a fine baritone voice and would entertain his friends with songs from grand opera, the music hall, or, best of all, from his self-composed repertory. He will be long mourned, for he was a family doctor of the best type, a true gentleman, a loyal friend, and a perfect host.

Dr. W. A. KIRKPATRICK died suddenly while visiting a patient on August 19. He was 47 years of age. William Alexander Kirkpatrick was born at Kelloe, Co. Durham, and was educated at Barnard Castle School and the University of Durham. He graduated M.B., B.S. in 1927. He had been in general practice at Skelton-in-Cleveland for 20 years, and he was also for a long time associated with the Cleveland Cottage Hospital. He was a justice of the peace for the North Riding of Yorkshire and chairman of the Juvenile Court at Loftus. He was a member of the British Medical Association of long standing, his offices including that of secretary of the Cleveland Division for several years. He also represented the Division at meetings in London during the war. He was a member of the Hazel Grove Lodge of Freemasons. His cheerful personality will be greatly missed both by his patients and his colleagues. He leaves a widow and three children, to whom great sympathy is extended.—F. O. G.

Dr. HERBERT ANDERSON ECCLES, of New Herrington, Co. Durham, died on August 29 at the age of 54. His studies at Aberdeen University were interrupted by the first world war, in which he served for four years in a field ambulance. He resumed his studies after the war ended, and graduated M.B., Ch.B. in 1923. After holding house appointments at the Children's Hospital, Aberdeen, and the Royal Infirmary, Sunderland, he settled in practice at New Herrington in 1925. He maintained his interest in service matters and acted as medical officer to the 7th Battalion Durham Light Infantry. On the outbreak of the second world war he joined his unit and served overseas in several theatres. He became an A.D.M.S., attaining the rank of lieutenant-colonel. Dr. Eccles was a keen rugby football enthusiast and played for Durham County on several occasions, including against the "All Blacks" team of 1924. As a practitioner he took a personal interest in his patients, not only in their illnesses but in their family affairs. Their welfare affected him much more than was generally appreciated. To those who had not the privilege of knowing him well he may have appeared unduly forceful and even blunt. Below this façade there existed a kind, almost sentimental, nature and a sincerity which endeared him to all who gained his friendship. He was a member of the B.M.A. for all his professional life and served on the executive committee of the Sunderland Division for many years. He will be sadly missed by a wide circle of friends in the North-east, in Edinburgh and Aberdeen, and particularly at his class reunion dinners which he so faithfully attended.—A. A. McI. N.

Dr. C. D. HENRY, who was a medical practitioner in Wellington, New Zealand, for nearly 50 years, died suddenly on July 13. He was the son of Dr. Joseph Henry, who served with distinction in the Maori war in the Auckland province and was afterwards member of the New Zealand Parliament. Claude Dawson Henry was educated at Wellington College, Cambridge University, and St. Bartholomew's Hospital. He graduated M.B., Ch.B. in 1894, and proceeded M.D. in 1906. After qualifying he returned to New Zealand and practised in Wellington continuously up to the time of his retirement to Silverstream some 11 years ago. He was honorary consulting physician to the Wellington Hospital, and was police

surgeon for 37 years. At Cambridge he was an enthusiastic cricketer and oarsman, and never lost interest in those sports. His kindness and consideration for his patients made him a much-loved man, while his qualities of character generally led to his appointment as a Commander of the Order of St. John. He is survived by his widow and four daughters.

Dr. T. David Lambert writes: May I be permitted to add a few words to the obituary of Dr. CLIVE VINCENT (August 26, p. 531)? I was fortunate enough to be a student with him at King's College and King's College Hospital, and later he joined me on the resident staff of the Connaught Hospital, Walthamstow. As a student he was extremely popular and most unconventional. He never seemed to work hard, but he always had a thorough grasp of his subject. His penetrating remarks while working and his succinct humour while relaxing were all the more stimulating when placed against the background of wartime difficulties meeting the students of his day. His brilliant photography set a very high standard for student hobbies. It was when he joined the resident staff of the Connaught Hospital that his abundant qualities shone through a certain shyness and it became evident that here was a man to be relied upon in any emergency. He attended to the never-ending flood of casualties with great good humour, and was loved by all the staff. On many occasions patients went out of their way to tell me how his kindness had helped them. To a fellow resident he was always willing to lend a helping hand in any capacity, and I can truly say that he made my stay at the Connaught memorable for the chance of working with him: it is hard to believe that such a charming and alive person is so soon lost to us. We are much the poorer for our loss, and our great sympathy must be extended to his widow.

Universities and Colleges

UNIVERSITY OF LONDON

The following special University Lectures have been arranged: at Westminster Medical School (Meyerstein Lecture Theatre), Horseferry Road, Westminster, London, S.W., Tuesday, October 10, 5.30 p.m., "Nature and Properties of Certain Metalloprotein Enzymes," by Professor D. Keilin, F.R.S., Molteno Institute, Cambridge; at London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C., Wednesday, October 11, 5.30 p.m., "The Development of Modern Renal Physiology," by Professor Homer W. Smith, College of Medicine, New York University; at St. Mary's Hospital Medical School (Wright-Fleming Institute Lecture Theatre), Paddington, London, W., Tuesday, October 17, 5 p.m., "Hormones of the Sympathetic Nervous System and the Adrenal Medulla," by Professor U. S. Von Euler, M.D., Fisiologiska Institutionen, Stockholm; at University College (Anatomy Theatre), Gower Street, London, W.C., Wednesday, December 6, 5.30 p.m., "The Cytoarchitectonic Organization of the Spinal Cord," by Professor Bror Rexed, Associate Professor, Karolinska Mediko-Kirurgiska Institutet, Stockholm. The lectures are addressed to students of the University and to others interested in the subjects. Admission is free, without ticket.

UNIVERSITY OF SHEFFIELD

Professor F. A. E. Crew, M.D., D.Sc., F.R.S., Bruce and John Usher Professor of Public Health and Social Medicine, University of Edinburgh, will deliver the opening sessional address of the Faculty of Medicine in the Firth Hall of the University, on Wednesday, October 11, at 5 p.m. His subject will be, "The Changing Emphasis in Medicine."

The Services

Group Captain C. H. C. Searby, R.A.A.F., has been appointed Honorary Surgeon to the King *vice* Air Vice-Marshal Sir Victor Hurley, K.B.E., C.B., C.M.G., V.D., R.A.A.F.(ret.).

No. 35

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended September 2.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each Infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1950 (a)	(b)	(c)	(d)	(e)	1949 (Corresponding Week) (a)	(b)	(c)	(d)	(e)

Stillbirths	187	21	25			185	21	32		
Rate per 1,000 total births (including stillborn)			31					37		

* Measles is not notifiable in Scotland, and the returns are therefore an approximation only.

† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

‖ Includes puerperal fever for England and Wales and Eire.

¶ Primary pneumonia no longer notifiable in Eire.

EPIDEMIOLOGICAL NOTES

Poliomyelitis

Notifications of poliomyelitis in the week ended September 9 were: paralytic, 327 (302); non-paralytic, 186 (189); total 513 (491). The figures for the previous week are in parentheses. There was an increase of 25 paralytic cases and a decrease of 3 non-paralytic cases compared with the preceding week. Non-paralytic cases in the week under review comprised 36.2% of the total compared with 38.5% in the preceding week.

Stafford had an increase of 15 notifications compared with the week before, otherwise any increases were fairly generally distributed. Material decreases occurred in Durham 7 and Norfolk 8. The following county areas have notified no cases in the five weeks up to and including September 9—Cambridge and Radnor. In the same period the following contributed 1 notification only—Suffolk (West), Isle of Ely, Soke of Peterborough, and Anglesey.

The uncorrected notifications for the week corresponding to that under review in 1947, 1948, and 1949 were 708, 76, and 306, respectively.

Total uncorrected notifications for 1950 up to and including the week under review are 5,126. The corresponding figures for 1947, 1948, and 1949 were 4,984, 1,214, and 2,647, respectively.

Discussion of Table

In *England and Wales* decreases were recorded in the number of notifications of measles 864, acute poliomyelitis 98, and whooping-cough 54; increases were reported for scarlet fever 80, acute pneumonia 58, and dysentery 19.

The largest declines in the incidence of measles were in London 117, Middlesex 81, Gloucestershire 57, and Essex 46. The largest increases in the number of notifications of whooping-cough were in Nottinghamshire 43 and Staffordshire 36, and the largest decreases were in Warwickshire 48, Middlesex 35, and London 29. No changes of any size occurred in the local trends of scarlet fever. The chief feature of the returns for diphtheria was an increase of 7 in Lancashire.

The main centres of dysentery were Lancashire 34 (Southport C.B. 6, Warrington C.B. 6); Leicestershire 25 (Leicester C.B. 25); Yorkshire West Riding 27 (Bradford C.B. 9); Cheshire 15 (Dukinfield M.B. 15); Durham 12; and London 9.

The largest returns of acute poliomyelitis were from Yorkshire West Riding 45 (Leeds C.B. 9, Sheffield C.B. 8); Lancashire 38 (Liverpool C.B. 9, Manchester C.B. 7, Salford C.B. 7); Gloucestershire 33 (Bristol C.B. 26); London 30 (Lewisham 5, Woolwich 4); Warwickshire 30 (Birmingham 20, Coventry C.B. 7); Durham 28 (Easington R.D. 4); Staffordshire 25 (Wolverhampton C.B. 6, Coseley U.D. 5); Essex 24 (Ilford M.B. 4, Thurrock U.D. 4); Kent 19 (Bexley M.B. 4); Middlesex 17 (Hendon M.B. 4); Norfolk 16 (Norwich C.B. 4, Depwade R.D. 4, Wayland R.D. 4); Leicestershire 16 (Leicester C.B. 11); Lincolnshire 13; Northumberland 13 (Newcastle-upon-Tyne C.B. 5); Southampton 12 (Bournemouth C.B. 6); Devonshire 12; and Glamorganshire 10.

In *Scotland* infectious diseases were less prevalent than in the previous week, with the exception of a rise of 21 in the number of notifications of dysentery; the falls included scarlet fever 29, measles 19, and whooping-cough 15. A small decline in the incidence of scarlet fever was recorded in every area except the northern. The rise in dysentery was due to an outbreak with 36 notifications in Stirling county. The other large centres of dysentery were Glasgow 42 and Edinburgh 13. A fall of 6 occurred in the number of notifications of acute poliomyelitis; the decline was confined to the western area, where 13 fewer cases were notified than in the preceding week. The largest returns of acute poliomyelitis were from Glasgow 17, Dundee 8, Fife county 8, and Edinburgh 5.

In *Eire* increases occurred in the number of notifications of whooping-cough 20 and scarlet fever 12, and a decrease of 14 was recorded for measles. The increase in the incidence of whooping-cough was general throughout the country, while the trends of scarlet fever and measles were mainly due to the experience of Dublin C.B.

In *Northern Ireland* an increase of 11 in the number of notifications of whooping-cough was the only variation in the trends of infectious diseases. Although the number of notifications of acute poliomyelitis was unchanged there were six areas involved compared with three in the preceding week.

Quarterly Returns for Northern Ireland

During the *fourth quarter of 1949* the birth rate was 19.9 per 1,000, and was 1.4 below the average of the five preceding fourth quarters. The infant mortality was 46 per 1,000 registered live births; it was 2 above the rate for the preceding fourth quarter, but 10 below the average of the five preceding fourth quarters. The general death rate was 11.3 per 1,000, being 0.2 below the average of the five preceding fourth quarters. The 332 deaths from the principal epidemic diseases included: diarrhoea and enteritis under 2 years 168, influenza 97, whooping-cough 41, diphtheria 10, and measles 8.

Quarterly Returns for Scotland

During the *first quarter of 1950* the birth rate was 18.5 per 1,000, being 1.1 below the average for the preceding five first quarters. The infant mortality was 46 per 1,000 registered live births, and was 14 below the five years' average for the first quarter. The general death rate was 14.7 per 1,000, and was 0.3 below the average of the five preceding first quarters. 294 deaths were attributed to the principal epidemic diseases; these included 256 from influenza, 22 from whooping-cough, and 9 from cerebrospinal fever. No deaths were registered as due to diphtheria. The death rate from all forms of tuberculosis was 65 per 100,000, that from respiratory tuberculosis being 58. The former rate is 13 below, and the latter 12 below, the rate for the first quarter of 1949.

Week Ending September 9

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 658, whooping-cough 3,682, diphtheria 44, measles 2,530, acute pneumonia 192, acute poliomyelitis 513, dysentery 205, paratyphoid fever 11, and typhoid fever 6.

Medical News

British Legion Village

Preston Hall, the British Legion village at Maidstone, Kent, celebrated its silver jubilee last April and has now published an illustrated brochure to mark the occasion. During the 25 years of its existence the village has provided the means for the treatment, training, and rehabilitation of over 10,000 ex-Service men and women suffering from pulmonary tuberculosis. It now contains 135 houses. One and a quarter million pounds have been paid in wages, and the industrial output of the rehabilitation factories has amounted to £2,190,000. Arrangements have been made with the Ministry of Labour for training to be given in carpentry, electrical and engineering maintenance, motor repairing, printing, painting and decorating, office routine, book-keeping, nursing, and hospital work. Since the introduction of the National Health Service Act the hutted hospital and main building at Preston Hall have been taken over by the hospital service, but the rehabilitation section (with over 200 beds), the factories, and the village remain with the British Legion. Both the hospital and rehabilitation sections still admit ex-Service patients from all parts of the country.

Director of Institute of Obstetrics and Gynaecology

On the retirement of Professor James Young from the Chair of Obstetrics and Gynaecology at the Postgraduate Medical School of London at the Hammersmith Hospital the Committee of Management of the Institute of Obstetrics and Gynaecology have invited Mr. Charles Read, M.B., F.R.C.S.Ed., F.R.C.O.G., to accept the newly created post of Director of the Institute.

International Congress on Diseases of the Chest

Sir Alexander Fleming was presented with the Gold Medal of the American College of Chest Physicians at the First International Congress on Diseases of the Chest, which was held at the Carlo Forlanini Institute, Rome, Italy, on September 17–20.

Congress of Cardiology

At the recent International Congress of Cardiology held in Paris the British Government was represented by Professor Crighton Bramwell and the Medical Research Council by Professor J. McMichael. Upwards of 50 members of the British Cardiac Society attended the congress, their representative being Sir John Parkinson.

COMING EVENTS

Hunterian Society

The official opening of the library and museum of the Hunterian Society and the annual party will take place at 41, Portland Place, London, W., on Thursday, October 5, from 6 to 8 p.m. The inauguration ceremony will be performed by the Rt. Hon. Lord Horder.

Wrexham and District Clinical Society

A dinner-meeting of the Wrexham and District Clinical Society will be held at Wynnstay Arms Hotel, Wrexham, on Thursday, October 5, at 7.30 p.m. After dinner Professor A. M. Boyd, professor of surgery in the University of Manchester, will speak on "The Management of Obliterative Vascular Disease of the Lower Extremities."

Royal Dental Hospital of London

The prize distribution and conversazione of the Royal Dental Hospital of London School of Dental Surgery (University of London) will be held at the Royal Dental Hospital, 32, Leicester Square, London, W.C., on Friday, October 6, at 8 p.m.

Maida Vale Hospital Medical School

Sir Hugh Cairns, Nuffield Professor of Surgery in the University of Oxford, will deliver the address on "Colloid Cyst of the Third Ventricle" at the opening of the autumn session of the Maida Vale Hospital Medical School on Friday, October 6, at 5 p.m. Admission is free to all medical graduates by ticket obtainable from the dean of the medical school, Maida Vale Hospital for Nervous Diseases, Maida Vale, London, W.9.

St. Stephen's Hospital

A concentrated week-end course on "The Chronic Rheumatic Diseases," with lectures, ward rounds, and practical demonstrations, will be held at the Rheumatism Unit of St. Stephen's Hospital, Fulham Road, Chelsea, S.W., on Saturday and Sunday, October 7 and 8. The course will be opened by the Rt. Hon. Lord Amulree, whose subject will be "The Social and Economic Aspects of the Chronic Rheumatism Disease." Sir Adolphe Abrahams will preside, and among those taking part are Drs. Francis Bach, Peter Bishop, Grace Batten, Eric Bywaters, Philip Ellman, David Shaw, and A. G. Signy, and Mr. Timbrell Fisher.

Austrian Congress of Occupational Medicine

The first Austrian Congress of Occupational Medicine will be held at the Billroth Haus, Frankgasse 8, Vienna, from October 17–19. Although primarily intended for Austrian specialists, it is expected that a number of delegates from other countries, particularly Germany, will attend. The World Health Organization will be represented by Dr. Burger, medical director of Philips, Eindhoven; and the International Labour Office will also be represented. At the close of the congress members will be able, if they wish, to participate in a sightseeing tour of industrial undertakings in Austria from October 20–24. Further particulars may be obtained from the secretary of the congress, Dr. Fritz Vering, Hygiene-Institut der Universität Wien, Kinderspitalgasse 15, Vienna 9.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Tuesday

INSTITUTE OF OPHTHALMOLOGY (UNIVERSITY OF LONDON), Judd Street, London, W.C.—September 26, 5.30 p.m., "*Mechanism of Accommodation*," by Mr. E. F. Fincham.

Wednesday

MIDDLESEX COUNTY MEDICAL SOCIETY.—At Ashford Hospital, London Road, Ashford, September 27, 4 p.m., annual general meeting, "*Leonardo da Vinci 'On the Human Body'*" (illustrated by slides), chairman's address by Dr. K. D. Keele.

Thursday

INSTITUTE OF OPHTHALMOLOGY (UNIVERSITY OF LONDON), Judd Street, London, W.C.—September 28, 5.30 p.m., "*The Ocular Aspects of Hypertension*," by Mr. E. F. King.

Friday

CAMBRIDGE MEDICAL SOCIETY.—At Addenbrooke's Hospital, Cambridge, September 29, 2.30 p.m., two B.M.A. films will be shown: (1) "*Curare in the Treatment of Poliomyelitis*"; (2) "*A Severe Case of Infantile Paralysis*." Dr. C. G. Eastwood will open the discussion.

INSTITUTE OF OPHTHALMOLOGY (UNIVERSITY OF LONDON), Judd Street, London, W.C.—September 29, 5.30 p.m., "*The Avoidance of Complication in the Surgery of Cataract Extraction*," by Mr. H. H. Skeoch.

KENT AND CANTERBURY HOSPITAL, Canterbury.—September 29, 8 p.m., clinical meeting.

● ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS, 58, Queen Anne Street, London, W.—September 29, 2.30 p.m., "*The Evolution of the Gynaecologist*," William Meredith Fletcher Shaw Memorial Lecture by Professor A. Leyland Robinson.

APPOINTMENTS

Dr. J. Greenwood Wilson, Medical Officer of Health, Cardiff, Glam, will take office as chairman of the council of the Royal Sanitary Institute on October 1, 1950.

DADDS, J. H., M.B., M.R.C.P., Consultant Chest Physician, Portsmouth Area, South-west Metropolitan Regional Hospital Board.

STOCKS, A. VERNON, M.B., Ch.B., D.P.H., Divisional Medical Officer (Lancashire County Council), Health Division No. 15 (comprising Eccles, Swinton and Pendlebury, Worsley, and Irlam).

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Carnaghan.—On September 11, 1950, at Queen Elizabeth Hospital, Birmingham, to Marjorie, M.B., B.S. (formerly Bryan), wife of James Carnaghan, B.Sc., a daughter.

Hall.—On September 5, 1950, at King's College Hospital, London, to Diana, wife of G. F. M. Hall, M.D., a daughter—Wendy Macdonald.

Hamilton.—On September 12, 1950, at 69, Gerrard Street, Lozells, Birmingham, to Dr. Frank Hamilton and Mrs. Hamilton (formerly Lloyd-Morgan), a sister for Adrian—Susan.

Hylton.—On September 9, 1950, to Dr. Lorna Christine (formerly Petersen), wife of Dr. W. H. Hylton, a son.

Ritchie.—On September 8, 1950, in Edinburgh, to Dr. Elizabeth Ritchie, wife of Professor Anthony E. Ritchie, M.D., University of St. Andrews, a daughter.

West.—On September 11, 1950, at Grimsby, to Kathleen (formerly Stanhope), wife of Michael H. West, M.D., M.R.C.P., a daughter.

MARRIAGES

Broadhead—Moody.—On August 26, 1950, at Newport, Isle of Wight, Herman H. Broadhead M.A., M.B., B.Chir., to Jill Moody, S.R.N.

Shemilt—Brownscombe.—On September 25, 1950, at St. Decumans, Watchet, Philip Shemilt, M.B., F.R.C.S., to Janet Brownscombe.

DEATHS

Brennan.—On September 12, 1950, at Killarney, Charles Henry Brennan, M.C., L.R.C.P.&S.I.&L.M., D.P.H., late Kenya Medical Services.

Brodribb.—On September 16, 1950, at St. Augustine's Nursing Home, St. Leonards-on-Sea Aurthur Williamson Brodribb, M.B., B.Ch., J.P.

Burridge.—On September 15, 1950, at King Edward VII Hospital, Windsor, John Harold Burridge, M.B.E., M.R.C.S., L.R.C.P., of 70, Higher Drive, Banstead, Surrey.

Buxton.—On August 18, 1950, at 2, Eshe Road, Blundellsands, Liverpool, Doris Mildred Buxton, M.B., Ch.B., D.P.H., J.P.

Carruthers.—On September 12, 1950, at Meadow View, Wymondham, Norfolk, Norman Stuart Carruthers, F.R.C.S.Ed., D.L.O., aged 63.

Crosthwait.—On September 11, 1950, at "Kingswood," Surrenden Road, Brighton, William Sylvester Crosthwait, L.R.C.P.&S.I.&L.M., Major R.A.M.C., retired.

Macleod.—On September 9, 1950, at 1, Beech Avenue, Drummond, Inverness, Donald Macdonald Macleod, F.R.C.S.Ed.

Ogle-Skan.—On September 11, 1950, at 141, Lapwing Lane, Didsbury, Manchester, Henry William Ogle-Skan, M.R.C.S., L.R.C.P., aged 67.

Raymond.—On September 12, 1950, at Worthing Hospital, John Kimber Raymond, M.B., C.M., D.O.M.S., of 39, Winchester Road, Worthing, Sussex.

Vane-Sutton.—On September 10, 1950, in London, Harold John Vane-Sutton, M.R.C.S., L.R.C.P., of 2, Warwick Close, Kensington, London, W., aged 54.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Continued Jaundice

Q.—*A case giving all the indications of simple catarrhal jaundice is still not completely recovered after three months. Treatment has been by diet, vitamin supplements (including vitamin K), methionine, simple diuretics, and rest in bed. The liver and gall-bladder feel normal, and liver-function tests all indicate the absence of significant liver damage. In the evening the urine is almost free of bile pigments and the conjunctivae are clear. In the morning, however, the urine is green and the conjunctivae are pigmented. Is there any advice you can give me about this case?*

A.—It is a wise rule to review the diagnosis critically whenever jaundice, apparently due to infective hepatitis, has lasted for more than six weeks. The practitioner should ask himself whether the cause might not, after all, be obstruction of the extrahepatic biliary passages. The distinction is difficult to make, and when no clinical or biochemical indication exists a liver puncture biopsy may settle the diagnosis. If there is evidence of biliary obstruction, exploration becomes advisable.

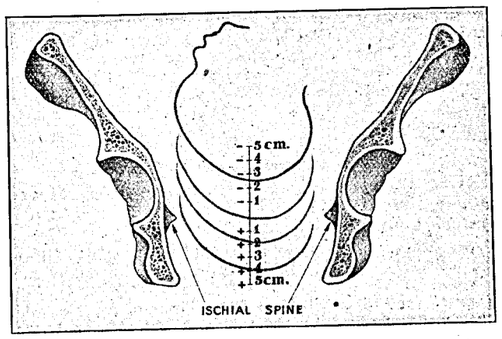
If parenchymatous hepatitis is established as the cause of the condition, the present treatment should be pursued patiently and in a spirit of restrained optimism. Subacute hepatitis may smoulder for six months or longer and then heal completely. The indications are for rest; a high-calorie diet, containing 120–150 g. of protein, a liberal quantity of carbohydrate, and enough fat to make it appetizing; and a full supplement of vitamins, including folic acid and crude liver extract.

Persistent Climacteric

Q.—*An unmarried woman, now 64, had her uterus removed for fibroids when she was 42 years of age. The ovaries were conserved, so she did not develop menopausal symptoms until four years after the operation. Since then—that is, for nearly 20 years—symptoms have continued in the form of hot flushes, sweating, and other vasomotor disturbances, which tend to get worse rather than better. Various oestrogens (including stilboestrol), corpus luteum hormone, and thyroid have been repeatedly tried, with no improvement. The basal metabolic rate was −12% before thyroid therapy, rising to +6% afterwards. Does the syndrome represent a prolonged climacteric, or is it something which tends to become chronic and to develop into a pathological entity? In any case, what is the cure?*

A.—The circumstances and the symptoms certainly point to a climacteric disturbance in the first place, and there is no doubt that in some women such disturbances can persist for many years. Sometimes the trouble is prolonged as a result of irregular and uncontrolled oestrogen therapy, and this too can create a degree of oestrogen resistance. Even so, however, it should be possible to control menopausal symptoms, temporarily at least, with an oestrogen as strong as stilboestrol, and if the symptoms do not respond it is fairly safe to assume that they are not due to the climacteric. This would appear to be the case here, and it is quite possible that even if the initial symptoms were genuine the condition is now one of neurosis. Apart from symptoms there is nothing in the clinical picture to indicate an endocrine disorder. The B.M.R. readings do not represent significant departures from normal. It might be worth trying to arrange with one of the larger laboratories for an estimation of the gonadotrophin output in the urine. If the symptoms are genuinely "menopausal" the level of this hormone should be considerably raised; if it is not, then another diagnosis must be looked for before treatment can be decided.

Substitutes for Morphine



Q.—*How can the possibility of vomiting after morphine injection be averted? What is the maximum dose of morphine that can safely be given to patients with severe colic, and when and how often can the dose be repeated? What is a reliable substitute with all the advantages of morphine but unattended by vomiting and perhaps constipation?*

A.—Diamorphine (heroin) is less likely to cause vomiting and constipation than morphine. It is, however, a most powerful drug of addiction, and for this reason should never be frequently used, except in terminal cases of incurable malignant disease. The best substitute for morphine in severe pain due to colic is pethidine in doses of 100 mg., especially as it has an anti-spasmodic action in addition to its analgesic effect, whereas morphine causes contraction of smooth muscle and in cases of colic should therefore be given along with atropine. Pethidine is unlikely to cause vomiting or constipation and would seem to be the drug of choice in the circumstances mentioned. The maximum official dose of morphine is ½ gr. (21 mg.), though in most strong adults in very severe pain ½ gr. (32 mg.) can be given safely, and in those addicted to its use even larger doses may have to be employed. The frequency of subsequent doses can be judged only by the condition of the patient, but it is usually unwise to repeat a large dose of morphine without an interval of at least four hours.

Diameters of the Pelvis

Q.—*I have read in an article by S. A. Kaufman that the capacity of the mid-pelvis is estimated from the sum of the interspinous and posterior sagittal diameters, measured by x-ray pelvimetry. Could you please tell me what the posterior sagittal diameter is? Also in describing the position of the vertex in forceps deliveries—i.e., low, mid-low, or mid-forceps—he writes, "... when the bony vertex had reached the pelvic floor, corresponding to a station of +5. When the vertex was between the level of the spines and the pelvic floor, corresponding to a station of +1 to +4..." Would you please explain these "stations"?*

A.—This method of describing the station or degree of engagement of the foetal head was introduced by De Lee, of Chicago, and is described in De Lee and Greenhill's *Principles and Practice of Obstetrics*. (Fig. 259 on p. 233 of the ninth edition, 1947, is reproduced below.) The line between the tips of the ischial spines is taken as zero, and

when the vertex is below this the station is said to be +1 or +2, etc., the figures representing centimetres. When the vertex is above the interspinous line it is said to be −1 or −2, etc., according to the number of centimetres it falls short of engagement. The posterior sagittal diameter, as the term is ordinarily used, applies to the pelvic outlet, and is the distance between the lower end of the sacrum and the mid-point of a line drawn between the tuberosities of the ischium. It is not clear from the question whether the author quoted had in mind the distance between the sacrum and the mid-point of a line joining the ischial spines, but this seems a possibility.

Local Application of Streptomycin

Q.—*Can a solution of the calcium salt of streptomycin be successfully intubated into wounds through non-synthetic rubber tubing in the same manner as sodium penicillin, as a guard against infection, following the routine excision and débridement?*

A.—Streptomycin has been comparatively little used as a local application. The chief indication for this is the elimination or suppression of Gram-negative infection (*Proteus, Ps. pyocyanea,* etc.) from infected wounds or burns preparatory to skin-grafting. It could be used in the way suggested without harm and possibly with some benefit. That it is not so used is due to three reasons. (1) Prophylactic local applications to serious wounds ceased to be relied on when penicillin became available in sufficient quantities for parenteral use in such cases. (2) Penicillin, whether used locally or parenterally, is preferable for wound prophylaxis, since it is more efficient against Gram-positive infections, which are much more important than Gram-negative. It is highly active against streptococci and staphylococci and moderately so against the *Clostridia* of gas gangrene; and the respective activities of streptomycin against these two classes of organism are moderate to slight and *nil*. (3) Since bacteria tend to develop resistance to streptomycin readily and rapidly it should not be used except for the deliberate and well-considered treatment of a known infection. Three salts of streptomycin have been used—the hydrochloride, sulphate, and calcium chloride complex. Presumably the questioner refers to the latter. The answer applies to any of them.

Post-vaccinal Encephalitis

Q.—*Were any cases of post-vaccinal encephalitis recorded during the war, when millions of Service men and women must have been vaccinated against smallpox, often for the first time in their lives?*

A.—Information about the occurrence of post-vaccinal encephalitis from 1927–46 has been reported by E. T. Conybeare (*Mon. Bull. Min. Hlth,* April, 1948, p. 72). There it may be noted that in the age group over 15 years 42 cases of post-vaccinal encephalomyelitis were reported in the six years 1939–44, compared with only 13 in the preceding six years. Corresponding figures for the age group 2–15 years were 4 and 12, respectively. These data suggest that cases were occurring among young adults following vaccination on recruitment to the Services. In the whole period there was a preponderance of males in the young adult group but not in the younger age groups. Most of the cases occurred after primary vaccination. Conybeare estimates that the incidence of post-vaccinal encephalitis among young adults after primary vaccination was around 1 in 90,000 and the mortality rate 4 to 5 per million.

Test-papers for Sterilization

Q.—*I would be grateful for information regarding the nature of test-papers used to indicate adequate sterilization of syringes and other articles sterilized by dry heat.*

A.—The papers presumably referred to are intended to test the efficiency, not of sterilization by dry heat, but of autoclaving. Their preparation was described by R. J. Willan (*Lancet,* September 7, 1940, p. 294). Pieces of paper on which the word "sterilized" is printed are "lightly smeared with a mixture of starch 1 oz., iodine gr. 7, pot. iodide gr. 7, water to 10 oz., which when dry completely hides the lettering underneath a brownish-black coating." One of these is placed in the middle of a package of articles to be sterilized. It is said that if a temperature of 113° C. is reached the paper is decolorized and the printed word "sterilized" appears on a white background. A possible objection to this method of control—which applies also to the use of ampoules of a liquid which changes in colour from red through yellow to green—is that it takes insufficient account of the length of time for which the requisite temperature is maintained. The most reliable method of testing the efficiency of autoclaving is to introduce a package containing dried bacterial spores of known heat resistance, which are cultivated afterwards.

There is no similar method, so far as we are aware, of indicating the attainment of a temperature of 160° C., which is necessary for absolute sterilization by dry heat. There is also less necessity for such a test, since an ordinary thermometer can easily be introduced into the oven used for this purpose. Continental authorities rely on the browning of wool used to plug tubes containing syringes, but this is caused only by heating to about 180° C.—an unnecessarily high temperature.

Hereditary Influences in Paget's Disease

Q.—*Is there any evidence that Paget's disease assumes familial or hereditary characteristics? I have just encountered a case of a woman of 77 who is developing it. Her sister died earlier in the year of the same complaint, and there is evidence that their mother also suffered from it. Is there any chance of it appearing in the present generation?*

A.—It is assumed that the question refers to Paget's disease of bone. There is some evidence of hereditary and familial influences in this disease, though these are not pronounced. In 7 of 90 cases collected by Elmslie (*St Bart's Hosp. J.,* 1908, **44**, 121) other members of the family were affected, and many other instances have been recorded in brothers and sisters, or in parents and offspring. The most recent authoritative account of this affection appeared in the *Journal of Bone and Joint Surgery* (British volume), May, 1950.

Raynaud's Disease

Q.—*I have a patient with severe Raynaud's disease of many years' standing. Sympathectomy has been done on one side with no improvement, and the patient is unwilling to consider further operative treatment. Can you please let me know what is at present considered the best medical treatment for this condition? Several of the fingers are gangrenous at the tips.*

A.—There is general agreement that for true Raynaud's disease the most satisfactory treatment is sympathectomy. It is important to stress the adjective "true," because Raynaud's syndrome is often symptomatic of organic vascular disease resisting all treatment. It would be wise to encourage the patient to submit to a "novocain block" of the cervical sympathetic, as this would allow an accurate forecast of the effect of sympathectomy to be given.

Recently benzylimidazoline ("priscol") has been shown to benefit many patients with Raynaud's disease. It should be prescribed in doses of 25 mg. four times daily by mouth. Side-effects of this drug, especially palpitations, flushing, and giddiness, may be troublesome. Local acetyl-β-methylcholine ("carbachol") ionization is helpful in some patients.

NOTES AND COMMENTS

Nocturnal Cramps.—Dr. MARIE STOPES writes: Further to your reply on this (September 2, p. 584) it may be useful to ask if the patient uses a rubber hot-water bottle. Some years ago when pure rubber ones were not obtainable I suffered nightly agonies of cramp for a few weeks till I realized it was caused by the rubber. I discarded it in favour of a hot brick and have never had a touch of cramp from that day.

Dr. G. D. LAING (Limpsfield, Surrey) writes: I have always found that calcium gluconate three tablets t.i.d. is an almost certain cure, and it often improves the general health. I have used it for over 30 years and found it most effective.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY SEPTEMBER 30 1950

SMOKING AND CARCINOMA OF THE LUNG

PRELIMINARY REPORT

BY

RICHARD DOLL, M.D., M.R.C.P.

Member of the Statistical Research Unit of the Medical Research Council

AND

A. BRADFORD HILL, Ph.D., D.Sc.

Professor of Medical Statistics, London School of Hygiene and Tropical Medicine; Honorary Director of the Statistical Research Unit of the Medical Research Council

In England and Wales the phenomenal increase in the number of deaths attributed to cancer of the lung provides one of the most striking changes in the pattern of mortality recorded by the Registrar-General. For example, in the quarter of a century between 1922 and 1947 the annual number of deaths recorded increased from 612 to 9,287, or roughly fifteenfold. This remarkable increase is, of course, out of all proportion to the increase of population—both in total and, particularly, in its older age groups. Stocks (1947), using standardized death rates to allow for these population changes, shows the following trend: rate per 100,000 in 1901–20, males 1.1, females 0.7; rate per 100,000 in 1936–9, males 10.6, females 2.5. The rise seems to have been particularly rapid since the end of the first world war; between 1921–30 and 1940–4 the death rate of men at ages 45 and over increased sixfold and of women of the same ages approximately threefold. This increase is still continuing. It has occurred, too, in Switzerland, Denmark, the U.S.A., Canada, and Australia, and has been reported from Turkey and Japan.

Many writers have studied these changes, considering whether they denote a real increase in the incidence of the disease or are due merely to improved standards of diagnosis. Some believe that the latter factor can be regarded as wholly, or at least mainly, responsible—for example, Willis (1948), Clemmesen and Busk (1947), and Steiner (1944). On the other hand, Kennaway and Kennaway (1947) and Stocks (1947) have given good reasons for believing that the rise is at least partly real. The latter, for instance, has pointed out that "the increase of certified respiratory cancer mortality during the past 20 years has been as rapid in country districts as in the cities with the best diagnostic facilities, a fact which does not support the view that such increase merely reflects improved diagnosis of cases previously certified as bronchitis or other respiratory affections." He also draws attention to differences in mortality between some of the large cities of England and Wales, differences which it is difficult to explain in terms of diagnostic standards.

The large and continued increase in the recorded deaths even within the last five years, both in the national figures and in those from teaching hospitals, also makes it hard to believe that improved diagnosis is entirely responsible. In short, there is sufficient reason to reject that factor as the whole explanation, although no one would deny that it may well have been contributory. As a corollary, it is right and proper to seek for other causes.

Possible Causes of the Increase

Two main causes have from time to time been put forward: (1) a general atmospheric pollution from the exhaust fumes of cars, from the surface dust of tarred roads, and from gas-works, industrial plants, and coal fires; and (2) the smoking of tobacco. Some characteristics of the former have certainly become more prevalent in the last 50 years, and there is also no doubt that the smoking of cigarettes has greatly increased. Such associated changes in time can, however, be no more than suggestive, and until recently there has been singularly little more direct evidence. That evidence, based upon clinical experience and records, relates mainly to the use of tobacco. For instance, in Germany, Müller (1939) found that only 3 out of 86 male patients with cancer of the lung were non-smokers, while 56 were heavy smokers, and, in contrast, among 86 "healthy men of the same age groups" there were 14 non-smokers and only 31 heavy smokers. Similarly, in America, Schrek and his co-workers (1950) reported that 14.6% of 82 male patients with cancer of the lung were non-smokers, against 23.9% of 522 male patients admitted with cancer of sites other than the upper respiratory and digestive tracts. In this country, Thelwall Jones (1949—personal communication) found 8 non-smokers in 82 patients with proved carcinoma of the lung, compared with 11 in a corresponding group of patients with diseases other than cancer; this difference is slight, but it is more striking that there were 28 heavy smokers in the cancer group, against 14 in the comparative group.

Clearly none of these small-scale inquiries can be accepted as conclusive, but they all point in the same direction. Their evidence has now been borne out by the results of a large-scale inquiry undertaken in the U.S.A. by Wynder and Graham (1950).

Wynder and Graham found that of 605 men with epidermoid, undifferentiated, or histologically unclassified types of bronchial carcinoma only 1.3% were "non-smokers"—that is, had averaged less than one cigarette a day for the last 20 years—whereas 51.2% of them had smoked more than 20 cigarettes a day over the same

period. In contrast, they estimated from the experience of 882 other male patients that 14.6% of general hospital patients of the same age composition as the bronchial carcinoma cases are "non-smokers" and only 19.1% smoke more than 20 cigarettes a day. They found a similar contrast between the 25 women with epidermoid and undifferentiated bronchial carcinoma and the other female patients, but no such association with smoking could be found in the small group of patients with adenocarcinoma.

Present Investigation

The present investigation was planned in 1947, to be carried out on a sufficiently large scale to determine whether patients with carcinoma of the lung differed materially from other persons in respect of their smoking habits or in some other way which might be related to the atmospheric pollution theory. Patients with carcinoma of the stomach, colon, or rectum were also incorporated in the inquiry, as one of the contrasting groups, and special attention was therefore given at the same time to factors which might bear upon the aetiology of these forms of malignant disease. A separate report will be made upon these inquiries. The present study is confined to the question of smoking in relation to carcinoma of the lung.

The method of the investigation was as follows: Twenty London hospitals were asked to co-operate by notifying all patients admitted to them with carcinoma of the lung, stomach, colon, or rectum. For the most part these hospitals were initially confined to one region of London (the north-west), to allow ease of travelling, but others were subsequently added to increase the scope of the inquiry. A list of those taking part is given at the end of the paper. The method of notification varied; in some it was made by the admitting clerk on the basis of the admission diagnosis, in others by the house-physician when a reasonably confident clinical diagnosis had been made, and in yet others by the cancer registrar or the radiotherapy department. None of these methods is likely to have resulted in complete notification, but there is no reason to suppose that those who escaped notification were a selected group—that is, selected in such a way as to bias the inquiry—as the points of interest in the investigation were either not known or known only in broad outline by those responsible for notifying.

On receipt of the notification an almoner, engaged wholly on research, visited the hospital to interview the patient, using a set questionary. During the inquiry four almoners were employed and all the patients were interviewed by one or other of them. As well, however, as interviewing the notified patients with cancer of one of the four specified sites, the almoners were required to make similar inquiries of a group of "non-cancer control" patients. These patients were not notified, but for each lung-carcinoma patient visited at a hospital the almoners were instructed to interview a patient of the same sex, within the same five-year age group, and in the same hospital at or about the same time. (Where more than one suitable patient was available the choice fell upon the first one in the ward lists considered by the ward sister to be fit for interview.)

At two specialized hospitals (Brompton Hospital and Harefield Hospital) it was not always possible to secure a control patient by this method, and in such cases a control patient was taken from one of the two neighbouring hospitals, the Royal Cancer and Mount Vernon Hospitals. Even with this relaxation of the rule control cases were deficient at the Brompton Hospital and the numbers had to be made up by using the records of patients who had been interviewed as cancer patients, either there or at the Royal Cancer Hospital, but in whom cancer was finally excluded. Because of these differences in technique the records obtained from these hospitals were analysed separately. As, however, the results were in accordance with those found at the other hospitals, all the records are presented here as a single series.

In view of the method of notification used it could not be expected that the diagnosis then given would invariably be accurate. The diagnosis of each patient was checked, therefore, after discharge from or death in hospital, and this check was made in all but nine instances (0.4% of the total). In these few cases (three of carcinoma of the lung, two of carcinoma of the stomach, two of carcinoma of the rectum, and two non-cancer) no records of any sort could be traced, and they have had to be classified according to the information available at the time of their interview. As a general rule the hospital diagnosis on discharge was accepted as the final diagnosis, but occasionally later evidence became available—for example, by histological examination at necropsy—which contradicted that diagnosis. In these instances a change was made and the diagnosis based upon the best evidence.

The Data

Between April, 1948, and October, 1949, the notifications of cancer cases numbered 2,370. It was not, however, possible to interview all these patients. To begin with, it had been decided beforehand that no one of 75 years of age or more should be included in the inquiry, since it was unlikely that reliable histories could be obtained from the very old. There were 150 such patients. In a further 80 cases the diagnosis was incorrect and had been changed before the almoner paid her visit. Deducting these two groups leaves 2,140 patients who should have been interviewed. Of these, 408 could not be interviewed for the following reasons: already discharged 189, too ill 116, dead 67, too deaf 24, unable to speak English clearly 11, while in one case the almoner abandoned the interview as the patient's replies appeared wholly unreliable. No patient refused to be interviewed.

The proportion not seen is high, but there is no apparent reason why it should bias the results. It was in the main due to the time that inevitably elapsed between the date of notification and the date of the almoner's visit. The remaining 1,732 patients, presumed at the interview to be suffering from carcinoma of the lung, stomach, or large bowel, and the 743 general medical and surgical patients originally interviewed as controls, constitute the subjects of the investigation. The numbers falling in each disease group—that is, after consulting the hospital discharge diagnoses—are shown in Table I. The carcinoma cases are here divided into two groups: Group A consisting of cases in which the diagnoses were confirmed by necropsy, biopsy, or exploratory operation, and Group B of the remainder.

TABLE I.—*Number of Patients Interviewed in Each Disease Group, Subdivided According to Certainty of Diagnosis*

Disease Group	No. of Cases		
	Group A. Diagnosis Confirmed at Necropsy, etc.	Group B. Other Criteria of Diagnosis	Total
Carcinoma of lung	489	220	709
" " stomach	178	28	206
" " colon and rectum ..	412	19	431
Other malignant diseases ..	—	—	81
Diseases other than cancer (controls)	—	—	709
Other cases	—	—	335
Excluded	—	—	4
All cases	—	—	2,475

The 81 patients classified in Table I as having "other malignant diseases" were interviewed as cases of carcinoma of the lung, stomach, or large bowel, or as non-cancer controls. On the subsequent checking of the diagnosis either they were found to have primary carcinoma in some site other than one of those under special investigation or histological examination showed that the growth was not, in fact, carcinoma—for example, sarcoma, reticulo-endothelioma, etc. The 335 "other cases" either were interviewed as cases of carcinoma of the lung, stomach, or large bowel and were subsequently found not to be cases of malignant disease or, having been interviewed as non-cancer controls, they became redundant when the cases of carcinoma of the lung with which they were paired were found not to be carcinoma of the lung. The four "excluded" cases were excluded on grounds of doubt about their true category. Two were diagnosed at hospital as primary carcinoma of the lung, but there was reason to suppose that the growths might have been secondary to carcinoma of the breast and to carcinoma of the cervix uteri respectively; the other two showed evidence of primary carcinoma in two of the sites under special investigation—that is, lung and colon, and stomach and colon.

The 709 control patients with diseases other than cancer form a group which was, as previously stated, deliberately selected to be closely comparable in age and sex with the carcinoma of the lung patients. Comparisons between these two groups are shown in Table II.

TABLE II.—*Comparison Between Lung-carcinoma Patients and Non-cancer Patients Selected as Controls, With Regard to Sex, Age, Social Class, and Place of Residence*

					Abroad or in Services ..	15	4
All ages	649	60	649	60	Total (M + F) ..	709	709

* One control patient was selected, in error, from the wrong age group.

It will be seen that the lung-carcinoma patients and the control group of non-cancer patients are exactly comparable with regard to sex and age, but that there are some differences with regard to social class and place of residence. The difference in social class distribution is small and is no more than might easily be due to chance ($\chi^2=1.61$; n=2; $0.30<P<0.50$). The difference in place of residence is, however, large ($\chi^2=31.49$; n=5; $P<0.001$), and Table II shows that a higher proportion of the lung patients were resident outside London at the time of their admission to hospital. This difference can be explained on the grounds that people with cancer came to London from other parts of the country for treatment at special centres. When a comparison is made between the 98 lung-carcinoma patients and the 98 controls who were seen at district hospitals in London—that is, those regional board hospitals which do not have special surgical thoracic or radiotherapeutic centres—the difference disappears. Of these 98 patients with carcinoma of the lung, 56 lived in the County of London, 42 in outer London, and none elsewhere; of their non-cancer controls the corresponding numbers were 60, 38, and 0, clearly an insignificant difference.

It is evident, therefore, that the control group of patients with diseases other than cancer is strictly comparable with the group of lung-carcinoma patients in important respects but differs slightly with regard to the parts of England from which the patients were drawn. It is unlikely that this difference will invalidate comparisons, but it must be kept in mind; fortunately, it can be eliminated, if necessary, by confining comparisons to the smaller group of patients seen in the district hospitals.

Assessment of Smoking Habits

The assessment of the relation between tobacco-smoking and disease is complicated by the fact that smoking habits change. A man who has been a light smoker for years may become a heavy smoker; a heavy smoker may cut down his consumption or give up smoking—and, indeed, may do so repeatedly. An acute respiratory disease may force the sufferer to stop smoking, or he may be advised to stop for one of many pathological conditions. In 1947 a further complication was introduced by the Chancellor of the Exchequer, the duty on tobacco being raised to such an extent that many people made large cuts in the amount of tobacco they smoked—often to restore them partially or completely in the succeeding months. Fortunately the interviewing of patients was not begun till a year after the last major change was made in the tobacco duty; in any case the effect was minimized by interviewing the control patients *pari passu* with the lung-carcinoma patients, so that the change in price is likely to have affected all groups similarly.

The difficulties of a varying consumption can be largely overcome if a more detailed smoking history is taken than is customary in the course of an ordinary medical examination—for example, one man who was described in the hospital notes as being a non-smoker admitted to the almoner that he had been a very heavy smoker until a few years previously. In this investigation, therefore, the patients were closely questioned and asked (*a*) if they had smoked at any period of their lives; (*b*) the ages at which they had started and stopped; (*c*) the amount they were in the habit of smoking before the onset of the illness which had brought them into hospital; (*d*) the main changes in their smoking history and the maximum they had ever been in the habit of smoking; (*e*) the varying proportions smoked in pipes and cigarettes; and (*f*) whether or not they inhaled.

To record and subsequently to tabulate these details it was necessary to define what was meant by a smoker. Did the term, for example, include the woman who took one cigarette annually after her Christmas dinner, or the man of 50 who as a youth smoked a couple of cigarettes to see whether he liked it and decided he did not? If so, it is doubtful whether anyone at all could be described as a non-smoker. A smoker was therefore defined in this inquiry as a person who had smoked as much as one cigarette a day for as long as one year, and any less consistent amount was ignored. The histories obtained were, of course, a function of the patient's memory and veracity. To assess their reliability 50 unselected control patients with diseases other than cancer were interviewed a second time six months or more after their initial interview. Table III shows the comparison between the two answers obtained

TABLE III.—*Amount of Tobacco Smoked Daily Before Present Illness as Recorded at Two Interviews With the Same Patients at an Interval of Six Months or More*

First Interview No. of Persons Smoking	Second Interview. No. of Persons Smoking						
	0	1 cig.–	5 cigs.–	15 cigs.–	25 cigs.–	50 cigs.+	Total
0	8	1					9
1 cig.– ..		4	1				5
5 cigs.– ..		1	13	3			17
15 cigs – ..			4	9	1		14
25 cigs.– ..				1	3	0	4
50 cigs.+ ..					1	0	1
Total ..	8	6	18	13	5	0	50

to the question "How much did you smoke before the onset of your present illness?"

The answers to the other questions on smoking habits showed a variability comparable to that shown in Table III. It may be concluded, therefore, that, while the detailed smoking histories obtained by this investigation are not, as would be expected, strictly accurate, they are reliable enough to indicate general trends and to substantiate material differences between groups.

Smokers and Non-smokers

The simplest comparison that can be made to show whether there is any association at all between smoking and carcinoma of the lung is that between the proportion of lung-carcinoma patients who have been smokers and the proportion of smokers in the comparable group of subjects without carcinoma of the lung. Such a comparison is shown in Table IV.

TABLE IV.—*Proportion of Smokers and Non-smokers in Lung-carcinoma Patients and in Control Patients with Diseases Other Than Cancer*

Disease Group	No. of Non-smokers	No. of Smokers	Probability Test
Males: Lung-carcinoma patients (649)	2 (0·3%)	647	P (exact method) = 0·00000064
Control patients with diseases other than cancer (649) ..	27 (4·2%)	622	
Females: Lung-carcinoma patients (60)	19 (31·7%)	41	$\chi^2 = 5{\cdot}76$; n = 1 0·01 < P < 0·02
Control patients with diseases other than cancer (60) ..	32 (53·3%)	28	

It will be seen that the vast majority of men have been smokers at some period of their lives, but also that the very small proportion of those with carcinoma of the lung who have been non-smokers (0.3%) is most significantly less than the corresponding proportion in the control group of other patients (4.2%). As was to be expected, smoking is shown to be a much less common habit among women; but here again the habit was significantly more frequent among those with carcinoma of the lung. Only 31.7% of the lung-carcinoma group were non-smokers, compared with 53.3% in the control group.

Amount of Smoking

In the simple comparison of Table IV all smokers have been classified together, irrespective of the amount they smoked. In Table V they have been subdivided according to the amount they smoked immediately before the onset of the illness which brought them into hospital. (If they had given up smoking before then, they have been classified according to the amount smoked immediately prior to giving it up.) This classification is described subsequently as "the most recent amount smoked."

TABLE V.—*Most Recent Amount of Tobacco* Consumed Regularly by Smokers Before the Onset of Present Illness; Lung-carcinoma Patients and Control Patients with Diseases Other Than Cancer*

Disease Group	No. Smoking Daily					Probability Test
	1 Cig.–*	5 Cigs.–	15 Cigs.–	25 Cigs.–	50 Cigs.+	
Males: Lung-carcinoma patients (647)	33 (5·1%)	250 (38·6%)	196 (30·3%)	136 (21·0%)	32 (5·0%)	$\chi^2 = 36{\cdot}95$; n = 4; P < 0·001
Control patients with diseases other than cancer (622)..	55 (8·8%)	293 (47·1%)	190 (30·5%)	71 (11·4%)	13 (2·1%)	
Females: Lung-carcinoma patients (41)..	7 (17·1%)	19 (46·3%)	9 (22·0%)	6 (14·6%)	0 (0·0%)	$\chi^2 = 5{\cdot}72$; n = 2; 0·05 < P < 0·10 (Women smoking 15 or more cigarettes a day grouped together)
Control patients with diseases other than cancer (28) ..	12 (42·9%)	10 (35·7%)	6 (21·4%)	0 (0·0%)	0 (0·0%)	

* Ounces of tobacco have been expressed as being equivalent to so many cigarettes. There is 1 oz. of tobacco in 26·5 normal-size cigarettes, so that the conversion factor has been taken as: 1 oz. of tobacco a week = 4 cigarettes a day.

From Table V it will be seen that, apart from the general excess of smokers found (in Table IV) in lung-carcinoma patients, there is in this group a significantly higher proportion of heavier smokers and a correspondingly lower proportion of lighter smokers than in the comparative group of other patients. For instance, in the lung-carcinoma group 26.0% of the male patients fall in the two groups of highest consumption (25 cigarettes a day or more), while in the control group of other male patients only 13.5% are found there. The same trend is observable for women, but the numbers involved are small and the difference here between the carcinoma group and their control patients is not quite technically significant. If, however, the female lung-carcinoma patients are compared with the total

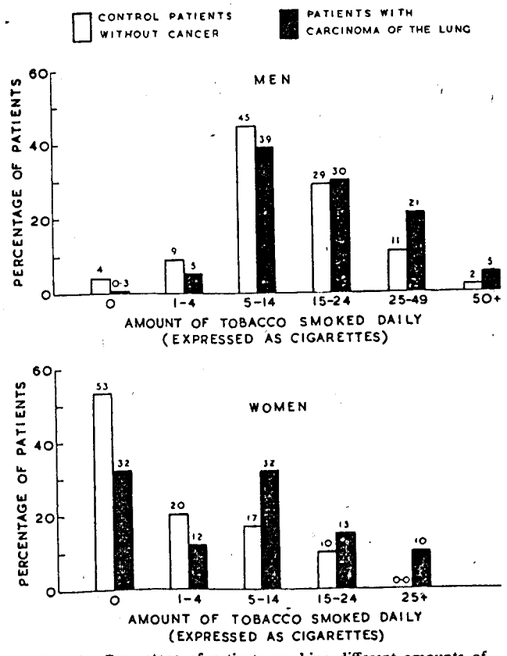

FIG. 1.—Percentage of patients smoking different amounts of tobacco daily.

TABLE VI.—*Maximum Amount of Tobacco Ever Consumed Regularly by Smokers; Lung-carcinoma Patients and Control Patients with Diseases Other Than Cancer*

Disease Group	No. Smoking as a Daily Maximum					Probability Test

Females: Lung-carcinoma patients (41)..	6 (14·6%)	15 (36·6%)	12 (29·3%)	8 (19·5%)	0 (0·0%)	$\chi^2 = 7{\cdot}58$; n = 2; 0·02 < P < 0·05 (Women smoking 15 or more cigarettes a day grouped together)
Control patients with diseases other than cancer (28) ..	12 (42·9%)	9 (32·1%)	6 (21·4%)	0 (0·0%)	1 (3·6%)	

TABLE VII.—*Estimate of Total Amount of Tobacco Ever Consumed by Smokers; Lung-carcinoma Patients and Control Patients with Diseases Other Than Cancer*

Disease Group	No. Who have Smoked Altogether					Probability Test
	365 Cigs.–	50,000 Cigs.–	150,000 Cigs.–	250,000 Cigs.–	500,000 Cigs.+	
Males: Lung-carcinoma patients (647)	19 (2·9%)	145 (22·4%)	183 (28·3%)	225 (34·8%)	75 (11·6%)	$\chi^2 = 30{\cdot}60$; n = 4; P < 0·001
Control patients with diseases other than cancer (622)..	36 (5·8%)	190 (30·5%)	182 (29·3%)	179 (28·9%)	35 (5·6%)	
Females: Lung-carcinoma patients (41)..	10 (24·4%)	19 (46·3%)	5 (12·2%)	7 (17·1%)	0 (0·0%)	$\chi^2 = 12{\cdot}97$; n = 2; 0·001 < P < 0·01 (Women smoking 15 or more cigarettes a day grouped together)
Control patients with diseases other than cancer (28) ..	19 (67·9%)	5 (17·9%)	3 (10·7%)	1 (3·6%)	0 (0·0%)	

number of women interviewed—that is, bringing in the other cancer groups interviewed and making appropriate allowance for age differences between them—then the significance of the trend in their case also is established ($\chi^2 = 13.23$; n = 2; P approximately .0001).

The results given in Tables IV and V are shown together graphically in Fig. 1. (The percentages in the figure are not all exactly the same as those in the tables. In the figure the percentages are based on the total number of patients in each disease group, smokers and non-smokers alike; in Table V they are percentages of smokers alone.)

Smoking History

Going one stage further, it has been noted earlier that the amount smoked daily at any one period does not, of course, necessarily give a fair representation of the individual's smoking history. This has been overcome to some extent in the previous tables by classifying a patient as a non-smoker only if he has never smoked regularly, by classifying him according to the amount he last smoked regularly if he had given up smoking, and by ignoring changes in smoking habits which had taken place subsequent to the illness which brought the patient into hospital. Other methods of analysis have also been adopted. Thus Table VI shows the results in the two main groups when a comparison is made between the maximum amounts ever smoked regularly, and Table VII shows a comparison between the estimated total amounts of tobacco smoked throughout the patients' whole lives. The estimates of the total amount smoked (expressed as cigarettes) have been made by multiplying the daily amount of tobacco smoked by the number of days that the patient has been in the habit of smoking and making allowance for the major recorded changes in the smoking history. Such estimates may, needless to say, be only very rough approximations to the truth, but they are, it is thought, accurate enough to reveal broad differences between the groups.

The results in Tables V, VI, and VII are, it will be seen, closely similar. Whichever measure of smoking is taken, the same result is obtained—namely, a significant and clear relationship between smoking and carcinoma of the lung. It might perhaps have been expected that the more refined concepts—the maximum amount ever smoked and the total amount ever smoked—would have shown a closer relationship than the most recent amount smoked before the onset of the present illness. It must be supposed, however, that any greater efficiency that might be introduced by the use of these measures is counterbalanced by the inaccuracy which results from requiring the patient to remember habits of many years past. It seems, therefore, that we may reasonably adopt "the most recent amount smoked" in subsequent tables as the simplest characteristic to describe a patient's smoking experience.

Comparisons of the age at which patients began to smoke, the number of years they have smoked, and the number of years they have given up smoking are shown in Table VIII.

It will be seen that the lung-carcinoma patients showed a slight tendency to start smoking earlier in life, to continue longer, and to be less inclined to stop, but the differentiation is certainly not sharp and the difference is technically significant only with respect to length of time stopped.

Cigarettes and Pipes

So far no distinction has been made between cigarette and pipe smokers, and it is natural to ask whether both methods of smoking tobacco are equally related to carcinoma of the lung. Again the difficulty arises that a man who describes himself as a pipe smoker may have smoked cigarettes until shortly before interrogation, or, alternatively, he may have had his teeth extracted and substituted cigarettes for his pipe. To overcome this, we have excluded

TABLE VIII.—*Age of Starting to Smoke, Number of Years Smoked, and Number of Years Stopped Smoking in Lung-carcinoma Patients and Control Patients with Diseases Other Than Cancer (Male and Female)*

Age at Starting	Lung-carcinoma Patients		Control Patients		No. of Years Smoking	Lung-carcinoma Patients		Control Patients		No. of Years Stopped	Lung-carcinoma Patients		Control Patients

All ages ..	688		650		Total	688		650		Tota	688		650	
$\chi^2 = 2{\cdot}40$; n = 2; 0·30 < P < 0·50					$\chi^2 = 4{\cdot}65$; n = 2; 0·05 < P < 0·10					$\chi^2 = 8{\cdot}59$; n = 2; 0·01 < P < 0·02				

all the men who gave a history of having ever consistently smoked both pipes and cigarettes and have compared the proportions of "pure pipe" and "pure cigarette" smokers among the lung-carcinoma and non-cancer control patients. The results are as follows: of the 525 lung-carcinoma patients who had smoked either pipes or cigarettes but not both 5.7% were pipe smokers and 94.3% were cigarette smokers; of 507 control patients with other diseases 9.7% were pipe smokers and 90.3% were cigarette smokers. The lower proportion of pipe smokers, and the corresponding excess of cigarette smokers, in the lung-carcinoma group is unlikely to be due to chance ($\chi^2=5.70$; $n=1$; $0.01<P<0.02$).

It therefore seems that pipe smoking is less closely related to carcinoma of the lung than cigarette smoking. On the other hand, it has been shown in Table V that light smoking is less closely related to carcinoma of the lung than heavy smoking, so that the result might be explained merely on the grounds that pipe smokers tend to smoke less tobacco.

In fact, pipe smokers do consume, on the average, less tobacco than cigarette smokers, but this is unlikely to be the whole explanation of the relative deficiency of pipe smokers observed in the carcinoma group. We find a higher proportion of cigarette smokers and a lower proportion of pipe smokers among the lung-carcinoma patients than among the control group of non-cancer patients at each level of consumption of tobacco—that is, at 1–4, 5–14, 15–24, and 25+ cigarettes or their equivalent a day. On the other hand, if we consider the "pure pipe" smokers by themselves and subdivide them according to the amount smoked, then we find a higher proportion of the carcinoma patients than of the control group in the higher smoking categories—that is, smoking more than 6 oz. of tobacco a week. In short, the results of this subdivision are similar to those shown in Table V for all smokers. It seems that the method by which the tobacco is smoked is of importance and that smoking a pipe, though also related to carcinoma of the lung, carries a smaller risk than smoking cigarettes. With the data at our disposal we are unable to determine how great the difference in risk may be.

Inhaling

Another difference between smokers is that some inhale and others do not. All patients who smoked were asked whether or not they inhaled, and the answers given by the lung-carcinoma and non-cancer control patients were as follows: of the 688 lung-carcinoma patients who smoked (men and women) 61.6% said they inhaled and 38.4% said they did not; the corresponding figures for the 650 patients with other diseases were 67.2% inhalers and 32.8% non-inhalers. It would appear that lung-carcinoma patients inhale slightly less often than other patients ($\chi^2=4.58$; $n=1$; $0.02<P<0.05$). However, the difference is not large, and if the lung-carcinoma patients are compared with all the other patients interviewed, and the necessary allowance is made for sex and age, the difference becomes insignificant ($\chi^2=0.19$; $n=1$; $0.50<P<0.70$).

Interpretation of Results

Though from the previous tables there seems to be no doubt that there is a direct association between smoking and carcinoma of the lung it is necessary to consider alternative explanations of the results. Could they be due to an unrepresentative sample of patients with carcinoma of the lung or to a choice of a control series which was not truly comparable? Could they have been produced by an exaggeration of their smoking habits by patients who thought they had an illness which could be attributed to smoking? Could they be produced by bias on the part of the interviewers in taking and interpreting the histories?

Selection of Patients for Interview

The method by which the patients with carcinoma of the lung were obtained has been discussed earlier; there is no reason to suppose that they were anything other than a representative sample of the lung-carcinoma patients attending the selected London hospitals. The control patients, as was shown in Table II, were exactly comparable so far as sex and age were concerned and they were sufficiently comparable with regard to social class for the difference between the two series to be ignored. They were not wholly comparable from the point of view of place of residence. The difference in this respect, however, was that more of the lung-carcinoma patients came from small towns and rural districts, and the figures in this inquiry show that consumption of tobacco per head in these areas is less than in London. Clearly this feature cannot have accounted for the observation that the lung-carcinoma patients smoked more. Further, if the comparison is confined to patients seen in district hospitals—and all of these resided in Greater London—the results are the same (Table IX).

TABLE IX.—*Most Recent Amount Smoked by Lung-carcinoma and Control Patients Seen in District Hospitals (Male and Female)*

Disease Group	No. Smoking Daily				
	0	1 Cig.–	5 Cigs.–	15 Cigs.–	25 Cigs.+

Control patients with diseases other than cancer (98) ..	9	9	50	19	11

$\chi^2 = 11.68$; $n = 4$; $0.01<P<0.02$

It might possibly be argued that the choice of a control group of patients with various medical and surgical conditions has, of itself, resulted in the selection of subjects with a smoking history less than the average. This would seem very unlikely, as we know of no evidence to suggest that less than average smoking is a characteristic of persons with any one group of diseases, and it certainly could not be held that it is equally a characteristic of persons suffering from all diseases other than carcinoma of the lung. Yet in Table X the smoking habits of the patients

in five main groups of diseases are compared, allowing for their sex and age composition, and no significant difference can be demonstrated between them. (We have

brought into this table all the patients with diseases other than carcinoma of the lung.)

As in other tables where sex and age differences between groups have had to be taken into account, the "expected" numbers have been obtained by taking the actual numbers of patients with each type of disease in each age and sex subgroup, and calculating what proportion of them would fall in each smoking category if they had had exactly the same habits as all the patients included in the Table. In other words, we have computed what ought to be the smoking habits of each disease group if it behaved in each sex and at each age like the total population of patients, and compared them with what, in fact, they were. The relatively large numbers of non-smokers in some of the groups are due to the fact that these disease groups included many old women.

There remains the possibility that the interviewers, in selecting the control patients, took for interview from among the patients available for selection a disproportionate number of light smokers. It is difficult to see how they could have done so, but the point can be tested indirectly by comparing the smoking habits of the patients whom they did select for interview with the habits of the other patients, other than those with carcinoma of the lung, whose names were notified by the hospitals. The comparison is made in Table XI and reveals no appreciable difference between the two groups.

* See footnote to Table X.

It can therefore be concluded that there is no evidence of any special bias in favour of light smokers in the selection of the control series of patients. In other words, the group of patients interviewed forms, we believe, a satisfactory control series for the lung-carcinoma patients from the point of view of comparison of smoking habits.

Patient's Smoking History

Another possibility to consider is that the lung-carcinoma patients tended to exaggerate their smoking habits. Most of these patients cannot have known that they were suffering from cancer, but they would have known that they had respiratory symptoms, and such knowledge might have influenced their replies to questions about the amount they smoked. However, Table X has already shown that patients with the other respiratory diseases did not give smoking histories appreciably different from those given by the patients with non-respiratory illnesses. There is no reason, therefore, to suppose that exaggeration on the part of the lung-carcinoma patients has been responsible for the results.

The Interviewers

When the investigation was planned it was hoped that the interviewers would know only that they were interviewing patients with cancer of one of several sites (lung, stomach, or large bowel) but not, at the time, the actual site. This, unfortunately, was impracticable; the site would be written on the notification form, or the nurse would refer to the diagnosis in pointing out the patient, or it would become known that only patients with cancer of one of the sites under investigation would be found in one particular ward. Out of 1,732 patients notified and interviewed as cases of cancer, the site of the growth was known to the interviewer at the time of interview in all but 61. Serious consideration must therefore be given to the possibility of interviewers' bias affecting the results (by the interviewers tending to scale up the smoking habits of the lung-carcinoma cases).

Fortunately the material provides a simple method of testing this point. A number of patients were interviewed who, at that time, were thought to have carcinoma of the lung but in whom the diagnosis was subsequently disproved. The smoking habits of these patients, believed by the interviewers to have carcinoma of the lung, can be compared with the habits of the patients who in fact had carcinoma of the lung and also with the habits of all the other patients. The result of making these comparisons is shown in Tables XII and XIII, and it will be seen that the smoking

habits of the patients who were incorrectly thought to have carcinoma of the lung at the time of interview are sharply distinguished from the habits of those patients who did in fact have carcinoma of the lung (Table XII), but they do not differ significantly from the habits of the other patients interviewed (Table XIII).

It is therefore clearly not possible to attribute the results of this inquiry to bias on the part of the interviewers, as, had there been any appreciable bias, the smoking habits of the patients thought incorrectly to have carcinoma of the lung would have been recorded as being like those of the true lung-carcinoma subjects and not the same as those without carcinoma of the lung.

We may add that the results cannot be due to different workers interviewing different numbers of patients in the cancer and control groups, for, while the four interviewers

did not see exactly the same proportions of patients in all the groups, the proportions were very close. Moreover, if the patients seen by each of the interviewers are treated as four separate investigations, highly significant differences are found between the lung-carcinoma patients and the other patients interviewed in three instances. In the fourth the difference is in the same direction, but, owing to the small number of patients seen, the results are not technically significant (P lies between 0.10 and 0.05; in this instance the almoner had to stop work because of illness, having seen only 46 patients with carcinoma of the lung).

Discussion

To summarize, it is not reasonable, in our view, to attribute the results to any special selection of cases or to bias in recording. In other words, it must be concluded that there is a real association between carcinoma of the lung and smoking. Further, the comparison of the smoking habits of patients in different disease groups, shown in Table X, revealed no association between smoking and other respiratory diseases or between smoking and cancer of the other sites (mainly stomach and large bowel). The association therefore seems to be specific to carcinoma of the lung. This is not necessarily to say that smoking causes carcinoma of the lung. The association would occur if carcinoma of the lung caused people to smoke or if both attributes were end-effects of a common cause. The habit of smoking was, however, invariably formed before the onset of the disease (as revealed by the production of symptoms), so that the disease cannot be held to have caused the habit; nor can we ourselves envisage any common cause likely to lead both to the development of the habit and to the development of the disease 20 to 50 years later. We therefore conclude that smoking is a factor, and an important factor, in the production of carcinoma of the lung.

The effect of smoking varies, as would be expected, with the amount smoked. The extent of the variation could be estimated by comparing the numbers of patients interviewed who had carcinoma of the lung with the corresponding numbers of people in the population, in the same age groups, who smoke the same amounts of tobacco. Our figures, however, are not representative of the whole country, and this may be of some importance, as countrymen smoke, on the average, less than city dwellers. Moreover, as was shown earlier, the carcinoma and the control patients were not comparable with regard to their places of residence. The difficulty can be overcome by confining the comparison to the inhabitants of Greater London.

If it be assumed that the patients without carcinoma of the lung who lived in Greater London at the time of their interview are typical of the inhabitants of Greater London with regard to their smoking habits, then the number of people in London smoking different amounts of tobacco can be estimated. Ratios can then be obtained between the numbers of patients seen with carcinoma of the lung and the estimated populations at risk who have smoked comparable amounts of tobacco. This has been done for each age group, and the results are shown in Table XIV. It must be stressed that the ratios shown in this table are not measures of the actual risks of developing carcinoma of the lung, but are put forward very tentatively as proportional to these risks.

Thus Table XIV shows clearly, and for each age group, the conclusion previously reached—that the risk of developing carcinoma of the lung increases steadily as the amount smoked increases. If the risk among non-smokers is taken

* Ratios based on less than 5 cases of carcinoma of the lung are given in italics.

as unity and the resulting ratios in the three age groups in which a large number of patients were interviewed (ages 45 to 74) are averaged, the relative risks become 6, 19, 26, 49, and 65 when the number of cigarettes smoked a day are 3, 10, 20, 35, and, say, 60—that is, the mid-points of each smoking group. In other words, on the admittedly speculative assumptions we have made, the risk seems to vary in approximately simple proportion with the amount smoked.

One anomalous result of our inquiry appears to relate to inhaling. It would be natural to suppose that if smoking were harmful it would be more harmful if the smoke were inhaled. In fact, whether the patient inhaled or not did not seem to make any difference. It is possible that the patients were not fully aware of the meaning of the term and answered incorrectly, but the interviewers were not of that opinion. In the present state of knowledge it is more reasonable to accept the finding and wait until the size of the smoke particle which carries the carcinogen is determined. Until this is known nothing can be stated about the effect which any alteration in the rate and depth of respiration may have on the extent and site of deposition of the carcinogen (Davies, 1949).

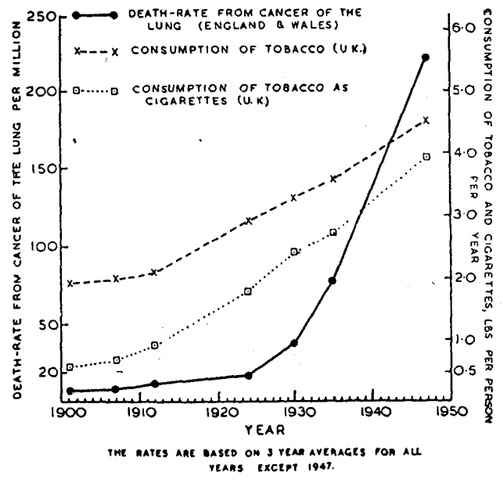

FIG. 2.—Death rate from cancer of the lung and rate of consumption of tobacco and cigarettes.

How, in conclusion, do these results fit in with other known facts about smoking and carcinoma of the lung? Both the consumption of tobacco and the number of deaths attributed to cancer of the lung are known to have increased, and to have increased largely, in many countries

this century. The trends in this country are given in Fig. 2, and show that over the last 25 years the increase in deaths attributed to cancer of the lung has been much greater than the increase in tobacco consumption. This might well be because the increased number of deaths in the latter years is partly an apparent increase, due to improved diagnosis; in other words, it is not wholly a reflection of increased prevalence of cancer of the lung. On the other hand, it is possible that the carcinogenic agent is introduced during the cultivation or preparation of tobacco for consumption and that changes in the methods of cultivation and preparation have occurred as well as changes in consumption. However that may be, it is clearly not possible to deduce a simple time relationship in this country between the consumption of tobacco and the number of deaths attributed to cancer of the lung.

The greater prevalence of carcinoma of the lung in men compared with women leads naturally to the suggestion that smoking may be a cause, since smoking is predominantly a male habit. Although increasing numbers of women are beginning to smoke, the great majority of women now of the cancer age have either never smoked or have only recently started to do so. It is therefore tempting to ascribe the high sex ratio to the greater consumption of tobacco by men. If this were true it would be expected that the incidence of carcinoma of the lung would be the same among non-smokers in both sexes. In this series, 2 out of 649 men and 19 out of 60 women with carcinoma of the lung were non-smokers.

To calculate the incidence rates among non-smokers of either sex it is necessary to estimate the number of non-smokers in the population from which the patients were drawn. For reasons given earlier this cannot be done, but an estimate can be obtained of the expected sex ratio of cases occurring among non-smokers in the Greater London area. From the experience of the patients without carcinoma of the lung who lived in Greater London at the time of their interview it can be calculated that there were, in 1948, 175,000 men and 1,582,000 women in London between the ages of 25 and 75 who had never been smokers according to our definition of the term. Taking these figures, subdivided by age, in association with the age distribution of the 16 cases of carcinoma of the lung observed among non-smokers living in Greater London, it can be calculated that, if the incidence of the disease were equal among non-smokers of both sexes, one case should have occurred in a man and 15 in women. In fact, the observed ratio was 0 to 16.

This finding is consistent with the theory that the risk of developing carcinoma of the lung is the same in both men and women, apart from the influence of smoking. It is not, however, possible to demonstrate with the data at our disposal that different amounts of smoking are sufficient to account for the overall sex ratio.

As to the nature of the carcinogen we have no evidence. The only carcinogenic substance which has been found in tobacco smoke is arsenic (Daff and Kennaway, 1950), but the evidence that arsenic can produce carcinoma of the lung is suggestive rather than conclusive (Hill and Faning, 1948). Should arsenic prove to be the carcinogen, the possibility arises that it is not the tobacco itself which is dangerous. Insecticides containing arsenic have been used for the protection of the growing crop since the end of the last century and might conceivably be the source of the responsible factor. This, too, might account for the observation that deaths from cancer of the lung have increased more rapidly than the consumption of tobacco.

Summary

The great increase in the number of deaths attributed to cancer of the lung in the last 25 years justifies the search for a cause in the environment. An investigation was therefore carried out into the possible association of carcinoma of the lung with smoking, exposure to car and fuel fumes, occupation, etc. The preliminary findings with regard to smoking are reported.

The material for the investigation was obtained from twenty hospitals in the London region which notified patients with cancer of the lung, stomach, and large bowel. Almoners then visited and interviewed each patient. The patients with carcinoma of the stomach and large bowel served for comparison and, in addition, the almoners interviewed a non-cancer control group of general hospital patients, chosen so as to be of the same sex and age as the lung-carcinoma patients.

Altogether 649 men and 60 women with carcinoma of the lung were interviewed. Of the men 0.3% and of the women 31.7% were non-smokers (as defined in the text). The corresponding figures for the non-cancer control groups were: men 4.2%, women 53.3%.

Among the smokers a relatively high proportion of the patients with carcinoma of the lung fell in the heavier smoking categories. For example, 26.0% of the male and 14.6% of the female lung-carcinoma patients who smoked gave as their most recent smoking habits prior to their illness the equivalent of 25 or more cigarettes a day, while only 13.5% of the male and none of the female non-cancer control patients smoked as much. Similar differences were found when comparisons were made between the maximum amounts ever smoked and the estimated total amounts ever smoked.

Cigarette smoking was more closely related to carcinoma of the lung than pipe smoking. No distinct association was found with inhaling.

Taken as a whole, the lung-carcinoma patients had begun to smoke earlier and had continued for longer than the controls, but the differences were very small and not statistically significant. Rather fewer lung-carcinoma patients had given up smoking.

Consideration has been given to the possibility that the results could have been produced by the selection of an unsuitable group of control patients, by patients with respiratory disease exaggerating their smoking habits, or by bias on the part of the interviewers. Reasons are given for excluding all these possibilities, and it is concluded that smoking is an important factor in the cause of carcinoma of the lung.

From consideration of the smoking histories given by the patients without cancer of the lung a tentative estimate was made of the number of people who smoked different amounts of tobacco in Greater London, and hence the relative risks of developing the disease among different grades of smokers were calculated. The figures obtained are admittedly speculative, but suggest that, above the age of 45, the risk of developing the disease increases in simple proportion with the amount smoked, and that it may be approximately 50 times as great among those who smoke 25 or more cigarettes a day as among non-smokers.

The observed sex ratio among non-smokers (based, it must be stressed, on very few cases) can be readily accounted for if the true incidence among non-smokers is equal in both sexes.

It is not possible to deduce a simple time relationship between the increased consumption of tobacco and the increased number of deaths attributed to cancer of the lung. This may be because part of the increase is apparent—that is, due to improved diagnosis—but it may also be because the carcinogen in tobacco smoke is introduced into the tobacco during its cultivation or preparation. Greater changes may have taken place in the methods involved in these processes than in the actual amount of tobacco consumed.

Co-operating Hospitals.—Brompton, Central Middlesex, Fulham, Hackney, Hammersmith, Harefield, Lambeth, Lewisham, Middlesex, Mount Vernon and the Radium Institute, New End, Royal Cancer, Royal Free, St. Bartholomew's,

St. Charles's, St. James', St. Mary's, St. Thomas's, University College, Whittington.

We are indebted to the staffs of the above-named hospitals for having allowed us to interview their patients and to have access to the hospital notes; also to the individual members of the staffs, both medical and lay, who notified the cases and collected the notes for examination. The work could not have been carried out without their co-operation. Sir Ernest Kennaway and Dr. Percy Stocks took part in a conference called by the Medical Research Council, at which this investigation was initiated, and we have been fortunate in having their helpful advice throughout its course. Professor W. D. Newcomb has advised us on individual problems of pathology. We are most grateful for this assistance. Finally, we wish to thank Miss Marna Buckatzsch, Miss Beryl Iago, Miss Keena Jones, and Miss Rosemary Thomson, who interviewed the patients and helped with the analysis of the results; and Dr. J. T. Boyd for assistance in the calculations.

REGIME FOR TREATMENT OF SEVERE AND ACUTE LIVER DISEASE

BY

A. L. LATNER, M.D., M.Sc., D.I.C., A.R.C.S.

(From the Section of Chemical Pathology, Department of Pathology, Royal Victoria Infirmary, Newcastle-upon-Tyne)

In spite of increasing biochemical knowledge on the subject of liver necrosis, the high mortality rate of severe liver disease of acute onset remains a therapeutic challenge. Once coma has occurred a fatal outcome is probable; a recovery is always an event of note.

It is, however, a remarkable fact that even patients suffering from massive necrosis may linger on for a number of days. This is in marked contrast to the short period of survival of animals after hepatectomy. Moreover, in so-called "acute yellow atrophy" several of the liver's functions may remain apparently normal until death. Even the fasting blood-sugar level may remain within normal limits. This must surely mean that enough liver tissue survives to carry out certain highly important metabolic processes. There is also reason to believe that the histological picture of massive necrosis is not unrelated to post-mortem autolysis, and that much more liver tissue survives during life than is apparent after death (van Beek and Haex, 1943).

These facts are of great importance. If practically all the liver were necrotic during life, then treatment would obviously be useless. On the other hand, if large numbers of liver cells were diseased but not dead the possibility would remain that the process was reversible, and that a successful treatment might eventually be discovered. In the hope that the latter state of affairs actually occurs, I have been attempting over a number of years to treat these cases on biochemical principles.

Earlier Work

Some three years ago treatment was begun in a series of six patients in coma from acute liver disease (Latner and Mowbray—paper in preparation). By daily intravenous administration, each patient received 1 to 3 g. of cystine in addition to glucose and plasma. The importance of this amino-acid in the prevention of experimental necrosis had already been demonstrated (Glynn *et al.*, 1945). All these cases presented the clinical picture of "acute yellow atrophy" and all had a fatal outcome.

A gross amino-aciduria has been demonstrated in severe liver disease by paper chromatography (Dent, 1949). In view of the known increase in the amino-acid content of the blood, including the thioamino-acids, Dent has suggested that the necrotic liver cannot utilize them and they could not therefore be of much use in curative treatment.

There was some possibility that a reflex circulatory upset affecting the liver might prevent the cystine reaching the liver cells. With this possibility in view, tetraethylammonium bromide was administered to our sixth case as soon as it became obvious that there was no response to cystine. The downhill progress of the patient was in no way affected.

These discouraging results made it obvious that we were thinking along incorrect lines. The diseased liver cell required cystine to prevent necrosis but could not utilize it adequately from external sources. The problem, therefore, was to render the cells less sensitive to cystine deficiency, so that they could utilize their own cystine until such time as recovery was complete enough to allow them to use the amino-acids of surrounding tissue fluid. From this point of view the role assigned to tocopherol in the production of experimental hepatic necrosis (Schwarz, 1944; György, 1947; Himsworth and Lindan, 1949) assumes great importance. This vitamin has therefore been included in the regime of treatment described below.

The intracellular oxidative processes of the liver and other organs also require other vitamins. In their absence toxic products accumulate which could easily be a factor in the final death of liver cells. The successful application of massive doses of the vitamin-B group in the cholaemia of cirrhosis has already been reported (Patek *et al.*, 1948). This form of therapy was therefore also included in the regime.

Recent knowledge of the state of dynamic equilibrium of the body proteins also has a bearing on this problem. It seems likely that proteins are not only destroyed by wear and tear but are continuously being broken down and resynthesized at a remarkably rapid rate. This protein turnover can be demonstrated with radioactive tracers. One would not be far wrong in stating that every protein in the body was in a state of dynamic equilibrium with all other proteins (Whipple, 1948). The liver has been described as the master organ for protein metabolism. The diminution of the plasma proteins in severe disease of this organ could profoundly upset the normal equilibrium of the tissue proteins and so lead to metabolic upsets. The resulting toxic metabolites could act unfavourably on already damaged liver cells. It therefore becomes of great importance to administer plasma protein in severe liver disease, and for this reason it has been included in the regime.

Vitamins of the B group have been administered along with a dextrose solution in normal saline. The saline vehicle has been used because of the remarkable tendency for these patients to develop low plasma-chloride levels, probably related to vomiting and possibly to associated renal failure.

Large amounts of dextrose administered intravenously can lead to a dangerously low level of plasma potassium. This was in fact demonstrated in the one fatal case of this series. For this reason every pint (570 ml.) of dextrose in saline has also contained 0.5 g. of potassium chloride.

All patients in coma are very liable to develop aspiration pneumonia. This is well seen in liver necrosis; such patients seem to have a marked tendency to infection. For this reason penicillin has been administered daily. If this fails to control infection streptomycin may be used.

The Regime

The regime, as finally developed, is as follows.

Infusion 1.—To each pint of 10% dextrose in normal saline are added 50 mg. of thiamin hydrochloride, 150 mg. of nicotinamide, and 50 mg. of riboflavin as well as 0.5 g. of potassium chloride.

Infusion 2.—This consists of plasma to which the vitamins alone have been added in the same concentrations as in Infusion 1.

The patient's blood group is immediately determined and appropriate donors are contacted. Penicillin, 1,000,000 units, is administered daily for 10 days. During each 24 hours three separate pints of Infusion 1 are administered intravenously at six-hourly intervals and after a further six hours one pint of Infusion 2 is given. During this period 300 mg. of tocopherol is administered intramuscularly in three divided doses.

This treatment is continued until such time as fluids can be safely administered by mouth; usually two or three days. It is important to administer the tocopherol by mouth as soon as possible, as it is said to be much more effective by the oral route (Goettsch and Pappenheimer, 1941). As recovery sets in, the vitamin dosages are halved on consecutive days until they can be replaced by a reliable polyvitamin preparation, which is continued through convalescence.

As soon as the patient is able to take fluids by mouth, "hepovite" is administered in gradually increasing dosage until the patient is receiving 2 oz. (62 g.) daily in addition to the ordinary diet.

Unfortunately, in the early stages haemorrhagic incidents are common. In this series they have taken the form of epistaxis or melaena. It is of the greatest importance to be constantly on the alert for signs of severe haemorrhage. This must be treated by the immediate administration of appropriate amounts of fresh donor blood, to each pint of which the vitamins have been added in the same concentrations as in the infusions. It must be emphasized that for this purpose stored blood is useless, as the haemorrhage is due among other factors to prothrombin deficiency.

If an infection which is obviously not responding to penicillin develops, a course of streptomycin may be given. Sedatives are best avoided. However, these patients are liable to become very restless and extremely difficult to nurse, and on occasion it may be necessary to administer paraldehyde. Morphine should not be given.

The treatment has now been given in five instances, details of which follow. For the sake of brevity the regime is referred to as "the intravenous liver regime."

Case 1: Massive Necrosis Complicating Infective Hepatitis

A housewife aged 42 was jaundiced and stuporous on admission and soon lapsed into coma. One week previously she had felt unwell and had a temperature of 102.4° F. (39.1° C.). She suffered from anorexia and nausea, but drank quite copiously. Five days before admission she began to vomit a great deal, and this continued for three days. She had not vomited since, but suffered from severe nausea. Her temperature became normal two days before admission. By the next day she had become drowsy, and gradually got worse until she was answering questions only when spoken to sharply. Jaundice now became evident.

On examination it was found that she could be roused with difficulty to say an occasional word. She reacted vigorously to painful stimuli. Her conjunctivae were yellow and her skin slightly jaundiced. Her abdomen was tender all over, especially in the right upper quadrant, with some guarding on deep palpation. The liver could not be palpated, but there was a reduction in the area of hepatic dullness. Some bruising was present over the right lower shin, and the plantar responses were flexor. Her temperature was 98° F. (36.7° C.), pulse rate 92 a minute, and blood pressure 160/95 mm. Hg.

A specimen of urine contained albumin and bile pigments but no casts. The white cell count was 7,800 per c.mm. The serum thymol turbidity and flocculation were respectively 21 units and ++++. The plasma alkaline phosphatase and blood urea were respectively 18 units (Jenner and Kay) and 21 mg. per 100 ml.

Intravenous therapy was begun immediately. In this case the infusions contained no added potassium chloride, and tocopherol was given in much lower dosage than in the regime already described. The patient soon became extremely restless, and sedation was necessary. In spite of this, generalized twitchings of her muscles developed. On the second day of treatment she still remained comatose, with periods of extreme restlessness. By the afternoon of the next day she began to recover from her coma and was able to take fluids by mouth. The improvement continued, and by the fourth day of treatment she was speaking quite rationally and taking fluids well. On the fifth day she was much improved and talking quite rationally. She was feeling better but somewhat weak.

At this stage a cellulitis had begun in her right leg—the limb into which the intravenous drip was being administered. Her temperature was now 102° F. (38.9° C.). Sulphadimidine was given in an unsuccessful attempt to combat the infection. The temperature continued to rise, and by the next day it had reached 104° F. (40° C.), and she lapsed once more into coma. Her blood potassium was only 10.9 mg. per 100 ml. Her blood urea was 70 mg. per 100 ml. and the white cell count 23,000 per c.mm. In spite of the administration of 5 g. of potassium chloride by mouth and 2 g. intravenously she remained in coma and died next day.

One cannot escape the conclusion that the cellulitis played a large part in the causation of death, which may also have been contributed to by the lowered blood potassium. It was because of this case that potassium chloride was subsequently introduced into the routine intravenous therapy and the dosage of vitamin E was increased to 300 mg. daily. It is possible that the administration of streptomycin might have been a life-saving procedure.

Case 2: Infective Hepatitis with Massive Necrosis

A boy aged 9 was somewhat jaundiced on admission. He was delirious and had violent screaming bouts. He had first felt unwell five days previously and became delirious with severe epistaxis during the next 24 hours. The delirium continued up to the day of admission, when jaundice first appeared.

On examination he was seen to be very ill and somewhat dehydrated. A tinge of jaundice was present in the skin and conjunctivae, and purpuric spots were present on his back. His respirations were 45 a minute, his temperature was 99.4° F. (37.4° C.), and pulse rate 104. The liver seemed slightly enlarged. There was no neck rigidity and the plantar responses were flexor. Some moist sounds were present over both lungs. A specimen of urine contained albumin and bile pigments. Blood examination revealed a plasma bilirubin content of 4 mg. per 100 ml. and an alkaline phosphatase of 16.8 units (Jenner and Kay) per 100 ml. The thymol reactions were normal, but cephalin-cholesterol flocculation was ++++.

At this stage he was given 1,000,000 units of penicillin daily, and this was continued for 12 days. Next day he was very ill indeed, with alternating coma and restlessness. He had become more deeply jaundiced and a morbilliform eruption appeared on his trunk. The diagnosis of acute yellow atrophy was made and the prognosis was regarded as extremely grave. Examination of the urine by paper chromatography revealed a gross amino-aciduria.

The intravenous liver regime was now begun. In this case, however, all the vitamins were administered by intramuscular injection. On the third day after admission the patient suffered a severe epistaxis and his haemoglobin was shown to be 50% of normal. He was therefore given a pint (570 ml.) of blood. Next day he was much improved, was rational, and was able to drink. The drip was discontinued. He made rapid progress and was discharged 18 days after admission. Leptospiral agglutinations were negative 18 days after the onset of illness.

He was readmitted 10 days later for a lung abscess which responded well to treatment. When last seen, a year later, he appeared to be in good health.

Case 3: Massive Necrosis of the Puerperium

A housewife aged 25 was admitted in a confused and somewhat stuporous condition two days after the delivery of her first child. There was some jaundice of the skin and conjunctivae. She had begun vomiting a week before the birth of her child, and two days before delivery a slight jaundice was noted. It was hoped that delivery would result in improvement, which was apparent at first, but after 48 hours she relapsed into an almost comatose condition.

On examination liver dullness was markedly diminished: this was confirmed by a number of observers. She was somewhat confused, but could be made to answer questions more or less rationally. At this stage her urine contained bile but no albumin. Tyrosine and leucine crystals could not be demonstrated microscopically, but paper chromatography revealed a gross amino-aciduria. Blood examination disclosed a plasma bilirubin content of 3.36 mg. per 100 ml. The alkaline phosphatase and total serum protein were respectively 17.8 units (Jenner and Kay) and 4.2 g. per 100 ml. The plasma prothrombin was 61% of normal average and the serum thymol reactions were normal. The serum potassium level was only 12.3 mg. per 100 ml.

The patient was placed on the intravenous liver regime for three days and made a rapid recovery. One week later her serum protein had risen to 5.25 g. and her prothrombin was 88% of normal average. She was now shown to have a macrocytic anaemia, but marrow puncture revealed normoblastic erythropoiesis and no megaloblasts were seen. It is interesting to note that other cases in this series have developed a similar condition. The anaemia responded well to the administration of folic acid and a transfusion of the packed cells of two pints (1.14 l.) of blood. When last seen, six months later, she was in normal health.

Case 4: Hepato-renal Syndrome Following Cholecystectomy

A housewife aged 36 was obviously gravely ill when I first saw her. She was deeply jaundiced, vomited copiously, and was in a stupor from which she could not be roused. Her eyes remained turned upwards. She had been admitted to hospital 11 days previously with a history of deepening jaundice of 16 days' duration, not associated with pain but accompanied by severe nausea and itching. There had, however, been intermittent attacks of biliary colic for about eight months.

On admission, laboratory examination revealed that each 100 ml. of her plasma contained 13 mg. of bilirubin and 10.8 units of alkaline phosphatase (Jenner and Kay). The plasma prothrombin was 92% of normal average and the serum thymol reactions showed a turbidity of 5 units and ++++ flocculation. In spite of this evidence of hepatocellular damage, it was decided to operate because of the previous history of biliary colic. Cholecystectomy was performed and a small stone removed from the common bile duct, into which a drain was inserted. On the day after operation a transfusion of two pints of blood became necessary because of continual oozing from the wound. The patient was restless and vomiting, and her condition continued to deteriorate, with deepening jaundice. Because of continuous vomiting, intermittent gastric drainage was performed. She gradually became stuporous and developed oliguria.

Because of her abdominal incision, I was unable to carry out a complete clinical examination. This was made even more difficult by the presence of a large haematoma in the wound, which was still oozing blood. The spleen was not enlarged, and nothing abnormal was demonstrated in her chest. Her temperature was 99° F. (37.2° C.) and her pulse rate 100 a minute. A specimen of urine contained bile, and paper chromatography revealed a gross amino-aciduria. Her plasma bilirubin and blood urea were now respectively 32 mg. and 136 mg. per 100 ml.

The intravenous liver regime was immediately started and was continued for six days. For the first few days the patient remained exceedingly ill, with copious vomiting and well-marked oliguria. The wound haematoma increased in size but the jaundice diminished. On the last day of the regime the plasma bilirubin had fallen to 6.4 mg. per 100 ml. The blood urea, chloride (as Cl'), and potassium were respectively 200, 226, and 16.9 mg. per 100 ml. She was now able to take sips of fluid by mouth, and hepovite was administered. Oliguria still persisted, and in view of the low plasma chloride three pints (1.7 ml.) of 2.7% saline were administered intravenously over a period of 12 hours. This raised the plasma chloride to 311 mg. per 100 ml. (as Cl'), but the blood urea also rose to 440 mg. per 100 ml. A profuse diuresis now set in accompanied by much improvement in the patient's condition. In five days the blood urea had fallen to 110 mg. per 100 ml. The plasma chloride was now well within normal limits and the plasma bilirubin was 1.6 mg. per 100 ml. The red blood cell count was found to be only 2,800,000 per c.mm., the blood haemoglobin was 6.51 g. per 100 ml. A transfusion of two pints of blood was therefore given and folic acid administered.

On discharge, a fortnight later, all biochemical investigations were within normal limits. A high-protein diet supplemented by 2 oz. (62 g.) of hepovite daily was prescribed. When last seen five months after discharge she was fit and well and had obviously gained much weight. She had returned to normal housework.

Case 5: Acute Massive Necrosis of the Puerperium

A housewife aged 25 was admitted in a desperately ill condition; she was jaundiced and comatose. At the thirtieth week of her second pregnancy she felt weak and breathless and suffered from headaches and swelling of the ankles. Six weeks later she first saw a doctor, who delivered her of a stillborn child. Within half an hour she collapsed, became delirious, and then sank into a state of coma, and was admitted to Preston Hospital, North Shields. There was now persistent hiccup, and a deepening jaundice became evident. She was obviously moribund, and in this condition was transferred to the Royal Victoria Infirmary for treatment.

On examination it was found that she could occasionally be roused to mumble a few incoherent words. She suffered from repeated hiccup, jerking movements, and muscular twitchings. She was fairly deeply jaundiced and a well-marked fetor hepaticus was detected. Some spider naevi were present on her arms and face. There was also some palmar erythema. A number of bruises were present over the lower region of her back, particularly over the sacrum. In this position an early bedsore was evident. There was marked diminution of liver dullness and the uterus was enlarged to some 3 in. (7.6 cm.) above the symphysis. Crepitations and areas of diminished air entry were detected over both lung bases. The plantar responses were flexor. Her pulse rate was 100 a minute, blood pressure 70/40 mm. Hg, and temperature on admission 97.4° F. (36.3° C.).

A specimen of urine contained bile but no albumin, and a gross amino-aciduria was demonstrated by paper chromatography. This latter finding was confirmed in subsequent specimens. Examination of the blood revealed a red cell count of 3,600,000 per c.mm. and a leucocytosis of 33,200 cells per c.mm. The blood haemoglobin content was 7.4 g. per 100 ml. Plasma bilirubin, alkaline phosphatase, and total serum protein were respectively 5.6 mg., 21.5 units (Jenner and Kay), and 4.95 g. per 100 ml. The thymol reactions and zinc sulphate flocculation were within normal limits. The blood urea was raised to 352 mg. per 100 ml.

The patient was immediately placed on the intravenous liver regime and the response was dramatic. Twenty-four hours after admission she was free from hiccup for short periods and was able to recognize her relatives. She could now take some fluids by mouth. Forty-eight hours after admission she developed a severe melaena, which continued for three days and necessitated the administration over this period of five pints (2.84 l.) of blood containing added vitamins. During this time it was thought unnecessary to administer any plasma. The hiccup vanished on the third day of treatment, and she was alert and smiling and taking her food. The drip was discontinued on the fifth day.

She now developed a temperature of 102.4° F. (39.1° C.). In spite of the penicillin therapy a cellulitis of her right leg had developed and the bedsore had increased in size. Physical signs were still present over both lung bases. The penicillin was discontinued and a 10-day course of streptomycin begun with a dosage of 0.5 g. twice daily. As a result of this therapy her temperature fell to normal and all signs of infection disappeared. The slow healing of the bedsore somewhat prolonged her stay in hospital. On the twelfth day of her illness the plasma prothrombin was 70% of normal average, and subsequent blood examination revealed normal plasma bilirubin, alkaline phosphatase, and blood urea. The flocculation tests were, however, now abnormal. Leptospiral agglutinations were negative.

She was discharged from hospital six weeks after admission, and when last seen, six weeks later, was feeling perfectly well, had gained weight, and had returned to all her household duties. Nothing abnormal could be demonstrated by physical examination. Serum flocculation tests were markedly abnormal; the thymol and zinc sulphate turbidities were respectively 7 and 16 units, and the thymol and cephalin flocculations were each ++++.

Discussion

In five consecutive cases of severe liver disease there has thus been only one death. The expected mortality was much higher. Even the patient that died recovered from her coma. Her eventual death was in some measure due to a superadded infection and possibly to the fact that she did not receive the full regime.

Those patients who recovered have been observed for periods of up to one year. The most remarkable fact has been the degree of recovery they apparently achieved. After a preliminary period of weakness, lasting about a month and associated with fairly easy fatigue and swelling of the ankles, there has been a gradual return to apparently normal health. Three of the patients have remarked spontaneously on the great subjective improvement that occurred during the first few days of treatment. One now claims she feels better than she has done for years.

It is interesting to note that three of the patients developed a macrocytic anaemia during their stay in hospital. In one instance (Case 5) normoblasts were found in the peripheral blood.

It is felt that no apology need be made for the polytherapy. The liver is, after all, a highly complex organ, and it would be presumptuous to assume that any single substance could bring about its recovery from severe disease.

It might well be suggested that those cases that recovered would have done so spontaneously. Most medical men of some experience will remember having seen or heard of at least one case of severe liver disease which did not have the expected fatal outcome. It is extremely unlikely, however, that the recovery of four out of five consecutive cases would be unrelated to treatment. In this connexion it has already been mentioned that death occurred in each of six similar cases seen by me. In fact, this latter group may be regarded as a control series, as similar diagnostic criteria were used. It must be emphasized that all the cases that recovered showed at some stage the clinical picture of so-called "acute yellow atrophy." They all had gross amino-aciduria, which is known to be associated with a very grave prognosis (Dent, 1949).

Liver disease of acute onset and of great severity is fortunately relatively uncommon in this country. The cases herein reported have been seen over a period of three years. This work was done in a hospital which serves an extensive area and so a relatively large number of cases were seen in that time. The absolute number is, however, somewhat small, and for this reason it would perhaps be wise to restrain one's enthusiasm. The results of therapy have proved so remarkable that it is hoped that others will adopt the same regime in similar cases and so help to arrive at a final assessment of its value.

In conclusion, it should be pointed out that this form of therapy may also be used prophylactically after surgical operations on patients with severe liver impairment. These are notoriously bad surgical risks. The regime has already been successfully applied in two such cases.

Summary

A regime for the treatment of severe liver disease of acute onset is described.

Five cases have been treated, with only one death.

In contrast, six cases treated with cystine intravenously showed 100% mortality.

Two further cases have been successfully treated prophylactically after surgical intervention.

I am much indebted to various colleagues on the staff of the Royal Victoria Infirmary, Newcastle-upon-Tyne, for giving me such free access to their patients.

The Ministry of Supply has recently given details of a new product from the Harwell atom pile which may take the place of radium in the treatment of some skin diseases. This is Ir^{192}, an isotope of the metal iridium. To make Ir^{192}, iridium is "cooked" inside the atom pile for three months. It is then ready for clinical use, although after a month it must be returned for further treatment inside the pile. The new isotope is not only cheaper and more plentiful than radium—it costs £12 to hire one dose for four weeks—but, because the radiation it emits is less powerful than that of radium, it can be used for treating skin disorders without danger of harming the bone structure underneath the skin. For the same reason very much less lead screening is required to shield the operator, and the equipment which houses the isotope is simpler and less expensive than radium appliances.

THE SYNDROME OF OBSTRUCTION OF INFERIOR VENA CAVA IN CHILDHOOD

BY

HARRY ANGELMAN, M.D., M.R.C.P., D.C.H.
E. G. HALL, M.B., Ch.B., B.Sc.

AND

R. SPENCER, M.B., Ch.B., B.Sc., F.R.C.S.Ed.
(From the Department of Child Health, University of Liverpool)

Obstruction of the inferior vena cava is uncommon at any age, but in children its incidence, especially when developmental in origin, is notably rare, and diagnosis in the early stages presents difficulties. Three cases are here described, all showing the same syndrome, although in one of them the obstruction was shown by venography to be in the femoral and iliac veins.

Case 1

A girl aged 4 years 10 months attended the out-patient department in March, 1949. Her parents had noted the development of enlarged veins over her abdomen when she was 18 months old, a few months after she had begun to walk. At the age of 3½ years a dilated vein became apparent along the inner side of her right leg. It was thought that the affected veins were increasing slowly in size; they were most noticeable when she laughed or cried. Apart from some nocturnal enuresis which had been present since infancy, no other abnormal features had been noted. She never became cyanosed, and did not lag behind other children in taking exercise. Her parents had taken her to hospital when she was 2 years old to obtain advice about the large veins, but no special treatment was recommended.

Her mother, a diabetic of 20 years' standing, was admitted to hospital during the fourth month of her pregnancy and remained there until fit to return home after delivery. No clinical details were obtainable from the hospital, but she said

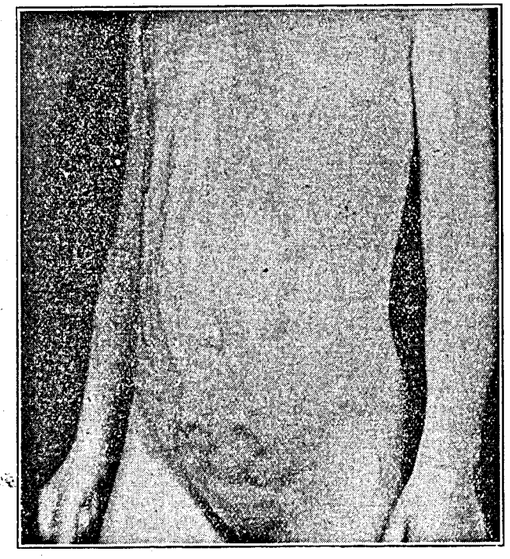

FIG. 1.—Case 1. Infra-red photograph of the superficial collateral venous circulation.

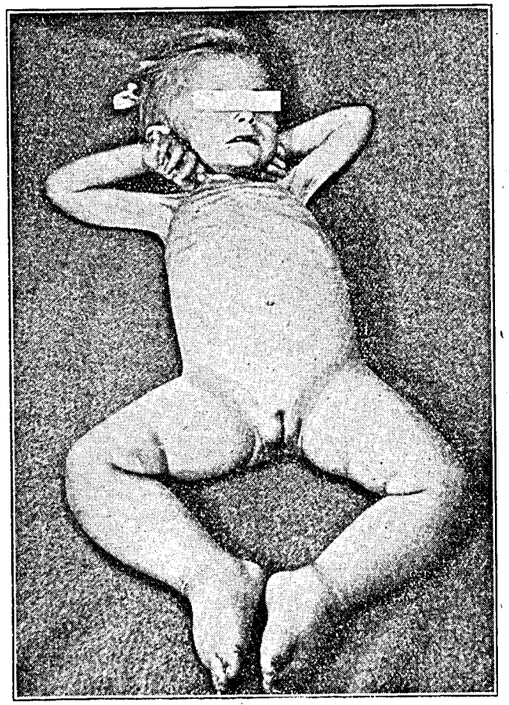

FIG. 2.—Case 2. Photograph of child after admission to hospital: Oedema evident, but the veins on the abdominal wall do not show.

that the baby had been born five weeks prematurely after she had been four days on the labour bed; and she had been given a spinal anaesthetic during the prolonged course of the labour. She did not see her baby until it was 3 weeks old, and at that time it looked healthy. The umbilicus was clean and healed. The weight at birth was not known, but at 5 weeks the infant weighed 6 lb. 9 oz. (3 kg.), and she was discharged from hospital at the age of 2 months. Various types of milk food were tried, as there was a tendency to vomit after feeds. The developmental history was normal, and the previous illnesses were rubella when 4 years old, and measles five weeks before the present observations. The father was quite well and there were no other children.

On examination the child was found to be lively and active and her weight was normal. Her mucous membranes were of a healthy pink colour. Dilated superficial veins were present over the lower part of her chest and especially over the abdominal wall, mainly on the lateral aspects, but there was no caput medusae (Fig. 1). The right medial saphenous vein was dilated, but not markedly so. Slight pitting oedema was present in the legs, below the knees. The blood flow in the dilated veins was from below upwards and they increased in size and tension when she strained and held her breath. The muscles of her calves, thighs, and buttocks were hypertrophied and powerful. Her heart and lungs were normal, and no mass could be palpated in her abdomen or pelvis.

She was admitted to hospital for further investigation. Her urine was free from albumin, cells, or casts. The Wassermann reaction was negative. A plain radiograph of her abdomen and an intravenous pyelogram were both normal, as were a full blood count, including bleeding and clotting times, and an electrocardiogram. A venogram was considered, but the admittedly slight risk involved in the procedure was not

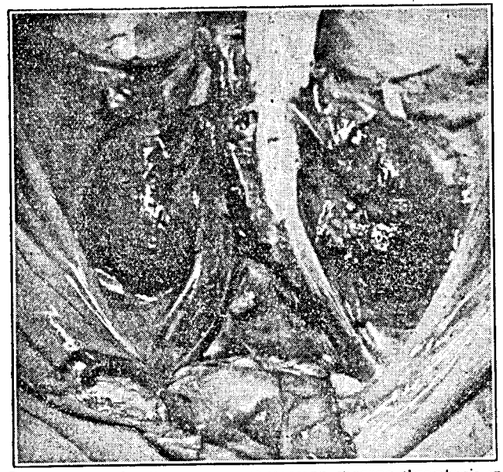

FIG. 3.—Case 2. Post-mortem photograph showing thrombosis in the inferior vena cava and renal veins.

considered justifiable since the parents were unwilling for any further investigation to be undertaken unless it would give help in treatment. Laparotomy was ruled out, as a serviceable collateral anastomosis had developed and there was no question of any mass compressing the inferior vena cava.

Case 2

A female child aged 15 months was admitted to hospital with a provisional diagnosis of acute nephritis. Three weeks previously she had developed diarrhoea, which continued for five days, and during this period she had passed six to eight motions a day. Since that time she had remained rather listless. One week before admission to hospital she was noted to have oliguria and some oedema of her feet. Her previous history revealed that she was born one month prematurely, her birth weight being 5 lb. 6 oz. (2.4 kg.), but her subsequent progress had been normal and free from incident.

On examination she appeared pale and puffy. There was marked oedema of both legs and of the abdominal wall below the umbilicus (Fig. 2). The superficial veins over the abdominal wall were prominent and their blood flow was from below upwards. The blood pressure was 145/95 mm. Hg. Her urine was loaded with albumin, containing a moderate number of red cells and occasional leucocytes, with some granular and hyaline casts. A blood count showed: haemoglobin, 9.4 g. per 100 ml. (Haldane); white cells, 13,200 per c.mm., with a slight excess of polymorphs. The blood urea was 38 mg. per 100 ml., and the total serum protein 4.4 g.%, with albumin 2.7 g.%.

A week after admission the right kidney was felt to be enlarged, and a few days later the left kidney could also be palpated. The oedema persisted and later involved the face and arms. The retinae remained quite normal. Urinary examination on several subsequent occasions showed the presence of albumin, moderate numbers of red cells and leucocytes, but no casts. The blood urea eventually rose to 56 mg. per 100 ml., and a later blood count showed: haemoglobin, 8.9 g. per 100 ml.; red cells, 3,000,000 per c.mm.; white cells, 36,600 per c.mm. A few days before she died some purpuric spots appeared on the abdominal wall, and an empyema developed in the right side of her chest.

At necropsy the whole length of the inferior vena cava, both renal veins, the left lateral sinus, and some branches of the pulmonary arteries were all found to be thrombosed. The thrombosis of the inferior vena cava extended from its origin in the abdomen right up to its entrance into the right auricle (Fig. 3). Extensions of the clot ran into but did not occlude the main hepatic veins. Above the renal veins it was firm, pale, dry, and retracted, and appeared to be of more recent origin than the clot in the lower third of the vessel. Both kidneys were slightly enlarged, but of normal appearance on cross-section, and histologically showed organizing thrombus, with recanalization at some sites in occasional arcuate veins. The large veins at the hila of the kidneys were of similar microscopical appearance, several showing extensive deposits of calcium. The thrombi in the main renal veins, lateral sinus, and lower third of the vena cava were apparently of the same age histologically. The thrombi in the branches of the pulmonary artery were also old and showed calcium deposition. Thus it seems that the initial thromboses occurred in the smaller branches of the renal veins. It is possible that the thrombosis in the branches of the pulmonary artery was superimposed on emboli.

Case 3

A girl aged 6 years 4 months was admitted to hospital in December, 1949, as the school medical officer had noted the presence of enlarged veins over the lower part of her abdominal wall during the course of a routine medical inspection. The enlarged veins had been present for three years and had caused her no inconvenience. There had been no swelling of her feet and no urinary symptoms. She led a full and active life without any undue distress on physical exertion.

Inquiry into her past history revealed that delivery had been normal and that she had been breast-fed up to the age of 7 months. When 14 months old she had been admitted to hospital because of a skin rash which involved the hands and feet. No diagnosis of the rash had been made, but while in hospital gastro-enteritis developed and an intravenous drip was set up in the right saphenous vein at the ankle. There was a history of a slight convulsion during this treatment, but she was later discharged from hospital quite well. At the age of 4 years 7 months she was admitted to hospital for febrile convulsions associated with pneumonia. Nine months later she was re-admitted with febrile convulsions associated with respiratory infection. It was soon after this latter illness that the enlarged abdominal veins were first noted.

Her mother suffered from pernicious anaemia, but her father and two sisters were in good health. The older members of the family were all liable to varicose veins.

On clinical examination the patient was noted to be a well-developed girl for her age. The abdomen was slightly prominent in the hypogastric region, and over the same area dilated superficial collateral veins were to be seen (Fig. 4). A large vein was visible arising from the region of the femoral canal on the left side, but there were no dilated veins in the

FIG. 4.—Case 3. Infra-red photograph showing superficial venous collateral circulation.

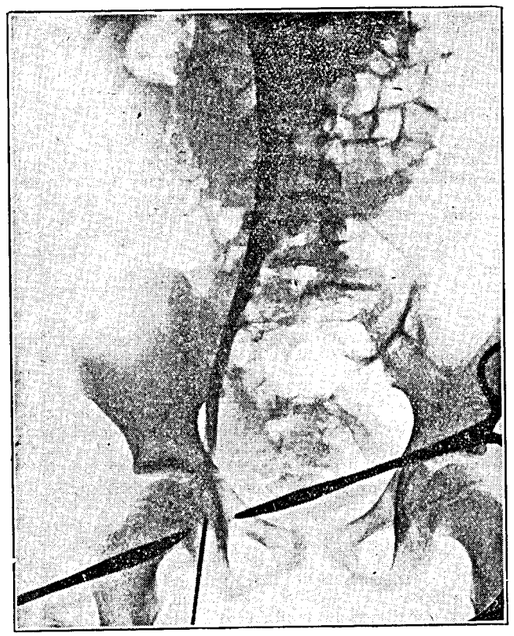

FIG. 5.—Case 3. Venogram, right side: this shows a normal picture. The left margin of the inferior vena cava is not entirely clear-cut, but this is probably due to displacement of the pyelosil by blood flowing in from the left common iliac vein.

legs. It was not possible to demonstrate the direction of the blood flow; strenuous exercise made the veins stand out a little more prominently, but no oedema of the legs followed. The remainder of the clinical examination revealed no abnormality.

Her blood count, blood urea, urinary examination, and urea-clearance test were all normal, and liver-function tests, including thymol turbidity and flocculation, colloidal gold, alkaline phosphatase, and serum bilirubin were also normal. It was decided to do a venogram.

Technique.—A sedative was given pre-operatively. The right femoral vein was exposed in the inguinal region, using local analgesia, and care was taken not to cut or damage any tributary veins. Then 15 ml. of 50% "pyelosil" was injected into the femoral vein in 15 seconds, and radiographs were taken at 5, 10, and 15 seconds from the beginning of the injection. An identical technique was used on the left side some days later. The left femoral vein was difficult to identify and to inject, as it was considerably thickened (see Figs. 5 and 6).

Discussion

Pleasants (1911) wrote a comprehensive report on obstruction of the inferior vena cava, which should be read by all interested in the subject for its detailed discussion of pathology. In dealing with the subject of congenital obstruction he mentions eight reported cases and includes one case of his own, but in only two instances was the developmental origin confirmed at necropsy. In the first (Cavasse, 1897), the vena cava below the renal veins was represented by a small fibrous cord, not connected with the veins of the legs but with a free ending at the level of the aortic bifurcation. The right femoral vein ended as a free fibrous cord just above the entrance of the saphenous vein. The patient died at the age of 54, a superficial collateral venous circulation not being evident until two years before his death. The clinical history of this case is in accord with the fact that dilated superficial veins do not appear unless other deep veins additional to the vena cava are obstructed. In the second case (Meyer, 1903) the patient was a youth aged 18 who died of erysipelas. At necropsy the upper part of the inferior vena cava at the level of the diaphragm and the superior vena cava above the entrance of the great azygos vein were obliterated, only fibrous remnants of the vessels remaining. The entire venous circulation was returned to the heart through the great azygos vein.

Four of the remaining cases were considered by Pleasants to be due to thrombosis occurring at or before the time of birth. The other three patients were all males, their ages being 17, 27, and 30 years. None of these patients had any history of an acute illness in the first few years of life, but in all the enlarged superficial veins had been noted in infancy. They all had varicose ulcers on their legs, but oedema was not evident.

One can postulate from the clinical findings that Case 1 has an obstruction not only of the inferior vena cava but also of the deep venous collaterals, as indicated by the presence of enlarged superficial veins in the abdominal wall. The finding of normal kidney function and absence of albuminuria probably places the lesion below the level of the renal veins. The oedema of the legs on exertion and the presence of a dilated right internal saphenous vein suggest that the iliac veins have been involved. No caput medusae is present, the enlarged veins are situated mainly on the lateral aspects of the abdominal wall, and neither ascites nor jaundice has been noted. The widespread occlusion of deep veins in this case must almost certainly be due to thrombosis, but there is no clue to why it occurred in early life.

FIG. 6.—Case 3. Venogram, left side: the femoral vein cannot be seen. The width of the external and common iliac veins is reduced and their outline is irregular. Dilated tortuous collateral veins are well shown.

It is rare for thrombosis of the inferior vena cava to present with a clinical picture of nephritis. Derow *et al.* (1939) have reported a case similar in many respects to Case 2, but the tempo of its course was slower. It concerned a boy aged 15, who, after an initial attack of nausea, vomiting, and anorexia, experienced pains in the costovertebral region. His urine contained albumin, some red and white blood corpuscles, and casts. He later developed oedema of his legs and ascites, and his blood proteins were low, with reversal of the albumin/globulin ratio. Enlarged veins then appeared on the front of his abdomen and chest. He died 22 months after the first symptoms had appeared, and necropsy revealed extensive thrombosis of the inferior vena cava, renal veins, portal veins, and proximal parts of the mesenteric veins. Some recanalization of the thrombosed portions of the affected vessels was present.

It is known that thrombosis of the inferior vena cava usually starts in the lower third and spreads upwards. It is rare for the clotting to begin in the renal veins and then spread to the vena cava. Accounts have been written of primary renal venous thrombosis in infancy by Morison (1945) and Fallon (1949), but in none of their cases was the vena cava involved. It is difficult to state the true reason for thrombosis occurring in this case. Dehydration, marasmus, and sepsis have all been postulated as causes, but there must be some other factor, otherwise the condition would occur much more frequently.

Case 3 is one of partial obstruction of the left common femoral and iliac veins, but it is included in this article to exemplify the difficulty of differential diagnosis. Without the help of a venogram the diagnosis would have remained one of obstruction of the inferior vena cava. Keller (1949) has reported a case of deep venous thrombosis occurring at the junction of the right femoral and saphenous veins in a male infant. The infant's grandfather forcibly compressed the upper parts of the legs while holding him during a ritual circumcision. The obstruction in the femoral vein was demonstrable as a filling defect in the venogram. Again, it is difficult to state the cause of the thrombosis in Case 3. If it had been present on the right side one would have tended to blame the intravenous drip. It is true that thrombosis spreads over from one common iliac vein to that on the other side, but the right common iliac vein in this case shows a normal outline in the venogram.

In view of the fact that a venogram was not done in Case 1, criticism might be levelled at the diagnosis. However, the superficial veins are so markedly dilated and extensive over the abdomen and chest that it is justifiable to assume that the inferior vena cava has been involved.

Obstruction of the inferior vena cava sounds a catastrophic event, but judgment of its gravity has been coloured by the fact that it is so often associated with diseases which of themselves may be fatal. Shattock (1913) described the case of Dr. W. Rivers Pollock, who, while a student at Cambridge, won the 120 yards hurdle race against Oxford. He held his breath all the time he was running, and while lying on the grass after the race he noticed a pain in his back. Oedema of the legs and lower part of the trunk soon followed, and a few days later dilated veins appeared on his legs and abdominal wall. His urine contained albumin. This occurred when he was 24 years old, but he lived for a further 25 years and spent a busy life in obstetric practice. At necropsy the inferior vena cava was found to be a flat ribbon-like structure from the hepatic veins downwards, both renal veins being occluded at their junction with the vena cava.

Another case of thrombosis of the inferior vena cava following exertion has been described by Foster, Brouwer, and Kurtz (1941), while Keen (1940) has described a case of thrombosis of the inferior vena cava, discovered in a dissecting-room subject aged 71. The former patient led a quite strenuous life, while the latter was not known to have suffered any disability attributable to caval obstruction. Nylander (1941) has for seven years observed a boy aged 9 who developed thrombosis of the inferior vena cava following osteomyelitis of the pelvis, and found his development to be quite normal.

We have felt justified in giving a good and hopeful prognosis to the parents of Cases 1 and 3, and the children's activities have not been restricted. It is possible that later in life, if pregnancy occurs, the condition might be aggravated by pressure of the gravid uterus on the deep collateral veins. Varicose ulcers may also be a troublesome feature in later years. The child described in Case 1 realizes that the appearance of her abdomen differs from that of her playmates, but so far it has not caused any psychological difficulties and she plays happily amongst other children, even when the prominent veins are in full view.

Summary

Two cases of obstruction of the inferior vena cava and one case of obstruction of the right common femoral and iliac veins are described in children. One patient has died, but the other two continue symptom-free and in good health. The subject is briefly reviewed.

We wish to thank Professor Norman B. Capon for permission to publish Case 1 and for his guidance in the preparation of this article. We also thank Dr. John D. Hay for his valuable help. Thanks are due to Dr. W. E. Crosbie, medical superintendent, Alder Hey Hospital, for permission to publish Cases 2 and 3, and to Mr. R. R. Green for the clinical photographs.

The progress made in the provision of special schools for handicapped children since the end of the war were given recently by Mr. George Tomlinson, the Minister of Education, who was speaking in Manchester at a conference of the Special Schools Association. He said that local education authorities had provided 121 new special schools during the last five years, 90 of them boarding schools. As a result, the number of children in special schools had increased in the last four years from 38,500 to over 47,000. Authorities had also opened 47 boarding homes for about 1,000 children and in addition were providing home tuition for another 1,000 children. They were making increasing use of independent special schools when places in their own schools were not available: about 600 handicapped children were being provided for in this way. The supply of teachers for special schools had kept pace with the increase in the number of handicapped children provided for, and there had been an increase of over 30% in the number of such teachers during the last 4½ years. Mr. Tomlinson agreed that there were shortages of special-school accommodation for nearly all categories of handicapped children. The provision of new special schools had to compete with the provision of schools for normal children, but he thought local education authorities were doing a good job of work.

SOME UNUSUAL BUT INSTRUCTIVE SURGICAL EMERGENCIES

BY

H. D. MOORE, F.R.C.S., F.R.C.S.Ed.

Surgical Tutor, the General Infirmary, Leeds

If the cause of acute symptoms is clear, proper treatment is begun without delay, including, if necessary, a well-placed incision. Only too often, however, the diagnosis is in doubt even in common conditions; and in uncommon ones the delays and difficulties are obviously increased.

The delays which occur are shown by the following eight cases, only two of which were admitted to hospital within twelve hours of the onset of the symptoms, two being delayed for two days, two for three days, one for seven days, and one for ten days. The difficulties in diagnosis are seen in the case reports which follow, and in the literature: for instance, in strangulation of the stomach in a diaphragmatic hernia operation is commonly delayed until gangrene has occurred (Warren, 1919), in biliary peritonitis a wrong diagnosis is usual (Fifield, 1926), and in strangulation of gut through a hole in the greater omentum a correct diagnosis has not been reported.

The following histories, with a brief discussion of the literature, are therefore presented in the hope that they may help in the diagnosis and treatment of future cases.

Strangulated Diaphragmatic Hernia

Case 1

A boy aged 16 was admitted on December 16, 1949, complaining of central abdominal pain, vomiting, and constipation for 10 days. His vomiting, which had occurred several times each day, consisted only of small amounts of greenish fluid; but his abdomen had become increasingly distended and he had passed neither faeces nor flatus for five days.

In June, 1949, he had had a similar attack lasting for three days, accompanied by pain in the left shoulder, but this attack had been mild and its history was not elicited until later. At the age of 16 months he had had a thoracotomy at the Radcliffe Infirmary for a left-sided empyema, and it was noted at the time that the tube was low and did not drain well. He had otherwise been in good health with normal appetite and bowel actions.

On examination (T. 98° F.—36.7° C.; P. 100; R. 20) his tongue was moist, his skin elastic, and he did not look ill, but his abdomen was very distended, with "ladder patterns" of bowel and visible peristalsis. There was a scar 2¼ in. (6.25 cm.) long in the left ninth intercostal space in the posterior axillary line. No other abnormality was found in the chest or elsewhere.

A plain radiograph of the abdomen and chest showed gross small-bowel dilatation and fluid levels, the stomach below the diaphragm in its normal position, and a small loop of bowel with a fluid level within the chest, in a postero-lateral position.

Gastric suction and intravenous fluids were begun and the abdomen was opened through an upper left paramedian incision. It was found that the splenic flexure of the colon had entered a diaphragmatic hernia to the left of the oesophagus and was tightly held, but the exposure was inadequate because of the distended gut. The incision was therefore continued across the rectus and into the tenth intercostal space, and the diaphragm was divided as far as the hernia, the procedure being extrapleural. It was then seen that omentum as well as gut had herniated and that the omentum was adherent to the sac, which was not lined with peritoneum. The omentum was divided, the gut was reduced and found to be viable, and the diaphragm and wound were repaired with continuous sutures of braided nylon.

The boy's condition caused some anxiety for 48 hours, but then became satisfactory and he went home on the eighteenth post-operative day. A barium meal and enema two months later showed no recurrence of the hernia.

Case 2

A woman aged 36, five months pregnant with her first child, was admitted as an emergency case on February 1, 1950. She had complained for one week of pain in the left hypochondrium through to the back, made worse by deep breathing, together with regurgitation of her food and slight shortness of breath on exertion. There were no other symptoms, but she had suffered from occasional attacks of epigastric discomfort and flatulence after meals for some years.

On examination (T. 98° F.—36.7° C.; P. 102; R. 24) she looked well, and was not short of breath or cyanosed. Her trachea was to the right of the midline, the apex beat to the right of the sternum, and the left side of the chest moved less than the right. There was dullness at the left base and breath sounds were absent, but neither bowel sounds nor splashing were heard in the chest, and the abdomen showed no abnormality.

Radiographs of the chest showed the heart displaced to the right and a large translucent area in the left side of the chest which, at first sight, appeared to be a cyst of the lung; a barium meal, however, showed it to be stomach within the chest, but with the cardio-oesophageal junction and the pylorus in their normal positions. It is of interest to note that when the patient was lying flat and on her right side some air and barium passed on into the duodenum.

On February 6 there was some lower abdominal pain and pain in the left shoulder; regurgitation of food continued. Next day the patient was retaining no food, so that laparotomy was decided upon.

Upon opening the abdomen a localized collection of pus and barium was found around a perforation of the cardio-oesophageal junction at the point where it was compressed by the hernial orifice in the diaphragm. The perforation was repaired, a tube was put down to the area, and a jejunostomy was done, but her condition was unsatisfactory after the operation. She miscarried on February 10 and died on the 13th.

Post-mortem examination revealed a diaphragmatic hernia, about 3 in. (7.5 cm.) in diameter, to the left of the oesophagus, and through it had passed almost the whole stomach, the splenic flexure of the colon, and the spleen. The stomach and colon were tightly compressed by the margins of the hole in the diaphragm, and there was an area of necrosis of the stomach at the site of the perforation (presumably from pressure of the hernial margin) and some blackening of the colon where it passed through the ring. There was no peritoneal lining to the hernial sac, which occupied two-thirds of the left side of the chest.

Comment on Cases 1 and 2

In the diagnosis of Case 1 it was obvious that there was a low intestinal obstruction, but its origin was not at first clear, although the thoracotomy wound had been observed. That a diaphragmatic hernia might follow thoracotomy in infancy was not considered until the *x*-ray films had been seen; and the case illustrates not only the possibility of such a hernia but the value of a plain radiograph of the abdomen, including the lower chest, in all cases of intestinal obstruction.

The actual cause of the hernia must remain doubtful. Bryan (1921) and Harrington (1948) state that a diaphragmatic hernia may follow an empyema or the use of a drainage tube near the diaphragm, but quote no cases; nor has it been possible to find cases reported. It seems more probable that the diaphragm was injured at the time of operation, because it was noted that the tube was very low in the chest and never drained properly; and it is well known that injuries to the diaphragm heal badly. Indeed, Guthrie (1855) stated that they never heal, although this has been shown to be incorrect (Greig, 1919; Meyer, 1919).

Case 2 illustrates one way in which a diaphragmatic hernia may present—that is, with repeated vomiting without other symptoms and with signs in the chest which are not obviously due to the presence of gut (Gaudier and Labré, 1918) and in which the *x*-ray findings at first sight suggest a pulmonary lesion or a raised diaphragm (Carter and Giuseffi, 1948).

I have been unable to find reports of any cases of intraperitoneal perforation of the stomach at the diaphragmatic ring, presumably from pressure necrosis, but Gaudier and Labré record a case which ended fatally from repeated haematemeses and was found at necropsy to have bled from an ulcer. The ulcer was on the lesser curvature of the stomach, most of which had herniated through the diaphragm into the chest, and was at the site of the firm diaphragmatic ring and away from the usual ulcer sites; the authors considered it to be due to the pressure of the ring.

Those diaphragmatic herniae which come to the surgeon as emergencies (Astley Cooper, 1804; Guthrie, 1855; Gaudier and Labré, 1918; Warren, 1919; Bryan, 1921; Harrington, 1948; Carter and Giuseffi, 1948; Borrie and Foreman, 1948) are usually the result of penetrating wounds, but congenital herniae and those resulting from crushing injuries also strangulate. The injury is nearly always on the left side, and most of the traumatic herniae which strangulate do so within three years of wounding, but may do so many years later. Even those on the right may obstruct (Astley Cooper, 1804).

Most of these patients have had no warning of impending trouble and are in good health at the time of strangulation; but about one-third have had premonitory symptoms, and many of these are in poor condition from voluntary starvation because of pain with their meals and vomiting. These warning symptoms can be divided into four groups: (*a*) Abdominal, of which the chief are "indigestion," pain in the epigastrium and other regions, vomiting, and constipation; (*b*) respiratory, such as dyspnoea on exertion or after meals; (*c*) cardiac, such as palpitations and precordial pain; (*d*) recurrent fever. Many of these patients have been treated as malingerers or have had a previous operation without any relief of their symptoms.

The actual obstructive attack is usually brought on by straining, coughing, or a meal. It is heralded by colic or upper abdominal pain which may radiate to the shoulder, and by vomiting; and it is well to bear in mind that these cases may present in two ways—the one being as an ordinary intestinal obstruction (Case 1), and the other as a strangulation of the stomach characterized by frequent vomiting and a flat empty abdomen (Case 2). Other signs may be entirely absent (Case 1), or may consist of dullness and diminished movement of the left side of the chest, with an apex beat which is displaced to the right (Case 2), and perhaps bowel sounds or splashing in the thorax. If the strangulation has lasted long enough, as is common because of the difficulties in diagnosis, there will be a serosanguineous effusion in the chest cavity, sometimes in large quantities, with dyspnoea, cyanosis, and tachycardia, which are apt to lead to a diagnosis of a purely pulmonary lesion.

The *x*-ray findings may consist of a heart displaced to the right, obvious bowel or stomach in the chest, or an apparently raised diaphragm or of appearances as in Case 2. If the effusion is big enough it may mask the underlying lesion. And, finally, the patient may be so ill that an *x*-ray examination is not attempted.

Treatment is operative. Conservative measures always result in death, as is so well described by Guthrie; but even with operation, unless undertaken very early, the prognosis is poor.

The incision can be abdominal (Harrington advises one parallel to the costal margin for the left side), which is most satisfactory if the bowel is not distended and if the liver is mobilized by division of the left triangular ligament; it can be thoracic, which is necessary on the right and good on the left because the contents of the hernia are usually adherent to the margins of the opening in the diaphragm or to the praecordium or chest wall, although it has the disadvantage, particularly if resection of gut is needed, of opening the pleura (but it is necessary to remember that the pleural cavity will usually communicate with the abdomen when the gut is withdrawn, whatever incision is used); or it may be abdomino-thoracic, which gives good exposure and can remain extrapleural, as in Case 1.

Biliary Peritonitis

Case 3

A man aged 59 had on the morning of December 7, 1948, an attack which his doctor diagnosed as acute cholecystitis. He was admitted on the evening of the 9th with a temperature of 101° F. (38.3° C.), pulse 120, and respirations 30 a minute. He was ill, with a dry tongue and lax skin and an obvious generalized peritonitis, which was thought to be arising from a ruptured empyema of the gall-bladder, although there were no localizing signs. He was not jaundiced.

Gastric suction, intravenous fluids, and chemotherapy were begun, and the abdomen was opened when his condition was a little better. The gut was found to be reddened and distended and there was much free bile in the peritoneal cavity. The gall-bladder, cystic duct, and common bile duct were thick and oedematous as far as the foramen of Winslow, where there was a hole 1 cm. in diameter in the common duct; below this the duct felt normal. No stones were found in the gall-bladder or ducts, or lying free; nor was there any localization of the perforation or of the bile by adhesions or omentum. The gall-bladder, which contained bile of normal appearance, and the common duct were drained.

Progress was not satisfactory, and on December 18 an upper intestinal fistula developed. On December 24 his abdomen burst. The leaking bowel presented and was found to be jejunum; this was repaired. On January 8 the wound burst and was again repaired, and on January 17 the patient died.

Case 4

A woman aged 62 was admitted as an emergency on February 24, 1949 (T. 97.4° F.—36.3° C.; P. 70; R. 20). Her history and physical findings were suggestive of acute cholecystitis of some 12 hours' duration, and she had suffered for some years from "indigestion" and flatulence after meals, especially with fatty foods.

Six hours later her pain was more severe and was generalized, as was her tenderness, and there was some distension of the abdomen; but her general condition, pulse, temperature, and respiration rate were unchanged. She clearly had a generalized peritonitis, but the normal temperature and pulse and the lack of toxicity made its origin doubtful, as it was not realized at the time that a biliary peritonitis can present in this way.

Her abdomen was opened and was found to contain much normal-looking bile, of which 20 oz. (568 ml.) was aspirated. There were a few adhesions between the gall-bladder and duodenum, but a close examination of the biliary system revealed no other abnormality. No site of biliary leak could be found.

Drainage of the gall-bladder was decided upon, and it seemed reasonable to do this internally rather than externally. A cholecyst-jejunostomy was therefore done.

Her post-operative course was uneventful and she was discharged on the seventeenth post-operative day. She has remained well up to the time of writing—more than a year later.

Case 5

A man aged 79 was admitted as an emergency on October 4, 1949 (T. 99° F.—37.2° C.; P. 80; R. 25), with an obvious generalized peritonitis and faint jaundice. His pain had begun 48 hours and his jaundice seven to eight days before admission. He was cyanosed, with gross venous congestion, and had a history of precordial pain with effort for some years, and breathlessness and swelling of the feet for one year. There was no past history suggestive of cholecystitis.

On opening the abdomen free normal-looking bile was found and some 25 oz. (710 ml.) sucked out. The gall-bladder was red, thickened, and distended, with one or two blackened areas but no perforation. No site of leakage was found, but the examination was cursory because of the patient's general condition. The gall-bladder, which contained bile normal in appearance and no stones, was drained and a second tube put into the region of the common duct.

The patient's cardiac condition remained precarious, and he died on the fifth post-operative day from heart failure.

Necropsy revealed no perforations in the biliary system; but there were several stones in the common bile duct, and gross myocardial degeneration.

Comment on Cases 3–5

Free escape of bile into the peritoneal cavity from perforation of an inflamed gall-bladder or bile duct (Case 3) is not only rare but a most serious affair. McWilliams (1912) found it to occur in only 0.9% of over 3,000 operations on the biliary system. In 90% of these the gall-bladder had perforated, and half of the patients died, but of those operated upon within 12 hours, with drainage of the gall-bladder and its site or with cholecystectomy, only 15% perished. The diagnosis of these cases can be most difficult, as is shown by 28 cases from the London Hospital, reported by Fifield (1926), of which 4 were diagnosed as intestinal obstruction, 3 as perforated peptic ulcer, 2 as high appendix abscess, and only 9 as acute cholecystitis; the rest were described as peritonitis of unknown origin.

In contrast to the severity of an infected biliary peritonitis is the escape of sterile bile as the result of an injury. Numerous cases have been reported and discussed (Ricketts, 1905; Wangensteen, 1926; Mentzner, 1934). These patients survive in good health for days or weeks, but they finally all die unless the bile is removed by frequent tappings or operation.

To complete the discussion of biliary peritonitis from an obvious source, it is of interest to mention post-operative leakage. Such a leak is usually harmless, but it can be a most serious matter. Cases described by Douglas and Grey Turner (1940) and Lewis (1940) were characterized by much post-operative pain in the right hypochondrium, followed, some 12 hours later, by profound shock. Lewis's case recovered rapidly when the collection of bile was drained; the other did not rally enough for laparotomy, and died.

Free bile in the peritoneal cavity without a perforation of the gall-bladder or bile ducts (Cases 4 and 5) is well recognized but is a rare and interesting phenomenon, and Case 4 is of particular interest because of the normal appearance of the biliary system (except for a few adhesions), and because the diagnosis could have been made from the rapid onset of peritoneal irritation and intestinal distension, without a rise in temperature and without the signs associated with a bacterial peritonitis.

Both cases are of interest in that they seem to support the view of Buchanan (1918) and Stenson (1937), based on a review of some 40 cases from the literature, that biliary peritonitis cannot be explained on any one theory. Thus Clairmont and von Haberer (1910) showed that ligation of the common duct in dogs will cause a biliary peritonitis without a perforation, and described a case following obstruction of the common duct in man. They suggested that the rise of pressure and distension may allow filtration of bile from an apparently normal gall-bladder in some unexplained way; but in Case 4 no obstruction was found, and certainly no distension of the gall-bladder or ducts. Blad (1917) suggested that, where there is obstruction of the ampulla of Vater, there may be a reflux of activated pancreatic juice into the gall-bladder, producing a digestion necrosis and permeability of its wall to bile, but without rupture (this can be produced experimentally in dogs). This theory would account very well for Case 5, but does not seem applicable to Case 4.

In some cases there may be a small perforation which cannot be found, especially if it is retroperitoneal (Nauwerck and Lübke, 1913; Buchanan, 1918; Cope, 1925). This is suggested by a case of Sohn's (quoted by Stenson, 1937) in which a needle was put into the common bile duct to locate it during an operation unconnected with the biliary system. The field was dry at the end of the operation, but the patient subsequently died of a biliary peritonitis. At necropsy the hole in the common duct was found only with the greatest difficulty. This theory might account for both cases, but it is difficult to believe that a considerable escape of bile would occur without at least some distension of the gall-bladder.

Finally, the leak may have occurred from rupture of a small duct on the surface of the liver (Buchanan, 1918; Smith, 1926), but no abnormality of the liver was seen, and the good result following cholecyst-enterostomy in Case 4 suggests that the leak was from the main bile duct system. Whether anastomosis of the gall-bladder to jejunum was a good idea remains to be seen, but the post-operative course was excellent, the patient has remained well for a year, and reports from the Mayo Clinic (Walters, Gray, and Priestly, 1948) and others (Peterson and Cole, 1948) suggest that cholecyst-enterostomy is a satisfactory operation.

Herniation of Gut, with Strangulation, Through a Hole in the Greater Omentum

Case 6

A woman aged 86 was admitted on January 5, 1949, complaining of a constant pain in the epigastrium and right hypochondrium for six hours. She had vomited four times, and her bowels had not been opened for 24 hours, but she had been passing flatus.

Her temperature was 97.6° F. (36.4° C.), pulse 89, and respirations 20 a minute, and she appeared to be neither ill nor distressed. Upon examination of her abdomen a tender indefinite intra-abdominal lump, about 5 in. (12.5 cm.) in diameter, which moved on respiration and was freely mobile, was found to the right of the umbilicus. No other signs were observed.

On the 6th her pain had gone and there was no further vomiting, but the mass was much more distinct. On the 7th she had a recurrence of pain, which was now severe. There was no vomiting and her temperature was 98° F. (36.7° C.), but her pulse had risen to 130 and her respirations to 30 a minute. Her abdomen was very tender to the right of the umbilicus, and rigidity of the abdomen rendered the lump impalpable. There was no distension.

Laparotomy was decided upon, and the abdomen was opened through a right para-umbilical incision. The intestines were not dilated. It was found that the greater omentum was attached in the region of the right internal inguinal ring (there was no hernia), and ileum had passed and strangulated through a hole in the omentum at the level of the umbilicus, forming a rounded mass. The gut was gangrenous; it was resected and end-to-end repair done; the omentum was freed and the hole repaired.

Her post-operative course was uneventful and she was discharged on the fourteenth post-operative day.

Case 7

A woman aged 53 was admitted on December 7, 1949, complaining of vague abdominal discomfort for some days and, beginning 20 hours before admission, severe central abdominal colic and vomiting.

Some hours after the start of the severe pain she was seen by her doctor, who diagnosed acute cholecystitis and gave her ¼ gr. (16 mg.) of morphine and 1/100 gr. (0.65 mg.) of atropine. This relieved her for some hours, but the pain recurred. She was then given 50 mg. of pethidine every four hours until her admission.

On admission her temperature was 98° F., pulse 100, and respirations 20 a minute. She was not in pain, but had a furred tongue, and there was localized tenderness and guarding over an area about 6 in. (15 cm.) in diameter to the right of the umbilicus. It was thought that an indefinite lump could be felt in this area, but the guarding made it difficult to be sure. The abdomen was flat.

When the effects of the pethidine had worn off, her colic and vomiting began again and her tenderness became more generalized. Intestinal obstruction was diagnosed and the cause tentatively suggested.

On opening the abdomen, conditions identical with Case 6 were found (except that the bowel was viable). The contracted state of all the intestines was striking. The offending omentum was dealt with and her post-operative course was uneventful.

Case 8

A man aged 68 was admitted to the General Infirmary, Leeds, on July 2, 1950, complaining of generalized colicky abdominal pain and vomiting for three days. His bowels had not acted during this period, nor had he passed any flatus. He had noticed constant abdominal pain and tenderness for about 12 hours, as well as the more severe spasms of colic.

On examination the temperature was 98° F., pulse 80, and respirations 20. The patient looked ill and had a dry furred tongue. His abdomen did not move with respirations, and was very tender and rigid all over, with shifting dullness in the flanks.

Rectal examination revealed a tense fluctuant swelling in the recto-vesical pouch, which was considered to be distended gut. No other abnormal physical signs were found.

Aspiration of the stomach and intravenous therapy were begun and the abdomen was opened. Much free blood-stained fluid was found, together with a tense segment of lower ileum, which had strangulated through a hole in the edge of the greater omentum and was lying in the pelvis. It was gangrenous and was resected, and a side-to-side anastomosis was done. The rest of the small bowel was only slightly distended.

The patient's post-operative course was uneventful, and he was discharged to a convalescent home on July 10.

Comment on Cases 6–8

Of the 25 cases of strangulation of gut through a hole in the greater omentum (22 listed since 1840 and three described above) all but three presented as typical acute intestinal obstruction of small bowel (Martzloff, 1930; Sanes and Postoloff, 1944; Hindmarsh, 1949). Of the 12 case histories which were available, one (Curran, 1869) showed acute localized tenderness and hyperaesthesia over the strangulated gut. Four cases (Lisanti, 1899; Sanes and Postoloff, 1944; Hindmarsh, 1949; and Case 7) presented with a tender palpable mass which was the involved bowel. Two cases had definite localized signs (tenderness and hyperaesthesia, Martzloff, 1930; a tender lump, Case 6), although neither presented as an intestinal obstruction. These signs would be expected from the pathology, for when the gut passes through the omentum it lies just behind, and is indeed held in contact with, the anterior abdominal wall, and when it becomes congested it should be palpable and must produce local irritation of the parietes. It should therefore be possible to suggest the cause of an acute intestinal obstruction of small bowel presenting with either of the above signs.

Considering Martzloff's case (where symptoms were present for at least nine days), Case 6, where a lump was present for at least two days before it finally strangulated, and Case 7, where the patient had had abdominal discomfort for some days before the final attack, it is evident that the bowel does not necessarily strangulate at once; but in none of the cases described could it have been long through the hole, for in none was it adherent to the omentum.

Summary

Two cases of strangulated diaphragmatic hernia are described. These illustrate the two ways in which a strangulated diaphragmatic hernia may present—that is, with or without premonitory symptoms and with or without signs in the chest, and as either a typical intestinal obstruction or as an obstruction of the stomach with a flat, empty abdomen.

Three cases of biliary peritonitis are recorded: one with a perforation in the common bile duct, and two with no demonstrable site for the biliary leak.

The theories of causation, and the treatment, are briefly discussed.

Three cases of herniation of gut, with strangulation, through a hole in the greater omentum, are reported. Such cases nearly always present as an acute strangulation of small bowel and often have localizing signs, so that a pre-operative diagnosis is possible.

Cases 1-7 were admitted to the Radcliffe Infirmary, Oxford, and Case 8 to the General Infirmary, Leeds. I would like to thank Dr. A. M. Cooke and Mr. Elliot Smith for allowing me to include Case 2, and Mr. D. A. Abernethy and Mr. H. W. Symons for permission to treat the remainder and publish this report.

FAMILIAL CRISIS IN ACHOLURIC JAUNDICE

BY

F. GRAHAM MARSON, M.B., M.R.C.P.
Senior Medical Registrar, General Hospital, Birmingham

M. J. MEYNELL, M.D., M.R.C.P.
Clinical Pathologist, General Hospital, Birmingham

AND

H. TABBUSH, M.B., D.P.H.
Senior Assistant, Medical Officer of Health, Smethwick

There are on record at least seven instances of spherocytic anaemia in which the haemolytic crisis occurred in a number of members of a family within a short interval (Murray-Lyon, 1935; Scott, 1935; Dedichen, 1937; Damashek, 1941; Lyngar, 1942; Horne *et al.*, 1945; Owren, 1948). We should like to present a series of four cases which occurred in a family of seven.

Case 1

Thomas C., aged 32, a zinc sprayer, on August 12, 1948, became giddy, had the "shivers," and went to bed. The next morning he awoke perspiring. He got up, but soon after developed dizziness and nausea. On the 14th his doctor considered him to be a case of catarrhal jaundice. Next day the patient arose and nearly collapsed. He was then sent to the Smethwick Fever Hospital as a case of typhoid fever. When seen he complained of abdominal pain. He had noticed that on several occasions his urine was dark.

On examination his temperature was 101° F. (38.3° C.), and pulse 80. The conjunctivae had an icteric tinge, and the spleen was enlarged and tender. Blood culture revealed no growth. A blood count on August 16 showed: red cells, 2,700,000; haemoglobin, 55%; colour index, 1; white cells, 2,300 (polymorphonuclears 50%); packed cell volume, 24%; mean cell volume, 88 μ^3; mean corpuscular haemoglobin concentration, 33%. The urine contained no urobilin.

The patient was transferred to the General Hospital, Birmingham, on August 19 under Professor Thomson. He was symptom-free and slightly icteric; the spleen was two finger-breadths below the costal margin; and his knee-jerks were diminished. Otherwise no abnormal physical signs were found. On the day of admission his blood count was as follows: red cells, 1,900,000; haemoglobin, 40%; colour index, 1.06; white cells, 6,300 (neutrophil polymorphonuclears 53%, eosinophils 4%, basophils 1%, lymphocytes 28.5%, monocytes 11%, metamyelocytes 1.5%, Türk cells 1%); packed cell volume, 15%; mean cell volume, 80 μ^3; mean corpuscular haemoglobin concentration, 37%; the red cells showed anisocytosis and spherocytosis; reticulocytes, 0.1%—two days later they were 0.4%.

The Donath-Landsteiner and acid haemolysin tests were negative. Agglutinations for leptospires were negative. Coombs's test was negative. The patient was Group O rhesus-positive. Urine at this time showed large amounts of urobilinogen. The serum bilirubin was 0.7 mg. per 100 ml.; direct van den Bergh negative; blood urea, 22 mg. per 100 ml.; Wassermann reaction doubtful; Kahn test negative.

On August 21, nine days after the onset of illness, a sternal puncture revealed:

		%		Normal %
Polymorphonuclears	Neutrophil	28·00		20–50
	Eosinophil	1·50		0–4
	Basophil	0·25		0–1
Metamyelocytes	Neutrophil	22·50		2·8–12
	Eosinophil	0·50		0–2·5
	Basophil	—		—
Myelocytes	Neutrophil	15·50		2–8
	Eosinophil	—		0–1
	Basophil	—		—
Premyelocytes		0·25		0·5–5
Myeloblasts		—		0–2·5
Lymphocytes		7·00		5–20
Plasma cells		1·00		0–1
Reticulum cells		1·75		—
Normoblasts	Late	0·50		7–19
	Intermediate	2·25		4–15
	Early	11·75		
Macronormoblasts	Late	0·25		—
	Intermediate	—		—
Proerythroblasts		6·75		0–4
Haemocytoblasts		—		0–1

Megakaryocytes were normal in number and appearance. The marrow showed some slight increased cellularity and a shift to the left of the erythroid and myeloid series.

On August 23 his blood count showed a marked change: red cells, 2,810,000; haemoglobin, 50%; colour index, 1.08; white cells, 16,100 (polymorphonuclears 52.5%, eosinophils 0.5%, lymphocytes 16.5%, monocytes 4.5%, premyelocytes 0.5%, myelocytes 4.0%, metamyelocytes 21.5%); reticulocytes, 16.2%; platelets, 439,000 per c.mm. A fragility test showed: commencing haemolysis, 0.60% saline (control, 0.40% saline); complete haemolysis, 0.32% saline (control, 0.32% saline).

By August 26 his reticulocytes were 25.2%, and on the 30th his haemoglobin had risen to 72%. A fragility test repeated several weeks later showed: commencing haemolysis, 0.64% saline (control, 0.44% saline); complete haemolysis, 0.44% saline (control, 0.32% saline).

Case 2

Thomas C., jun., a schoolboy aged 10, became ill with vomiting on August 1, eleven days before his father. He complained of headache and pain in the eyes, and was noticed to become rapidly pale. He was admitted to the fever hospital with a diagnosis of meningitis.

On examination he was extremely pale and had a temperature of 99.4° F. (37.4° C.). No other abnormal signs were found. The blood culture was sterile. His blood count five days after the beginning of the illness was as follows: red cells, 1,500,000; haemoglobin, 30%; colour index, 1; polymorphonuclears, 77%, with 3% myelocytes. He was transfused with two pints (1.14 litres) of blood, and his condition rapidly improved. The spleen was not palpable. He was transferred to the General Hospital on August 24.

On admission his blood count was: red cells, 3,910,000; haemoglobin, 76%; colour index, 0.97; white cells, 14,400 (neutrophil polymorphonuclears 75%, eosinophils 3%, lymphocytes 17.5%, monocytes 4.5%). Films showed anisocytosis, spherocytosis, and some polychromasia. Reticulocytes, 8.4%; platelets, 352,000 per c.mm. He was Group O, rhesus-positive. Coombs's test, the acid haemolysin test, Donath-Landsteiner test, and Wassermann reaction were negative. A fragility test showed: commencing haemolysis, 0.56% saline (control, 0.44% saline); complete haemolysis, 0.32% saline (control 0.28% saline).

The urine showed an excess of urobilin. Serum bilirubin was 1.1 mg. per 100 ml.; blood urea, 72 mg. per 100 ml.; and leptospiral agglutinations were negative. The sternal puncture showed increased cellularity. There was no other abnormality.

Cases 3 and 4

Case 3.—Valerie C., aged 6, first had abdominal pain and vomiting on August 10. She was admitted to the fever hospital on the 16th and found to be extremely pale, with a slight icteric tinge. Her temperature was normal. A blood count showed: red cells, 2,700,000; haemoglobin, 40%; colour index, 0.74; white cells, 20,600 (polymorphonuclears 50%, metamyelocytes 21%, myelocytes 7%). Anisocytosis, poikilocytosis, and polychromasia were present. Thirty-two normoblasts were seen in 200 white blood cells.

Case 4.—Baby Irene, aged 2, was noticed to be off colour for a few days at this time, but her condition did not cause undue alarm. A film done on September 1 showed anisocytosis, spherocytosis, and polychromasia. No other investigations were made.

Other Members of the Family

Mrs. C. and two daughters, Joan and Mary, were examined as out-patients. Fragility tests, van den Bergh test, reticulocyte count, and stained films were all negative. None of these three had an attack like the other members. A number of relations of Thomas C., sen., were examined. No evidence of spherocytosis was discovered apart from a slight but distinct spherocytosis in his mother.

The family has been kept under observation for over a year. Apart from an increased reticulocyte count and spherocytosis in the affected members, there is nothing to report.

Discussion

Owren (1948), who reports a series of crises occurring in a family within a short time of each other, gives the most complete observations yet published. In one patient, seen before the crisis began, he was able to study the events throughout. He concludes, with justification, that the crisis should not be called haemolytic, but aplastic. On the fourth day the red cell precursors had almost completely disappeared from the marrow. It was packed with myeloid cells showing maturation arrest with a diminution in segmented polymorphs. The megakaryocytes appeared normal in numbers and appearance. He states that in the crisis the output of urobilinogen in the urine diminishes, as does the serum icteric index. The degree of diminution would obviously depend on the length of the crisis. The crisis is marked by pallor and not icterus. In the case of Thomas C., sen., the interesting features are: when first seen he had a low white count and the urine showed no urobilin; when seen by us his reticulocytes were 0.1% and on the eleventh day after the onset they were 16.2%. This would appear to coincide with the evidence of Owren.

Dacie and Mollison (1943) have shown that the life-span of the red cell in this condition is less than 14 days. If there is marrow aplasia the red count should be halved in a week. During the crisis some azotaemia results, and blood ureas up to 160 mg. per 100 ml. are recorded. The cause of the latter, he suggests, is due to renal anoxia.

Dameshek and Bloom (1948) describe similar events in a case of haemolytic anaemia; unfortunately there was no familial evidence of the disease. They claim that the erythroid cells show maturation arrest in the proerythroblast stage at the height of the crisis. It is quite possible that if this case had been studied earlier in the crisis a picture not unlike that reported by Owren might have been found. These authors emphasize the point that the red cells in the peripheral blood were predominantly spherocytic during the crisis, and subsequently, with recovery, there was evidence of macrocytosis and spherocytosis. They use this as evidence for the view that in the crisis there is increased activity of a hypothetical haemolysin producing spherocytes. This assumption is obviously unsound; for if, as had been shown, there is a gross diminution in reticulocytes in the peripheral blood during the crisis the red cells will to a large extent be spherocytes.

Dameshek would explain the crisis as a combination of hypersplenism and a hypothetical haemolysin. Spherocytosis can be produced experimentally by introducing anti-red-cell sera, and is also found in acquired haemolytic anaemias in which a haemolysin can be demonstrated by the Coombs test. Not all acquired haemolytic anaemias showing evidence of a haemolysin produce spherocytosis.

A spherocyte is an old cell. The ageing process may occur rapidly, as in haemolytic anaemias. It is possible to conceive of other factors producing rapid ageing apart from haemolysins. Presumably in familial acholuric jaundice this is an inherited trait. Removal of the spleen does not alter the state of the red cell, which continues spherocytic. Crises usually disappear. In a very few instances recurrences have taken place. It seems acceptable that a condition of hypersplenism exists in this disease and that spherocytosis is a congenital abnormality of rapid ageing which has nothing to do with the activity of haemolysins.

The cause of the crisis still remains to be elucidated. Certainly, when a number of cases occur in a family it would point to an infection having an "incubation period." The common occurrence of gastro-intestinal symptoms—for example, nausea, vomiting, diarrhoea, abdominal pain—would fit in with an intestinal infection. It is known, however, that the haemolytic process, as produced experimentally, will cause a rise in temperature.

Summary

A series of crises is recorded in a family, four members of which were shown to have spherocytic anaemia of the familial type. All but one recovered spontaneously. Transfusion of two pints of blood was required in one case.

We wish to thank Professor A. P. Thomson for permission to publish; Dr. R. Gaddie for biochemical examinations; Dr. W. Weiner for rhesus typing and the Coombs tests; Miss E. Tacon, senior technician, for carrying out numerous haematological investigations; and Miss P. M. Weight, secretary, for her efforts in compiling and typewriting.

The National Smoke Abatement Society celebrated its 21st birthday by holding its annual conference at Margate on September 27–29. In addition to discussions on railway smoke, and on domestic smoke prevention, particularly in the new towns, an afternoon was devoted to two papers on respiratory disease and atmospheric pollution. In one of them, Mr. R. E. Waller, of the Department of Pathology at St. Bartholomew's Hospital, pointed out that such carcinogenic substances as arsenic and 3:4-benzpyrene are known to occur in smoke from burning coal and in domestic soot, and described experiments to measure the 3:4-benzpyrene concentration in the atmosphere at different times of the year. It is highest during the winter, especially during fog, when the concentration may rise to 33 μg. per 100 cubic metres of air, and down to 1–2 μg. in the summer. It seems fairly certain that the source is the inefficient combustion of coal in the ordinary domestic fire, rather than the chimneys of properly working industrial furnaces and power stations, and the amount of benzpyrene in road dust and motor vehicle exhaust smoke is quantitatively small compared with that from coal. Atmospheric benzpyrene is present in the air in smoke particles and not appreciably as free vapour, and it is therefore important to know the size of these particles before being able to estimate the chance of the carcinogen reaching the lung tissue and being retained there. Until this fact is available, the relation of smoke to cancer of the lung will remain unsettled.

INTERSTITIAL EMPHYSEMA IN MEASLES

BY

J. J. LINEHAN, M.D., D.P.H., D.C.H.

Medical Superintendent, Croydon Isolation Hospital

If judged by the nature and limited number of references to it in the medical literature, the above complication of measles would appear to be very rare. I have therefore been prompted to report the occurrence of three cases at Croydon Isolation Hospital within a period of little over a year.

Case Reports

Case 1.—A girl aged 6 developed measles on January 28, 1949, the rash appearing on February 3. Interstitial emphysema of the chest wall was recognized by the practitioner in attendance on February 5 and admission to hospital was sought. On admission the emphysema was found to be of moderate degree, extending over the greater part of the left side of the chest wall and slightly into the left side of the neck along the line of the trachea. It was not sufficient to cause any obvious swelling of the tissues affected. There was no respiratory distress. Rhonchi were audible over the entire chest, but were of a high-pitched whistling type over the upper part of the left lung. (I believe that the latter phenomenon was in some way related to the source of the emphysema.) There were no other noteworthy features except that the measles rash, which was still well marked on admission, was of the type in which haemorrhagic effusion had occurred into the skin lesions—not in itself an uncommon phenomenon. The patient had a troublesome though not exceptionally severe cough. The emphysema was maximal on admission and thereafter absorbed rapidly so as to become imperceptible within four days. Other chest signs and symptoms cleared up with similar rapidity. Sulphadimidine by mouth was the only treatment given.

Case 2.—A boy aged 5½ was admitted late at night on March 20, 1949, as an emergency case because of respiratory distress. The illness began on March 14 with the usual catarrhal symptoms. The measles rash developed on the 18th. There was a history of persistent cough following influenza in the previous December. On admission a well-marked interstitial emphysema extended over both sides of the chest wall and upwards through the neck into the tissues of the cheeks. There was obvious swelling of the neck and face, especially on the left side. A moderate degree of dyspnoea and slight cyanosis were present. The patient had a cough which was not unduly troublesome, and scattered rales were heard throughout the chest. A fading morbilliform rash and measles stomatitis conformed to the stage of the illness. Besides giving sulphonamides, treatment in an oxygen tent was considered advisable. As in Case 1, there was immediate and rapid improvement. The oxygen was discontinued the next morning, and five days later no detectable emphysema was present. Except for the subsequent development of tonsillitis and otitis media, recovery was uneventful.

Case 3.—A boy aged 5½ was admitted on February 17, 1950, as a case of measles and pneumonia. The measles began on February 7, the rash appearing on the 11th. On admission the skin still showed the staining of a morbilliform rash and the mouth was still inflamed. Interstitial emphysema extended over the entire left side of the chest and upwards on each side of the trachea. The patient had an irritable cough and a cyanotic tinge, but was not dyspnoeic. I could not definitely determine whether there were any adventitious sounds apart from those arising from the emphysema. Again the subcutaneous emphysema cleared up rapidly from the time of admission and was fully absorbed by February 23. Rales were audible in the left base until March 2 and may have been related to the emphysema-producing lesion. An *x*-ray photograph of the chest showed no further abnormality apart from the appearance of air in the chest wall.

Discussion

Some textbooks on infectious diseases make no reference to interstitial, subcutaneous or surgical emphysema as a complication of measles, while those that do refer to it treat it as a very rare complication.

Goodall (1928) states : "As very rare complications [of measles] I have met with cases of nephritis, endo- and peri-carditis, parotid abscess, cellulitis with or without sloughing, and extensive (surgical) emphysema of the trunk and neck. (One case—the patient a boy of 6 years—had bronchitis with severe attacks of coughing : he recovered.)"

Rolleston and Ronaldson (1939) state : "Subcutaneous emphysema is another infrequent occurrence. It may be associated with bronchopneumonia or develop apart from any gross pulmonary lesion, when it has been attributed to rupture of the alveoli, bronchi, or larynx as the result of violent coughing. Ronaldson (1927), in reporting two cases in which cough was not a feature, suggested that weakening of the alveolar wall by toxic action rather than by over-distension was the usual explanation of this occurrence in measles."

Price (1947) states : "Rarely, mediastinal and subcutaneous emphysema have occurred."

In none of my cases was the cough particularly severe, which would confirm Ronaldson's suggestion that the cough can produce this effect only when combined with some pathological process in the respiratory tract. In this connexion, I think that the description of "autemphysema" in the *British Medical Journal* of January 14 and February 4, 1950 (pp. 105, 308), is suggestive. It is described how surgical emphysema is self-induced by malingerers by wounding the buccal mucosa and strongly distending the cheeks with air.

Measles has a well-known capacity for producing ulceration of mucous membranes, and such ulcers could act similarly to the self-induced trauma of the malingerer. I feel that some such discrete ulceration in the respiratory tract is a more probable source of air entry than a weakening of the alveolar walls by toxic action as suggested by Ronaldson. Cases in which measles toxaemia damaged the alveolar walls might be expected to produce more general evidence of lung involvement than was present in the cases I have described. The involvement of the chest wall in each case would indicate that the air did escape from some part of the respiratory tract within the lung, the subsequent spread being via the root of the lung and mediastinum to the tissues of the chest wall and neck, extending in one case to the face.

In the one case in which the face was involved, I think that origin from the buccal mucosa can be excluded. There was no evident lesion in the mouth. Also, in the description of cases produced by mouth injuries to which I have referred, the chest wall is not mentioned as being involved, though there was marked generalized swelling of the face and neck. I think, therefore, that in my three cases the causative lesion was intrapulmonary, probably a small ulcer in one of the larger bronchi. A common feature in all three cases was that the amount of air in the tissues rapidly reached a maximum and thereafter was progressively absorbed. This also would favour the idea of a single small lesion capable of sealing up quickly. So far as it is permissible to draw any generalized conclusion from three cases, it would seem that a favourable prognosis can be given even when the initial condition is somewhat alarming.

Medical Memoranda

Contamination of Caesarean Wounds by Vernix Caseosa

The vernix caseosa, though one of the potential contaminants of the operative field in the caesarean operation, has for various reasons received as such little or no attention. Some of the neglect has been due to a belief that because the vernix is sterile it is therefore innocuous, some to a proper preoccupation with the problems of contamination by pyogenic organisms. That the vernix is not, however, an entirely innocuous contaminant is illustrated by the events that follow the rupture of an ovarian dermoid cyst. Such an accident, whether spontaneous, puerperal, or operative, is succeeded quite rapidly by a severe peritoneal reaction, and this usually in turn by a secondary invasion of the peritoneum by pyogenic organisms. Even a small amount of free sebaceous material may determine the reaction; in a recent case a severe lower abdominal peritonitis followed the rupture of a cyst no larger than a pullet's egg.

If the dermoid cyst that bursts is large, or if at operation much of the contents escape into the peritoneal cavity, a diffuse plastic peritonitis is certain unless a thorough cleansing is carried out at once. If any pockets of sebaceous material are left behind, then at the best the accident may be followed by the development of localized residual abscesses here and there throughout the peritoneal cavity, even under the diaphragm. Indeed, it may fairly be stated that a dermoid cyst is the one ovarian tumour which must not be tapped at operation.

Both the vernix caseosa and the contents of dermoid cysts, allied as they are in constitution, have similar properties as contaminants; both are unabsorbable and can be removed from the operation area only by a slow phagocytosis, a process carrying the certainty of adhesions and the chances of secondary infection. It seems likely that the escape of vernix into the peritoneal cavity or its inclusion in the abdominal incision is a potential cause of caesarean morbidity. This may be one of the reasons why caesarean section wounds seem more apt than others to heal by second intention; after a period of apparent healing by first intention pus is discharged from their lower end. On seeing an ugly caesarean scar it must be a common experience to draw the inference that the uterine scar must be equally unsound, an inference indeed almost expected from an examination candidate, yet to find at the repeat section that the secondary scar tissue is confined to the abdominal wall, the uterine scar itself being quite sound.

The amount of vernix soiling the operative field varies a great deal. For one thing the amount found covering the foetus varies for reasons that are as yet not understood. Again, the method by which the child is extracted has a bearing on the amount escaping into the wound. More escapes when the child is delivered by the breech or when any difficulty arises in the extraction. Large flakes escaping into the operative field are of course readily seen and removed. It is, however, important to look for and remove the smallest fragments and to recognize the potential contamination coming from the vernix which adheres to the gloves and swabs. Inspection of the surface of water used for rinsing the hands or the swabs will often show a film of liquefied vernix. All these are sources of contamination.

Once the importance of vernix spill is appreciated, suitable precautions come readily to mind. Packing off the peritoneal cavity before the uterus is opened is not a real protection, for once the foetus is extracted these packs always lie loose. "Tetra" cloths as usually employed do not protect the deep layers of the incision. The real protection is twofold; (1) a change of gloves, swabs, and rinsing water immediately the uterine incision is closed and before the peritoneum covering the lower segment is sutured; and (2) a meticulous removal of every fragment of the vernix caseosa from the operative field, the most likely places being the front of the broad ligaments and the lower angle of the abdominal incision behind the rectus sheath. If a transverse abdominal incision is used a careful inspection of the recess behind the lower flap of the sheath should be made. It is well, too, to wipe all the raw surfaces with a clean swab before any attempt at closure.

PERCY MALPAS, Ch.M., F.R.C.S., F.R.C.O.G.

Pethidine as an Adjunct to Nitrous Oxide and Oxygen Anaesthesia

Mushin and Rendell-Baker, in 1949, published a memorandum on the use of pethidine as a supplement to nitrous oxide and oxygen anaesthesia, a method which they had seen used successfully in America and had themselves adopted on 100 occasions. It appeared that this method might well be a useful innovation, and such has proved to be the case in the 150 administrations here recorded.

METHOD

The method suggested by Mushin and Rendell-Baker was adopted and has been adhered to throughout this series, although they themselves have on occasion given increased doses of pethidine.

The routine in the present series has been as follows : (1) Premedication has been by "omnopon" 1/3 gr. (22 mg.) and scopolamine 1/150 gr. (0.43 mg.) for all adults between the ages of 17 and 60 years; over 60 years, omnopon 1/6 gr. (11 mg.) and scopolamine 1/300 gr. (0.21 mg.). (2) Induction has been by a "sleep" dose of sodium thiopentone—usually between 0.2 and 0.3 g. is given in 5% solution. (3) Anaesthesia is begun with nitrous oxide and oxygen. (4) Pethidine is given in a dose of 25 mg. intravenously as soon as anaesthesia is smoothly established. (5) Tubarine or "flaxedil" is given at the requisite time should there be any undue movements of the patient or should great relaxation of the muscles be necessary.

This routine has been the standard in all cases except three. Of these, two were tough farm-labourers, and each had to have 0.5 g. of sodium thiopentone followed by 37.5 mg. of pethidine. The third was a girl who received 0.5 g. of sodium thiopentone originally, as she was to be examined under an anaesthetic before operation was decided upon.

The following table shows the nature of the cases which were selected as suitable :

Cases in the Series

Hernia (inguinal and femoral) ..	31	Hydrocele	2
Orthopaedic	19	Nephrolithotomy	1
Mastectomy (simple and radical)	12	Cystotomy	1
Varicose veins	10	Gynaecological; abdominal (hysterectomy, ovarian cyst, etc.)	27
Cystoscopy	3		
Prostatectomy (Millin's)	2		
Appendicectomy	10	Vaginal hysterectomy ..	1
Haemorrhoidectomy	3	Vaginal repair	13
Colostomy	4	Dilatation and curettage ..	7
Gastrectomy	1	Laparotomy	1
Circumcision (adult)	2		

A start was made with minor extra-abdominal cases, and gradually the scope was widened as more experience and confidence were gained. The method has now been adopted as almost routine except for the more difficult upper abdominal cases, such as gastrectomy. One gastrectomy is quoted here, but was not a complete success owing to the mistiming of a further dose of flaxedil, which led to the peritoneum being insufficiently relaxed for easy suture.

General Observations

Patients seldom suffer any side-effects from the use of pethidine. In a few cases there has been a marked reduction in the frequency, although not in the volume, of respiration. In two cases the respiration was reduced to seven a minute, and in one case to three. Adequate ventilation was easily obtained by "assisted respiration."

It is sometimes a little difficult to maintain adequate oxygenation combined with sufficient depth of anaesthesia during the earlier stages of the operation, but this is overcome by waiting a few minutes, allowing time for the patient to become stabilized on nitrous oxide, and giving an increased percentage of oxygen.

No significant alterations of blood pressure have been recorded as due to pethidine.

One outstanding feature is that apparently the sphincter ani becomes sufficiently insensitized to allow of such operations as haemorrhoidectomy and posterior colporrhaphy to be done without alteration in the patients' respiration and without any evidence of distress.

It is a little difficult to judge at what interval of time pethidine begins to exert its maximum effect, but probably this varies between five and ten minutes, as judged by the incidence of reflex movements when under the anaesthetic. It is possible that the more prolonged administration of nitrous oxide affects this estimate. It has not been found necessary to repeat the dosage of 25 mg. of pethidine at intervals of 25 to 30 minutes, and the effect of a single dose has been known to last up to 1½ hours.

Recovery is rapid, often occurring in the theatre, and almost always on the way back to the ward. Patients will almost immediately open their eyes upon request and will answer questions, but there is a varying period of amnesia lasting up to 1–1½ hours.

Another valuable point is that post-operative pain seems to be considerably reduced, and patients operated upon in the morning often do not require any post-operative sedative until late in the evening.

The present series is not large enough for the incidence of pulmonary complications to be judged accurately, but they have been remarkably few, and it is felt that this may largely be due to the reduction of immediate post-operative pain and the consequently increased movements of the patients.

The series reported is small, and further investigation is proceeding, but it was felt justified to publish results up to date in order to stimulate interest in a method which appears to be safe and also promises improvingly good results as more experience is gained in its use.

Post-pneumonic Collapse of Right Lower Lobe Relieved by Bronchoscopic Aspiration

Atelectasis of the whole lung or of one lobe, whether post-operative or post-pneumonic, is considered to be due to bronchial obstruction. The sequence of events in either case is very much the same : (1) Production of excessive secretion. (2) Formation of occluding masses because of the recumbent position and reduced respiration through splinting of diaphragm and pain. (3) Movement of these masses upwards in the tract by ciliary action, somewhat on the principle of a ball-valve, allowing air to get out during expiration but preventing air getting in during inspiration. The shape of the bronchus being narrower in its distal portion than proximally explains how a plug of mucus can act in that manner. (4) Progressive shrinkage of the affected lobe takes place (aided by absorption of air into the blood stream) as the plug of mucus becomes immobilized by atmospheric pressure.

Whereas *post-operative* collapse and relief by bronchoscopic aspiration has been extensively reported, I could find mention of only two cases of *post-pneumonic* collapse relieved in this way (Mainzer, 1931). I therefore venture to report the following case.

Case Report

A married woman was admitted to the French Hospital on February 24, 1949, with a 10-day history of post-influenzal cough. Her temperature was 103° F. (39.4° C.) and pulse 120.

Physical examination showed dullness at the base of the right lung, which was opaque on *x*-ray examination. A diagnosis of lobar pneumonia with small pleural effusion was made by Dr. L. P. E. Laurent. Penicillin injections in full doses were given. The patient became afebrile and improved generally, but the dullness on the right side remained. *X*-ray examination four weeks after admission revealed a solid lower lobe with the diaphragm drawn upwards and the heart pulled to the right. The physician and the radiologist now began to suspect a neoplasm blocking the inferior bronchus.

The patient was referred to me, and bronchoscopy was carried out on March 29. The right main bronchus appeared congested, the entrance to the inferior bronchus was patent, and no neoplasm was seen. A bronchoscopic sucker was then introduced about an inch beyond the entrance to the lower lobe. While aspirating and withdrawing the sucker at the same time, a thick gelatinous, tenacious mucous plug was seen adhering to the distal end of the sucker. The patient's relief was almost immediate.

Within a few days physical examination showed some return of pulmonary function. Successive radiographs revealed the lobe expanding gradually, the diaphragm descending, and the heart resuming its normal position. Tomograms confirmed the absence of a neoplasm. The patient left hospital on May 2, having made a complete recovery.

Reviews

HAEMATOLOGY AND CLINICAL MEDICINE

Hemorrhagic Disorders. A Guide to Diagnosis and Treatment. By Paul M. Aggeler, M.D., and S. P. Lucia, M.D. Lettered and illustrated by Phylura Gibbs, Helene Cleare, and Jean Thompson under the supervision of Ralph Sweet. (Pp. 112. £3 15s.) Chicago: University of Chicago Press. Cambridge: University Press. 1950.

Atlas der Blutkrankheiten. By Dr. Karl Schleip and Professor Albert Alder. Fourth edition. (Pp. 256; 140 coloured illustrations. No price.) Berlin and Munich: Urban and Schwarzenberg. 1949.

Klinische Pathologie der Blutkrankheiten. By Professor Rudolf Schoen and Professor Walter Tischendorf. (Pp. 521; illustrated. M. 57.) Stuttgart: Georg Thieme. 1950.

The first two of these three works on haematology are picture books and can be briefly reviewed. The pages of the text of Aggeler and Lucia's book on haemorrhagic disorders were reproduced from an exhibit designed for teaching at the University of California Medical School. Anyone who has visited the Wellcome Medical Museum in London will be familiar with the use of panels of letterpress and pictures for visual education. Here there are some 80 pages on the same lines illustrating the physiology of haemostasis, the manifestations and treatment of haemorrhagic disorders, and the methods and results of special investigations. There is a final chapter on therapeutic agents and procedures, and a good bibliography. The book is prettily produced and will be useful to those planning similar teaching by demonstration. It would not be unfair to call it a child's guide to the haemorrhagic diseases, or to add that few children can afford £3 15s. for a book of this kind.

Schleip and Alder's book is the post-war fourth edition of an established atlas of blood diseases, with which Alder's atlas of the bone marrow has now been combined. The text is simple and orthodox, and the 140 pictures in colour are all of good quality. They are paintings which have been reproduced by a four-colour process. Slightly conventionalized, they will be more useful for teaching than for the settlement of haematological controversy. Plate 38 depicting ring bodies is reminiscent of Picasso's work, and the student must not expect Nature to imitate art quite so closely. The relatively short section on bone marrow gives the impression of an afterthought, and to separate the section on bone marrow from that on peripheral blood is not justified in an atlas of this kind; the material should be arranged in terms of processes and diseases. Many atlases of the blood are now appearing, probably more than the market can support. Schleip and Alder's belongs to the student class, which is already numerous and where survival depends on price and on the value of the plates as a guide to recognition of the simpler cytological subdivisions. Custer's atlas has given us a fair view of the morbid anatomy of the bone marrow, but there is still need for a definitive series of pictures of blood cells stained by the Romanowsky technique. This is unlikely to be achieved without international co-operation.

Schoen and Tischendorf's book on clinical pathology of the blood diseases is a more serious and important book than the other two reviewed here. It is a full-scale textbook of clinical haematology in the best German tradition and it is a work of scholarship. It is dated 1950, and the most recent discoveries outside as well as inside Germany have been digested, assimilated, and included in the text. The book begins with a section on the normal morphology and physiology of the blood-forming organs. There follows a short chapter on the interpretation and the errors of the technical methods. The authors then discuss the diseases of the blood under the headings of anaemias, disturbances of the marrow and spleen, haemorrhagic diseases, blastomatous disorders, and leukaemoid reactions. A final section is on the inheritance and familial incidence of blood diseases. The book is well produced, with full references and bibliography. It is printed in smallish type on a large page, with relatively few illustrations, and will not appeal to the casual reader. English readers likely to be specially interested are those who have a good knowledge of either German or haematology, and those who are delighted to see evidence of the renascence of German scientific publications.

Yet this book has perhaps a more general message for us. Its authors are a university professor of medicine and his senior assistant, and they write :

> "In spite of all recent developments, internal medicine is a unitary discipline which joins its many sectional parts into one whole. The synthesis between the clinic and special knowledge is possible only when the community of clinical workers develops its specialists by scientific investigation in the sectional parts. These will then not succumb to the danger of narrow specialism, but within the framework of the clinic they will preserve the vision of larger connexions, the general view."

This is still the faith in America, where the members of university departments of medicine inevitably engage in scientific investigation, and where the two leading textbooks of haematology have been written by university professors of medicine, Sturgis and Wintrobe. Aggeler and Lucia are professors of medicine engaged in instructing students in clinical medicine. Schleip and Alder are Privatdozenten; that is to say, assistant professors of internal medicine. In Great Britain we do not have the same belief in the competence of the physician to master laboratory procedure or to advance scientific knowledge, and the clinic, as distinct from the preclinical departments, has never been university-minded. The present hospital service has evolved out of the eighteenth-century voluntary hospital, the Emergency Medical Service, and the medical services of the armed Forces. The result is a service which is organized in terms of specialists. The medical specialist is a man who sees patients and the clinical pathologist is a man who examines specimens of blood. As medical establishments grow, their channels of communication are increasingly the standardized form for request and report. Recent letters to the *Journal* indicate that both sides are capable of a jealousy about their spheres of work which is more characteristic of the craft unions than the liberal professions.

Centralized clinical pathology has great advantages in the wider distribution of health care, though in the absence of control by the price mechanism it is likely to lead to some form of rationing of laboratory investigations. Not only are centralized laboratories necessary for clinical pathology in the regions, but so also are special centres for the organization of blood transfusion and blood grouping and similar purposes. It is less easy to justify the centralization of clinical pathology in the teaching hospitals, which have a special part to play in the National Health Service. They already have university departments of pathology, but they have not organized their clinical departments on university lines. This is a manifestation of the popular confusion of the function of the health services and the universities, of the regional hospitals and laboratories and the teaching hospitals. The results of this confusion are particularly obvious in haematology, where it is often impossible to make a clear distinction between investigation and treatment, so that the divorce of control of the patient from control of the laboratory may prevent the study of the patient as a whole.

L. J. WITTS.

APPLIED PHYSIOLOGY

Einführung in die pathologische Physiologie. By Professor F. Grosse-Brockhoff. (Pp. 645; 306 figures; bound, M. 39.60.) Berlin, Göttingen, and Heidelberg: Springer. 1950.

Disordered function is the essence of disease, and from the clinical point of view it is of more immediate interest than structural change. Applied physiology accordingly forms a substantial part of medicine and surgery. The short course in the subject customary in our medical schools should be regarded simply as an introduction to more detailed instruction in it at the bedside. It is doubtful whether undergraduates need textbooks of applied physiology, the essentials of the subject being integral parts of clinical instruction; graduates, on the other hand, may find such books useful, although many topics are too complex for textbook discussion and are best studied in the original literature.

Professor Grosse-Brockhoff intends his work to supplement Rein's *Physiologie* and Lehnartz's *Chemische Physiologie* and refers readers to these for detailed information. The book is a comprehensive and well-written summary of the subject and seems to be the result of efficient card-indexing. Everything possible has been done to make it easy for the reader to find what he wants: the analytical table of contents occupies twelve pages and makes the excellent index almost superfluous. Paper, printing, and binding are up to the best pre-war German standards. The book will be useful chiefly to German students but may also interest teachers of applied physiology outside Germany. The English-speaking world is already well catered for by the standard works of Samson Wright, Best and Taylor, and Fulton—to all of whom the author acknowledges his debt.

RAYMOND WHITEHEAD.

REGIONAL DERMATOLOGY

Regional Dermatologic Diagnosis: A Practical System of Dermatology for the Non-specialist. By Ervin Epstein, M.D. (Pp. 328; 148 illustrations. 42s.) London: Henry Kimpton. 1950.

Theoretically the idea of regional dermatology is attractive, for most dermatoses have their characteristic sites, but in practice this approach does not lend itself to treatment in a textbook. Sabouraud published a manual of regional dermatology in 1905, and an English translation appeared in 1906. Dr. Epstein has now produced an elegant little volume, well illustrated on the same lines. In an appendix he indicates the twenty dermatoses that constitute 75% of dermatological practice. Not more than two or three are limited to one region; the rest may occur anywhere on the body, a few having certain sites of election. That limits the value of a treatise on regional dermatology. Inevitably there is constant repetition, but the tyro may be helped by reference to such a work and be led to seek further information in standard textbooks.

That the author does not discuss chilblains in his account of finger lesions may reflect a low incidence in America. Neurodermatitis of eyelids, chronic eczema of wrists, secondary syphilis of the forehead, and lupus vulgaris of the neck are some further important omissions. Acute disseminated lupus erythematosus is mentioned in the section on the hand and chronic lupus erythematosus omitted, but the catalogue of regional diseases is on the whole accurate and adequate. The general practitioner, for whom the book is intended, will find this a helpful guide to diagnosis.

In the *Irish Medical Directory and Hospital Yearbook* for the year 1950 (Parkside Press, Dublin; 15s. 6d.) the Ministers for Health of Northern Ireland and Eire refer briefly to some of the recent legislation in their countries. Dame Dehra Parker says there is definite promise that the structure of the health services in Northern Ireland has been laid on solid foundations. There are signs, she writes, that the public are becoming accustomed to the new services and are making use of them far more as a matter of necessity than as a novelty, which at first often seemed to be the case. Accommodation for tuberculous patients has been increased during the year. Dr. Noel C. Browne, commenting on the state of affairs when self-government came to Southern Ireland, says that about one-third of the people of Dublin were living in dwellings which were or should have been condemned. Undernourishment was the rule in town and country, and tuberculosis rife. Inadequate health services laboured in vain against these evils. To-day, he writes, the people are better housed, better clothed, and better fed by far than they were 30 years ago. In the next seven years about £20.000.000 will be spent on hospitals, sanatoria, and other enterprises. The *Directory* sets out clearly the names and particulars of medical practitioners as well as of the hospitals, and there is a useful index to the hospitals.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY SEPTEMBER 30 1950

CIGARETTES AND CANCER

The steady increase in the recorded deaths from cancer of the lung is startling. In 1922 there were 612 deaths from this cause in England and Wales, compared with 9,287 in 1947—a fifteenfold increase. The trend is the same in all countries where Western civilization is predominant, except apparently in Iceland. There can be little doubt that the incidence of cancer of the lung is really increasing, and tarred roads, exhaust gases, common respiratory infections, certain types of occupation, and tobacco smoking have all been blamed for the greater frequency of the disease. Of these possible causes smoking seems the most likely, for the rise in the death rate from cancer of the lung has followed a great increase in the consumption of tobacco and cigarettes. Several groups of workers have undertaken investigations to prove or disprove the suggested association. It is not easy to adopt an unbiased attitude to the concept that smoking may cause cancer: we are all either smokers or non-smokers, and each group may regard the other as prejudiced. It is said that the reader of an American magazine was so disturbed by an article on the subject of smoking and cancer that he decided to give up reading. Those who smoke more than 40 cigarettes a day, allowing ten minutes per cigarette, are occupied with smoking for about 6½ hours. There are no days off, and therefore the heavy smoker smokes for about 46 hours a week. This almost amounts to an occupation. Moreover, smokers heavily outnumber non-smokers, and this complicates statistical considerations. Even so, the proof that cancer of the lung is associated with smoking must obviously be based on statistical and not on clinical evidence. In this country Dr. Richard Doll and Professor A. Bradford Hill, whose paper is published in the opening pages of this issue, have carried out a meticulously conducted inquiry, the results of which have very serious implications, for they conclude that "smoking is a factor, and an important factor, in the production of carcinoma of the lung." They also put forward the admittedly speculative suggestion that above the age of 45 the risk of developing the disease is fifty times as great among those who smoke twenty-five or more cigarettes a day as among non-smokers.

The ideal investigation would be to compare the incidence of lung cancer in a population exclusively composed of non-smokers with that in populations composed of smokers of various grades, from very light to excessive. The method adopted by Doll and Bradford Hill, who began their inquiry in 1947, was to obtain notifications of patients with cancer of the lung, stomach, and large bowel from twenty London hospitals, and to arrange for the interview of these patients by one of four almoners who were allotted to this work. The patients with cancer of the stomach and large bowel served for purposes of comparison, but the almoners also interviewed a control group of patients who did not have cancer but who, case for case, were of the same age and sex as the patients with cancer of the lung. The patients thus interviewed amounted to 2,475 and included 489 cases of cancer of the lung confirmed by necropsy, biopsy, or exploratory operation, and 220 others in whom the diagnosis was probably correct but made on different grounds. All the patients were asked whether they smoked or not, and, if they smoked, how many cigarettes or ounces of tobacco. An obvious preliminary difficulty was to decide where the line should be drawn between smokers and non-smokers, and also how to classify those who had once been smokers but had stopped. The definition of a smoker adopted in this inquiry was "a person who had smoked as much as one cigarette a day for as long as one year."

By comparing the proportion of patients with lung cancer who were smokers and the proportion of smokers in the comparable group of patients without lung cancer, Doll and Bradford Hill were able to show not only that the vast majority of men with carcinoma of the lung had been smokers at some period of their lives but also that the very small proportion (0.3%) of those who were non-smokers was most significantly less than the corresponding proportion (4.2%) in the control group. Further, there were relatively more heavy smokers among the patients with cancer of the lung (26% of the men and 14.6% of the women) than among the controls (13% of the men and none of the women). The risk, in fact, seemed to vary in approximately simple proportion to the amount smoked. Very similar results to those obtained by Doll and Bradford Hill have recently been reported from the U.S.A. by Wynder and Graham.[1] Their study covered 684 cases of bronchogenic carcinoma, 634 of the patients having been personally interviewed. They found that the non-smokers among male patients with cancer of the lung amounted to 1.3% of the total, compared with 14.6% of non-smokers among men in the general hospital population without cancer. Whereas only 19.1% of men in the latter were classified as "excessive and chain-smokers," as many as 51.2% of the patients with cancer came into this category.

In a recent report from Iceland Dungal[2] has drawn attention to the comparative rarity of lung cancer in

that island. His study is based on the records of 1,939 necropsies performed in Reykjavik from 1932 to 1948. There were 417 malignant growths in this series and 12 cases of primary lung carcinoma. This is a very much smaller proportion than is found in other comparable communities. Dungal points out that smoking, and particularly cigarette smoking, has only recently become popular in Iceland on a scale at all resembling that in most European countries. In 1945 the consumption of tobacco per head in Iceland reached 1 lb. per annum, whereas this figure was passed in Great Britain as long ago as 1920. It remains to be seen whether the incidence of lung cancer increases in Iceland during the next twenty years.

In the English investigation great pains were taken to avoid any sort of bias. The most likely source of error would seem to be in the interviewing, for even those who have no possible reason for being untruthful can be badly let down by their memories. Nevertheless, it is difficult to suggest what other precautions Doll and Bradford Hill might have taken to counter all possible criticisms of their method of investigation. They have even been able to show statistically that the results were in no way influenced through the fact that the interviewers knew in most cases whether or not the patient they were questioning had cancer of the lung. One unexpected result of the investigation was that inhaling cigarette smoke was not distinctly associated with lung cancer. In fact patients with this disease inhaled slightly less often than the controls. Wynder and Graham found that the proportion of men who smoked cigarettes as opposed to pipes among the patients with bronchogenic carcinoma was greater than that among the general hospital population of the same age-group, and they concluded that "the greater practice of inhalation among cigarette smokers is believed to be a factor in the increased incidence of the disease." Doll and Bradford Hill also found that pipe smoking was less closely related to cancer of the lung than cigarette smoking. They were not able to demonstrate with the data at their disposal that cancer of the lung is commoner in men than women because men smoke more, but they do suggest that their findings are consistent with the theory that, apart from the influence of smoking, the risk of developing carcinoma in the lung is the same in both men and women.

There is shortage of convincing experimental evidence about tobacco as a cause of cancer. Animals subjected to an atmosphere of smoke from mechanically smoked tobacco can be compared, not with smokers, but with non-smokers in a smoking compartment. It has never been proved experimentally that carcinogens are formed during the smoking of tobacco, though this would not be surprising in the light of the probable results of destructive distillation of any organic matter under conditions of restricted oxygenation. Kennaway[3] prepared carcinogenic tar from such different material as yeast and human skin. The distillation of coal in gasworks yields carcinogenic tar, and workers in the tar and pitch industry are eligible for compensation if they contract cancer of the exposed skin. Apart from the carcinogens which may be formed as a result of the burning of tobacco, it is also possible, as Doll and Bradford Hill point out, that arsenic in the insecticides with which the tobacco plants are sprayed could act as a carcinogen.

The practical question which the doctor in practice has to answer is whether any of his patients—for instance, those with smoker's cough—should be advised to give up smoking. In most textbooks of medicine and pathology reference is made to betel-nut chewer's cancer of the mouth. This is accepted as a well-established case of causal relationship, yet the actual incidence of cancer of the mouth in the population at risk would be difficult to compute accurately, since the habit is almost universal in many Asian communities. Certainly most betel-nut chewers do not contract cancer of the mouth; nor do many pitch and tar workers contract cancer of the skin, nor chimney-sweeps cancer of the scrotum. There is no evidence about the degree of risk which cigarette smokers take, but it does apparently increase in direct proportion to the amount smoked daily and to the total duration of the habit.

MECHANISM OF RELIEF IN RHEUMATOID ARTHRITIS

Increased fat deposition is one of the signs of Cushing's syndrome, many of the metabolic features of which are widely attributed to increased adrenal cortical activity. Knowledge of the alterations in fat metabolism caused by adrenal steroids is less far advanced than that of changes in carbohydrate metabolism. The deposition of liver glycogen which may be thus induced is accompanied by hyperglycaemia and glycosuria. There is also known to occur a process of gluconeogenesis whereby the conversion of amino-acids to carbohydrates is increased. This process will not account for the total increase in carbohydrate which may be observed—which suggests diminished utilization. Carbohydrates "spared" in this way may undergo conversion to fat. Since Kendall[1] showed that 11-dehydrocorticosterone could induce an increase in the total fat content of the mouse carcass there has not been much work on this problem, though Evans and his colleagues[2] succeeded in demonstrating that adrenocorticotropin had the same effect on hypophysectomized rats. Ingle and his

co-workers[3] also found histological evidence of fatty infiltration of the liver in rats "force-fed" with carbohydrates and injected with A.C.T.H. In spite of rather scanty evidence these workers felt there might be some impairment of liver function. It must be acknowledged that attempts to produce fatty infiltration of the liver with A.C.T.H. have not been uniformly successful, for Jefferies[4] found that, although pituitary extracts would cause this condition, A.C.T.H. would not. Payne,[5] in short-term experiments with mice, found the potency of the "fat mobilizing factor" of the anterior pituitary was not related to the adrenocorticotropic potency of the preparations employed. In spite of this, the effect seemed to be dependent on the normal activity of the adrenal cortex, which probably maintained a basic level of glycogen as an intermediate in the fat-mobilizing process.

Against this background, which is not in all respects consistent, Archer[6] has lately propounded a theory that the beneficial effects of A.C.T.H. in rheumatoid arthritis may be dependent on the development of fatty infiltration of the liver and consequent hepatic dysfunction. He compares some of the biochemical changes found in jaundice and pregnancy—conditions associated with the alleviation of rheumatoid arthritis—with some of those caused by injections of A.C.T.H. It is unfortunate that one of these changes, hypercholesterolaemia, is the reverse of that often observed after A.C.T.H. injection,[7] and the only remaining feature in common appears to be decreased tolerance for carbohydrates. Archer states that gold, bismuth, and other drugs used in the treatment of rheumatoid arthritis are potentially damaging agents to the liver, and he puts forward some evidence to show that improvement after the administration of these drugs can be related to the appearance of abnormalities in the thymol turbidity, cephalin flocculation, and serum protein.[8] Many gaps need to be filled in before a theory such as this can be substantiated. Although it can be accepted that the adrenal cortex influences the deposition of body fat, the part it may play in inducing fatty infiltration of the liver is less clear. The deposition of fat in the liver which may occur in Cushing's syndrome could to some extent be associated with the cardiovascular changes found in that condition. The relation of fatty infiltration of the liver to impairment of cellular function needs to be more precisely defined. The conjecture that the success of gold therapy in rheumatoid arthritis is dependent on changes in the liver must also be examined further.

CANCER OF THE CERVIX

Statistical studies of the same subject may point to surprisingly diverse conclusions, because different observers may place different interpretations on the multiple variables concerned. Thus in the case of cancer of the cervix some investigators assess results on the basis of the clinical stage of the disease at the first full examination, while others correct the stage when the findings at operation or necropsy show the clinical assessment to have been incorrect. This latter approach may at first seem more scientific, but where it is employed the results of operative treatment cannot strictly be compared with the results of radiotherapy because the stage of the growth is not estimated by the same process. Nevertheless many facts of interest as well as of clinical significance are disclosed in three statistical surveys of cancer of the cervix which have been published in the last year. In the first of these, Maliphant[1] in this *Journal* reviewed 1,200 cases diagnosed between 1922 and 1946 and discussed the incidence and the relative importance of certain factors predisposing to this form of malignant disease. He found that the age of maximum risk was between 55 and 59. This serves as a reminder that more than half of the cases of cervical carcinoma occur after the menopause, a fact also emphasized by the other two investigators, Harnett[2] and Morris and Meigs.[3] In Harnett's 859 cases of cancer of the cervix the menopause occurred after the age of 48 years in only 17.8%, while in 288 cases of cancer of the body of the uterus the comparable figure was 30.4%. This lends support to the contention of Corscaden and Gusberg[4] that carcinoma corporis is commoner in women in whom the menopause has occurred later than the average.

Maliphant calculated the risk of carcinoma of the cervix in any one year between the ages of 35 and 64 to be 1 in 1,500 in parous women and 1 in 21,000 in single women. It is well known that cervical malignancy is predominantly a disease of parous women, but Maliphant observed that marriage alone, without pregnancy, doubled the risk. Here again the three surveys are in agreement, but Morris and Meigs also found that marriage below the age of 20 was a significant factor, for 45.4% of their patients could be put in this group as against 18.6% for the general female population of Massachusetts. Their figures, however, like those of Lane-Claypon,[5] do not bear out Maliphant's contention that the risk in the parous woman varies directly with the number of her pregnancies. None of the three surveys brought to light any evidence which directly

[7] Report of Discussion, ibid., 1949, **58**, 849.

incriminated the oestrogens as a cause of cancer of the cervix, and, in fact, in 75 of the 1,938 cases reviewed by Morris and Meigs bilateral oophorectomy had been carried out some years previously. In all three investigations a varying number of growths are reported to have arisen in the cervical stump after subtotal hysterectomy. The number of such cases can be and should be reduced, because, as Morris and Meigs point out, the risk of stump cancer is greater than whatever additional risk there may be in performing total in preference to subtotal hysterectomy—assuming the operator possesses the degree of surgical skill expected of those undertaking major surgery.

The commonest presenting symptom in cervical cancer is irregular or abnormal bleeding, often after coitus. In Harnett's series this was so in 67.5% and in the American series in 86%. It is surprising, however, to find that the second commonest presenting symptom (42%) in Morris and Meigs's series was pain, for this is commonly believed to be a relatively late complaint. Harnett found that in over 25% of his cases there was a lapse of more than six months between the onset of symptoms and medical consultation, and that in 10% the doctor allowed more than one further month to elapse before carrying out a vaginal examination. These errors of omission which delay diagnosis must affect the prognosis in individual cases, for it has been clearly and repeatedly shown that the results of treatment depend directly on the stage of the disease at which it is applied. Strangely enough, however, both Maliphant and Harnett found no close relation between the duration of symptoms and the stage of the cancer; indeed Harnett found the same five-year cure rate for cases treated within six months of the first symptom as for cases treated more than six months after the onset of symptoms. In Morris and Meigs's series, however, there was a consistent relationship between the duration of symptoms and the stage of the disease; and their five-year cure rate was 10% higher when treatment was commenced before symptoms had been present for six months.

There can be no possible doubt that early diagnosis must improve the outlook for the patient. For this reason the routine annual gynaecological examination of women over 35 has been recommended, but the number of cancers likely to be found in this way which would not otherwise have been detected would be relatively very small. Maliphant estimated that for every woman with cervicitis who developed carcinoma one thousand did not. The screening of women for uterine cancer by routine vaginal smears is employed in some clinics in the U.S.A., but this method is expensive, the number of trained cytologists is small, and there is at least a 10% false-negative rate. According to Novak[6] a positive test appears on the average once in every 500 hours of cytological study. In Chicago recently a simple chemical test for cancer of the cervix has been discussed.[7] As yet, however, none of these diagnostic aids is without some serious disadvantage, and none is a substitute for a competent vaginal examination and unrestricted recourse to biopsy. Meanwhile more should be done to inform, without alarming, the public of the importance of early consultation when gynaecological symptoms present, and the practitioner must regard the exclusion of cancer of the uterus as a necessity in all such cases.

CIRCULATORY OVERLOAD FROM TRANSFUSION

Now that it is so easy to obtain blood and plasma they tend to be transfused too readily. No transfusion should be given until the medical man in charge of a case is convinced that it is really necessary, and even then the risks must be borne in mind.

The dangers of whole blood and plasma transfusion fit into three main groups: first, immunological reactions; second, the risk of serum hepatitis; and, lastly, risks of circulatory embarrassment resulting from a too large or too rapid transfusion. This last hazard is common to all types of fluid administered intravenously. It can be avoided only by an accurate assessment of fluid needs, combined with a careful watch for the first signs of cardiac embarrassment during transfusion, especially a rise in peripheral venous pressure. The clinical signs of dehydration—a rising pulse rate and urine concentration, loss of skin elasticity and ocular tension, with dryness of the tongue—may be confusing at times. When there has been no haemorrhage or loss of plasma protein, the plasma specific gravity measured by the copper sulphate method[1] is a useful guide. This test is rapid and simple; for every 0.001 rise in plasma specific gravity above the normal level of 1.027 the patient may be presumed to lack 200 ml. of water. Again, blood concentration from dehydration can be assessed by determining the cell : plasma ratio with a haematocrit. This was seen to be especially useful in the late war during the treatment of burn shock, where rapid initial dehydration from exudation of protein and increased capillary permeability led to profound shock. Rapid and maintained plasma infusion to a normal and constant haematocrit value produced a steep fall in mortality.[2] When post-haemorrhagic dilution has taken place the packed cell volume will give a reasonable index for blood replacement, cells from 500 ml. of blood being required to raise the average packed cell volume 5%. Where the haemorrhage is of unknown size and there has been no time for compensatory dilution of blood, but rapid transfusion is indicated, the estimate of quantity must be made

by noting the improvement of blood pressure, and fall in pulse rate, with improvement in peripheral circulation. It is in these cases that a rapid transfusion is most needed but the dangers of over-transfusion are still present. For example, Pierce, Robbins, and Brunschwig[3] recently reported a method of rapid blood transfusion by means of an oxygen cylinder and flow-meter connected to the air-induction tube of the standard blood-transfusion bottle. The combined risks of excessive transfusion and air embolism,[4] even with the most careful supervision, must outweigh any possible advantages this technique might have in emergency treatment.

Three groups of cases are especially sensitive to a too rapid or too large transfusion. First, there are those subjects in whom the myocardium is not normal. Holden, Cole, and Portmann[5] stress again the dangers of overload in the atherosclerotic patient, or those with ischaemic heart disease. They point out that a rise in pulse rate and a fall in blood pressure during transfusion may not be an indication of further haemorrhage but rather of developing heart failure from overloading with fluid. Here the clue to the true position is the progressive and persistent rise in venous pressure which will precede the onset of pulmonary oedema. A transient rise in venous pressure will occur in normal subjects transfused with large quantities of fluid, but it is accompanied by little change in pulse or blood pressure.[6] In the second group typified by the severely anaemic patient, with a rapid collapsing pulse, warm pulsating extremities, high pulse pressure, and a raised venous pressure, even comparatively small transfusions may precipitate congestive cardiac failure.[7] Here very cautious transfusion of packed red cells should be given, with careful observation of venous pressure. Any further rise in the already high venous pressure should call for either the slowing or the cessation of the transfusion. If heart failure occurs, raising the head of the bed to encourage venous pooling in the legs is useful, and intravenous digitalis should be given. The third group includes those cases in which, it has recently been suggested, death from anuric or oliguric uraemia is probably due to overloading with water and to tissue oedema rather than to so-called uraemic toxaemia.[8 9] In this group it is important to restrict fluid, whether parenteral or by mouth, to a maximum 1,000 ml. more than the urine output for 24 hours. This will allow for replacement of water lost insensibly in respiration, etc., and prevent over-hydration.

ABDOMINAL ANGINA

Discussion of intra-abdominal vascular disease is usually limited to a consideration of massive mesenteric thrombosis or embolism with extensive infarction of the bowel. But there is evidence that abdominal pain or angina, comparable to cardiac angina or to claudication of the extremities, may accompany arteriosclerosis in the mesenteric vessels. It may also be possible that small infarctions of the intestine may heal without perforation if the terminal arterioles only are affected. Dunphy[1] reported that 7 out of 12 patients fatally ill with massive mesenteric thrombosis gave a history of repeated attacks of abdominal pain, previously undiagnosed, preceding the fatal attack by months or years. Cushman and his co-workers[2] described a patient who was treated for mesenteric thrombosis and died from another cause six months later. Necropsy revealed a healed infarct of the ileum. The Massachusetts General Hospital has reported the case-history of a patient subject to recurrent attacks of abdominal pain who had had two negative laparotomies and was then found to have gross arteriosclerosis of the mesenteric vessels and a fresh occlusion of the superior mesenteric artery.[3] Berman and Russo[4] have described the findings in a patient in whom abdominal pain was thought to be due to abdominal angina. This patient, a woman of 72, had had cramp-like pain for four weeks, more severe in the left side of the abdomen. For one week the pain was almost periodic, coming on two hours after eating. It was worse after large meals. The bowels were normal, and no melaena had occurred. A laparotomy was performed because of increasing pain and tenderness, and a moderate amount of serosanguineous fluid was found in the peritoneal cavity, together with numerous fine, flame-shaped haemorrhages in the mesentery of the middle part of the jejunum adjacent to the bowels. In the centre of this area there was a partially organized infarcted area (about 5 cm. in length) of the small bowel, with dimpling and contraction of the serosa. Peristaltic waves passed through this area, and it was decided to close the abdomen. Subsequently, by avoiding large meals, she had only occasional episodes of abdominal colic. Unexplained abdominal pain in the elderly is a not uncommon clinical problem, and a vascular cause should be included in the differential diagnosis. Berman and Russo consider that pain—"abdominal angina"—may arise from ischaemia associated with arteriosclerosis without infarction, but it is perhaps more probable that minor degrees of infarction are the cause of the more prominent symptoms.

COLONIAL HEALTH SERVICES

The standard of health in the colonial territories has greatly improved since the end of the war. A Command Paper[5] recently presented to Parliament by the Secretary of State contains some encouraging statistics. The health returns from Singapore, Malaya, and Hong Kong have improved each year since 1945. Singapore now claims to be the healthiest seaport in the East, with a death rate in 1949 as low as that in England and Wales, and an infant mortality of 72, compared with 130 ten years ago. In Cyprus in 1949 the death rate was one of the lowest in the world, and here the infant mortality has fallen from 180 to 70 in seven years. In the West Indies group, including Jamaica and Trinidad, the average length of life since 1921 has increased by more than fifteen years. The main cause for these improvements is the effective control of malaria, facilitated by the development of the new insecticides, particularly D.D.T., which may also prove to be hardly less effective in combating the tsetse fly. Other successes recorded are with chloramphenicol in treating scrub typhus in Malaya, the sulphone-derivatives in treating leprosy, and B.C.G. vaccine in preventing tuberculosis. The general policy of the medical administration is to push B.C.G.

vaccination on the widest possible scale. In Kenya an extensive survey of the extent of tuberculosis has been completed, and progress along the same lines is being made in Northern Rhodesia and Uganda. An anti-tuberculosis campaign is proceeding vigorously in Fiji and in the Far East. Out-patient clinics have been established in the West Indies as adjuncts to sanatorium treatment.

The provision of sufficient hospital beds for the curative services remains an acute problem almost everywhere, but many hospital extensions have lately been made. In Northern Rhodesia (Broken Hill) a large hospital is nearing completion; new hospitals have been opened in the Somaliland Protectorate and in Zanzibar; plans for an ambitious scheme for the teaching hospital in Jamaica are well under way; and in many parts of the colonial territories new hospitals or special units have been set up. These territories comprise a population of 70,000,000 and an area of 2,000,000 square miles, and are highly varied geographically, economically, and culturally. The medical and health services must be adaptable, and much use is being made of mobile teams. There are mobile child-welfare clinics in Fiji and other territories, mobile health clinics in Cyprus and Malaya, and in Sarawak a system of mobile maritime dispensaries—ultimately to number fifteen—is being established. Though the medical work is so varied, the factor which militates most strongly against the development of the health services is the continuing shortage of fully qualified doctors. Recruitment of new staff during the year 1949–50 has not at any time kept pace with requirements, and at the end of the year the outstanding vacancies for medical officers totalled almost 200. Under a six-year scheme inaugurated in 1947 the Nuffield Foundation has made it possible for distinguished consultants to visit East and West Africa. Visits were paid last year by specialists in ophthalmology, paediatrics, internal medicine, venereal diseases, industrial health, and tropical medicine. All were completely successful and highly appreciated by the medical officers and Governments concerned, and it is clear that the scheme will do much to keep progress in all branches of medicine in the African colonial territories in line with modern trends in the United Kingdom.

HETRAZAN AND FILARIASIS

There is now little doubt that "hetrazan" (1-diethyl carbamyl-4-methylpiperazine hydrochloride) is to a certain extent an effective remedy against infections by filarial worms, especially *Loa loa*, the causal agent of Calabar swellings, and *Wuchereria bancrofti*, the main causative agent of filarial elephantiasis. Maldonado and his colleagues,[1] for instance, in Puerto Rico, found that in a Government-supported home for boys 31 of the 297 inmates harboured the microfilariae of *W. bancrofti*. No anti-mosquito measures of any sort were undertaken, and biting was practically unlimited; but hetrazan was given to 30 of those infected, a dose of 2 mg. per kg. body weight being administered three times a day at meal-times. At the end of a 21-day course 26 boys were free from microfilariae, and as a result of the reduction in microfilariae the incidence of infected mosquitoes, *Culex quinquefasciatus*, immediately fell very considerably. Similarly Hewitt and his colleagues[2] gave 100-mg. tablets three times a day for seven days to adults and proportionately less to children throughout the West Indian Island of St. Croix. Before treatment 15.9% of the population had been infected: a year later only 6.7% were positive, and, even when present, the numbers of microfilariae were then so low that most cases were probably not infective to mosquitoes. Although there were some minor complaints no serious reactions occurred, and in general treatment was well tolerated. The only reactions of any severity have been those reported in British Guiana, and even there they were few and far between.[3]

The mode of action of hetrazan is obscure. Although Hewitt and his colleagues[4] found that in frogs hetrazan directly affected the microfilariae of *Folyella dolichoptera*, no similar action has been seen on the microfilariae of *Litomosoides carinii* in the cotton rat. But Hawking and his colleagues[5] bring forward evidence to show that the drug acts like an opsonin, rendering the microfilariae susceptible to phagocytosis when they are present in the liver though they are less susceptible when they are in the spleen and marrow. The store of microfilariae in the pleural cavities is not destroyed, because no active phagocytic mechanism is present. *In vitro* hetrazan has no discernible effect on adult worms, but *in vivo* an intensive course of hetrazan was found to kill 9.3% of 431 adult female worms, whereas in control untreated animals only 0.76% of the worms died. Male worms of the cotton-rat filaria appear to be less susceptible than the females. Filarial worms present in the mosquito are unaffected. It seems probable that with *Loa loa* in man microfilariae also are much more susceptible than adult worms to hetrazan, though, as Stefanopoulo[6] has pointed out, adults may sometimes appear under the skin, die, and be absorbed or form small cysts.

To be effective in human beings one course of hetrazan is rarely enough; there is still need for more active compounds, and Sewell and Hawking[7] have tested no fewer than 280 compounds in cotton rats infected with the filarial worm *Litomosoides carinii*. Activity was limited to certain groups. All the antimony derivatives studied had an action on adult worms, as had 4 out of the 12 arsenicals investigated. Some activity against adult worms was found in 23 of 35 anil- and styryl-quinolines and benzthiazoles, and in two phenanthridinium salts and a cyanine dye as well. However, clinical trials in man on this type of compound have not been very encouraging.[8] In the diguanide series proguanil was the only one that was slightly active. Curiously enough, of all the substances tested only two showed any direct action on microfilariae—hetrazan and N:N:N:-trimethyl-N-diethylcarbamyl ethylene diamine. For the present, therefore, hetrazan, combining low toxicity with considerable chemotherapeutic activity, must be considered the most promising drug for the treatment of human filariasis.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

PINK DISEASE

BY

W. S. CRAIG, M.D., F.R.C.P.Ed., F.R.S.Ed.

Professor of Paediatrics and Child Health, University of Leeds

Pink disease is a clinical entity met with only in children. Most cases occur between the ages of 6 months and 3 years. The disease shows no predilection for either sex. Breast-fed infants enjoy no special immunity. There is a marked seasonal incidence, the majority of cases in this country occurring between December and April. Although statistics are not available there are grounds for believing that year-to-year variations in the incidence of pink disease are related to the severity of the winter, and that children in rural areas are more liable to develop the condition than those living in cities.

The condition is of particular importance to the family doctor because in the early days it may give rise to suspicions of one of the commoner infectious diseases, and because the exacting demands of the patient over a prolonged period inevitably disturb household routine. Treatment is dependent for success upon patience on the part of both family practitioner and parents, and upon the family doctor's ability to retain the confidence and co-operation of the mother.

The Fully Developed Clinical Picture

In its fully developed form the clinical picture of pink disease is unmistakable. The appearance of the child is one of abject misery. He is peevish and fretful, and whines unceasingly. Pathetically resigned to the misery of his own condition, he vents his irritability on others only when disturbed. He shows no response to any form of attention and is completely disconsolate. He resents approach, but is equally discontent when left to his own resources. All interest in toys is lost. Food has no attraction, no

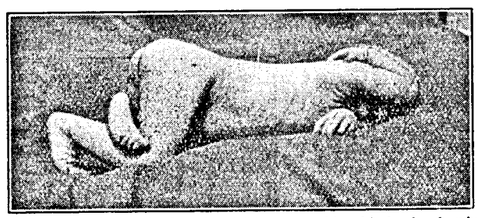

FIG. 1.—A typical attitude: the child is scratching his back, chewing his arm, and rubbing his feet together.

matter how varied or how attractively prepared. The child dislikes facing the light. Photophobia is common but may be absent, and when present it may be severe or slight. Aversion to light leads the child to turn his back to the window and to bury his head in the pillow or assume the so-called knee–elbow position. Whatever his position, he is never still, continually scratching himself, rubbing his hands and feet, or chewing his fingers (Fig. 1). If weakness keeps him recumbent he wriggles and writhes incessantly (Fig. 2). He may even pull his hair out. In its extreme form restlessness ceases only when, with fatigue added to weakness, the child falls asleep through sheer exhaustion. When this takes place sleep usually occurs during the day, the child continuing to be noisy and restless during the night.

The erythematous changes which have given rise to the name pink disease are to be looked for in the hands and feet. When dry and warm the extremities are bright pink in colour. If cold and clammy they have a bluish-red

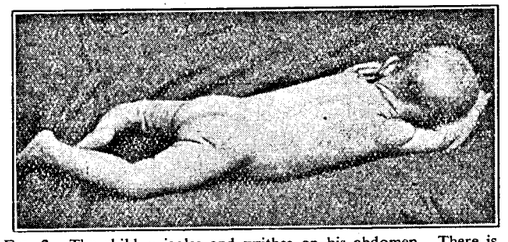

FIG. 2.—The child wriggles and writhes on his abdomen. There is an extensive erythema, wasting is severe, and the hair has fallen out.

appearance. The discoloration is most pronounced in the tips of the fingers and toes. Proximally it lessens in intensity and is scarcely perceptible above the level of the wrists and ankles. The erythema may vary from time to time in intensity and, less often, in extent. It may disappear completely, only to reappear. In addition to being discoloured the extremities are "puffy" or swollen, but there is no pitting oedema.

The skin over the affected parts has a glazed appearance and is often the site of local desquamation. Extremities showing these changes have been aptly described as looking like "raw beef" or "washerwoman's hands" (Fig. 4). Sensory changes occur and account for the local irritation evidenced by infants and for the feelings of tingling and numbness described by older children. Handling or manipulation of the extremities does not cause pain. The erythematous changes are not always confined to the hands and feet. Bright redness of the cheeks or of the nose may first attract attention, but is not met with in the

FIG. 3.—Another typical attitude in a child who has been disturbed. Peevishness, photophobia, wasting, hypotonia, and swelling of the feet are all evident. (Professor Charles McNeil's case.)

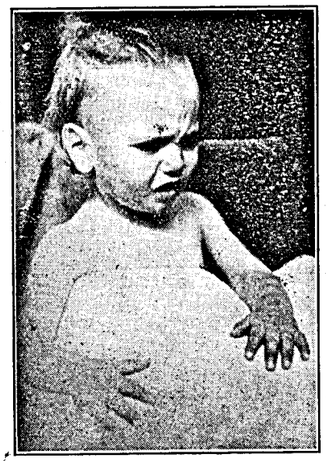

FIG. 4.—Showing the picture of abject misery, the "raw beef" hands, and pronounced photophobia. (Professor Charles McNeil's case.)

absence of changes in the hands or feet.

Excessive sweating is common and may become so profuse that the patient is literally drenched in perspiration many times daily. Persistent and profuse sweating in an afebrile child of under 3 years of age should always raise the question of pink disease. Sweating is accompanied by thirst, but by a thirst which is not commensurate with the amount of fluid lost via the skin; the former gives rise to a sudaminal rash which adds to the patient's acute discomfort. Occasionally sweating is absent. In that event the dry powdery skin covering the emaciated trunk and limbs contrasts strikingly with the sodden condition of the hands and feet.

Invariably lack of sleep, loss of appetite, unrelieved fatigue, and profuse sweating contribute to a severe loss in weight and to a state of unmistakable physical weakness. The abdomen may be scaphoid. These developments are accompanied by a generalized loss of muscle tone. The degree of hypotonia is so extreme as not to be entirely accounted for by the physical condition as a whole. Individual muscles or muscle groups lack bulk—and such bulk as they possess moulds readily in response to the gentle pressure of the bed-clothes with which they are in contact. Equally striking is the impression of a jelly-like consistence obtained by the examiner on gently palpating or handling the muscles. The tendon reflexes may be diminished or absent, but there is no muscular paralysis in the strict sense of the word.

Tachycardia is present in all cases, and is usually so pronounced that it can be confidently recognized despite the fretful reaction of these children to examination. The blood pressure is appreciably raised, but confirmation of this is not necessary for the purposes of diagnosis In an uncomplicated case the temperature is normal or slightly below normal: and there are no characteristic changes in the blood picture.

Development of the Picture

Such, then, is the clinical picture in fully developed form reached gradually over a period of several weeks. Rarely is the onset sudden. Usually it is gradual. In retrospect the earliest signs or symptoms are recognized as having been those of a mild upper respiratory catarrh. The catarrh may consist of little more than a discharging nose. There may or may not be slight fever. Not infrequently this is the only febrile phase during the entire course of an uncomplicated case of pink disease. Sometimes the catarrh tends to persist. More usually it simulates a mild coryza, disappears in less than a week, and is regarded at the time as having been a passing incident. A few days elapse, and then it is noticed that the child is not his usual self. The mother is disappointed that he has not improved according to her expectations and may even decide that "perhaps after all he has had an attack of influenza." More than anything else the child remains strangely restless: peevishness is added to restlessness, appetite is lost, and sleeplessness follows. In these circumstances any suggestion of photophobia should lead to a tentative diagnosis of pink disease even in the absence of discoloured or swollen extremities.

The more gross changes which occur in the hands and feet are preceded by the appearance of a general erythema covering limbs and trunk alike. The erythema is of a transient nature. After a varying interval of time it loses its general character and fades away over the trunk and limbs while becoming intensified in the hands and feet. When this stage has been reached there can be no mistaking the diagnosis. Symptoms may continue to worsen, but not necessarily so. Improvement can, and often does, set in without development of the complete clinical picture which has been described. In a case of average severity the clinical climax is reached in some six to eight weeks.

The Stage of Recovery

Whether signs and symptoms are of severe or moderate degree the disease runs a long course. In the mildest cases recovery takes six to eight weeks (Fig. 5). In general it

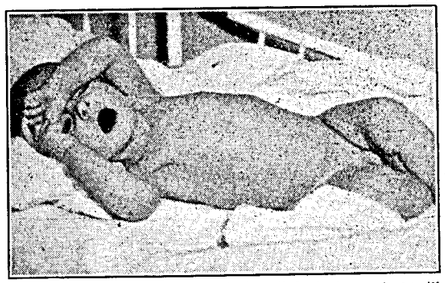

FIG. 5.—A child has passed the clinical climax but still shields his eyes from the light. Note the loose "pendulous" musculature of the limbs.

can be said that the time taken to reach the stage of clinical climax corresponds approximately to the further time required for symptoms to disappear completely. In the severest cases twelve months may elapse from the onset of the disease before symptoms finally and completely disappear. The trials of slow recovery are aggravated by the tendency for progress to be erratic and for relapses to occur.

FIG. 6.—Secondarily infected skin lesions. Wasting is severe and the extremities are swollen and discoloured.

Complications

Estimates concerning the incidence of fatal results vary from 5 to 10%. Intercurrent infections constitute the main threat to life. Of these the most serious is broncho-

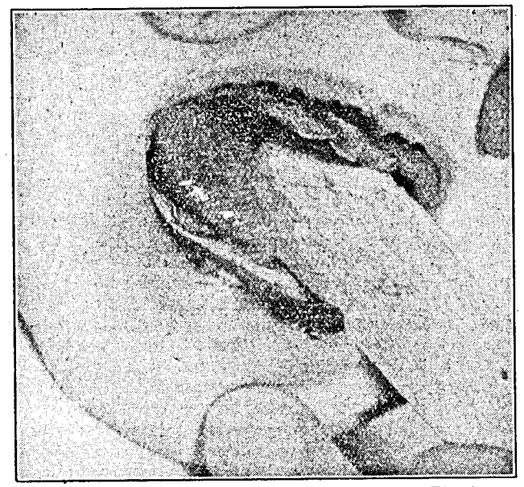

FIG. 7.—Swollen, deeply coloured, unhealthy gums. The incisor teeth subsequently fell out.

pneumonia. Exceptionally, sudden unexpected death follows acute cardiac failure. Pyelitis and otitis media may develop and the stools may become fetid. Trophic lesions are common, more especially in severely debilitated cases running a prolonged course. Rashes and other skin lesions which have become secondarily infected are slow to heal (Fig. 6).

If there is secondary infection the glands draining the affected areas become enlarged and sometimes tender. Fingers which have been rubbed or chewed are apt to become the site of resistant pulp or nail-fold infections. The hair may fall out. Frequently the gums are unhealthy in appearance, being swollen and of an unusual deep mulberry colour (Fig. 7). Gingivitis and stomatitis soon follow if measures are not taken to prevent the child biting his hands and fingers. When this occurs the teeth may fall out. Rectal prolapse is the commonest of the less serious complications. Children recovering from pink disease do so completely, except in so far as chest complications may result in varying degrees of pulmonary collapse and septic skin conditions may leave permanent scarring. Second attacks of pink disease do not occur.

Aetiology

The cause of pink disease is unknown. Allergy, endocrine dysfunction, toxicity due to arsenic and ergot, and photo-sensitivity have all been suspected in their day. Within recent years it has been suggested that mercury contained in medicinal tablets, ointments, or teething powders may be a contributory cause. This view is based on the finding of large amounts of mercury in the urine of children in whom a diagnosis of pink disease has been made and who have been given mercury in one of the forms mentioned. By no means all children excreting mercury in the urine show signs of pink disease, and it is possible that the development of the condition may be dependent in part upon individual susceptibility to mercury intoxication.

The significance of mercury as an aetiological factor must be looked upon as *sub judice*. The same may be said concerning prevailing theories that pink disease is a deficiency disease or a virus infection. Suspicions that pink disease was a form of polyneuritis stimulated trial of intensive vitamin B and liver therapy. Pioneer work along these lines gave promising results which have not been universally substantiated by subsequent clinical experience or by experimental studies. Those who favour the theory that pink disease is a virus infection are influenced by the catarrhal symptoms at the time of onset; by the liability of cases to occur in small local "crops"; and by recorded findings, at the few necropsies which have been carried out, of diffuse infiltrative lesions involving the cord and brain substance and of degenerative changes affecting the peripheral nerves.

Management and Care

The diagnosis of pink disease calls for a frank explanation of the implications. There is no specific treatment. Parents are readier to accept what is, after all, an unpalatable fact if they are at the same time told of prevailing doubts concerning aetiology. Mention of infection will prompt the question, "Is it catching?" The parents can be unhesitatingly reassured that there is little likelihood of any other member of the household contracting the condition. Recorded instances of two children in the same household suffering simultaneously from pink disease are few in number. On the other hand, it is not altogether rare for two members of a family to develop the condition at widely separated intervals—usually of years.

Inevitably the mother or father will ask concerning the desirability of hospital care. Many factors have to be taken into account in giving an answer. Whatever the ultimate decision the parents must know of their child's increased susceptibility to secondary infections and of the risks of his contracting such an infection in hospital. The mother should be told, and told with conviction, that she has it in her power to make a special contribution to the care of her child.

No matter the ideal, however, there is no escaping the practical difficulties. The mother may be too exhausted or her duties in the home may be such as to rule out any question of the child's being retained at home. Other circumstances peculiar to the home may point to the necessity for transfer of the child to hospital. So may the condition of the patient himself. The state of his skin and mucous membranes may call for more continuous nursing care than the district nurse can be expected to give; or the child may be so reluctant to take food that gavage in hospital is essential. In giving his advice the family doctor will be influenced by his knowledge of the facilities offered by whatever hospital he has in mind.

If it is decided to treat the child at home, full advantage should be taken of any home nursing service in the locality. Provided always that the suggestion appeals to her, steps should be taken to relieve the mother of some of her routine household duties by applying to the medical officer of health for the services of a home help. Alternatively, the help of an understanding relative or neighbour can be enlisted. Where arrangements of this sort are impracticable, a not altogether satisfactory compromise can sometimes be effected by temporarily admitting the child to hospital during such time as the mother gets a much-needed short rest.

For home treatment a room should, if possible, be selected which is quiet and well ventilated, which can be shaded without being completely darkened, and in which there is space for a couch or bed where the mother can rest during such time as the patient is asleep. An even room temperature in the neighbourhood of 60° F. (15.5° C.) should be maintained. Unless compelled by weakness to remain in bed the child should be allowed up for short periods once or twice daily, provided that he does not overfatigue himself and provided that he is protected from

draughts. With the disappearance of tachycardia the patient can be allowed out of doors, but must in the first instance be protected from direct sunlight, extremes of temperature, and boisterous winds.

The child should be given a warm as distinct from a hot bath morning and evening. In order to soothe and lessen skin irritation boric crystals (2 oz.—57 g.) should be added to each gallon (4.5 litres) of bath water. A preferable alternative is to bath the child in warm normal saline. Soap should not be used. Bathing must be followed by careful drying with a warm towel and by the application of pulverized fuller's earth or of a high-grade *baby* dusting powder. Calamine lotion is commonly used, but is less effective. Special attention should be paid to situations where there are opposed skin surfaces. The eyes should be bathed and the mouth rinsed with normal saline or boric lotion. Clothing must be light, and the garments next to the skin should be of cotton or silk. Frequent changes of clothing are necessary to avoid chilling while sweating persists. Cardboard splints may have to be applied to the limbs to prevent rubbing. Cotton mittens and socks are useful in protecting the hands and feet.

Feeding

Every effort must be made to ensure that the child obtains adequate nourishment despite his lack of appetite. If the mouth and gums are tender he should (depending upon his age) be fed by feeding-bottle or by a feeder to the spout of which a soft rubber tube has been attached. The use of metal spoons should be avoided as being likely to cause pain. Nourishment should be given frequently—hourly if necessary—in small amounts, and lukewarm or cold according to the child's preference. According to age, chicken jelly, coddled egg, barley jelly, fruit jelly, the cream of fresh milk, and ice-cream (from a reliable source) can be offered. With improvement of appetite in a child of over 9 months choice can be extended to include "smooth" items of semi-solid nourishment such as Benger's food, cornflour pudding, carefully prepared oat flour, egg custard, and fruit juices. At a later stage calves' liver, chicken, and rabbit (all of which should be pounded) and creamed vegetables can be gradually added. Hard or "crumbly" items of diet should not be given until the child shows a readiness to take them. At all times fluids should be allowed generously in the form of diluted milk, provided it does not prove nauseating, or of fresh fruit juices, suitably diluted and sweetened. The aim should be to establish the child on a full diet as soon as he is able to tolerate it.

Although there is no proof that pink disease is of itself a deficiency state the debilitated condition of the child with pink disease requires that an adequate vitamin intake should be assured. In a severe case it is a wise precaution daily to give cod-liver oil (in amounts corresponding to 1,500–2,000 i.u. of vitamin D), ascorbic acid (50 mg.), and one of the reliable preparations of the vitamin B complex.

Sedation

The restlessness and lack of sleep call for sedation. Chloral hydrate is the drug of choice (1–3 gr.—0.06–0.2 g.). On occasion potassium bromide (2–5 gr.—0.13–0.32 g.) is effective when chloral fails, but is apt to give rise to a bromide rash. Sometimes a combination of the two drugs gives the best results. Exceptionally, recourse to phenobarbitone for a limited period of time is necessary. Medicaments, no matter what their form, known to contain mercury should not be given; it should be remembered that teething powders are suspect in this connexion. The risk of secondary infections has been mentioned. Penicillin or sulphonamide therapy is indicated when these threaten, but is not to be regarded as an essential part of routine treatment. Atropine has been employed as a means of controlling the sweating, but the advantages are more than offset by the aggravation of thirst which results. Artificial sunlight and massage therapy are of value after symptoms of irritation and photophobia have disappeared and when the stage of convalescence is being approached. A simple bitter tonic is useful at this stage.

Ideally, the city child should be sent to the country for convalescence—preferably inland rather than to the seaside. In her own interest the mother should if possible accompany the child. Follow-up care must have as one aim the prevention of delayed respiratory complications.

DISORDERED SOCIETY

BY

R. N. TRONCHIN-JAMES, M.R.C.S., L.R.C.P.

Working in an international organization for the care of refugees, in Austria, over a period of some 18 months, my attention has been drawn to interesting behaviour patterns, which, as I shall try to show later, seem to lend themselves to a more general application—that of human behaviour in the insecure and disordered world that we live in at present. After all, the refugee is the physical example of the insecurity that may overtake any of us.

The subject being complicated and controversial, only brief mention can be made of those working for or with the refugees and their motives for doing this work, and of the attitudes of the members of the occupying Power, the Austrian authorities, the voluntary agencies (mostly of various religious denominations), and members of missions sent by Governments to select candidates to emigrate to their various countries.

In the area to which I refer the organization employed an international staff of 45, comprising 12 different nationalities, to supervise the care of the refugees. A temporary organization of this type and size had not existed before, and many of the posts had no parallel elsewhere, so that the holders often had had entirely different training for doing the same job. For instance, "eligibility officers" decided whether a refugee should be accepted as a responsibility of the organization (with enormous advantages to the small proportion of stateless people who were entitled to this privilege), and "resettlement officers" gave the opportunity for and facilitated emigration. Such professions have not existed before and probably have no future to them, yet their incumbents were of overwhelming importance to the refugees.

The members of the occupying Power mostly dreamt of returning home, and anticipated fate by living a life in these alien fields as akin to that at home as possible. They were nominally all-powerful in the life of the organization and of the refugee, but—with rare, though important, exceptions—avoided contact with the problem except at the highest levels, where it could not be avoided. At times the Austrians performed their obligations to the refugees, which were considerable, only under duress.

The mission members were treated with particular respect, because it was they alone who could achieve the most important work of the organization, by selecting candidates to emigrate to their respective countries. That they also suffered from the frustrations and insecurity of modern life, even with their diplomatic passports and privileges, was nicely demonstrated when (in the middle of its work interviewing refugees) the members of the mission of a certain South American republic heard of a revolution in their country that made refugees of them also. The feelings of the candidates they had accepted for emigration, a work of course nullified by the upheaval, can be imagined.

Observations on Refugees in the Field

In dealing with a subject where so many factors come into play it is necessary to pass from the general to the particular. I shall limit myself to consideration of the non-Jewish refugees, and give a few rough statistics. Though a large number of statistics are available, I find that their value is vitiated by many factors, such as the transient nature of some of the population (a pogrom in Bucharest would produce two trainloads of Jews, who would depart just as rapidly to Israel as soon as arrangements were made) and the unevenness of the standard of data upon which the statistics were based: the figures I use are adjusted for such factors so as to have statistical value. My observations are mainly personal, though confirmed by discussions with others trained to observe and working in the same field.

Over the 18-months period some 30,000 non-Jewish refugees were in my medical charge; my work was largely administrative, with from 45 to 60 doctors and numerous ancillaries to assist me, and with a general hospital of 300 beds, a children's home, and other necessary installations. I had occasion to indulge in clinical medicine on few occasions only, such as when I discovered that the physicians at the hospital did not ask for, nor the pathologists know how to determine, the rhesus blood factor. My work went far beyond the fields of administrative medicine, because of the opportunity and co-operation of those in other branches of the organization.

The refugees referred to were ex-Allied nationals who had been deported by the Germans as slave labourers, or those who had fled for political reasons from Communist-occupied countries. About half of them lived, completely dependent on the organization, in hutted camps (or former barracks), where they received all the essentials of life free—lodging, food, fuel, medical care.

Refugee Population Under Consideration

	Oct. 1, 1948	March 31, 1950
Living in camp	12,450	6,000*
Living out of camp	11,482	4,294
Total eligible refugees ..	23,932	10,294

Resettled or repatriated during this period: 17,000 refugees.

* Including the following in special medical installations: 254, Refugee General Hospital; 105, Chronic Sick Home; 254, Old People's Homes.

The chief object of our work was, however, resettlement—that is, to encourage and facilitate emigration of the refugees to countries where they could become citizens; a few refugees also were repatriated to the countries of their origin in accordance with their wish. They consisted of nationals of all the countries of Eastern Europe, the first wave from the Baltic and Ukraine, and later from the Balkans, Czechoslovakia, and Hungary.†

†The Yugoslavs formed the biggest group, followed closely by the Hungarians. Next came the Ukrainians, then Czechs, Poles, and Russians. The Rumanians and Balts were the last considerable group.

In about the same proportion as a typical community in Europe they consisted of aristocrats and professional and working classes. I cite a few examples:

A Czechoslovak, a prosperous lawyer of middle age. His grandmother was a Jewess, and under the Nazis he was put in a concentration camp; with the Allied victory he regained possession of his practice and his house, but when Czechoslovakia acquired a Communist Government he was adjudged a "bourgeois" and dispossessed once more. He fled to Austria.

A Bulgarian peasant who owned a few acres and two cows; he was an ardent Catholic, and fled when the Communists took over his country.

An Estonian father and son, farm labourers, who were deported by the Germans in 1940 for slave labour. They got into Austria when the war came to an end, but have heard nothing from the rest of their family, who remained in Estonia. The father has an injured leg from an accident and, being 52, was not accepted by any country for emigration; the son refuses to leave without him.

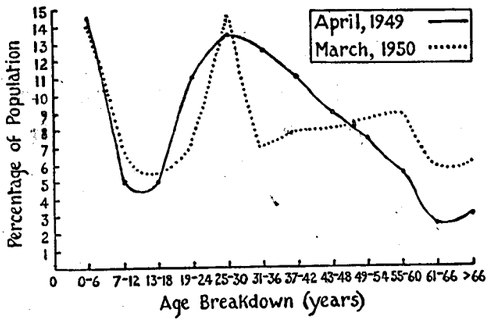
A Yugoslavian coal-miner. He was a trade unionist, and, although a poor man who earned his living hewing coal, he had to flee when his brother was put into prison for his activities with the trade union.

A Hungarian count. His house was occupied as a school and his land taken away. The secret police were interested in him because he was receiving letters from abroad; he was warned that he was going to be arrested as a spy, so he fled the country.

About half the refugees fled their countries with their families, taking very little with them. The "hope that springs eternal in the human breast" did small service to refugees; hardly any of those with whom I had dealings made preparations against such an eventuality. A typical example was a friend of mine, a member of an old Czech family who had vast wealth and estates. When he fled he did not have any ready cash in the house, and the family jewels were inaccessible in a bank: he left literally in the clothes he stood up in.

These refugees lost nearly all those material things and psychic factors that give a sense of security. Not only were they no longer members of a "fatherland"; they had lost membership of their village or town community, of their social or professional group. Even if they found work they were badly paid and in a disadvantageous position in comparison with the native workers. They held most tenaciously to what they still possessed, and most important of all were any family members who had escaped with them.

A family of seven members—father and mother in their early forties, two sons, a daughter and son-in-law, with a baby—refused a most advantageous resettlement offer (where the father could work in his own profession as an engineer) because they could not take along their 82-years-old ailing grandmother. The father continues his job as luggage porter at the local station for a pittance.



There are many such examples. So much having been given up when they fled as refugees, it was tragic to see the future of a whole young family sacrificed for the sake of one senile member. The enormous importance of this factor was overlooked administratively when setting up installations such as for vocational and rehabilitation training; it proved impossible to get the candidates to leave their families for a few months to travel a few dozen miles to enjoy the advantage of such training, which might be vital in getting them accepted by a country for resettlement. The difficulty in persuading a family to move from one pitiful room in a hut to another in a camp 10 miles away was another example of this conservatism: the room contained the few possessions they had escaped with or since acquired; they feared to change the room, feared that unimaginative bureaucracy would put their possessions

in store and not allow them to be used in their new habitation, or that they would get lost en route.

They clung also to their identity of national origin. In spite of their all being reduced to kinship at the lowest common denominator of existence—demand for security, warmth, food, and a roof—they maintained this identity. I had to be constantly on guard that the chief doctor at the hospital, a Hungarian, did not introduce his fellow-countrymen into every vacant post.

The first of the refugees were the youngest, healthiest, most active and alert. They had wasted little time in escaping from a dangerous or intolerable life, and emigrated as soon as possible to whatever country would accept them.

The age breakdown shows (non-Jewish refugees living in camps): April, 1949—out of 4,943 refugees 72.5% were under 42 years; March, 1950—out of 3,400 refugees 63% were under 42 years. The following graph gives the breakdown figures in greater detail.

The requirements of the resettlement missions varied, and often the most likely candidate was turned down without any reason being given. A healthy well-educated man of 47, whom I knew well, was rejected by 14 different missions before being accepted by the fifteenth. I discovered the reason for his rejection on one of these occasions over a glass of beer with the mission chief. The candidate was of Russian extraction, having left Russia in 1922, and the mission had secret orders not to accept any people of Russian extraction. The candidates were presented so that the country of the mission would not be accused of discrimination.* This was an extreme example, but it was most disheartening for the candidates to be presented and then rejected, and contributed to the form of neurosis which was prevalent among refugees, and which is described below.

Refugee Neurosis

On arrival in Austria the refugees were placed in camps, and all immediate responsibility was removed from them; they did not think about the future, and acquired a form of "institutional neurosis" with characteristic inertia. They had great difficulty in obtaining work and did not exert themselves to do so, mostly finding that they could not work in their own professions. This passivity and lack of initiative was encouraged by their dependent situation and loss of self-respect. The whole pattern of their social behaviour was broken down; those who had been Nazi slave labourers had not been permitted to marry, and now saw no reason for doing so, having lived with one woman, and perhaps had several children by her, over a number of years; refugees of Russian birth were legally prevented from marrying foreigners, a rule supported by Austrian law, even though they were refugees.

It is to be expected that people reduced to so extreme a condition of misfortune would lose much self-respect and dignity. There was regression to infantile emotional behaviour, squabbling, and feuding, with complete preoccupation with the present. At the hospital, where refugees worked and lived in conditions most nearly approximating to the normal of all those in our care, competent middle-aged doctors would hold secret meetings behind closed doors over some insignificant personal quarrel, jeopardizing the whole valuable work of the hospital and their own respected status. When the Hippocratic oath was recalled to their attention they behaved like children caught at the jam cupboard. Many of the doctors had had important positions in their own countries, and some had managed to escape with their motor-cars as well as their families: the chief doctor led a string quartet at the hospital. In spite of all these opportunities for normal living, however, they showed the same refusal to face the future and the same dependence as the other refugees. There was never any question of disciplinary problems; they worked extremely well and loyally, but they had as much sense of dignity as a small child. It was the job of those caring for them to goad them into activity: notices that they would have to care for themselves after a certain date, when the organization would be closing, were treated with scepticism. I cite an example:

Four months before the organization was scheduled to close, a doctor of 35, with a wife and two children, was offered a post as a doctor in an American dependency on three years' contract at $4,000 a year and his U.S. citizenship papers. It was a wonderful offer, but in spite of the persuasions of many people he delayed so long in accepting it that he nearly lost the opportunity by default. He had no reason for not accepting, nor any plan for the future. It was only by removing his present, as you might say—I dismissed him from his position in the hospital—that he was made to understand how very insecure that present was, with one small room in which his whole family lived and a pittance of a pay (less than one-tenth of what he was offered in the U.S.A.).

Once a refugee had been accepted to emigrate the conflict produced by the approaching date of departure produced a rash of physical complaints. Persons who had striven to get accepted by the mission fell and broke their legs, or their dentures were not ready by the date the transport was leaving, or they disappeared into hospital to have their varicose veins operated on. The reluctance of the older people to move was more understandable. Many of them had never travelled before: to go to a strange country, where an unknown language was spoken, far from Europe, perhaps leaving relatives behind, and (for the professional classes) to do a new and menial job, were powerful deterrents.

Acute neurosis of the kind that takes a patient to a doctor with symptoms was almost non-existent. The refugee had plenty of opportunity to go to the doctor and little else to do (there was never less than one doctor living and working in each camp per 400 population). I looked very carefully into the diagnostic criteria of the doctors but without producing evidence of these forms of neurosis.†

*Just at the time that this unfortunate man went through this experience an official poster was issued: "The organization is closing; you must make up your mind *now* whether you want to resettle. After June 30 the chance will have gone."

†I instructed the doctors to record all cases of persons going sick without a clear physical cause—e.g., back, stomach, and headache, sciatica, indigestion—and persons with a physical complaint that did not recover as quickly as could be anticipated under treatment, but still failed to get evidence of neurosis.

The incidence of psychosis in the population described was less than 0.1%. Hebephrenic schizophrenia was the predominant form.

The neurosis I describe is of an all-pervading chronic anxiety type, with suppression of volition, similar to what is seen when somebody suffers a severe shock—such as death of an important member of his family. These subjects brood on the past, barely live in the present, and give no thought to the future. The circumstances in which the refugees were placed were not conducive to the recovery, after due passage of time, that normally takes place following such a catastrophe in a mentally healthy person. These symptoms continued for years. The symptoms of neurosis met with in a normal community seem to be a luxury of civilization and an ordered society: typical hysteria—conversion symptoms without insight or hypochondriacal plaintiveness—is not seen among refugees; nor is the typical anxiety state. Nervous restlessness, dejection, apathetic lack of concentration, loss of appetite, unsatisfactory rest ("I need more sleep than usual, but awake tired, Doctor"), bad temper, etc., do not manifest themselves as symptoms. For instance, the apathy that I have described is not associated with excessive anxiety over or irritability in relation to their children or with lack of interest in them; the fathers share the mothers' work in caring for them, and this in spite of the fact that a whole family live in one small room and spend most of the day in it on top of each other—the typical father having no occupation. It is as if the father adopted what is usually considered in Europe as a passive female attitude and not a male active aggressive form of behaviour.

The refugee population was largely Slav in ethnic origin, and the Slavs are notoriously fatalistic: this I have taken into consideration, and what I describe goes far beyond this characteristic temperamental trait. It occurred as widely among refugees living outside camps as among those within, since neither group had security of status. When people are reduced to a simple struggle to survive, conversion or anxiety symptoms can achieve no object: in a totalitarian society illness is not tolerated among captives or slave labourers, so that survival often depends on not being ill—a fact of which the unconscious seems to take cognizance. That neurosis in such a community emerges when it is rewarded was borne out by findings among Jewish refugees, who occupied separate camps and whom otherwise I do not refer to. Here there was a noticeable amount of neurosis of the typical forms, which can be explained by the fact that the Jewish relief organizations were wealthy and thrust attentions on this smaller group of refugees. Symptoms produced tangible results (special food or living accommodation, a month in a mountain or spa hotel for "convalescence"). The Jewish population were also under great pressure to emigrate: the Israel Government would literally accept any Jew, without the tests which other countries demanded regarding age, health, profession, or morality, and which gave the other refugees time for adjustment or acquisition of the passive neurosis I have described. The world-wide wave of sympathy for Jews that followed their persecution, and the power, politically and over public opinion, of American Jewry, also placed them in a special category as refugees.

Conclusions

With his loss of national, civic, class, and professional identity the refugee has suffered permanent personal loss. The emotional impact of this loss is similar to that on someone in normal circumstances suffering the death of a most important member of his family. The symbolic importance of these factors on the emotional equilibrium must be stressed: in them is inherent the source of confidence, independence, self-respect, and the aggressiveness essential for making an adjustment to new circumstances in a different environment. People dealing with refugees must appreciate this, so that they can strive to replace these factors temporarily and, by understanding the refugee's loss, make him feel confident that he himself will be able to regain his status personally and permanently. This therapy cannot be carried out by people who are emotionally incapable of understanding it and either (*a*) identify themselves with the refugees in their plight, thus perpetuating their mental state by justifying it and condoning their hopelessness; or (*b*) by projection make a scapegoat of the refugee so as to give themselves a feeling of superiority, thus turning into an apparent reality what happens to be temporarily true as a result of a material situation.

Using the comparison of a refugee with a bereaved person, the psychological principles can be considered whereby refugees should be handled so as to achieve a complete recovery from the state of shock and the subsequent anxiety state that their situation has created. These principles can be divided into four stages: (1) The actively sympathetic and supportive. The friend encourages the bereaved to abreact and gives sympathy in an active manner. He insists on the bereaved staying with him and taking meals in his house. (2) The passively sympathetic. The friend allows the bereaved to abreact, but does not encourage him; he tries to divert him by unobtrusively placing opportunities of social or other activity in his way. (3) The actively encouraging. The friend will suggest to the bereaved that it is time he "cracked out of it," that it is what "she" would have wanted him to do, that he is still young or still has valuable work to do. (4) The coercive. If the therapy has not worked after going through the above stages the friend will now tell the bereaved that he is indulging himself, that he is being a bother to his friends, and that he had better do something about it or they will all be fed up with him.

Translated into terms of the refugee, the corresponding stages would be: (1) Take him into a camp; give him clothes, food, warmth, and appreciation of one's active concern for his welfare, including mental welfare (understanding and sympathy for what he has lost). (2) Divert him from his painful thoughts of the past by bringing to his attention the opportunities to resettle, to rehabilitate (medically, or to learn a trade that will be of value in a new life). Bring jobs to his attention and encourage him to work while awaiting resettlement. (3) He should be taken in hand briskly, the organization purposively replacing the lost "father figures." That this is an active need on the refugee's part was proved by his response if treated in this way: it is no good stopping at stage 2, leaving the onus of taking action on the refugee, and going straight on to stage 4 if he does not. The father figure may be stern, but he must be understanding and sympathetic; if he chastens it must be to produce results. (4) The threat of withdrawal, or actual withdrawal, of assistance from the refugee. In practice this stage was arrived at without putting stage 3 into effect, and therefore failed as a therapeutic measure, merely enabling the organization to free itself of responsibility.

Many refugees found jobs on their own initiative in the local economy, but for this reason the organization ceased to be interested in their welfare; they were merely exploited as cheap labour because of their disadvantageous position in relation to the native population. Rehabilitation and vocational training centres should be set up as a first

consideration. Life in camps and special installations should be arranged to give refugees the nearest approximation to a normal family life: every effort should be made to avoid institutional conditions, with the abnormal and dependent attitude that they imply, which perpetuate the pathological emotional state of the refugee.

Refugees have existed as long as the human race, but only recently has the human conscience evolved to the state of considering refugees a responsibility of mankind as a whole. This international organization was founded on grounds of expediency, and nothing of its scope had existed before. The work of the organization was (and is) a great physical success in caring for and resettling so many people under so many difficulties. However, that this work can be nullified if the psychological aspect does not receive full consideration is exemplified by the following press cutting from an American newspaper: "A 42-years-old refugee from Lithuania who had been over six months in New Orleans was found, having hung himself yesterday, after hearing a radio programme in which he believed he heard his name mentioned as going to be deported as a spy. Mrs. Y, his kindly sponsor, commented that she was never able to make him believe that he was in a free country."

Summary

Observations made over 18 months on a refugee population of 30,000 in Austria are recorded.

Although the population under consideration consisted of people of every age group and many nationalities, various creeds, and different professional, social, and economic status, their situation reduced them to a common plight with similar mental reactions.

The symptoms of more typical reactive or conversion neurosis were not found in this large population.

A form of neurosis widespread among the refugees is described. The symptoms are those of emotional shock persisting for years, with suppression of active and aggressive psychic qualities, lack of volition, and emotional incapacity to consider the future. There is positive resistance to change even though the present may be most insecure, uncomfortable, and completely different from the previous pattern of life.

The physical care of these refugees was good, and the physical necessity of emigrating them to new countries was dealt with energetically and with considerable success.

A primary object, when such situations have to be dealt with in the future, should be to aim at restoring the refugees to mental health as a first consideration, so that each regains the fullest vigour of his ethnic and individual capacities for dealing with the new situation and environment that he has to face. The capacity for adjustment to a new situation in which the individual is placed is a criterion of his mental health for community living. To restore to the refugee the fullest enjoyment of that capacity should therefore be a prominent aspect of the work of an organization caring for refugees, and, if successful, would enormously decrease the amount of purely supportive work that has to be done.

The Board of the Institute of Physics announces that the Institute's Certificate in Laboratory Arts will not be awarded after 1951 in view of the establishment of the Intermediate Certificate for Laboratory Technicians by the City and Guilds of London Institute. This institute has agreed that holders of the Institute of Physics Certificate shall be eligible to enter, should they so wish, the course for the Advanced Laboratory Technicians Certificate, which is to be established shortly, on the same terms as those who have passed examinations for the new Intermediate Certificate. Students who have already begun courses for the Institute of Physics Certificate will be able to complete these by 1951, after which the Institute of Physics will no longer examine in Laboratory Arts.

A MEDICAL STUDENT IN PRAGUE

BY

P. L. C. DIGGORY

President of the British Medical Students Association

Since few people can nowadays penetrate the Iron Curtain it is possible that even the personal and general impressions gained by a medical student observer to the World Student Congress, held in Prague in the second half of August, will be of interest to readers of the *Journal*. In Communist countries it appears impossible to divorce medicine from political life, and it will therefore be necessary to outline something of the Congress and of the political atmosphere prevailing before dealing with specifically medical questions.

Importance of Youth Movement

In Eastern European countries the youth movements and the student body as a whole have very much more importance than is granted to them in Great Britain. Mass youth rallies have come to form a normal part of the political life of "The Peoples' Democracies," and during the last 12 months Budapest, Sofia, East Berlin, and Prague have each been the scene of such a gathering. The recent Student Congress in Prague was the result of very extensive preparations, and must have been heavily subsidized by the Czechoslovakian State.

On arrival at Prague airport we were met by a small committee of welcome, and every student was presented with a bouquet of flowers; we were then whisked through the customs and taken by special bus direct to the Congress headquarters. *En route* we could not fail to notice the immense scale of the preparations; the streets were decorated and every shop displayed posters of welcome. Even the buses and trams carried slogans in honour of the Congress.

Giant portraits of Stalin smiled down at us from many public buildings, but it is difficult to know whether these were specially erected for the Congress or whether they now form a part of the normal street decorations.

The facilities provided for delegates in Prague were excellent. We were accommodated in large student hostels, and extremely efficient arrangements were made for the provision of food, easy travel, and free entertainment. It is typical that a whole fleet of buses had been diverted from their normal duties in the city and placed at our disposal.

During our stay we were to come to realize the privileged position of students in Czechoslovakia, all of them receiving a generous Government grant. In addition they are provided with accommodation in student hostels at extremely cheap rates. They are allowed to use workers' canteens and are able to travel on all forms of transport at greatly reduced fares. The president of the Czechoslovakian National Union of Students is *ex officio* a member of the Czech Parliament.

It will be realized that these privileges are not attained without sacrifice. To gain admission to a university in Czechoslovakia a student requires recommendations regarding his "reliability." The very fact that all students receive a grant from the State makes it possible for the Government, by withdrawing this grant at any time, to dismiss individual students. All faculties of the universities include in their curricula the compulsory study of political science: for 12 months every medical student must study this subject, and in his final examinations he sits a compulsory paper.

The whole system of education in Czechoslovakia has been remoulded since the Communists came into power. Political education is now an intrinsic part of the curriculum in even the most elementary schools. The young school-children first join the pioneer movement, which closely resembles the *Hitlerjugend*. A uniformed contingent of this organization paraded before the Congress, and a little boy of about 10 made a speech of welcome devoted largely to an attack upon the "Anglo-American imperialists." In second- and third-grade schools the Czech or Slovak languages are learned together with one foreign language. Before the war German or French was the usual foreign language selected; these have now been replaced by Russian.

The Student Congress

The Congress was the largest student gathering ever to be held, and it is perhaps not surprising that with over 1,500 students assembled in one hall informal debate was impracticable. In point of fact, most speakers used the rostrum to deliver a political diatribe rather than to address the assembled students.

Once again the amenities afforded were beyond reproach, and the simultaneous translation of all speeches into five languages and their transmission through a headphone system equalled the facilities at Lake Success.

The first indication of the trend which was to be followed in later speeches was given in the address of welcome by the Deputy Prime Minister, who bitterly attacked the Western Powers, with particular reference to American "aggression" in Korea, and who ended with a eulogy of the U.S.S.R. and of Stalin. This line was followed not only by the students themselves but also by a succession of guest speakers, including the Czech Prime Minister, several Ministers of Cabinet rank, the heads of the Churches, delegates of shopworkers and peasants, visiting scientists, and various other well-known personalities.

Many of us received our worst emotional shock when three bishops, heads of the Roman Catholic, Orthodox, and Czech national churches, made political speeches in support of the Stockholm appeal in addressing the Congress. The Orthodox bishop ended his address: "The blessing of the Almighty Lord on our great goal; long live unafraid the true fighters for peace, at the head of whom is our great Stalin."

The Congress sessions were conducted under a façade of democratic procedure, but actually the major decisions, and the very atmosphere and demonstrations, were clearly controlled by the leaders, and in particular by the Russian delegation. There were many instances of undemocratic behaviour of the Congress Praesidium, perhaps best exemplified by the fact that formal speeches had to be handed in 24 hours in advance, ostensibly to allow time for preparation of translations. Actually by this procedure not only was the secretariat able to call upon speakers in a pre-selected and carefully calculated order, but there is strong evidence that the draft speeches of certain Western delegates were made available in advance to the Communist speakers who had been chosen to reply. Occasionally even the façade of democracy broke down and the chair became openly partisan.

A significant feature of the Congress was the number of demonstrations which were directed against the Western students. Most of the demonstrations followed the same general pattern, and to understand them it must be appreciated that for the Communist students the atmosphere was one of almost religious fervour. The speaker would launch an attack on the "Anglo-American imperialists," usually followed by personal abuse of Mr. Jenkins, leader of the British delegation, and ending with either "Long Live Peace!", "Down with Imperialism!", or "Hands off Korea!" These exhortations were invariably followed by hysterical cheering and clapping, generally leading on to the newly developed technique of "rhythm-clapping," where words or syllables are accentuated by rhythmic hand-clapping. At this stage the cheering students would surge forward to the rostrum to embrace and to shower flowers upon the speaker, who would then be carried shoulder-high down the hall, usually together with the remainder of his delegation, and almost invariably paraded round and round the tables of the British delegation. It is mortifying to have to report that the British Communist students present—about 70 in all—played a leading part in these demonstrations. They presented the Korean delegation with a gift of penicillin, and delighted to carry these Korean students and their army leader round their British colleagues to the chant of "Hands off Korea!"

The demonstrations, which were to some extent symbolic, with the triumphant marching of the Eastern students around and between the tables of the isolated Western delegations, were undoubtedly a strong propaganda point, demonstrating the unity of "the students of the world" against the "imperialists." Unfortunately such demonstrations also broadened and perhaps biased the attitudes and opinions of the Western students, and hastened the splitting of the students present into two ideological groups. The Congress may not have actually increased the difficulties in the way of co-operation between students of the East and West, but it certainly made these difficulties more obvious.

Since Eastern students are prevented from travelling freely abroad it has been argued that the presence of students holding different views must have been an influence for good. Unfortunately the majority of students attending the Congress were drawn from the *élite* of Communism and were beyond the reach of argument; while the highly biased reporting in Eastern European newspapers made it impossible for the Western arguments to be heard beyond the Congress hall.

Colonial students were well represented, and, although the majority of their leaders were militant and aggressive Communists who mouthed slogans and expounded the universal panacea of Marxism, there were a number of colonial speakers whose reasoned arguments and obvious sincerity commanded respect. Delegates from Imperial countries came to realize how urgent it is that our system shall offer to colonial dependants the opportunity for a speedy rise in their living conditions and, in general, a fuller life under free democratic conditions. If we do not act quickly then these peoples will seek such benefits elsewhere. It is foolish to imagine that Russia can expand her colonial empire only by war: inactivity and neglect by colonial powers will effect the conquest far more certainly than military means.

Medicine

Any British medical student abroad is certain to be interested in the health services, and it is surprising to find that in a Communist State the national health service is as yet available only to approximately two-thirds of the population. There is no separate health tax comparable with the contributions to the National Health Insurance scheme in this country, but both the cost of health services and that of the national insurance scheme are borne by the State from funds raised by direct and indirect taxation. The organization of the service seems to be developing on

parallel lines with changes in most European countries; the importance of the general practitioner is rapidly decreasing and emphasis is being laid on the hospital and specialist services. We were told that a large number of new hospitals have been and are being built under the recent five-year plan, and in some districts experimental "health centres" have already been set up.

During our stay we were taken over two of the largest hospitals in Prague and some of us were also able to visit the International Student Sanatorium at Trebotov. In addition, it was possible to establish a more informal contact with some Czech doctors. We concluded that the hospital buildings were excellent, the main equipment—still largely German or American—very good, but that the minor equipment, such as hypodermic syringes, small surgical instruments, stethoscopes, needles, etc., was of an incredibly poor quality, probably because of the difficulty in obtaining stainless steel in Czechoslovakia. At a time when students in Britain are planning to establish special facilities for their tuberculous colleagues so that something of the university atmosphere and teaching may be available to them even while ill, it was particularly interesting to visit the International Student Sanatorium at Trebotov, where some of these aims have already been achieved. It is difficult to believe that the sanatorium is only 20 kilometres from Prague; it is surrounded by a pine and birch forest, and the atmosphere of peace and beauty suggests the very depths of the country.

The Bulovka Hospital, the largest in Prague, is situated on the outskirts of the city on a pleasant hill overlooking the River Vltava. The grounds of the hospital must be several acres in extent, as each department is housed in a separate pavilion—a scheme which adds greatly to the aesthetic value and is appreciated by convalescent patients but which introduces many problems of administration. We found, however, that the hospital was over-centralized, each department or specialty to a large measure being autonomous, with all the perils that this implies.

Both at the Bulovka Hospital and at the other large Prague hospital visited student delegates were formally welcomed by the directors, who made very many political points in their addresses of welcome. We were told that because of the happiness and security under the new regime chronic alcoholism was declining, psychiatric disorders decreasing, V.D. almost a rarity, and prostitution wiped out. We found that this political atmosphere prevailed throughout the medical profession, and after a tour of the hospitals we took part in a medical discussion, which unfortunately confirmed our fears. During discussion a French Communist student asked for an explanation of how dialectical materialism had affected Czech medicine, and it was apparent in the discussion that every single doctor of the Czech hospital staff present felt compelled to take part. In fact discussion on this point could be ended only by the intervention of the director himself.

In Czechoslovakia a doctor theoretically works only seven to eight hours a day, and when newly qualified commences with a salary of 7,000 crowns a month. In practice, because of the shortage of doctors, he works longer and is paid more. The system of promotion is peculiar, and there is "a special remuneration for industrious workers" which allows the young doctor to reach the highest salary ranges of his profession—that is, in the order of 25,000 crowns a month. To give these figures some meaning it should be mentioned that the minimum legal wage is 1,800 crowns a month, and that the average wage of a skilled worker is around 5,000 crowns a month, while a shock-worker may earn three times as much.

It was impossible in such a short visit to obtain any but the most general and personal of impressions, but we admired the close and cordial relations existing between the medical and non-medical staffs of Czech hospitals. Even the humblest laundry maid was regarded, and regarded herself, as an integral member of the hospital team and was assured that her opinions and suggestions would be welcomed at regular meetings where all the staff were represented.

General Impressions

The newspapers in Czechoslovakia are completely censored and present only one point of view, a fact which is accepted by many Czech intellectuals as an essential temporary expedient. Foreign newspapers can be imported into Czechoslovakia only under licence. These licences are very hard to obtain, and though the British delegates made application at the beginning of the Congress the *Daily Worker* was always the only paper on sale. Similarly air-mail copies of other English newspapers dispatched direct to the students in Prague failed to reach them. The bookshops stock little but the works of Marx, Lenin, and Engels, and the only English books we saw translated were certain of the works of Dickens—for example, *Oliver Twist, Bleak House.*

Apart from the censorship of the Press there are many other inroads into the liberty of the individual. Open opposition to the Government is a crime against the State, and, though three political parties are said to exist, all three are Communist and their programmes differ solely in the way in which they would achieve a fully Communist regime. If we accept that Czechoslovakia is a police State the reports of students being followed are not surprising. This was certainly true in the cases of the leaders of the British delegation. Towards the end of our visit the B.M.S.A. representative found himself being followed in the most obvious manner. This experience, though at first unpleasant, in no way interfered with one's freedom of movement and could at times be quite amusing. The worship of the U.S.S.R. and "the great father, leader, and teacher —J. V. Stalin"—is a feature of everyday life in Prague. It was strange to find that portraits of Stalin took precedence over the Czech President; the red flag over the Czech national flag. Most of the rooms in the student hostels were decorated with portraits of Stalin, similar to those invariably displayed in hospital dining-rooms and clinics. The fact that two odes were sung to Stalin at a concert given by the Russian students surprised no one but the naive British.

Among the people there is a genuine and deep desire for peace, but they are being educated to "fight for peace," and they already fear "imperialist aggression." In the event of war the ordinary citizen of Prague has been so prepared that he will certainly believe aggression to originate in the West. The fear of Fascism remains very real after the Nazi occupation. We visited Lidice, where we saw harrowing relics which keep alive the hatred of Fascism. There is no doubt that the Communist argument runs: "This is what Fascism did to us—we are the enemies of Fascism—our enemies are Fascists and will do deeds like this."

The Ministry of Health has announced revised rates of payment for health visitors, district nurses and midwives, and other nurses employed in the public health service, and also for senior nursing staff in mental hospitals. These new rates have been agreed by the Nurses and Midwives' Whitley Council, following an award made by the Industrial Court, and they are retrospective to February 1, 1949.

ANAESTHESIA IN FRANCE

The Bengué Memorial Award Lecture for 1950 was delivered by Dr. Nadia du Bouchet, head of the Anaesthetic Centre, Broussais Hospital, Paris, at the Royal Institute of Public Health and Hygiene, in London, on September 20. Mr. C. Price Thomas, F.R.C.S., was in the chair. The subject of the lecture was "Modern Anaesthesia in France and its Developments Related to Cardiac Surgery."

Dr. du Bouchet said that for a long time the science of anaesthesia had been essentially Anglo-Saxon. The interest that followed the discovery of nitrous oxide and ether had spread rapidly throughout the world but soon had died out everywhere except in England and America. In France, and elsewhere on the European continent, only a very few isolated persons, who to-day assumed the stature of pioneers, had continued to be interested in this branch of medicine. The majority of Continental surgeons considered that the administration of an anaesthetic was an act of minor importance which required no special training, and were willing to leave it to a first-year student, orderly, or a nurse. During the German occupation France lived in isolation with her old-fashioned methods.

It was not until the liberation of France that French surgeons first came in contact with the British and American surgical teams which included not only a surgeon but also an anaesthetist who was on an equal footing with the surgeon. At the same time, the most advanced French surgeons realized that certain recently developed fields of surgery would remain closed to them unless they could call upon scientifically organized anaesthetic assistance. Modern anaesthesia in France dated from this realization, and if the progress made in the past four years were considered there was every reason to be proud.

At the instigation of Professor Moulonguet a course in anaesthesia was organized at the Paris Medical Faculty, for which a diploma was granted. This course includes one year of theoretical study and two years of practice in various Paris hospitals. In Marseilles the Medical Faculty organized a similar course, at the instigation of Professor Vernejoul. Next, Dr. Kern, who was trained in England during the war, had organized an anaesthetic service which included a practical teaching centre, and Professor d'Allaines had created a similar service at the Broussais Hospital, which was now a centre for teaching anaesthetics as well as for cardiovascular surgery.

Dr. du Bouchet then described the methods of anaesthesia for thoracic surgery used at Broussais Hospital, where in the last two and a half years some 300 patients with the tetralogy of Fallot had been operated upon. In particular she reviewed the difficulties experienced in perfecting the anaesthesia for this condition, the value of the electrocardiogram during the operation, and the problems arising from the ligation of the vena cava in decompensated cardiac patients.

The W.H.O.-Unicef campaign against syphilis and yaws in Haiti has recently been described in this *Journal* (September 16, p. 668). A similar campaign against yaws in Indonesia has resulted in the examining of more than 25,000 persons and the treatment of 5,000 in the first few months of operations. Progress was reviewed in New York a short time ago by Professor Kenneth R. Hill, W.H.O. consultant for the project. Eventually the campaign sponsors hope to examine 2,500,000 to 3,000,000 children and adults in selected rural areas of Indonesia. After a two-year period in which most of the supplies will be provided by Unicef the Indonesian Government will take over the campaign. In the hot, damp climate of the rural districts visited to date an average of one out of every five persons tested had yaws. "We have found that the germ causing yaws is killed and disappears from the sores within 24 hours of treatment with penicillin," Professor Hill reported. Penicillin is cheaper and better suited to mass campaigns than the arsenic injections used in a yaws control programme conducted in Indonesia in 1935 to 1940. Although yaws will not be completely wiped out in the two-year campaign, it is expected that the disease may be cleared up entirely in ten to fifteen years if the Indonesian Government continues to control operations along the lines now followed.

Correspondence

Distinction Awards

SIR,—May I say at the outset that I was not a member of any committees set up by the regional board or board of governors to give evidence on distinction awards. As chairman of the Consultants and Specialists Committee I felt that it would be unwise to participate in these procedures. Indeed my committee, which has agreed with the principle of distinction awards, when asked to give evidence decided not to send names of individuals, but contented itself with suggestions as to the factors which should be taken into account in assessing merit.

Mr. R. S. Murley (September 23, p. 726) completely clouds the issue and does not realize that the Central Consultants Committee has spent much time in discussing the merit awards system of augmenting the basic salary of a certain proportion of consultants, which augmentation was deemed equitable both by the Spens Committee and by Parliament following the masterly survey of consultants' incomes analysed by Dr. Bradford Hill. And it must be remembered that these distinction awards are an element in remuneration. This factor influenced the Central Consultants and Specialists Committee in accepting the terms and conditions of service of hospital medical and dental staffs.

The real issue raised by Mr. Murley's letter is whether Lord Moran is right in going round the country addressing meetings of non-teaching consultants in order to elicit more information. A chairman's task is difficult. He must be able to guide his committee, but he must also have full knowledge of the problem. After reading Mr. Murley's letter I went to hear Lord Moran address two meetings in Manchester. He gave an extremely lucid and frank account of the procedure which had been adopted. He stated that his committee had received valuable evidence from the board of governors, regional boards, the Royal Colleges, and the various faculties, but that he was anxious to have further evidence from the non-teachers. He gave me the impression that he wished no stone unturned, so that when the awards were made the profession would consider that the procedure adopted had been just and equitable.

Knowing the difficulty I have had to contend with in the Central Consultants Committee, in our regional board, and the Representative Meeting owing to the decisions of the grading committees, I consider that the profession should be grateful to Lord Moran for the thoroughness with which he is performing his unenviable task. Mr. Murley could argue quite forcibly that there might be other methods of distributing these moneys, which, I repeat, are an element in remuneration. But for the moment the present method has been accepted by the consultants.

As chairman of the Central Consultants and Specialists Committee I feel it is my duty to lay these facts before you.—I am, etc.,

Manchester. R. L. NEWELL.

Psychology and Science

SIR,—Dr. F. M. R. Walshe's interesting paper on "Humanism, History, and Natural Science in Medicine" (August 12, p. 379) seems to suggest that natural science is something apart, almost holy. He gives me the impression that he regards natural science as a series of neat white Athenian temples in which old gentlemen with long white beards teach their disciples exact and absolute truth. Apart in the semi-darkness of ignorance, living perhaps in huts and having beards of less beautiful whiteness, dwell the historical scientists who, poor wretches, know the truth imperfectly and teach error, although perhaps not with intent. Amongst these outcasts is to be placed the psychiatrist with his strange theories.

Now I have tremendous respect for Dr. Walshe, but this is a thing which I cannot accept. Science is, I feel, only a collection of facts and an attempt to explain them so that we can predict what will occur in certain circumstances. Scientists try to explain these facts by various theories, and when, sooner or later, one of these theories seems to be better than the others

it is accepted and may even, if it allows us to predict enough, be dignified as a "law." In my utter ignorance it seems to me that the theories of Freud are no more fantastic than the theories of Hughlings Jackson and much less outrageous than those of the mathematicians with their talk of expanding universes and continuous creation.

It seems to me that it is as scientific for Freud to ask a patient to lie on a couch and talk without interruption so that he can examine his mind as it is for Hughlings Jackson to ask him to lie on a couch to prod his body. Moreover, psychiatry has sufficient facts to predict fairly well—as well, for example, as neurology. If a schizophrenic comes to me I can tell his relatives what are his chances of recovery just as well as Dr. Walshe can tell a man suffering from disseminated sclerosis that he cannot do much to cure him.

I beg, Sir, that we come off our high horses and realize that we are all ignoramuses trying to help our sick fellows, and whether we call ourselves this or that matters not one jot so long as we do our best for them.—I am, etc.,

London, W.1. CLIFFORD ALLEN.

Training for General Practice

SIR,—It was to be expected that Dr. D. McI. Johnson's article of August 26 (p. 493) would call forth a spate of letters, from that of Dr. Geoffrey Evans (September 9, p. 622), who considers that Bart's "made a man of him," to that of Dr. W. A. Bellamy, with his superb old school tie and loyalty to everything good or bad. Doubtless Dr. Johnson has exaggerated, but there is much in what he writes. The object of all stages of education is to fit a person for what he has to do in life, and as by far the majority of hospital students are ultimately destined for general practice the main object of hospital training should be to turn out men with a knowledge of the things which a G.P. has to do.

It is obvious that he must have a general knowledge of medicine and surgery up to some accepted standard, but the tendency to-day seems to be to attempt to make him a little expert on an increasing number of special subjects. Much time is wasted in the exhibition of surgical procedures and medical rarities. I think it must be accepted that the newly qualified man is much more at sea in general practice than as a H.P. or H.S., and the reason for this must lie in his training. My father always maintained that no man should be allowed on a teaching staff who had not done two years as a G.P. I would suggest that much more teaching could be done in receiving-room and out-patient departments where men with this general experience would be dealing with the early stages of disease and treatment and so instil into their students that mental outlook which seems increasingly the perquisite of the good G.P.—I am, etc.,

Wanstead Park, Essex. M. C. STARK.

SIR,—My contemporary at Bart's, Dr. W. A. Bellamy, has leaped most efficiently to the defence (*Journal*, September 9, p. 622). As he says, there are things that he learnt that have been no use to him since, and I have no doubt he has learnt a lot in general practice that he was not taught at hospital. But it is a commonplace to say that the function of education is to make a man want to learn and to teach him the way to learn—not simply to pack him with a series of facts entirely based on their immediate practical value to him in everyday life.

A London medical student (*Journal*, August 26, p. 496) postulates that the first essential of qualification is the basic knowledge which is the stock-in-trade of the general practitioner, and that any further training should be additional—presumably postgraduate. However, is this basic knowledge all that is required? Should not the G.P. have a rather more general picture of medicine as a whole? He must know not only the immediate things he can do for his patient himself but also the things that might possibly be done for him by a specialist, and he must use his judgment to decide whether these things should be done in every case with a reasonable chance of benefit, having regard to the age, general condition, and circumstances generally of each individual patient.

However, I agree that a period or periods at intervals during his training should be, with great advantage to every student, spent working with an experienced G.P. Working in a general practice, with ready access to advice and help, is the only way of acquiring certain attributes in dealing with patients, their relatives, and their not entirely medical problems. It was a tremendous help to me while at Bart's to be continuously in contact with my father in general practice and to be able to some extent to correlate hospital training with the everyday work there.

With the present-day pressure of work in general practice, however, I foresee a great difficulty in getting sufficient numbers of general practitioners of the right type to give time to such periods of teaching.

To return to Bart's at the time Dr. D. McI. Johnson (*Journal*, August 26, p. 493) was so unhappy there—granting that too much time was spent in operating theatres, that some—not all by any means—set lectures were unhelpful, and that in some special departments my mind was in somewhat of a befuddled state, there was still a great deal to set on the credit side and indeed to very greatly outbalance the debit. In the first place, if practical teaching as opposed to too much theory is considered highly desirable I do not think I could be said to be unfortunate in my teachers, among whom were Sir Holburt Waring, Sir Girling Ball (who with some exaggeration used to say, "Never read a surgery book in my life, my boy"), J. B. Hume, John Hosford, Wilfred Shaw, A. C. Roxburgh, and a host of others too numerous to mention and with whom I did not perhaps come into quite such close contact. I should, however, also mention the very great deal to be learnt from a good nursing sister. I am sure that Miss Milne, Sister Henry of those days, will forgive me, if she reads these lines, for saying that there were times when my feelings towards her were homicidal but that the amount of help and knowledge she gave me was enormous. Secondly, I do not think it is possible to overrate what Dr. Geoffrey Evans (*Journal*, September 9, p. 622) has called "the tradition and atmosphere of St. Bartholomew's Hospital with its teachers, nurses, porters, and students," and I should add with its athletic clubs, students' union, and various societies and activities which, if one took the trouble to interest oneself in them, were such a source of enjoyment and inspiration. On the wall of my consulting-room opposite my desk is a photo of Sir Holburt Waring—his face is stern but there is that well-known flicker of a smile at the corner of his lips. Often in a crowded surgery when a patient has complained of some rectal symptom I have caught his eye—and have seldom been able to omit the rectal examination.—I am, etc.,

Gravesend. K. W. D. HARTLEY.

Visual Aids in Medical Teaching

SIR,—Having read the interesting and very instructive articles on medical education (*Journal*, August 26), which every young teacher should be compelled to read, it may perhaps be opportune to discuss in this connexion the subject of visual aids. The apparatus for such mechanical aids has been well described by Drs. R. Ollerenshaw and P. Hansell, but I agree with Professor Lauwerys that we have not yet learnt to use them to the best advantage. I have discussed the subject with my colleagues and find that most of them are far from enthusiastic about using such methods, and look upon a film only as an entertainment for the students. I think the idea still persists because most of the films last 20 minutes to half an hour. In my opinion, there is little if any value in such films in teaching medicine. What is really needed are short pieces of film, lasting perhaps two minutes, interspersed in a lecture to illustrate certain points. Some of these can best be illustrated by filmstrips or lantern slides. All these should also be available to the student outside the lecture hall.

In order to increase interest in such aids to teaching and to promote discussion it is hoped to arrange a joint meeting with the Royal Society of Medicine early in the New Year. It is also hoped to arrange some meetings, for film viewing, before the combined meeting takes place.—I am, etc.,

London, W.1. MALCOLM DONALDSON,
Chairman of the Medical Committee, Scientific Film Association.

Haematemesis from Leeches

SIR,—Dr. A. Cameron's interesting letter in this week's issue of the *Journal* (September 16, p. 679) prompts me to add that leeches may also cause haemoptysis. At the C.M.S. Hospital at Es Salt, some eighteen miles east of Dr. Cameron's refugee camp, quite a number of leeches have been removed from the throats of villagers and shepherds. One of the most grateful patients that I can remember was one from whom I removed a leech that was hanging in his trachea attached to the under side of a vocal cord. He had been coughing blood almost continuously for three days. One may swallow leeches or enable them to attach themselves to the pharynx either through drinking directly from the edge of a stream or through drinking stream-water from the spouts of stone water-jars into which it is difficult to see. The drinker holds the jar above his upturned face and pours the water straight into the pharynx, swallowing rhythmically the while without closing the lips.—I am, etc.,

Sheffield, 10. H. F. WEST.

Treatment of the Common Cold

SIR,—It was interesting to note in "Points from Letters" (September 9, p. 631) that I am not alone in presuming to dispute the findings and conclusions of the Medical Research Council and Lorriman and Martin trials. If we substitute "experience" for "impression" in your heading, the point at issue would be briefly summarized by "Clinical Experience versus Cold Science." Your correspondents may be unaware that as long ago as April 17, 1948, I recorded in your columns my own clinical observations and experiences over the previous two years in the use of antihistaminics in the treatment of the early stages of rhinorrhoea in acute coryza. This was followed later by the publication of the work and clinical experiences of others—Drs. Brewster, Arminio, Sweet, and Murray in America. All these published clinical experiences and results showed that it was likely that histamine activity occurred in the nasal mucosa during the early stages of acute coryza, and that if this could be controlled by adequate dosages of antihistaminics the secondary stage of muco-purulent catarrh did not occur and the condition was aborted.

The conclusions of the M.R.C. trials ask us to dismiss these clinical experiences as of no import by producing a mass of mathematical comparisons of the effects of an inadequate dosage of one antihistaminic with those of a presumed inert medication. In my view the only reliable estimation of the value of any therapeutic measure is the clinical observation of its use and adaptation over a prolonged period of time. After four and a half years of recorded personal clinical observations I can assure Colonel Crichton and Dr. Ambrose that their clinical impressions are largely in accord with my own experiences and those of other workers.

It might be trite to ask what therapeutic developments would be lost if we neglect to believe our own clinical experiences and accept "cold mathematics" in place of them.—I am, etc.,

Whitburn, Co. Durham. FRANK CORT.

Interesting Cancer Case

SIR,—The occurrence of multiple primary carcinomata has been taking up some space in the *Journal* recently. A case which has proved very interesting to me may be of interest to others of your readers.

A woman—aged 65—in 1940 had deep *x*-ray therapy for an evidently inoperable carcinoma of the right breast. When I first saw this patient in 1947 she had her entire right breast solid with an iron-hard growth. In the nipple area there was a fungating, bloody, spongy, smelling area, 3 in. in diameter, necessitating dressings every 10 or 15 minutes. The right axilla was filled with a massive growth as large as a tennis ball. Further examination revealed an obvious carcinoma in the left outer quadrant of the left breast with involvement also of the axillary glands. Furthermore, a basal cell carcinoma on the bridge of the nose was also bleeding and necessitating dressings. This seems to be an example of three primary carcinomata.

This woman is still alive as I write. She has had several three-month courses of methyl testosterone orally. Two weeks after the beginning of the first course the bloody discharge from both breast cancer and basal cell carcinoma ceased, and all three growths became increasingly reduced in size. There have been no dressings since. An intractable back pain was relieved as quickly.

I might add that a course of oestrogens, tried at the instigation of one of my colleagues, produced uterine bleeding in this post-menopausal patient.

Assuredly our ignorance of cancer is abysmal.—I am, etc.,

Wakefield, Quebec. J. H. S. GEGGIE.

Abnormalities in Developing Chickens

SIR,—Having read with very great interest the article by P. K. Duraiswami on insulin-induced skeletal abnormalities in developing chickens (*Journal*, August 12, p. 384), I would like to suggest that part of the work is repeated using fertile eggs in which the vitamin-B complex and manganese portions of the diet of the parent stock are known and standardized.

I do not doubt that his controls were adequate, but from the account given the eggs were taken from the same flock, and presumably they did not show the abnormalities mentioned. I introduce this point because in my examinations of some hundreds of "dead-in-shell" many of the conditions quoted by Mr. Duraiswami appeared quite regularly in so-called normal embryos. There can, of course, be no question of insulin-induced malformation in these cases. In practice one believes that they are linked with deficiencies of riboflavin and other members of the vitamin-B complex, and in some cases of chondrodystrophy also with manganese. The diet of the parent stock is faulty, but on other occasions it is an idiosyncrasy on the part of individual hens referable to their need for higher than normal amounts of the specific nutrients mentioned.

Mr. W. Marshall, of the Papworth Industries, has a very wide knowledge of the incidence of these embryonic abnormalities, and his paper to the Eighth World Poultry Congress should be read by all concerned, as well as the Storrs University *Bulletin* on "Hatchability and Environment."

Note how the head is tucked between the thighs, completely preventing hatching, and the position of the feet and toes.

Doubtless the whole matter is an interaction effect related to both genetic make-up and environment. In addition to the diet of the parent stock, marked fluctuations of temperatures during incubation are also known to be a major environmental factor. Presumably this is the equivalent of the "rubella" effect in pregnant women, and, if so, it shows the value of students having a knowledge of human as well as veterinary medicine where common problems are concerned.

I enclose a photograph of an abnormality of the type described.—I am, etc.,

London, E.C.4. W. P. BLOUNT.

A Foreign Body in the Rectum

SIR,—Mr. J. B. Prendiville's description of a foreign body in the rectum (*Journal*, September 16, p. 680) prompts me to report a case that came under my care many years ago. The body was a torpedo-shaped piece of hard smooth wood with rounded ends, 8 in. (20 cm.) long, 1 in. (2.5 cm.) in diameter at its wider end, and somewhat smaller at the other. A hole was bored

near one end to which was fixed a cord, and, the wood being heavier than water, the apparatus was used to locate obstructions in drains. The mentality of the patient may be judged by his statement that he inserted the piece of wood into his rectum to relieve an attack of constipation: his attempt had been only too successful, but, as he had omitted to have the cord attached, the body had become irrecoverable.

On examination the wood was found lying mainly in the sigmoid colon. Its upper end could easily be felt in the region of the umbilicus, but pressure at this end only displaced it downward a centimetre or two, and its lower end could just be reached high in the rectum, and pointing downward and backwards towards the hollow of the sacrum. As perhaps over-vigorous efforts by the house-surgeon and myself to recover the body were therapeutically futile, it was decided to expose the rectum and incise it from behind. After a spinal analgesic had been given the patient was re-examined and it was then found that, owing to the resulting relaxation of the pelvic musculature, the body was delivered bi-manually without the least difficulty.

If I am confronted again with a similar case, spinal analgesia will be used unless there are the strongest contraindications. Mr. Prendiville does not mention what anaesthetic he used.—I am, etc.,

Birmingham, 15. J. W. RIDDOCH.

Poliomyelitis in General Practice

SIR,—Dr. Florence M. E. Davies (*Journal*, September 9, p. 629) would seem to suggest the random administration of penicillin, "blind," to all febrile cases, but I would suggest that the following case histories indicate the dangers of such treatment and, incidentally, probably show that the cases with which she dealt were not poliomyelitis.

During the course of two months we have seen some 15 cases which we have thought to be poliomyelitis. In only three has there been paralysis, and one patient died. Case 1 is typical of the outbreak.

Case 1.—Boy, aged 9. "Off colour" for a few days, then began to complain of headache. When first seen the child was lying very still and looked very anxious. Temperature 104° F. (40° C.), pulse 120. Marked neck rigidity, Kernig's sign doubtful. Complained of pain in the mid-thoracic region on firm flexion of the neck. Admitted to the Lincoln County Hospital. Dr. Trevor Wright, paediatrician to the hospital, informed us that lumbar puncture showed no abnormality except an increased cell count (lymphocytes, 9 per c.mm.), a finding which would tend to confirm the diagnosis of poliomyelitis. Recovery was uneventful; no paresis was noted.

Case 2.—Boy, aged 6. A similar story to the above. When first seen the child had such slight neck rigidity as to make one doubtful of its significance, but on the next day there was a left facial palsy, a very marked neck rigidity, and Kernig's sign was definite. Dr. Trevor Wright confirmed our diagnosis of acute polioencephalitis.

Cases 3–14.—One adult, the remainder children, varying in age from 6 months to 14 years. The baby, aged 6 months, was found on lumbar puncture to have a pneumococcal meningitis. One boy, aged 7, died within 24 hours of admission to hospital from an acute left ventricular failure due, probably, to involvement of the brain stem. The adult came to the surgery one day with a paresis of his calf muscles (rt.) and gave a description of the same sort of febrile illness one week previously. All other cases made an uneventful recovery with prolonged and absolute bed rest.

Case 15.—Woman, aged 29, para 3, two months pregnant. The onset was similar to those above. When first seen the patient complained particularly of the headache. There was slight neck rigidity and an indefinite Kernig's sign. The husband was told that poliomyelitis could not be excluded, but the case passed from our care at that stage for two weeks. At the end of that time one of us (J. W. G.) was again called to see her, and she was found to have a 60–75% loss of power in the right glutei, vasti, and hamstrings. She stated that she had had some forty injections, which she was told were penicillin, into the right buttock and thigh, and that she had been told that the resultant pain and the loss of power were the natural results of the injections. She was referred to Dr. J. Gibson Barrie, medical specialist at the Boston General Hospital, who agreed that she had in fact been suffering from poliomyelitis, and the appropriate therapy has brought about some regeneration.

The particular interest here, to our minds, is that the paresis should be so localized to the area of local trauma, and that it should appear after such trauma in a case so similar to the many others we saw, in the majority of whom there was no trauma and no paresis. Points which we noted in all cases were a tachycardia disproportionate to the pyrexia, the apparent anxiety of the child, and the complaint of mid-thoracic pain on flexion of the head on to the chest.

It is recognized that the evidence of one case cannot be of any real statistical significance, but it is suggested that, apart from this interesting case, sufficient evidence of the possible dangers of indiscriminate intramuscular injections in the presence of poliomyelitis epidemics has already been published, and we now feel that we should be most unwilling to give "penicillin in huge doses—early in any febrile condition."—We are, etc.,

Spilsby, Lincs. C. E. FRISKNEY.
J. W. GIBB.

Poliomyelitis: Age Incidence

SIR,—Since the publication of Dr. W. Howlett Kelleher's article on poliomyelitis in the *Journal* (September 2, p. 570) I have been conducting a preliminary survey of 152 cases of confirmed poliomyelitis admitted to the Moxley Hospital, Wednesbury, from January 1 to August 31 this year, and my findings may be of interest.

Ninety-three of the cases (60%) occurred in children under the age of 5 years, and the incidence was as follows:

Age	*Males*	*Females*
Under 1 year	3	7
1–2 years	15	17
2–3 ,,	6	6
3–4 ,,	13	12
4–5 ,,	8	6

Of the ten infants under 1 year of age only one had been breast fed. The type of paralysis occurring in these infants was as follows:

Slight residual weakness of one limb	2
Forearm paresis requiring orthopaedic treatment (one limb)	2
Leg paresis below knee requiring orthopaedic treatment (one limb)	2
Complete paralysis of both legs	1
Complete paralysis of both legs and one arm (Breast-fed male of 8 months)	1
Paralysis of all limbs and respiratory involvement	1
Fatal bulbo-spinal case (male of 11 months)	1

—I am, etc.,

Wolverhampton. C. SIMPSON SMITH.

Spread of Poliomyelitis

SIR,—Sewage sludge is being very largely used as a manure in gardens and allotments. Obtained in bulk, it contains a considerable amount of moisture and sprouts a luxuriant growth of tomato seedlings. Is it not possible that lowlier and more resistant organisms may survive and retain viability even in the dried product? Might it not be a useful precaution to prohibit distribution of sludge from an area of known infection? Alternatively, a certificate could be issued to the effect that the material had been tested for the presence of pathogenic organisms and certified as safe for use.—I am, etc.,

Woldingham, Surrey. J. O. V. JONES.

Domiciliary Treatment of Tuberculosis

SIR,—The stimulating letter of Dr. R. Crosbie Walsh (*Journal*, August 26, p. 525) and the encouraging replies of Drs. Meyer, Gray, and Chatterjee (September 9, p. 626) should not pass unnoticed by hospital boards responsible for the tuberculosis service. It appears that the facilities for in-patient diagnosis, assessment, and early treatment, so obviously enjoyed by Dr. Crosbie Walsh, are in fact better than those available to the tuberculosis officer he has so long by-passed. Unfortunately, whilst individual patients so admitted under his care doubtless have the advantage over those long awaiting a regional hospital bed, the numbers so treated make a negligible contribution to solving the tuberculosis problem as a whole and have no appreciable effect on the tuberculosis officer's waiting-list. Not until such facilities can be offered to all practitioners will the problem be solved. Chest physicians at teaching hospitals, to which he refers, also enjoy full facilities but are able to deal only with a selected few of the total number of cases, and the main responsibility for providing treatment remains with the organized tuberculosis service. This rests with the hospital boards, and they must see to it that their chest physicians and their chest clinics are equipped and staffed at least on a par with those of the teaching hospitals. Only then will the confidence and co-operation of general practitioners be secured, particularly in those areas where the ill-housed, ill-equipped, under-staffed tuberculosis dispensary is not just a memory of the past but continues as before, victim of an economic freeze.—I am, etc.,

London, S.W.2. C. FREDERICK PRICE.

Emergency Leucotomy

SIR,—I read with great interest Dr. M. O'C. Drury's report in the *Journal* of September 9 (p. 609) on the response of his patient's chest lesion following leucotomy, without bed rest or any other active treatment, and this is extremely gratifying. I think, however, that Dr. Drury's case would have been even more interesting had he mentioned that the diagnosis of pulmonary tuberculosis in this patient was confirmed by the finding of tubercle bacilli in the patient's sputum. The description of the radiological findings and the whole course of the chest disease would, in the absence of a positive sputum report, suggest a lung abscess following inhalation of food during tube feeding; but no doubt Dr. Drury will be able to enlighten us on this.—I am, etc.,

Hounslow, Middlesex. R. HELLER.

SIR,—The case report which appeared in your issue of September 9, p. 609, raises the question of selective gyrectomy—a practicable neurosurgical procedure, but too little adopted in this country. The enthusiasm with which the full prefrontal operation was received in psychiatric clinics can no longer be justified by the conclusions of closely studied cases. The variety of operations at our disposal now has a fair statistical valuation, and the method adopted should have more than a mere logical basis. In each case it should be possible to assess the type and extent of functional derangement and to correlate these facts with the known effect of gyrectomy. Our knowledge of the frontal areas in man is by no means complete, but the results of systematic experiments have shown which selected areas give the most beneficial psychiatric sequelae. Most workers agree that a transorbital approach gives a lesion that has little permanent effect in chronic psychotics. On the other hand, bilateral ablation of areas 9 and 10 (Brodmann) alone may give dramatic relief to schizophrenics and involuted groups without the entailment of a full leucotomy; in the interesting case reported of anorexia nervosa it would appear to be the operation of choice.—I am, etc.,

Leeds. P. P. NEWMAN.

Streptomycin in Foetal Blood

SIR,—Kane (1950) reports the delivery of a live infant occurring during the course of tuberculous meningitis under treatment with streptomycin in the mother. He also reports an abortion at about the 17th week. His first patient commenced treatment in the 29th week of pregnancy and was given 1.6 g. daily intramuscularly in two equal doses until after her confinement. Intrathecal injection of 100 mg. streptomycin was also given for a shorter period. Streptomycin concentrations in the mother's serum ranged from 2–4 μg. per ml. The infant apparently suffered no ill effects, and is progressing normally. Details of a similar case which I had the opportunity of observing are given below.

A woman aged 29 developed tuberculous meningitis, confirmed bacteriologically, at the 25th week of her third pregnancy. Treatment was started in the 27th week with streptomycin calcium chloride by the intramuscular route, 0.5 g. six-hourly, and intrathecally 100 mg. daily. Intramuscular dosage was reduced to 1.5 g. daily five weeks later, and ceased after a total of 60 days. Intrathecal injections were discontinued on the same day, with an interval of eight days during the course. Except for slight deafness, tinnitus, and dizziness, her condition was considered to be satisfactory, and pregnancy progressed normally.

Six weeks later she was transferred to this hospital on account of a clinical relapse, and for her confinement. She was drowsy, somewhat deaf to spoken words, and unable to hear a watch tick. On the same day streptomycin was recommenced at a dosage of 0.5 g. six-hourly intramuscularly at 6 and 12 o'clock, and 200 mg. daily intrathecally.

Labour commenced at 1.15 p.m. on the fourth day, and she was delivered of a normal infant weighing 5 lb. 6 oz. (2.4 kg.) by forceps delivery at 6.10 p.m. The placenta and membranes were expelled at 6.15 p.m. A specimen of maternal blood was taken at 6 p.m., six hours after the last intramuscular injection of streptomycin. The concentration of streptomycin in the blood was estimated by a tube method using a standard strain of *Bact. friedländeri*, and was found to be 1 unit per ml. (Dr. L. L. Griffiths). The concentration of streptomycin in the cord blood immediately after delivery was estimated by the same technique and found also to be 1 unit per ml.

The mother's subsequent progress has been stormy, with two relapses. She is left with gross deafness at all frequencies and a visual field defect, but retains unimpaired her personality and mental and physical powers.

The progress of the infant, on the other hand, has been very satisfactory. The Mantoux reaction (0.1 ml. of 1:1,000 solution) remains negative at nine months, and radiological examination of the chest normal. The child is considered normal in every way for her age. It has not been possible to carry out accurate audiometric and vestibular function tests, but she responds normally to sounds and has not the intonation of voice characteristic of severe degrees of deafness.

I am indebted to Mr. S. R. M. Bushby, of the Wellcome Research Laboratories, for help and work in an attempt to estimate the streptomycin content of the placenta.

—I am, etc.,

Farnborough, Kent. P. N. SWIFT.

Kane, F. F., *British Medical Journal*, 1950, 1, 585.

Obstruction by Mango

SIR,—The article "Intestinal Obstruction Due to Food," by Mr. Neil Ward-McQuaid (*Journal*, May 13, p. 1106), and subsequent correspondence do not mention mangoes as a cause of obstruction. The following case observed by me might therefore be of interest.

An African male of about 30 years had recently acquired syphilis and a large bubo which broke down leaving a faecal fistula behind. In this condition he was admitted to hospital and an attempt was made to close the fistula surgically which was apparently successful. Three weeks after operation the patient, who had evaded supervision by frequent strolls into neighbouring villages, presented himself again, with distended abdomen, severe colicky pain, and a story of constipation for five days. On examination it was found that the fistula had reopened. No tumour could be felt. An enema had no result. Before further treatment could be given he collapsed and died. At the post-mortem examination the only significant finding was a large bolus of mango fibres impacted in the ileum near the ileo-caecal junction. The patient, having come from a famine area, had been eating mangoes, which were very plentiful at the time, almost continuously for one week.

I am grateful to the Director of Medical Services, Northern Rhodesia, for permission to publish this note.—I am, etc.,

N. Rhodesia. W. GILGES.

Modification of Boyle's Apparatus

SIR,—I read Dr. W. B. Primrose's account (September 16, p. 676) of his modification of Boyle's anaesthetic apparatus with interest, as it seems to be an inexpensive method of converting existing apparatus. However, he does not touch upon one of the main reasons for the design of special absorption units, which is that the basal oxygen flow was found not to vaporize sufficient ether to induce and maintain anaesthesia. The special absorption units incorporate ether vaporizers of special design, and so located that all the gases breathed by the patient pass through them once, as in the Coxeter–Mushin absorber, or twice, as in the M.I.E. absorber, each time they

complete a circuit of the apparatus. Apparently Dr. Primrose has not found it necessary to modify his apparatus to this end, and it would be interesting to know whether in fact he finds it suitable for ether anaesthesia; if so, it would seem a completely satisfactory substitute for the more expensive absorber units.—I am, etc.,

Winchester. D. ZUCK.

Cauterizing the Cervix

SIR,—Dr. Jean R. W. Ross has done well to draw attention (September 16, p. 647) once more to the importance of chronic cervicitis as a cause of gynaecological symptoms, particularly low backache, lower abdominal pain, especially in the right and left iliac fossa, frequency of micturition, and sterility. I have been cauterizing the cervix for this condition since 1929 and though I have not analysed my case records I feel sure that my results are comparable to hers in so far as the relief of these and other symptoms is concerned. The technique that I use differs somewhat from hers in a few respects. Thus I always begin the radial cauterization of the internal os—quite easy in the out-patient department—and without dilating the canal or using an anaesthetic. This is, I think, necessary, as in most cases there is an endocervicitis as well as the visible "erosion." I have long since ceased to order vaginal douches, as I feel that given by the patient herself they are as likely to introduce sepsis as to prevent it. I never get the patient back before ten weeks, as up to that time the cauterized area is still partly covered by granulation tissue. If then there is any unhealed area I recauterize it. Finally, before cauterizing it is well to touch the portio vaginalis and the cervical canal with pure "dettol" on a swab. Although I must have personally cauterized many hundreds of cases, including in every case the cervical canal, I have never met with one in which occlusion of the canal or of the external os occurred as the result of it, nor have I ever known it to cause dystocia.—I am, etc.,

Watford Heath. F. J. BROWNE.

Appeal for Bacteria

SIR,—I should be grateful if through the courtesy of your columns we could make an appeal for strains of *Pseudomonas aeruginosa*. We have carried out with some measure of success some work with a view to producing type-specific bacteriophages capable of lysing *P. aeruginosa*. We have, however, been able to deal only with strains obtained from the West of Scotland, and we should like, if possible, to get strains from other parts of the country. Any cultures sent to Professor J. P. Todd at the address below will be gratefully acknowledged and, if desired, the results of our findings communicated to the centre. Cultures should be accompanied with a note giving details of source and date of isolation.—We are, etc.,

Royal Technical College, George Street, Glasgow, C.1. JAMES P. TODD. CHARLES S. TERRY.

POINTS FROM LETTERS

A Plea for Better Understanding

Dr. C. E. BROWN (Whalley, Lancs) writes: With the present uncertain state of affairs pandemic throughout the world, and indeed with a war proceeding at the moment in Korea . . . some words should be said in an effort to understand and treat, with more comprehension than hitherto, that type of war casualty, the so-called "battle exhaustion" case, or, as he was more usually called, the "bomb-happy" case. Very often these men are shy, self-effacing, kindly, and sentimental; they have a greater depth of imaginative faculties, and because of this they feel pain both of the body as well as of the mind much more acutely than their fellow men. They are not psychopathic, nor do they suffer from endocrinological aberrations. These men are often misunderstood from the beginning, and because of their final failure to stand up to their extra burden become outcasts and are ostracized. . . . (They) need more careful initial examination when joining the Services, and should be assigned to more specific and suitable employment in their branch of the Service than has been done before in the last two wars.

Obituary

E. BOSDIN LEECH, M.D., F.R.C.P.

Dr. E. Bosdin Leech, consulting physician to the Manchester Royal Infirmary, died in Manchester on September 19, aged 75.

Ernest Bosdin Leech was the son of Sir Bosdin Leech, one-time Lord Mayor of Manchester and one of the promoters of the Manchester Ship Canal, and the nephew of David John Leech, the first professor of pharmacology at Manchester University. He was educated at Cheltenham College, Christ's College, Cambridge, and Manchester University. Qualifying in 1901, he graduated M.B., B.Chir. in 1903, and proceeded M.D. in 1907. After holding posts as house-physician, house-surgeon, medical registrar, director of the clinical laboratory, and resident medical officer at Manchester Infirmary he was elected to the honorary medical staff. He was a most enthusiastic teacher in the Manchester medical school. For many years he served on the cancer research committee in Manchester and on the board of the Chester Hospital. In another sphere of useful work he was a Home Office medical referee for industrial diseases. He took the M.R.C.P. examination in 1905 and became a Fellow in 1919. In the first world war he served with the R.A.M.C. in France, Mesopotamia, Southern India, and Belgium. For some 40 years Leech was one of the most active members of the Manchester Medical Society, working hard in its administration and building up its library, which is one of the best medical libraries in the country. He was elected president of the society in the 1934–5 session, the centenary year of its existence. This was an honour that pleased him all the more since his uncle had been president in its jubilee year 50 years before. His presidential address was entitled "Picturesque Episodes of Manchester Medical History." This was later published with many interesting illustrations. Leech presented to the society his own extensive and valuable collection of books about Manchester medical history and by Manchester medical men. Many of these books had come from the library of Dr. John Hull, the first president of the society. In 1938 he gave the Lloyd Roberts Memorial Lecture, entitled "Early Medicine and Quacks in Manchester." Besides being a great expert on local medical history Leech was also a keen antiquarian, being for many years a member of the Manchester Ancient Monuments and Lancashire Parish Register Societies. He was awarded the honorary degree of M.A. by Manchester University in 1937.

T. H. O. writes: With the passing of Bosdin Leech his colleagues and many generations of Manchester students mourn the loss of one who, above all else, commanded their affectionate respect. Brilliance was not his, nor did he make any pretensions to possess it, for in him sincerity was fundamental; but much knowledge and ability was devoted unsparingly to his hospital and medical school. Kindly and sympathetic, success brought no undue elation nor disappointment rancour, for he was incapable either of a mean action or an ungenerous word. His hospital has been fortunate in having been able to command the loyalty of so devoted a servant, and his friends will retain a memory of a good physician and a great gentleman.

Dr. CHARLES EDWIN PURSLOW, consulting obstetrical and gynaecological surgeon to the Birmingham United Hospitals, died in Birmingham on September 20 in his ninetieth year. He studied medicine at Birmingham University and graduated M.B.

(London) with first-class honours at the age of 23 in 1884. He proceeded M.D. two years later and took the M.R.C.P. examination in 1894. His main interest in medicine was in obstetrics, and after holding several house appointments he became honorary obstetric officer to the Queen's Hospital, Birmingham, in 1889. He was a lecturer in his subject at the University of Birmingham, and was an excellent teacher. A member of the B.M.A. for many years, he represented the Birmingham Division at meetings in London in 1915 and 1916.

Professor Hilda N. Lloyd writes: By the passing of "Charlie" Purslow, Birmingham has lost one of the "fathers" of medicine who has been an outstanding figure in the medical life of the city for the past 60 years. He served with devotion and loyalty until after the first world war the Birmingham hospitals and the expectant mothers who attended his out-patient clinics. The students who trained under him number hundreds, and several generations of them owe their knowledge and understanding of obstetrics to him. Purslow's image is particularly vivid in the memories of many of his students because he often was the medium through which they were introduced to surgery, since he operated on Saturday, the day when the preliminary classes were given. To watch his cheery rubicund face and figure operating—perhaps to produce a caesarean baby like a rabbit from a hat—was a memory that never faded. His sense of humour and equable temperament served him well in his dealings with his enormous following of patients. On the maternity district associated with the old Queen's Hospital his name was one to conjure with. Everyone knew and loved him, both patients and midwives, as well as the numerous progeny at whose birth he had presided. His surgery, though not spectacular, was sound; perhaps his asepsis to modern eyes would seem a little lacking, but his results were excellent. A great Victorian has passed, and with him a generation of great practitioners has now been closed. Men of his type were the salt of the earth, intensely individual and full of initiative and self-reliance. Purslow had few hobbies, but he was very fond of boating and sailing. He leaves behind a fragrant memory of work well done and a life well lived.

Dr. MARY BUCHAN DOUIE died on September 15 at the age of 89. She was the youngest daughter of the late Rev. D. Buchan Douie, of Largs, and she was educated at Edinburgh University and the London School of Medicine for Women. She graduated M.A. (Edinburgh) in 1893 and M.B. (London) in 1897. Almost immediately after qualification she became secretary of the London School of Medicine for Women, but she had to resign from this post in 1908 owing to ill-health.

S. T. W. writes: Dr. Douie's years at the London School of Medicine for Women were years of great activity, since, owing to continued large entries, the first rebuilding of the school was still in process at the time of her appointment. She showed a real knowledge of the school and its needs, bringing to bear on the problems which arose her own experience as a medical woman and the thoughtful energy which was one of her characteristics. During her last year she helped considerably the doctors who were trying to obtain the opening of the Royal Colleges to women, and it was a great satisfaction to her that their efforts were successful. After a complete recovery from her illness Dr. Douie took up active work again. She first helped Dr. Brodie, the professor of physiology in the University of Toronto, and on her return to England lectured for the L.C.C. and various societies. She had great mental and physical energy. Her wide knowledge of literature and her many journeys abroad, both on the Continent and in India, made her a most delightful and interesting companion. Although she has outlived most of her colleagues she will be missed by many of the younger generation and by her many friends.

Dr. WILLIAM HENRY WALKER MEWHIRTER died at his home in Belfast on August 14 at the age of 80. Born in Ballymena, County Antrim, he received his early education locally, and studied medicine at Queen's College, Belfast, graduating M.B., B.Ch. in 1898. He held the appointment of dispensary medical officer at Toome, County Antrim, from 1902 to 1919. During the 1914–18 war he served as a captain in the R.A.M.C., and from 1919 to 1937 was senior medical officer to the Ministry of Pensions at Birmingham, Blackpool, and Liverpool. Dr. Mewhirter served in the Merchant Navy as a medical officer from 1938, and continued serving in this capacity until his ship was torpedoed in the Indian Ocean in 1943. He then had to retire. In spite of increasing physical disability he retained his interest in professional matters. It was a measure of his kindliness and unselfishness that almost his last effort at speech was to inquire after the welfare of a neighbour: in this was epitomized a lifelong habit of outlook, devotion to duty, and courage of no mean order. His remaining contemporaries and colleagues will remember him with affection. Dr. Mewhirter was connected with the Masonic Order for more than 50 years. He is survived by his widow and two sons, to whom the sympathies of his friends are extended.—H. B. S.

Dr. H. MURRAY AGNEW, for nearly 30 years assistant school medical officer for Berkshire, died in Reading on August 30. He was the son of the late Dr. Samuel Agnew, of Lurgan, Northern Ireland, and he was educated at Lurgan College, the Royal Academical Institute, and Queen's College, Belfast. He qualified in 1904. During the first world war he served as a captain in the R.A.M.C. in France and Belgium. For his voluntary services to the civilian population during a serious epidemic in France he was awarded by the French President the Médaille de l'Assistance Publique. After demobilization he took the D.P.H.(Oxon), and in 1920 he was appointed assistant school medical officer by the Berkshire County Council.

W. R. H. writes: Many of his old colleagues will have learned with regret of the death of Dr. H. Murray Agnew, whose career in the school medical service, which began in 1920, was to last nearly to the end of his life. At that time in rural areas conditions were most discouraging, and a child's chances of overcoming physical handicaps depended very largely on the extent to which the individual school medical officer was willing to exert himself unofficially on his or her behalf. Agnew showed a truly missionary zeal in this direction, and the trust and appreciation of countless parents was his reward. A man of great kindness of heart, he never allowed the official aspect of his work to overshadow the human approach. His visits to rural schools were looked forward to by parents and teachers—and even by the children themselves—for he had a singularly disarming and genial way with them. He did not seek promotion: perhaps he realized that his ideals of service could best be achieved by continuing to devote himself to the work which he carried out with such a remarkable degree of faithfulness and skill. He really loved his work and had the satisfaction before he retired of seeing some of those whom he had known as children bringing their own children before him. His name will long be remembered with gratitude in many of the Berkshire villages which were the scene of his sustained and ungrudging labours.

Mr. FREDERICK CROOKS, for many years senior surgeon at the Nottingham General Hospital, died at Nottingham on August 31 at the age of 63. Mr. Crooks was born in County Derry, Northern Ireland, and educated at Cookstown High School and Queen's College, Belfast, where he gained many scholastic distinctions, graduating M.B., B.Ch. in 1911. He was appointed house-surgeon at the Nottingham General Hospital in 1911, and became resident surgical officer a year later. In 1914 he obtained the degree of Master of Surgery of Queen's University. Mr. Crooks served as a surgical specialist in the first world war, and upon his demobilization obtained his Fellowship of the Royal College of Surgeons of Edinburgh. In 1920 he was appointed honorary assistant surgeon to the Nottingham Children's Hospital, and a few years later became honorary surgeon, an appointment which he held until 1945, when he was appointed consulting surgeon to the hospital. In 1923 he was elected honorary assistant surgeon to the Nottingham General Hospital, where he devoted himself to establishing and developing an orthopaedic and accident department. Later he was appointed honorary surgeon to the hospital and surgeon

in charge of the accident and orthopaedic department. Other surgical appointments which he held were at the Nottingham City Hospital, the Chesterfield Royal Hospital, and the Berry Hill Rehabilitation Centre, Mansfield. During the second world war he was consulting orthopaedic surgeon to the Emergency Medical Service. Mr. Crooks had been treasurer, secretary, and president (for seven years) of the Nottingham Medico-Chirurgical Society. He was a fellow of the British Orthopaedic Association and president of the Nottingham Branch of the British Medical Association in 1948–9. Besides being a member of the orthopaedic advisory committee of the Sheffield Regional Hospital Board he was also a member of the No. 1 Hospital Management Committee, Nottingham. Mr. Crooks had a serious illness in 1945 from which he never completely recovered. Notwithstanding this his devotion to his work and patients never wavered, and he was actively engaged in his professional work until a few hours before his death. He was a brilliant surgeon who combined speed and dexterity greatly to the benefit of his patients. The excellence of the present orthopaedic and accident department of the Nottingham General Hospital is a tribute to his organizing ability and hard work, and the department will be a lasting memorial to him. The naming of the operating theatre at the Nottingham Children's Hospital—"The Frederick Crooks Theatre"—gave him great happiness. He was able to imbue his colleagues with his own enthusiasm, and no house-surgeon ever asked for help without receiving it in the kindest way. His foresight and wisdom in committee work were outstanding and his opinions were always valued highly. He married in 1920. It was always a pleasure to visit him and his wife, for their home was one of the happiest. Mr. Crooks will long be remembered with affection and admiration by his colleagues as well as by his numerous friends and patients. Their sympathy will be extended to his widow in her sudden bereavement.—J. S.

Mr. NORMAN STUART CARRUTHERS, surgeon-in-charge of the ear, nose, and throat department of the Norfolk and Norwich Hospital, died at Wymondham on September 12 at the age of 63. He studied medicine at Guy's Hospital and qualified in 1911. After holding a resident appointment as house-surgeon at Guy's he became senior clinical assistant at the Metropolitan Ear, Nose, and Throat Hospital, and surgical registrar at the Golden Square Throat Hospital. He obtained the Fellowship of the Royal College of Surgeons of Edinburgh in 1919 and the D.L.O. in 1924. For a short time he was in general practice in Acle, Norfolk, but in 1928 he became ear, nose, and throat surgeon at the Norfolk and Norwich and the Jenny Lind Hospitals in Norwich. He held these appointments until the time of his death. He was also aural surgeon and laryngologist to the City Isolation Hospital, Mundesley and Kelling Sanatoria, the Norfolk County Council, and the East Anglian School for Blind and Deaf Children. He published a number of papers on subjects connected with his specialty in this *Journal*. A keen member of the British Medical Association, Mr. Carruthers was at one time honorary secretary and later chairman of the East Norfolk Division.

Universities and Colleges

UNIVERSITY OF LONDON

INSTITUTE OF OBSTETRICS AND GYNAECOLOGY

The autumn term of the Institute of Obstetrics and Gynaecology (Chelsea Hospital for Women, Queen Charlotte's Maternity Hospital, and the Department of Obstetrics and Gynaecology at the Post-graduate Medical School) begins on October 2 and ends on November 25. General practitioners wishing further experience in obstetrics may attend on the practice of Queen Charlotte's Hospital for two or four weeks. They will be allowed to do normal deliveries and attend special lectures at all three hospitals of the Institute. An intensive course, suitable for those preparing for the M.D. and M.R.C.O.G. examinations, is being held from November 27 to December 9. Application forms and full details of fees may be obtained from the Secretary, the Institute of Obstetrics and Gynaecology, Chelsea Hospital for Women, Dovehouse Street, London, S.W.3.

No. 36

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended September 9.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each Infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Rate per 1,000 total births (including stillborn)			33					34		

* Measles is not notifiable in Scotland, and the returns are therefore an approximation only.

† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

‖ Includes puerperal fever for England and Wales and Eire.

¶ Primary pneumonia no longer notifiable in Eire.

EPIDEMIOLOGICAL NOTES

Poliomyelitis

Notifications of poliomyelitis in the week ending September 16 were: paralytic, 291 (327); non-paralytic, 187 (186); total, 478 (513). The figures for the previous week are shown in parentheses. The total decrease compared with the preceding week was 35, all but one of which represented paralytic cases. Non-paralytic cases in the week under review comprised 39.1% of the total. The uncorrected notifications for the corresponding week in 1947, 1948, and 1949 were 614, 74, and 342 respectively.

The counties showing the most significant decrease in the incidence of cases were the West Riding of Yorkshire, Warwick, and Stafford, with 16, 10, and 10 fewer cases respectively. Material increases were notified in Worcester (12) and Dorset (6). No county area has been free of infection during the six weeks up to and including that ending September 16. But only one case has been notified in Anglesey and in Cambridge; there have been only two cases in the Isle of Ely and in Radnor.

The total number of notifications for 1950 up to and including the week under review is 5,604. The corresponding figures for 1947, 1948, and 1949 were 5,598, 1,288, and 2,989.

Discussion of Table

In *England and Wales* a decrease occurred in the number of notifications of measles 883, scarlet fever 57, and acute pneumonia 43; an increase was recorded for dysentery 49 and acute poliomyelitis 22.

A fall in the incidence of measles was general throughout the country, the largest falls being in Yorkshire West Riding 131 and Lancashire 118. Only small variations occurred in the local trends of scarlet fever; the largest was an increase of 16 in London. The chief feature of the returns of diphtheria was a fall of 12 in Lancashire. The largest fluctuations in the trends of whooping-cough were decreases in Yorkshire West Riding 81 and London 45, and an increase of 52 in Warwickshire. Dysentery was most prevalent in Leicestershire (all cases in Leicester C.B. 53); Lancashire 44 (Droylsden U.D. 18); Yorkshire West Riding 35 (Bradford C.B. 12); London 11; and Durham 11.

The largest returns of acute poliomyelitis were from Staffordshire 40 (Wolverhampton C.B. 15, West Bromwich C.B. 4, Brierley Hill U.D. 4); Yorkshire West Riding 40 (Sheffield C.B. 10, Leeds C.B. 8); Lancashire 37 (Liverpool C.B. 15, Manchester C.B. 7); London 35 (distributed over 22 boroughs); Warwickshire 35 (Birmingham C.B. 19, Coventry C.B. 6); Gloucestershire 29 (Bristol C.B. 20); Essex 22 (Ilford M.B. 5); Middlesex 21 (Harrow U.D. 6, Ealing M.B. 5); Durham 21 (Sunderland C.B. 4); Kent 19 (Sevenoaks R.D. 5); Devonshire 16; Lincolnshire 15; Glamorganshire 14 (Pontardawe R.D. 4); Northumberland 13 (Newcastle-upon-Tyne C.B. 7); Surrey 12 (Egham U.D. 4); Southampton 12 (Bournemouth C.B. 6); and Leicestershire 11 (Leicester C.B. 6).

In *Scotland* a decrease was reported in the number of notifications of whooping-cough 88 and dysentery 12, and an increase was recorded for measles 36 and scarlet fever 19. Twenty-one more cases of scarlet fever were notified in the western area than in the preceding week. Nine further cases were reported from the outbreak of dysentery in Stirling county, where 36 cases were notified in the previous week. The other main centres of dysentery were Glasgow 49, Edinburgh 14, and Dundee 10. The notifications of acute poliomyelitis were 4 fewer than in the preceding week, but in the western area a rise of 4 occurred. The largest returns for acute poliomyelitis were from Glasgow 15, Fife county 8, Dundee 6, Lanark county 5, Dunbarton county 4, and Paisley 4.

In *Eire* an increase of 21 in the number of notifications of measles was the only variation of any size in the trends of infectious diseases.

In *Northern Ireland* a small general increase in the notifications of scarlet fever resulted in a rise of 14 in the total notifications. The notifications of acute poliomyelitis declined by 4, the largest returns being from Down county 6 and Antrim county 4.

Week Ending September 16

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 750, whooping-cough 3,086, diphtheria 37, measles 2,494, acute pneumonia 218, acute poliomyelitis 478, dysentery 215, paratyphoid fever 11, and typhoid fever 8.

Medical News

Medical Research Council Travelling Awards

The Medical Research Council announces that it has made the following travelling awards for the academic year 1950–1: *Rockefeller Travelling Fellowships in Medicine.*—Dr. R. I. S. Bayliss, Senior Medical Registrar, Postgraduate Medical School of London; Dr. R. V. Coxon, Betty Brookes Fellow, Department of Biochemistry, Oxford University; Dr. J. E. French, University Demonstrator, Division of Laboratories, and Registrar, Department of Morbid Anatomy, Radcliffe Infirmary, Oxford; Mr. J. A. Key, First Assistant, Department of Surgery, University of Durham, and Professorial Surgical Clinic, Royal Victoria Infirmary, Newcastle-upon-Tyne; Dr. R. A. Shooter, Assistant Bacteriologist, St. Bartholomew's Hospital, and Lecturer in Bacteriology, St. Bartholomew's Hospital Medical College, London; Dr. E. A. Wright, Junior Lecturer in Pathology, Guy's Hospital Medical School, London. *Dorothy Temple Cross Research Travelling Fellowship in Tuberculosis.*—Mr. A. M. Macarthur, Registrar, Thoracic Unit, Postgraduate Medical School of London. *Alexander Pigott Wernher Memorial Trust Travelling Awards in Ophthalmology and Otology.*—(*a*) *Travelling Fellowship in Ophthalmology,* Dr. R. K. MacDonald, University of Toronto, Canada; (*b*) *Travelling Grants in Ophthalmology,* Dr. V. K. Chitnis, Grant Medical College, Bombay, Mr. F. J. Damato, Malta, Dr. Ruby Joseph, India; (*c*) *Travelling Grants in Otology,* Dr. R. A. Cooper, Sir Jamsetjee Jeejeebhoy Hospital, Bombay, Mr. M. S. Harrison, Surgeon, Ear, Nose, and Throat Departments, Lincoln, Grimsby, Boston, and Scunthorpe Hospitals, Dr. J. D. Hood, Otological Research Unit, National Hospital, Queen Square, London, Mr. G. H. Livingstone, Ear, Nose, and Throat Surgeon, United Oxford Hospitals. *Travelling Scholarships in Medical Science (tenable in France under an exchange scheme with the Centre Nationale de la Recherche Scientifique).* Dr. D. G. F. Harriman, Neurological Registrar, Royal Victoria Hospital, Belfast, and Department of Pathology, Queen's University, Belfast; Mr. S. D. Wainwright, Division of Bacterial Chemistry, National Institute for Medical Research, London.

New Diploma in Tropical Medicine and Hygiene

The London School of Hygiene and Tropical Medicine is to hold a course, open to a limited number of students, for the newly established diploma in tropical medicine and hygiene of the University of London, to cover the academic year starting October, 1951. The preliminary course will consist of about four months' basic instruction, followed by an examination for the certificate; the second part, open only to those with at least twelve months' experience of medical practice in a tropical country, will also last for about four months, and lead up to the university's final examination for the diploma in tropical medicine and hygiene. In the second part of the course the student must elect to study tropical hygiene, or clinical tropical medicine, or medical biology. Inquiries should be addressed to the Dean, London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1, who can supply copies of the regulations.

Wills

Dr. Francis Vincent Denne, of Torquay, left £13,985; Surgeon Captain Alfred Woollcombe, R.N. (ret.), of Okehampton, £10,754; Dr. James Carslaw, of Bearsden, £16,974; Dr. Henry William Beach, of Weymouth, £29,934; Lieutenant-Colonel Ferdinand Simeon Le Quesne, V.C., R.A.M.C. (ret.), of Bristol, formerly of Jersey, £59,431; Dr. Reginald Treacher Bowden, of Boscombe, £48,693.

COMING EVENTS

Institute of Dermatology

The Institute of Dermatology (British Postgraduate Medical Federation, University of London) has arranged a series of lectures for the winter session 1950–1 to be given at the institute, St. John's Hospital for Diseases of the Skin, Lisle Street, Leicester Square, London, W.C., from October 3 to March 27, 1951, at 5 p.m. Fees for the lectures are £3 3s. per month, £15 15s. for six months. Registered medical students may attend on signing their names and giving the name of their hospital. Further particulars may be obtained from the dean. Details will be published in the *Journal* week by week under "Societies and Lectures."

Charing Cross Hospital Medical School

The inaugural address at the opening of the 1950–1 session of the Charing Cross Hospital Medical School will be delivered by Dr. Gordon M. Holmes, F.R.S., in the council room of the hospital on Thursday, October 5, at 4 p.m.

Welsh National School of Medicine

The opening sessional address of the Welsh National School of Medicine will be given on Thursday, October 5, by Professor A. D. Macdonald, Leech Professor of Pharmacology in the University of Manchester.

Institute of Child Psychology

The Institute of Child Psychology will hold a dinner at the Holborn Restaurant, London, W.C., on Wednesday, October 11, at 7.30 for 8 p.m. Dr. Margaret Lowenfeld will speak on her visit to the U.S.A. and on the future work and plans of the Institute.

Royal Army Medical College

The Royal Army Medical College has arranged a series of evening lectures to be delivered in the Lecture Theatre of the college (entrance in John Islip Street, London, S.W.) on Thursdays, October 12 and 26, November 9 and 23, January 11, 1951, and February 8, 1951, at 5 p.m. The programme will cover professional subjects of interest to both Service and civilian doctors, and will be open to all medical practitioners without fee. Details will be published in the *Journal* week by week under "Societies and Lectures."

Medical Librarianship

A course of five lectures on the literature and librarianship of medicine will be given by W. J. Bishop, F.L.A., Librarian, Wellcome Historical Medical Library, at the North-Western Polytechnic, Prince of Wales Road, London, N.W.5, on Fridays, October 13 and 27, November 10 and 24, December 8, at 7 p.m. The fee for the whole course is 6s.

Guild of Hospital Librarians

The Guild of Hospital Librarians has arranged a conference on "The Physical Care of Books, Including the Spread of Infection by Books," to be held at Chaucer House, Malet Place, London, W.C., on Wednesday, October 18, at 5.30 p.m. Members and others interested are invited to attend. The conference fee is 2s. 6d., and applications should be sent to the honorary secretary, the Guild of Hospital Librarians, c/o Library Association, Malet Place, London, W.C.1.

Public Health Lectures

A series of popular lectures on subjects relating to the public health will be delivered at the Royal Institute of Public Health and Hygiene, 28, Portland Place, London, W., on Wednesdays, October 18 and 25, and November 1, 8, 15, 22, and 29, at 3.30 p.m. Admission is free, without ticket. Details will be published in the *Journal* week by week under "Societies and Lectures."

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday

INSTITUTE OF OPHTHALMOLOGY (UNIVERSITY OF LONDON), Judd Street, London, W.C.—October 2, 5.30 p.m., "*Retinal Vasculitis*," by Mr. R. C. Davenport.

Tuesday

●INSTITUTE OF DERMATOLOGY, Lisle Street, Leicester Square, London, W.C.—October 3, 5 p.m., "*The History of Dermatology*," by Dr. R. M. B. MacKenna.

Wednesday

●INSTITUTE OF DERMATOLOGY, Lisle Street, Leicester Square, London, W.C.—October 4, 5 p.m., "*X-ray Technique*," by Dr. C. W. McKenny.

LONDON COUNTY MEDICAL SOCIETY.—At Royal Free Hospital (North-western Branch), Lawn Road, Hampstead, N.W., October 4, 3 p.m. Clinical meeting.

PHYSICAL SOCIETY: COLOUR GROUP.—At Imperial College, Imperial Institute Road, London, S.W., October 4, 3.30 p.m., 54th science meeting. Papers: "*The Dependence of Anomaloscope Matching on Field Size*," by Messrs. R. G. Horner and E. T. Purslow; "*Some Aspects of Colour Adaptation in the Central Fovea*," by Dr. E. N. Willmer.

Thursday

●INSTITUTE OF DERMATOLOGY, Lisle Street, Leicester Square, London, W.C.—October 5, 5 p.m., "*Physio- and Electro-therapy*," by Dr. R. T. Brain.

Friday

INSTITUTE OF OPHTHALMOLOGY (UNIVERSITY OF LONDON), Judd Street, London, W.C.—October 6, 5.30 p.m., "*The Placental Implant and Other Recent Therapeutic Measures*," by Mr. G. Mackie.

ROYAL SANITARY INSTITUTE.—At Central Library, Grimshaw Street, Burnley, October 6, 10.15 a.m., papers: "*Some Notes Relating to Ice Cream*," by Mr. F. Shuttleworth; "*Some Aspects of the Supervision of Food Supplies*," by Mr. J. King Shaw, M.R.C.V.S. Afternoon: visits will be made.

WHIPPS CROSS HOSPITAL MEDICAL SOCIETY, London, E., October 6. 8.30 p.m., "*Urology, Past, Present, and Future*," by Mr. A. Clifford Morson.

Saturday

BRITISH ASSOCIATION OF ALLERGISTS.—At Preliminary Training School, York County Hospital, October 7, 11 a.m., "*Allergy in Rheumatism*," by Dr. H. F. West; 11.30 a.m., discussion; 11.50 a.m., "*X-ray Appearances in Asthma*," by Dr. H. Royle; 12.20 p.m., discussion; 2.15 p.m., "*The Human Bronchus, a New Test in Experimental Physiology*," by Dr. L. M. Rosa; 2.30 p.m., "*Asthma Treatments Old and New*," by Dr. C. A. Clarke; 3 p.m., discussion; 3.20 p.m., "*The Role of Allergy in Dermatitis*," by Dr. H. R. Vickers; 3.50 p.m., discussion.

APPOINTMENTS

CLARK, D. H., M.A., M.B., M.R.C.P.Ed., D.P.M., Registrar, Maudsley Hospital, London, S.E.

MCWILLIAMS, LIONEL FRANCIS, *M.C.*, M.B., Ch.B., D.P.H., Deputy Medical Officer of Health, Bath.

MATTHEW, HENRY J. S., M.B., Ch.B., F.R.C.P.Ed., Assistant Physician (Consultant status), Royal Infirmary, Edinburgh.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Bogdanovitch.—On September 22, 1950, to Mhairi (née Irvine), wife of Dr. Andrew Bogdanovitch, a son.

Hirst.—On September 9, 1950, at Leeds, to Dr. Stella Armitage (formerly Speight), wife of Dr. John Hirst, a son.

Portch.—On September 11 1950, at The Grange, Woolavington, near Bridgwater, to Thelma (formerly Morris, S.R.N.), wife of Dr. G. G. Portch, a son—Stephen Ralph.

Sweetnam.—On September 6, 1950, at Ryde, Isle of Wight, to Elizabeth, wife of Dr. M. T. Sweetnam, a daughter—Angela Catharine.

Williams.—On September 18, 1950, at Southsea, to Rosalind, wife of Bernard Williams, F.R.C.S., a daughter.

MARRIAGES

Hunter—Wynne Griffith.—On September 1, 1950, in Anglesey, Dr. H. Dugmore Hunter, to Elizabeth Grace Wynne Griffith.

Macdonald—Findlay.—On September 14, 1950, at Vancouver, British Columbia, Canada, Donald Macdonald, M.B., Ch.B., Ochil Hills Hospital, Kinrossshire, to Jean Cunningham Findlay.

DEATHS

Derham.—On September 14, 1950, at 9, Albert Road, Bexhill, Thomas Hanson Crossfield Derham, M.B., C.M., late of Preston, Lancs, aged 76.

Doule.—On September 15, 1950, Mary Buchan Douie, M.B., of Hampstead, London, N.W., aged 89.

Elliott.—On September 18, 1950, in London, Patricia Ruth Elliott, M.B.E., M.B., B.S., of St. Andrew's Orthopaedic Hospital, Singapore, aged 63.

Fielding.—On September 15, 1950, Saville James Fielding, M.B., B.S., of 68, Bethel Street, Norwich, aged 69.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Muscular Spasm in Paraplegics

Q.—*How should severe muscle cramps in a paraplegic be treated?*

A.—Muscular spasm in a patient with paraplegia is an intractable symptom which causes much distress. Flexion movements are the most common, and, as these are excited reflexly, contact between the limbs and the bedclothes should be reduced as much as possible by means of a "cradle." Sedatives such as phenobarbitone may diminish the frequency and severity of the spasm. Recently curare has been used for this purpose, but reports on its efficacy are divided. Clarke and Hotston (*British Medical Journal*, 1948, **1**, 289) used "tubarine" (oily) in doses of 20 to 40 mg. intramuscularly once daily. One patient was much improved when this was prescribed with quinine sulphate 10 gr. (0.65 g.) three times a day by mouth; this combination might be worth further trial. The experiences of Kuhn, R. A., and Bickers, D. S. (*New Engl. J. Med.*, 1948, **238**, 615), were less encouraging.

Liver-function Tests in Infancy

Q.—*Could you let me know which liver-function tests are of value in the first two years of life, and for which particular types of lesion the individual tests are indicated? Where can I find some up-to-date information on this matter?*

A.—Liver-function tests in infancy are affected by both technical and physiological factors not present in adults. Thus, repeated bleedings are usually contraindicated, accurate urine collections may be difficult, and bile pigment metabolism is altered by the different nature of the bacterial flora of the intestine; this means that in the first few weeks of life bilirubin rather than stercobilin may be the principal faecal pigment and no urobilinogen may be formed. The proper dosage of drugs for tolerance tests is somewhat uncertain, and the normal limits for tests such as the serum alkaline phosphatase are difficult to define.

The most practical tests are probably the serum bilirubin, serum proteins, flocculation tests, urine tests for bilirubin and urobilinogen, and stool tests for the same two pigments. In the newborn the umbilical vein may be utilized for the bromsulphthalein test (see Mollison, P. L., and Cutbush, M., *Arch. Dis. Childh.*, 1949, **24**, 7). Such tests have been mainly used so far in the study of hepatitis, neonatal haemolysis, and in the demonstration of liver damage in conditions such as burns and familial hepatolenticular degeneration. Some further information may be obtained from Behrendt, H., *Diagnostic Tests for Infants and Children*, 1949, Interscience Publishers, New York.

Ephedrine and the Bladder

Q.—*An elderly male patient with mild bronchial asthma responds favourably to ephedrine in doses of ½ gr. (32 mg.) t.d.s. However, he complains that this causes difficulty in micturition, which he does not experience when not taking the drug. Is it possible in this case to combine the ephedrine with a parasympathomimetic drug which will correct the effect on the bladder without interfering with the action of ephedrine on the bronchial musculature? Is this effect on micturition usual, and how is it brought about?*

A.—It is quite common for ephedrine to produce vesical retention or frequency of micturition, as its sympathomimetic effect may increase the tone of the bladder or its sphincter. It is sometimes used with success for this purpose in nocturnal enuresis in children, though its undesirable effects on the bladder are most commonly observed in elderly men. The combination of a parasympathomimetic drug with ephedrine would antagonize the latter's beneficial action in asthma and would probably produce additional unpleasant side-effects. It would be better to try the effect of theophylline with ethylenediamine (aminophylline) in doses of 1½ to 3 gr. (97 to 194 mg.), which is often effective in mild bronchial spasm in the elderly without causing difficulty in micturition. Alternatively the patient could be taught to use an inhaler containing 1 in 100 adrenaline solution. It may seem paradoxical that both sympathomimetic drugs and parasympathomimetic drugs may increase bladder tone, but the innervation of the bladder is highly complex (too complex to describe adequately here) and it receives both motor and inhibitory fibres from both the parasympathetic and sympathetic systems.

Punch-drunkenness

Q.—*Is punch-drunkenness in boxers a real syndrome, and, if so, can it be considered as an occupational risk?*

A.—Punch-drunkenness, or, as it is sometimes called in the United States, "slug-happiness," is a real syndrome. Its pathological basis is thought to be multiple small traumatic haemorrhages or multiple areas of damaged nerve cells throughout the brain, resulting from repeated blunt head-injuries in boxers. The symptoms are usually of insidious onset, and occur especially in professional boxers who do not reach championship class and in order to make a living take part in a large number of fights, in many of which they receive considerable punishment. Loss of quickness on the feet and slowing up of the mental processes are early symptoms, and of course these result in the victims receiving even more punishment in the ring if, as often happens, for financial reasons they continue fighting. As the condition develops, muscle incoordination, tremor, extrapyramidal rigidity, ataxia, dysarthria and dementia gradually make their appearance. The clinical picture in an advanced case is one of extrapyramidal and cerebellar dysfunction combined with mental impairment.

Splenomegaly in Thrombocytopenic Purpura

Q.—*Is the spleen enlarged in thrombocytopenic purpura? Does an enlarged spleen contraindicate this diagnosis?*

A.—Palpable enlargement of the spleen occurs in about one-third of patients with primary or idiopathic thrombocytopenic purpura; it is never of notable degree. If the spleen extends more than 2 in. below the ribs, the thrombocytopenia is probably of secondary origin. Diseases, such as leukaemia, in which there is infiltration of the bone-marrow often present the combination of splenomegaly and thrombocytopenic purpura. Many varieties of splenic enlargement, unassociated with bone-marrow invasion, may be accompanied by thrombocytopenia which has been attributed to an inhibitory action of the spleen on platelet formation; this is the rule in congestive splenomegaly, and has been recorded in Hodgkin's disease, Boeck's sarcoid, kala-azar, and other forms of splenic tumour.

The Risk of Serious Congenital Malformations

Q.—*In your reply to the question about the inheritance of spina bifida (July 8, p. 122) you referred to "the one-in-forty chance that any random pregnancy will end in a serious malformation of one kind or another." What is the basis for this estimate?*

A.—In discussing with prospective parents the risk that their children may suffer from a particular hereditary abnormality it is useful to quote a figure for the chance that any random pregnancy may end in a serious malformation. The parents will then have a basis for comparison with the risk in their particular case. Without qualifications such a figure cannot be exact, as one would have to specify whether live births only are meant or whether stillbirths are included; there is actually no reason why late abortions should not be included also if data are available. Even with explanations and qualifications there must be differences of opinion about what constitutes a severe malformation; this accounts for a good deal of discrepancy in the published figures.

Malpas (1937) found 294 serious malformations in a series of 13,964 births, or one in 47. Laidtman (1948) found 73 in 3,593, or one in 49. Murphy (1947) estimated that 0.5% of live-born children and 3% of those stillborn are malformed.

Javert and Stander (1943) on the basis of 27.000 births give the high figure of just 3%, but some of the malformations included were of a relatively minor character. As pointed out by Carter (1950), however, it is possible that most series based on births in hospitals give too high a figure if, as is usual, emergency admissions are not separated from the booked cases. Taking the evidence as a whole, the figure of one in forty is probably too high if what constitutes a serious abnormality is fairly strictly interpreted and if it includes only those cases in which the malformation is apparent at birth. If, however, one includes also such errors of development, abiotrophies, and constitutional abnormalities as are manifested early in life it seems a reasonable estimate and an appropriate one to quote to parents.

Sensitization to Bee-stings

Q.—*A lady has kept bees for over ten years, and has been stung many times with little effect. Two days ago, however, after a sting on the arm, she developed an itching rash within minutes of the sting, apparently of an urticarial nature, her tongue swelled, and she had slight difficulty in breathing. A capsule of "benadryl" eased matters, and a day later she had only a swelling of the arm and forearm. I am wondering what will happen if she gets another sting, as the question of continuing bee-keeping depends on this.*

A.—The writer's experience is that bee-keepers are enthusiasts and often are not easily amenable to reason. We, as medical men, can but advise, and the advice in this case is: no further bee-keeping if the person wishes to be certain of avoiding further generalized reactions. It is agreed that occasionally a sensitized person may be stung and have but little reaction, but the chances are so very much against this possibility that the risk cannot be advised. It is also a possibility that the next sting may be followed by a more severe reaction, and it would seem but common sense to avoid endangering life.

Sinus Tachycardia and Neurosis

Q.—*An intelligent active professional man, aged 34, with severe neurotic traits, experiences attacks of palpitation which are provoked by emotional strain and by slight exertion or excitement after eating a meal. The palpitation is in the nature of a sinus tachycardia, developing gradually and ending gradually; it occasionally reaches 150 per minute and may last eight hours, provoking apprehension and sometimes nausea and faintness. Past history and clinical and electrocardiographic examination are negative. Reassurance and phenobarbitone have no effect. Can you suggest a drug which could be taken a short time before any of the provoking circumstances mentioned above are encountered?*

A.—There is no drug which will prevent attacks of sinus tachycardia in psychoneurotic subjects, other than sedatives, and these are relatively impotent, as in the present case. The patient has two alternatives. Either he may learn to tolerate his symptoms, knowing that they are innocent and cannot harm him, or he should see a psychiatrist and obtain direct treatment for his psychoneurosis. The latter is advised in view of the severity of his symptoms.

Horseshoe Kidney

Q.—*What is the treatment for horseshoe kidney? I have a patient with this condition, and he suffers from periodical attacks of renal colic which are increasing in frequency.*

A.—In the condition of horseshoe kidney the ureters usually pass anterior to the isthmus, and it is not uncommon to find a dilatation of the ureters above this level and, still more so, a dilatation of the renal pelves. The exact connexion of the two conditions is not always easy to explain, but in some cases at any rate there is good reason to assume that there is mechanical obstruction owing to the relationship of the ureters to the isthmus, and therefore an operation is sometimes performed for the division of the isthmus. When operating upon a horseshoe kidney for the calculi which are sometimes associated with the condition the opportunity may be taken of dividing the isthmus in the hope of encouraging better drainage from the kidneys.

In the case described by your correspondent it would seem that such an operation is indicated and that relief from pain should result. Before making a final decision, however, it will be desirable to examine all the radiographs which have been taken—presumably some of them are excretion urograms—and probably to carry out bilateral ascending pyelography to get more precise information about the renal anatomy. If urography shows that the kidneys are not obstructed, then it will be very doubtful if benefit would result from the operation of dividing the isthmus.

Sulphur and Rheumatoid Arthritis

Q.—*How does sulphur act in early cases of rheumatoid arthritis?*

A.—The suggestion that sulphur is of value in rheumatoid arthritis is based on tenuous clinical impressions and not on scientific observations. Its use is only sanctified by tradition, and there is no factual evidence of its efficacy or of the mechanism by which it is alleged to act.

Faecal Fats in Pancreatic Disease and Sprue

Q.—*I understand that lipolytic enzymes are secreted by the intestine as well as the pancreas. Is there any point, therefore, in determining split and unsplit fat in faeces in the investigation of a case of suspected pancreatic disease? What are the modern views on the value of split and unsplit fat determinations in cases of the sprue syndrome? In fat-balance tests in suspected sprue, is there any risk to the patient in giving a diet containing 50 g. fat per day?*

A.—Lipolytic enzymes occur in intestinal bacteria as well as in the succus entericus. In cases of pancreatic disease, with complete absence of pancreatic enzymes on duodenal intubation, there may therefore be normal splitting of faecal fat.[1] Differential analysis of faecal fats into split and unsplit fractions is of such limited value that its discontinuance seems reasonable. For the differential diagnosis of pancreatic disease and the sprue syndrome intraduodenal intubation is preferred.[2] Fifty grammes of fat may safely be used for balance tests in suspected cases of sprue. In general, sprue patients tolerate this amount of fat well, provided that fats containing a high proportion of long-chain saturated fatty acids are avoided.

NOTES AND COMMENTS

Substitutes for Morphine.—Dr. R. H. FREEDMAN (Glasgow) writes: I find that the tendency to vomit after a morphine injection ("Any Questions?" September 23, p. 737) may be lessened or prevented by dissolving the morphine tablet in an ampoule of "coramine" (1.7 ml.) rather than in sterile water.

Correction.—In the section of the educational number (August 26, p. 520) containing information about the special diplomas in the various branches of medicine we omitted to mention that the Royal Medico-Psychological Association has recently instituted a Diploma in Psychological Medicine, the first examination for which was held in November, 1949.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY OCTOBER 7 1950

CHILD HEALTH AND THE FUTURE*

BY

ALAN MONCRIEFF, M.D., F.R.C.P.

Nuffield Professor of Child Health, University of London; Physician, the Hospital for Sick Children, Great Ormond Street

I am deeply conscious of the honour conferred on me by the Trustees of the Dawson Williams Memorial Fund last year in recommending me as worthy of a prize for work for child health. I am particularly happy to be able to try in this lecture to discharge a debt to the forerunner whose name we honour. He was a noted paediatrician at the turn of the century, a member of the medical staff of the East London Hospital for Children at Shadwell who gave up his hospital work and practice to join the staff of the *British Medical Journal*, one of the few successful consultants ever to have devoted himself entirely to journalism. Dawson Williams gave me my first assignment (I believe that is the word) in medical journalism—an annotation on a book about medical missions, somewhere about 1923. I have been privileged to follow humbly in his career both as a paediatrician and in a part-time capacity in medical journalism.

When history is being made it is not always obvious to those taking part. At the present time and for some years past the improvement in infant and child health has been very remarkable, and yet the implications of this in the child-health services are not yet fully appreciated. Since much of what follows is in a critical mood it is necessary to state at the outset that those of us in academic posts in child health have a very definite responsibility in this matter, and in criticizing local authorities or central authorities in the health field we are including ourselves in our capacity as advisers or even participators in various aspects of the subject. Secondly, criticism will so far as possible have here its constructive side. It is proposed first to look at the infant-welfare scheme and next at the school health services. In each case the present arrangements will be scrutinized with special reference to what should be the objects of preventive paediatrics to-day—in other words, what are the diseases and disorders of children which call for preventive measures.

Infant-welfare Centres

To what extent does the average infant-welfare centre to-day differ from the milk depots of Budin in Paris of the last century or the earliest centres for distribution of milk and advice that were started in the north-western corner of England at the turn of the century? Milk is still distributed, with dried milk taking the place of milk in bottles. Vitamin preparations and certain infant foods are also distributed. Health visitors attend for weighing the babies and generally interpreting the advice of the medical officers who examine the infants periodically, advise on child care generally with special reference to diet, and deal to a varying degree with minor ailments. This service is correlated to an extent which varies in quality and quantity in different areas with home visiting by the health visitors. Immunization against diphtheria or vaccination against smallpox may be carried out in some centres either at the routine visits or at special sessions. Some medical officers do not approve of these services being mixed up with routine centre work, and yet they seem to me to be an essential part of preventive medicine. The compromise solution is, of course, to have special immunizing sessions.

To sum up, the infant-welfare centre began and has largely continued as part of a campaign to reduce deaths in infancy from digestive disorders. Indirectly the scheme has served to play a part in reducing the deficiency disorders. General advice on child care appears to vary very much in quality and in the energy with which it is given. It is unfortunately easy to get stale in this type of work, and it is perhaps a fair comment that in recent years the most valuable contributions to the management of breast-feeding, for example, have come, not as might have been expected from members of the infant-welfare service, but from "outsiders" such as Dr. Harold Waller and Dr. Charlotte Naish. This is a criticism not of individuals so much as of the way the service has somehow failed to produce opportunities for advances in knowledge. Indeed, with the well-known decline in breast-feeding it is pertinent to ask whether or not the infant-welfare service is everywhere pressing for natural feeding with full enthusiasm. I have heard a prominent medical officer of health state in public that he thought the merits of breast-feeding were greatly exaggerated. In quite recent times a medical practitioner, having carried out certain published investigations in breast-feeding, failed to secure appointment by a local authority for child-welfare work and was told that the lay members of the appropriate committee thought that she must be very narrow-minded and would expect all mothers to feed their babies. They considered that breast-feeding was an imposition on any woman now that the Government provided national dried milk. An infant-welfare service that is not whole-heartedly in favour of breast-feeding cannot surely be regarded as fulfilling its proper task in the community.

Yet by a paradox which is well recognized and not easy to explain a decline in breast-feeding has been accompanied by a sensational drop in the infant-mortality figures. For 1949 we are told that the provisional infant-mortality

*Dawson Williams Prize Lecture, delivered at the Annual Meeting of the British Medical Association, 1950.

rate is only 32 per 1,000 live births. Deaths certified as from gastro-enteritis in 1948 for the eleven months of the first year of life excluding the neonatal period were only a little over 2,000 for England and Wales, about half of the corresponding figure for 1947 and less than half of the total deaths in the same period in the same age group certified as due to bronchitis and pneumonia. Indeed, to-day after the newborn period it is acute respiratory disorders rather than digestive disorders which present the major difficulties. The preventive service has to a large extent won its fight against the scourge of infective diarrhoea as a national problem, although this is no excuse for allowing breast-feeding to decline still further or for slackening every effort to prevent outbreaks on a smaller scale in institutions. The newer antibiotics and a better understanding of the clinical management of the infant with the "diarrhoea and vomiting" syndrome may lower the death rate even further.

Need for Co-operation

Despite this remarkable improvement there are still gaps in the service, and this is particularly seen in the early weeks. There is not enough co-operation between the hospital, the general practitioner, and the child-welfare service in relation to the discharge of the newborn baby from hospital, and this is especially serious in reference to premature babies. The Biological and Medical Committee appointed by the Royal Commission on Population (1950) had something to say about this:

> "A serious defect in the maternity services is that women are often discharged from hospital on the ninth or tenth day before they have been taught how to handle their babies. Sometimes hospital almoners try to arrange for health visitors to supply the needed instruction, but this cannot always be managed, and the health visitor may not call for several weeks. Among women confined at home there is also frequently a gap between the time when the midwife ceases to come and the health visitor makes her first call, though during this period many women start taking their babies to infant-welfare centres and in this way receive continuing care and advice."

But it is the minority who receive this "continuing care and advice," and it ought to be the rule rather than the exception. A good slogan should be, "The health visitor on the doorstep to greet the mother on her arrival home." With a little organization between the ward sisters, the almoner, and the appropriate superintendent health visitor this can be achieved, and is achieved by some maternity hospitals and units. It might even go further and give the health visitor the chance to visit the hospital and see the mother before discharge. Continuity of feeding is important, especially if the baby is artificially fed, and maternity hospitals and units should see that their choice of dried milks, for example, and methods of feeding correlate closely with those available in the infant-welfare centres of the area to which mothers will subsequently go.

> In quite recent times, in a London borough which I would regard as well above the average for its standard of child-welfare work, a mother left hospital with her baby on a bottle with feeding instructions that could not be carried out at home, and she struggled in her amateurish way for nearly four weeks before bringing the baby to hospital. During the whole of that time no health visitor had called and the mother said she was too exhausted to get to a centre. A previous baby had died of gastro-enteritis in similar circumstances in another part of London.

If it is argued that the shortage of health visitors will not permit of these idealistic arrangements I would reply that in many areas health visitors are cluttered up with duties which intelligent lay people could perfectly well do. There is an urgent need for a sort of "job analysis" of a health visitor's work to see that she is not spending time as a clerk, a secretary, a food-store manager, and so forth.

Another method of co-operation in these early weeks which merits attention concerns the possible staffing of the paediatric side of maternity hospitals and units by medical officers of the local authority services. Both at Middlesex Hospital and at Queen Charlotte's Hospital I was privileged for some six years to look after the newborn babies in the wards and to follow them in orthodox infant-welfare centres attached to these hospitals. I am certain that it made for a high degree of continuity of care. Under the scheme proposed by the Ministry of Health circular 118/47, whereby joint appointments were advocated, with infant-welfare medical officers being eligible for part-time hospital work, I should have thought that hospital appointments for supervision of the newborn and of the premature infant would bring a measure of variety and responsibility to the work of infant-welfare-centre medical officers which is often lacking.

(At a different level, and for different reasons, the spirit of the circular is being carried out successfully at the Hospital for Sick Children, Great Ormond Street, whereby six medical officers of the London County Council attend for work in the out-patient department, one each day, and six registrars from the hospital supply one session each in the service of the London County Council. Similar schemes are no doubt in operation elsewhere.)

Prevention of Infections

This gap in the services in the early weeks is something which needs careful attention. The suggestions made require changes, and it is just the relatively unchanged nature of infant-welfare work over the past fifty years that causes some degree of anxiety. The infections of childhood that can be prevented by recognized methods of immunization are diphtheria, smallpox, and probably whooping-cough. Surely the welfare centre is the place where such methods should be preached and practised with the greatest hope of success.

The infectious disease, however, which has the highest numerical significance in childhood is tuberculosis. Dr. J. E. Geddes (1950), at the Eastbourne Congress of the Royal Sanitary Institute this year, gave the total deaths from infectious diseases for children under the age of 15 in Birmingham during the years 1946–9. In numerical order these ran as follows: scarlet fever, 2; diphtheria, 15; measles, 48; whooping-cough, 114; tuberculosis, 203. It is fair to ask, therefore, what the preventive child-health services are doing about tuberculosis. In the infant-welfare service the use of the tuberculin-patch test at intervals—for example every six months—followed by an *x*-ray examination if the test is found to have become positive, might prove very revealing, and I know that at some centres this is in fact the programme, or something like it. Yet when a young colleague of mine asked to be allowed to perform patch tests at a welfare centre at which he worked he was told by the medical officer of health that this could not be allowed, because it was not the "job" of the centre. This seems a strange decision. Surely the early detection of tuberculous infection, the tracking of contacts, and the use of B.C.G. vaccine for negative reactors amongst them could be made a fine co-operative effort between the infant welfare and the tuberculosis branches of the health service.

There is more to be said about this disease in relation to school-children. For the present it must be recorded with regret that a step in the prevention of tuberculosis is in some areas, for administrative reasons, not permitted amongst the most susceptible age group.

It has already been pointed out that respiratory disorders nowadays account for far more deaths than enteritis in the young infant. What can the infant-welfare service do about this problem? First, more must be known about the epidemiology and pathogenesis of respiratory tract infections in young infants. The work of Dr. F. J. W. Miller (1950) in Newcastle in this field will, it is hoped, be especially helpful. This is part of a morbidity survey carried out jointly by the University of Durham Department of Child Health and the Newcastle City Health Department. With the help of health visitors specially chosen for the work, a study of acute infections in the first five years of life is already revealing that acute infective disease at this age period is essentially a family infection. The "cold" of the baby or sore throat of the toddler is not an isolated phenomenon, but must be regarded, with special reference to prevention, from the basis of the household and the contacts all around in the family circle. This is an excellent example of field research by the preventive services at the infant-welfare-centre age. It may well indicate the lines upon which sound preventive measures to deal with acute respiratory disorders in infants can be evolved.

The Newcastle work lays stress upon the family as a unit in relation to infection of the "droplet" type. Has the infant-welfare movement as a whole given enough thought to the family as a unit in relation to its general work in child care? The father should certainly be known personally to the health visitor, and preferably also to the medical officer. It often occurred, when I was doing infant-welfare-centre work, that some aspect of the child's behaviour or even of physical appearance was clarified only after I had asked that the father attend. Actually, because of the peculiar circumstances of one of my centres with mothers who spoke little English and fathers who worked evening shifts in restaurants, I often had the pleasure of seeing the fathers attending with their babies, and I am sure that better work can be done with families in this way. This is particularly important with regard to psychological problems.

Mental Health

As modern methods of treatment and prevention have so radically improved the outlook for the child as regards physical disorders, it is possible to turn more definitely to study the psychological side, not on the relatively small scale available in the most valuable work of the child-guidance clinics dealing with more or less gross disorders, but in the much larger field afforded in the infant-welfare centres. More and more experts are tracing severe breakdowns of adolescence, leading to delinquency and mental misery, to events in the critical early years of life when disturbance of the profound yet delicate parent-child, and especially mother-child, relationship may wreak such havoc with a child's mind. The quality of advice on child care in the psychological field must vary very much, as in general terms the training of medical officers and of health visitors for this side of their work is minimal and is likely to remain so until radical reforms in the curriculum become effective. Unfortunately, too, the very mothers (and fathers) who are most in need of help are those who do not come to an infant-welfare centre. Yet the services of the centre—the advice—can be taken to them, and this is, in fact, being done in some areas as a method of tackling the "problem family." My point here is the simple one that the opportunity for establishing sound mental hygiene in the pre-school age is enormous, and yet, judging by the number of psychological troubles in later life, preventive measures are not proving very effective. In the figures for the "defects" found on routine medical inspection in schools of the London County Council (1948) the percentage of "psychological defects" is about the same as that for otitis media and for heart disease. The prevention of chronic ear trouble and of rheumatic heart disease is certainly approached with more enthusiasm than preventive mental hygiene.

A particular field in which the welfare centre could help is in regard to sex education. The recent developments in the schools whereby more sex instruction is being given has revealed that to begin sex education in the senior schools is much too late and may in fact lead, as it has done in the area of one school of my acquaintance, to almost an epidemic of sex offences between schoolboys and schoolgirls. What is happening is that the parents have no idea of how to deal with questions on sex matters or on the elementary facts of pregnancy and child-bearing. They fob the children off with unsatisfactory answers in early life, the child begins to learn from companions in the early years of school often in a soiled and dirty fashion, and then the "facts" are imparted in early adolescence, at an inflammable age, to children quite improperly prepared to receive them in this way. At the pre-school stage parents should be helped by series of talks on the whole subject of how to answer the inevitable questions of the young child. Discussion groups, especially if fathers can be persuaded to come, held in the evening would go a long way to help in this difficult and important field.

Yet another field in which somehow or other the infant-welfare centre ought to be doing more preventive work concerns the question of accidents. If the mortality figures for the 2- to 5-year-old group are examined it will be found that "violence" is responsible for the largest death rate. For 1948 the rate per million from this cause was 372 for males and 244 for females, compared with 222 and 208, respectively, for tuberculosis, 27 and 19 for diphtheria, 39 and 34 for measles, and 50 and 24 for appendicitis. The "violence" group can be subdivided into road-traffic accidents, which account for just under half of the total, and "other violent causes," which largely means burns and scalds. Is the infant-welfare service doing enough by means of educative measures—talks, posters, pamphlets—to play a part in preventing accidental deaths? It has been pointed out how very rare it is for a second case of severe burns to come to hospital from the same home (Colebrook, 1949), but what a tragically expensive way of teaching the parents. Instruction on non-inflammable clothes, especially night attire, on guards for open fires and stoves and all electric and gas fires, on street drill, and so forth seems to-day to be as important in preventing death and injury in childhood as instruction in infant feeding.

So far I have been dealing with the future of infant-welfare work as if the general pattern of the centre—the medical officer and the health visitor—was to remain essentially unchanged, and that such changes as were necessary were concerned with a different emphasis because of a changed disease pattern. It is important, however, to take this a stage further to see whether or not something more radical may not become desirable. This question largely arises because of the interesting studies in Luton of illness in infancy. The latest report from this town (Dykes, 1950) indicates that, whereas infant-mortality rates show a definite social gradient, infant morbidity does not. In less

favoured towns this may not yet be the case, but the Luton experience suggests that there comes a time when "no substantial reduction of infant sickness can be expected from general measures which fall within the scope of public health and social medicine." Since, however, a social gradient in regard to infant mortality still exists, it follows that practical measures may be expected to bring about a substantial reduction of the infant death rate.

I do not propose to discuss here the alarming conclusion that what determines—in a relatively favourable environment—whether an infant becomes ill or not in the first year of life is a constitutional factor to be controlled, if at all, by eugenics or by aspects of antenatal care which are not yet by any means apparent. What does seem important is that when an infant becomes ill the ultimate result of such illness would seem to depend upon the standards of care that are then applied. In the lower-income groups, failure to secure early medical attention may have, in the past, partly been governed by financial considerations, but education and lack of it as shown by fear and prejudice may have also played a part. It may be that with the passage of the National Health Service Act the financial barrier to early treatment will disappear.

The Luton report suggests that to lower the infant death rate still further will not necessarily be achieved, in a relatively favourable environment, by raising the income and economic status of the lowest social groups. "It seems rather," runs the report, "that this result will be achieved by ensuring that sick infants in the lower social groups are afforded a higher standard of medical and nursing care than some of them have hitherto enjoyed."

The Need for Change

Let us see where this is leading us. I have long held that preventive medicine should include not only measures to preserve health and prevent disease but also the adequate treatment of minor maladies and of serious illness in its early stages to prevent major catastrophes. The Luton experiences support this view. After a certain stage has been reached in the improvement of environment and the general standard of child care, further advances necessitate early medical help when infants are ill. Obviously at the early stage of illness treatment is best carried out in the home, with the use of hospital only when home circumstances are unfavourable.

The crucial question for the infant-welfare service is, "Who is to carry out this treatment?" I think the answer must be, "The family doctor," provided that he is given a better training in the care of sick children than has been possible in the curriculum of past times, and provided that he is given the services of home nurses well trained in the care of sick babies—a highly specialized type of work in grave danger of being submerged and lost in certain proposals for nursing reform. But if the next steps in reducing the infant mortality—the next steps in preventive work in the infant-welfare sphere—are to be along these lines, then surely the infant-welfare service must reorganize its whole staffing programme. Its medical officers should logically be the family doctors who will be carrying out the work in the homes as well as at the infant-welfare centres, and its health visitors must have a specialized training in the nursing of sick babies as well as in the education of mothers in the care of their children.

The infant-welfare centre would then become a consultative clinic where minor ailments could be treated, as well as continuing its educative functions and the preventive measures already discussed. The services of a consultant paediatrician will be required. This scheme would mean that, far from health visitors being given less training as nurses and more in social work, they would in fact require even greater training in the care of children in sickness and in health than they receive to-day.

It may be argued that Luton is not representative, that such revolutionary changes are unnecessary, and that the present pattern of infant-welfare work should continue. But the present-day facts of infant mortality and infant morbidity and their social significance are inescapable. A system largely planned and run on vital statistics which were valid 30 or 40 years ago may conceivably be ripe for revision. There is surely a case here for experiment on a bold scale, and a magnificent opportunity for infant welfare to step forward. Medical officers of health have expressed their feeling of frustration in the atmosphere of the Health Service. Surely a change in the whole mode of work of the infant-welfare service would give them an interest again in this field of preventive medicine.

School Medical Inspections

The school health service also presents aspects which have changed little in the last 30 or 40 years. The form of the medical service for school-children was largely determined in the period 1907–8 and was based on three routine medical inspections, the detection of defects, and arrangements for their treatment. In this basic service there has been little change. Workers in the service complain of the monotony of the school medical inspection, and whereas hitherto it has often been possible to dilute such work, so to speak, with maternity and child-welfare sessions, there is a clear lead in official circulars to let antenatal work go to obstetric teams and the child-welfare work, in part at any rate, to child-health officers.

Suppose that such officers, for the most part specialist paediatricians, also take over school medical sessions as they are already doing in some areas: it will surely be a waste of expensive medical man-power to employ such sessions in routine medical inspections. Across the Atlantic they have been asking for some years—what can the school physician detect that the school nurse cannot detect? I specially commend the New York study by Dr. Dorothy Nyswander (1942) and her colleagues for a more detailed answer than it is possible to give here. Workers in Canada have also criticized medical inspections by a school medical officer as being wasteful of time, money, and effort. It is argued that there are few defects which are not obvious on inspection or in which a careful history will not suggest the need for a medical examination. A competent nurse can "screen" the children and select those requiring a more detailed overhaul by a physician. Such a scheme is, I believe, already in operation in parts of Canada. In New York, as a result largely of the studies already mentioned, only entrants now have a complete medical examination and after that the school physician sees only children referred to him as a result of consultation between nurse and teacher.

Defenders of the present system will no doubt maintain that only by a medical examination can heart disease, for example, be detected. But without a history of rheumatism, without some cyanosis or shortness of breath, the apical systolic murmur in childhood is possibly best left undetected. If there is no history and the child is free from symptoms there is little danger of harm coming from the non-detection of a heart lesion. In any case it is illogical to insist that the heart must be examined by a doctor and not include full examination of the urine. The nurse could easily do the latter. She can also apply a tuberculin-patch test and refer those changing from negative to positive for further

examination, repeating the patch test at suitable intervals in the negative reactors. In view of the relatively high importance of tuberculosis in the mortality of childhood already mentioned it is surely illogical to defend current methods of inspection which do not include any special means to detect this important disease. Mass radiography is being used experimentally, I believe, for certain school-children, and the findings will be of great interest. There is almost certainly a field among school-children who react negatively to tuberculin for B.C.G. inoculation in certain circumstances.

If the school medical officer can somehow be released from the burden of routine inspections there is great scope for more interesting and more important work of a preventive type among children of school age. In passing, it is fair to record that the work of the school health service in regard to the handicapped child in this country is of a very high standard and the provisions made are viewed with admiration by visitors from many parts of the world. Moreover, the supervision of children in residential schools for the physically handicapped brings a special interest of a clinical type into the work of school doctors. This side of the work, however, is rescue work of a special and somewhat limited type dealing with a minority of lame ducks in the community. Even in this field I doubt if we are doing enough for the parents of educationally subnormal children or more especially the uneducable group. There is much unrelieved misery here.

Health Education by the School Doctor

On a much wider scale the health service can reach in the schools such an important population that the school doctor should be encouraged and able to play a part in the whole field of health education. He may or may not be a good teacher, but if he is, then surely he should be encouraged to take some part in teaching. Whether or not he does this, he should certainly be concerned with the syllabus, help to plan practical studies and visits of observation, and, above all, to see that the child learns the elements of hygiene by being able to practise them at school. This means that the school doctor should be directly interested in ventilation, lavatory and washing accommodation, drying facilities, and changing facilities. He should be concerned with school meals and milk in schools, using the opportunity to get the whole subject of food and nutrition, including food hygiene, put before the children.

In the field of physical education the school doctor should also be encouraged to show interest. There is a growing feeling that this subject, together with the whole study of remedial exercises, needs a more critical supervision than has hitherto been the custom. School medical records might well show that certain postural defects right themselves just as quickly without special exercises. I know that this is true in one area for scoliosis. School doctors could soon settle whether or not exercises are necessary for many conditions for which they are now ordered, and with this study the validity of the theories of certain schools and sects in physical education, and indeed in physiotherapy, could be tested.

There is also the question of the teaching of biology in schools and the associated problem of sex education. It is generally agreed that it is not wise for sex education to be dealt with in a highly specialized way by a visiting and strange teacher. But a school doctor who knows his school and is known by the children—by his contact in special medical examinations, through his interest in the food, lighting, and hygiene—would be no stranger, and he or she might well take some part in this important aspect of the curriculum. Such suggestions would bring the school doctor into much closer contact with the school staff than is generally the case to-day. They may learn to consult him on special problems concerning the children or concerning themselves. The head master or head mistress could come to find the doctor a real help in many aspects of the school life. In this way a contribution to health and happiness among school-children would be made which would be of far greater ultimate value than much of the inspection work done to-day.

In connexion with the school health work also I would commend the work of the school care committees in the London area. They are invaluable for much of the social and preventive work of the school services. They represent an aspect of social paediatrics for the child of school age which is an important part of the school health programme.

I have roamed far and wide in this subject. I repeat again that if there are faults in the child-health services to-day those of us in responsible positions must accept part of the blame. I have tried to indicate why I think the amazing change in the pattern of disease in infancy and childhood must mean a change in the methods and objects of preventive measures. I would especially stress the growing importance of such measures in the field of mental health.

I am aware that some, and possibly most, of the suggestions for changed procedure have already been adopted in certain areas by forward-looking authorities and their progressive medical officers. What can be done in one area can surely be done in most other areas. The child-health services of this country in their beginnings showed the whole world what could be accomplished in the fields of child welfare and school health. The changes, which seem to me urgently necessary, could well once again put these services right in the front of the campaign against death and disease and unhappiness in early life.

It will be clear that I am indebted to many sources for my ideas, some of which are recorded in the list of references. Apart from this there are many colleagues in the academic field and medical officers of health who have wittingly or unwittingly allowed me to gain access to their thoughts. I am also deeply grateful to St. Marylebone Borough Council, who employed me to conduct infant-welfare centres, and to the London County Council, who employed me as part-time medical officer in the school medical service for several years before the last war. Neither body is, of course, responsible for anything I have said in this lecture.

According to a Home Office paper issued recently there was less juvenile delinquency in England and Wales in 1949 than in 1948. Those under the age of 14 found guilty of indictable offences and dealt with by magistrates' courts numbered 21,152 in 1947; 26,715 in 1948; and 24,872 in 1949. Those under 17 but 14 or more were 13,861 (1947); 16,991 (1948); and 15,064 (1949). A decline was also noted in those of all ages under 17 found guilty in higher courts: 681 (1947), 728 (1948), 494 (1949). Local authorities are urged to hold conferences with interested statutory and voluntary bodies to study ways of preventing juvenile crime, and many have already begun this work.

MANAGEMENT OF MALPOSITIONS OF THE VERTEX*

BY

HECTOR R. MacLENNAN, M.D., F.R.C.O.G. F.R.F.P.S.

Gynaecologist, Victoria Infirmary, Glasgow; Senior Assistant to the Regius Professor of Midwifery, University of Glasgow

With so much maternity work being done in hospitals there is to-day a tendency to study the various problems associated with obstetrics solely from the statistical angle. Of course, much very useful information is gained by this approach; but it can be cold and lifeless, and there are some problems which can be expressed in another way. It is not my intention to belittle the value of these statistical analyses, especially when, for all I know, there may be a Hogben sitting amongst us. I would prefer, however, to present the subject from the angle of the practitioner of obstetrics who is working on his own without the panoply of the hospital around him to share his burden and sometimes to shield him from his failures. I would rather talk of my experiences as an obstetrician doing private domiciliary midwifery than as a consultant engaged in institutional midwifery. By so doing we can meet on common ground and compare notes.

During the past twenty years I have myself conducted a fair number of booked confinements: excluding emergency calls, there are over 2,500 which can be drawn upon. From such a number it is possible to form a judgment on what constitutes a difficult vertex presentation. In these cases I carried out my own antenatal work, and almost all the patients had a radiological examination at the thirty-sixth to thirty-seventh week. It was thus possible to select, with some accuracy, the cases of malposition of the vertex, and the malpositions which I here deal with are the occipito-posterior position with the head lying in the oblique diameter of the brim, the direct occipito-posterior with the head lying in the conjugate, and the occipito-lateral with the long axis of the head lying in the transverse diameter of the brim.

Incidence

The first question to be considered is, How often do we encounter such cases, and do they in fact give rise to difficulty in labour? I found among my cases that the occipito-posterior position with the head in the oblique occurred in 15%, the occipito-lateral in 26%, and the direct occipito-posterior in only 1%. The very great differences in the incidence of occipito-posterior presentation which are recorded by various authors are in all probability due to the fact that the diagnosis was made at different times—before the onset and during labour—and that hospital records are in themselves often incomplete, lacking accurate information from which a reliable figure can be ascertained. Thus we have such differences as:

Seidentopf	12.4% in Chicago and 1.4% in Leipzig
Munro Kerr ..	20–25% in private practice, early in labour
McBride	4% in Glasgow
McGregor	6.8% in Edinburgh

Prognosis of Difficulty

As to whether or not the occipito-posterior position causes a difficult labour, we find that Munro Kerr and Chassar Moir state: "Occipito-posterior positions of the vertex have in recent years come to be looked upon as the *bête noire* of obstetric practice. It may be a somewhat exaggerated view to take of this very common complication—we think it is; nevertheless, the difficulties which develop may occasionally be very serious—particularly in primiparae—and they always demand judicious handling." And Morris says: "The detection of an occipito-posterior position prior to the onset of labour should not cause alarm, for in a very high proportion of cases correction at least to an occipito-lateral position occurs spontaneously when labour commences." These are two ways of regarding the problem. I would prefer to express it in a different way. The manner in which I venture to suggest it strikes most of us who are engaged in domiciliary midwifery is that an occipito-posterior presentation in a primigravida may at any time from the onset of labour until its completion bring very considerable difficulties—with a prolongation of the first stage, perhaps a very difficult forceps delivery in the second stage, and a possibly complicated third stage—and on that account it causes us concern and anxiety from the time when we first diagnose the condition until the confinement is successfully accomplished.

It is agreed that the occipito-posterior position and deep transverse arrest are responsible for a high percentage of the stillbirths which occur in mature infants. These cases play a large part in producing the dystocia which may be followed by the trauma of a difficult delivery, and, later, the increased possibility of haemorrhage from an atonic uterus. Trauma and haemorrhage in many instances will in turn be followed by obstetric shock, which is one of the major causes of maternal mortality and is to-day responsible for over 30% of the deaths in our hospital. In our part of the world occipito-posterior and deep transverse arrest is the commonest cause of failed forceps now that the grosser degrees of contracted pelvis have become less common and the general standard of midwifery has improved.

Knowing that this is so, and appreciating the danger not only to the child but occasionally to the mother, we can now comfort ourselves with the knowledge that the majority of occipito-posterior cases do not fulfil our worst fears. This, however, is cold comfort if, having at the thirty-sixth week made a diagnosis of an occipito-posterior position, we cannot prophesy with any certainty in any given case how it will finish, and if only when the case is finished are we able to experience relief in the knowledge that this was one of the many easy cases which gave no trouble. Wisdom after the event is very little consolation for the anxious foreboding we may have had for the last week or two before the confinement and at the actual confinement itself. Therefore, while fully admitting that many of these cases have simple uncomplicated confinements, let us examine in more detail the difficulties which we know may confront us—and which we fear—in an endeavour to find ways and means to deal with them when they do arise.

I shall consider first the primigravida. When the diagnosis of occipito-posterior or occipito-lateral presentation is made at the thirty-sixth week we know that in a number of cases this will have become anterior by the time the patient goes into labour, but where the head is engaged or even partially engaged at this time it is unlikely that there will be any improvement in the position before labour starts: in this I differ from Munro Kerr and Chassar Moir, who say that the third and fourth vertex positions are infrequent before the onset of labour and that the largest proportion develop early in labour. They therefore make an arbitrary division into primary and secondary occipito-posteriors. I regard this as the very reverse of what actually happens in practice.

*A British Medical Association Lecture given to the Birmingham Division on March 28.

Can one correct the position antenatally? Buist's pads have been advocated, and recently by no less an authority than Farquhar Murray, but we in Glasgow have been unsuccessful with this treatment. Postural treatment has been recommended, and this also has in our hands failed to produce satisfactory results. I know of no means of correcting this malposition antenatally. If there is no method of correction, is there any value in diagnosis? Most certainly there is. Most primigravidae hope for an easy and quick labour. They are fortified in this hope by some of their fortunate friends who have had the experience. Where the doctor in charge knows that the occipito-posterior presentation exists he should be able to prepare the patient for a labour which is unlikely to be short. In so doing it is essential that he should not alarm her, and it may be of value to have a word or two with the relatives. It should again be stressed that there is no need to give them cause for undue apprehension or concern, but a certain amount of psychological preparation can be quietly instilled into the minds of the patient and her associates, so that if labour does not follow a rapid course she does not become unduly despondent or panicky. When well carried out, this psychological preparation can only increase the confidence of the patient in her doctor, and thus will have an incalculably beneficial effect upon the whole course of the labour.

Clinical Post-maturity

In cases where the head is high and the position is posterior or lateral, the antenatal period may be prolonged beyond the expected date of confinement. In other words, such cases often become clinically post-mature. Prophecy of such an occurrence by the doctor in charge will also increase the confidence of the patient and prevent that rising tide of impatience and perturbation which is so apt to occur when a primigravida goes more than a few days past her expected date.

So much for the psychological value of antenatal diagnosis of the occipito-posterior position.

The question of clinical post-maturity may now be considered a little more fully, for it is often here that we meet our first difficulty. The longer pregnancy continues past the expected date the larger the child may become, the harder the head, the less easy the moulding, and the more difficult the ultimate confinement. Are we justified in inducing labour in such cases?

Before answering this question there is a further essential in the diagnosis. It is desirable to make a pre-delivery assessment of the pelvic capacity. This can be done by an internal digital pelvimetric examination. The shape of the brim can to some extent be appreciated, and, what is much more important, the curvature of the sacrum. A sacrum which is flattened antero-posteriorly will markedly reduce the pelvic capacity, and its full significance must be appreciated in determining the future course of the labour. The prominence of the ischial spines and the length of the sacro-spinous ligament should be ascertained. Caldwell and Moloy allow two fingerbreadths as a rough guide to a normal sacro-spinous ligament. The mobility of the coccyx, the width of the subpubic angle, and the posterior sagittal diameter are all of great value in determining the pelvic capacity. In these days of radiology much can be learned from a lateral view of the pelvis, which can be taken at the same time as the diagnosis of the foetal position is confirmed, and, while perhaps to have an *x*-ray pelvimetry in every primigravida would be desirable, it is a counsel of perfection and not always feasible. It should not replace internal digital pelvic examination, as it is really, to my mind, an adjuvant rather than a primary factor in diagnosis. The width of the sacro-sciatic notch, whether it is acutely angled or obtuse, will help to guide one in assessing an android pelvis, and this can be appreciated from a simple lateral view.

It is not my purpose to discuss the value of radiological pelvimetry. My own impression is that too much stress is being placed upon this. None the less, it does play an important part in the assessment of pelvic capacity, and before deciding the question of induction in a clinically post-mature patient the pelvic capacity would require to be known.

Induction of Labour

Where the capacity appears ample a modified medical induction is usually justified in a primigravida when she is a few days past term; but surgical induction is another matter, and here at the moment I am referring strictly to the primigravida. While surgical induction by artificial rupture of the membranes in primigravidae may frequently be followed by a satisfactory labour, there are occasions when this is not so. Where the cervix is long and hard, where there is no attempt at taking up the internal os, where it is displaced into the posterior fornix, induction may be followed by a long latent period, and foetal distress may become evident before it is possible to effect a vaginal delivery. Surgical induction of labour is therefore inadvisable in primigravidae when the grounds are solely clinical post-maturity and occipito-posterior presentation.

There are, however, special circumstances in which surgical induction is, I think, well justified, and indeed almost obligatory. Let us take for example an occipito-posterior position occurring in the patient whose pelvic capacity, while not contracted in any serious way, is not more than adequate for the average baby and where the child appears to be getting larger—here the certainty of disproportion looms ahead; or in the patient with a minor degree of restricted pelvic capacity, especially in the mid-plane or cavity. Again, there is the type of patient who has been married for a number of years and to whom the baby is more than ordinarily precious. She need not necessarily be an elderly primigravida. There is also the case of clinical post-maturity where careful observation of the foetal heart has disclosed irregularities, where the movement of the foetus has been noticed by the patient to become less obvious, or where there is reason to suspect the possibility of impending intrauterine death of the foetus—a most difficult type of case to diagnose with accuracy. If we treat any of these cases expectantly, the result may be disastrous to the child, and it is on this account that a number are subjected to caesarean section—and yet caesarean section may be entirely unnecessary.

Trial Induction

I would therefore at this stage put in a plea for what I have called elsewhere "trial induction" in such cases. By "trial induction" I mean that surgical induction of labour may be carried out on the understanding that, should the induction prove unsuccessful, it may be followed by caesarean section, under an "antibiotic umbrella." By this means a number of successful inductions will result and some unnecessary caesarean sections will be avoided. I should repeat, however, that trial induction and caesarean section are procedures to be reserved only for special cases in circumstances other than the mere presence of an occipito-posterior in a clinically post-mature patient, and they do not fall within the ambit of domiciliary midwifery. With the clinically post-mature primigravida who is to be

delivered at home, it is usually best to wait until labour begins spontaneously, and this may mean leaving her for anything up to two or even three weeks.

In multiparous patients the problem can be easily solved. The cervix is usually soft and patulous, membranes rupture easily, and the practice of timely induction in such cases will often avert the danger of a large child which can make occipito-posterior presentation doubly difficult.

Prolonged First Stage

When the patient ultimately goes into labour the first stage may be considerably prolonged. Whether this is due to the fact that the presenting part inaccurately fills the pelvis and fails to elicit what has been described as the cervical reflex, or to incoordinate uterine action, which so frequently accompanies this type of case, or whether it is due to some other factor, I do not propose to discuss. Suffice it to say that a prolonged first stage of labour with the occipito-posterior position is commonplace. How, then, are we to contend with the difficulty? In the initial hours of the first stage no treatment whatever is required. The patient should already have been psychologically prepared for such an eventuality. It is a mistake to administer sedatives too early in these cases. Patients should be allowed to "get on with the job," which the vast majority are prepared to do, but they should be assured of help and relief if they experience discomfort which distresses them. The cult of relaxation is valuable in such cases, and, while the patient should be allowed to move around, she should also be allowed to rest. A combination of activity alternating with rest will help labour to establish itself satisfactorily.

There are very few hospitals in the country to-day in which a prolonged first stage of labour can be adequately managed. The provision of first-stage rooms is lamentably inadequate. Comfortable rooms attractively furnished with comfortable chairs, and newspapers and magazines, are what is required. All too frequently the patient is placed in a common-room with other patients in more advanced stages of labour. The whole situation is macabre. How much more fortunate is the primigravida in the familiar surroundings of her own home.

When the patient shows signs of weariness she should immediately be given sedatives. I need hardly add that any form of oxytocic is definitely contraindicated at this stage. Where a mild sedative is required it is often wise to begin with gas-and-oxygen or gas, oxygen, and "trilene" from a "Portanaest" or some similar machine. The patient who is properly instructed in the use of this will experience considerable relief and will continue to have contractions. It is a common mistake to withhold the use of gas-and-oxygen until the beginning of the second stage, and equally I would suggest that it is a mistake to give the patient trilene too early. Trilene is much more powerful than gas-and-oxygen and is better reserved for later in labour. When gas-and-oxygen has been used for a reasonable time—and I would suggest that a couple of hours at this stage constitutes a reasonable time—pethidine may then be given; this is a valuable and safe sedative, and can usually be repeated until the desired effect is achieved. Morphine will always be regarded as a powerful sedative and one of the best at our disposal, especially when it is combined with a little hyoscine, but this should be used with caution. The proper time for the administration of morphine and hyoscine is at night. It is in the long watches of the night that courage fails, and it is then that morphine is most called for. The amount of morphine to be given in a protracted labour is limited, and it should therefore be used when it is likely to be of the greatest advantage, which is usually at night.

Apart from sedatives, it is important also to emphasize that the patient should be allowed adequate nourishment in the first stage of labour. She should be encouraged to take her normal meals, as there is no likelihood of an impending anaesthetic. This maintains her strength and fortifies the glycogen reserve in her liver. It also engenders in the patient's mind the feeling that there cannot be very much wrong if she is taking her food normally. By the time she gets towards the end of the first stage, which is, I think, the most painful period of any labour, she should be given adequate sedation. At this time particular attention should be paid to the bladder. So much for the first stage in primigravidae.

The Second Stage: Timing Intervention

When the patient enters the second stage of labour with a difficult vertex presentation—that is to say, occipito-posterior or occipito-lateral—great obstetric judgment will require to be exercised; for at this stage intervention becomes possible, and the doctor must decide whether or not it should be undertaken. Opinion on this subject tends to be divided rather sharply into two schools—the ultra-conservative school which will allow almost unlimited time for long rotation to take place and for spontaneous delivery to be effected, and the ultra-radical school which will carry out what some of our American friends call prophylactic forceps delivery and extract the child as soon as the cervix is fully dilated.

Don't be afraid of the via media, because it is the road most often right, and, while in the last instance it is usually a matter for the doctor in charge, there are a number of points which would help him to form a correct judgment. If the first stage of labour has not been unduly prolonged, and if the patient's condition is good when she nears the second stage and the foetal heart is beating strongly, there is every reason to allow her sufficient time to deliver herself naturally. It is impossible to improve upon natural results in such cases. In contrast, there is the patient who has had a prolonged and exhausting first stage; it is then unusual to find that her expulsive efforts in the second are effective. In such cases the head will tend to lie in the mid-pelvic cavity and assume the position of deep transverse arrest. Where this arrest is allowed to persist over a number of hours the consequent moulding of the foetal head merely renders the ultimate forceps delivery more difficult, while the patient is less able to withstand such intervention.

I am not really suggesting that the patient's life is in any great danger, but there is no doubt that a degree of obstetric shock often follows a difficult forceps delivery in a patient who has been in labour for several days. Furthermore, to leave for a long time a patient whose baby is in the position of deep transverse arrest may result in a stillbirth, which is a tragic sequel to a protracted labour and likely to leave a permanent scar on the patient's mind, if not anywhere else. The late Dr. Eneas Mackenzie, one of the wisest and most experienced general-practitioner obstetricians, once said to me, "One of the reasons why doctors apply forceps is not because they are in a hurry, but because they do not like to see poor folk suffer," and, while modern analgesia has obviated much of this suffering, it cannot be used indefinitely in the second stage of labour without risk to the child. There is therefore a very definite place for intervention early in the second stage when the first stage has been prolonged, and correspondingly later in the second stage when the first stage has been normal.

The Emergency Call

Sometimes a doctor is called, as an emergency or for a second opinion, to see a patient with an occipito-posterior presentation in the second stage of labour, dystocia having already occurred, and he may find a tired and even exhausted mother and the prospect of a difficult forceps delivery. Adequate care in the first stage would have averted such a state of affairs, but when it does exist it must be overcome. One decision which has to be taken is when to intervene. Generally speaking, such cases are not suitable for domestic confinement, for the accoucheur will need a good anaesthetist, and at the completion of delivery a variety of urgent functions may require to be carried out simultaneously. The child may need resuscitation, an episiotomy may have to be repaired, and an atonic uterus may require attention on account of third-stage bleeding. It is unusual in domiciliary surroundings to have enough assistance to perform all these functions together satisfactorily.

It might not be inappropriate here to refer to some technical points in the delivery by forceps of the deep transverse arrest and of the persistent occipito-posterior, although I realize that in doing so I am entering a field of almost wild controversy. In the great majority of cases the experienced obstetric practitioner will find no difficulty in manually rotating the head into an anterior position, and this is especially so if the intervention has been started before moulding has become extreme. It may be necessary to push the head fairly high up in the pelvis to effect this, but in a primigravida there is really little danger of such a procedure causing undue extension of the head or prolapse of the cord. He will then apply forceps and deliver slowly.

One has become accustomed to the advice than fundal pressure should be applied in the delivery of a breech to maintain flexion, so I think it is wise to have an assistant to apply such pressure in a forceps delivery, and for the same reason. Reasonable fundal pressure begun just before the forceps traction can be very helpful, but the whole procedure must be done slowly. There is a tendency to-day to hurry forceps deliveries quite unnecessarily.

In the cases in which rotation is impossible, owing either to very marked moulding or to slight cephalo-pelvic disproportion, the head should be delivered by the application of Kielland's forceps to the head in the transverse position, and in expert hands this gives first-class results. Equally, in inexpert hands it causes extensive laceration of the pelvic floor.

Alternatively, forceps may be applied over the face and occiput (the actual application is more usually oblique), and moderate traction may be exerted until rotation occurs in the plane of the outlet, when the forceps are removed and reapplied. This is a time-honoured method of delivery, and a great deal of nonsense has been talked about its lethal effect upon the child. With fundal pressure and reasonable traction there will be less danger to the child from such a manœuvre than might be anticipated, for the head has accommodated itself to the pelvis and is really being helped to "find its own way out." To the ardent apostle of Kielland's forceps I should say, If you have learned to use them, continue to do so. To those who prefer axis-traction forceps and are accustomed to their use, I would say the same. This is the art of obstetrics which must be acquired rather than taught, and if the best results are to be obtained the artist must be allowed to use the tools which he finds most natural to him. I would suggest that proficiency in the use of both Kielland's and axis-traction forceps has much to commend it.

The Persistent Occipito-posterior

Where short rotation occurs and persistent occipito-posterior presentation results, this will often be diagnosed from the fact that the head fails to advance despite the strong expulsive contractions. In such cases the vulva frequently gapes, but the head, instead of coming on to the perineum as one might anticipate, remains well back in the pelvis. As soon as a diagnosis of persistent occipito-posterior presentation is made, delivery should be carried out by forceps, and in certain circumstances it is quite permissible, and indeed advisable, to deliver it as a face-to-pubis. I would suggest that the criteria for delivery as a face-to-pubis would be that the diagnosis has been late and gross moulding has occurred in the persistent occipito-posterior position, or that there is contraction of what has been called the ischio-pubic segment of the pelvis. This is, of course, the funnel-shaped or android pelvis of to-day. There is much more room for the biparietal diameter in the ilio-sacral segment, and delivery can be effected with less traction and trauma to the child with the head in the posterior position provided that an ample episiotomy is carried out.

An interesting comment upon this type of delivery is that on occasion an occipito-anterior or an occipito-lateral presentation may undergo rotation backwards into the hollow of the sacrum, where the outlet is slightly contracted. This was adequately described by Herman many years ago, and has been referred to again by Cameron and Hewitt amongst others. None the less, while it is permissible to deliver the baby face-to-pubis in the circumstances outlined, as a rule manual rotation of the head to an anterior position gives most satisfactory results, particularly in multiparous patients.

Delivery of the Occipito-posterior in a Multiparous Patient

In the multiparous patient a complication of the occipito-posterior position is occasionally encountered to which inadequate attention has been paid. Where the uterine contractions have been of poor quality the multipara may reach full dilatation with the head remaining high in the pelvic cavity. In such cases it may be necessary to attempt delivery on account of foetal distress or for some other reason. Where the degree of flexion of the head is poor, great difficulty may be encountered quite unexpectedly in that the head extends whenever traction is applied by forceps, with the result that the blades tend to slip; or, again, in such cases the head may suddenly recede in the course of rotation from the pelvic cavity and the assistant has difficulty in bringing it back into the pelvic brim. I have encountered prolapse of the cord in such cases, and even prolapse of a limb.

Where any such unanticipated complication arises there is much to be said for a manœuvre which for no very good reason has now fallen into desuetude. I refer to internal version. I have carried out internal version myself in nine cases—in two of my private patients and seven of my hospital cases—and have been able to secure a live child. Had the attempt at delivery with forceps been continued it would have resulted in undue trauma to mother and child. The conditions which must necessarily exist for internal version are a good anaesthetic with reasonable laxity of the uterus and some liquor amnii in the cavity. It should not need to be emphasized, however, that this is not a procedure to be indulged in by the obstetric tyro, but it

can be of great assistance and is not unduly difficult to anyone with some experience of difficult midwifery.

The Third Stage after Anaesthesia

Any discussion of the management of difficult vertex presentations would be incomplete without mention of the management of the third stage. Where labour has been protracted and delivery effected by forceps under anaesthesia, we should anticipate the probability of third-stage bleeding. The uterus is frequently atonic, partly from exhaustion and partly as a result of the anaesthetic. The practice of completing the delivery of the child and allowing the patient to recover from the anaesthetic before dealing with the placenta is, I am convinced, a bad one; for where this is done excessive loss in the third stage is all too common, and a later attempt either to express or to remove the placenta will cause shock, which the patient can ill withstand.

I now prefer to complete the third stage before allowing the patient to come out of the anaesthetic. My own practice is to inject ergometrine after the delivery of the child and, within minutes, to deliver the placenta. This may sometimes be spontaneous where the anaesthetic is light. Often it can be easily effected by a mere expulsion, but, where this does not occur, expression or even manual removal is definitely preferable to administering a second anaesthetic some time after delivery and before the patient has had time to recover fully from the shock of the first. The so-called hour-glass constriction of the uterus rarely occurs, and when it does it can be easily overcome.

As I mentioned at the beginning of this lecture, I make no claim to any originality in the procedures which I have outlined in the management of cases of difficult vertex presentation. Sometimes, in this period of rapid medical progress, there is a danger of the obvious becoming less obvious. It is therefore advantageous to review the principles upon which we base our practice. I have tried to apply to my own practice some of the scientific advances which have been placed at our disposal during the past twenty years, and by so doing have endeavoured to enhance the art which has been handed down to us by generations of teachers and to evolve therefrom a form of management of difficult vertex presentations. This form of management, on the whole, has been found to give good results.

Basic principles for the provision of health care for children of school age have been defined by a group of medical men, health educators, and nurses called together by the World Health Organization under the chairmanship of Dr. Fraser Brockington (U.K.). The committee emphasized the need for school health services to be organized co-operatively. They should be "team projects," involving parents, community, professional groups, social agencies, and others interested in the welfare of the child. They should, moreover, be a direct continuation of pre-school services and be so correlated that the benefit of information about the child accumulated during the pre-school period might be available in the school health programme. Healthy school buildings, with good ventilation and lighting, and adequate washing and sanitary facilities, should not only promote the child's health but also serve as an educational example to the community. The committee considered that preventive measures against communicable diseases in childhood should be organized by each school; and, "for the very reason that the school is the centre of educational stimulation in most communities, it has a unique role to play in the dissemination of knowledge about communicable diseases." The committee also recommended the establishment, wherever possible, of health education programmes with parents and community groups, adapted to the social, cultural, and economic environment in which the children are living.

TREATMENT OF SEVERE HYPERTENSION WITH HEXAMETHONIUM BROMIDE

BY

ALLAN CAMPBELL, M.B., F.R.F.P.S.

AND

ERIC ROBERTSON, M.B., B.Sc.

Medical Registrars, Royal Alexandra Infirmary, Paisley

A number of drugs producing a fall in blood pressure have been investigated in an attempt to obtain a gradual but sustained fall in patients suffering from severe hypertension, as a support to the commonly employed measures of rest, sedation, limitation of salt intake, and diuretics. Treatment with thiocyanate has been reported on by Hines (1946) and Watkinson and Evans (1947), and this work has been reviewed favourably by Alstad (1948). More recently tetraethylammonium salts have been used by Lian and Bergamo (1948), Stead *et al.* (1948), and others. With these drugs it is possible to produce a marked fall in both the systolic and diastolic blood pressures, but protracted treatment is unsatisfactory in that it is limited by serious side-effects and by difficulties of administration.

Paton and Zaimis (1948) drew attention to the clinical potentiality of hexamethonium in hypertension, as they had found that, compared with tetraethylammonium, it gave a slower onset of action combined with a greater potency and longer duration of effect. They have recorded a detailed study of the ganglionic blocking action of hexamethonium and pentamethonium (Paton and Zaimis, 1949), the former being the more active. The clinical effect of these compounds upon the blood pressure was subsequently examined by Arnold and Rosenheim (1949), Burt and Graham (1950), and Kay and Smith (1950).

From this work it was evident that these drugs were capable of producing a marked and protracted reduction of the systolic and diastolic pressures, and they were therefore used in the treatment of patients suffering from severe hypertension. Eight cases of hypertension with papilloedema were selected for this trial and were treated with hexamethonium bromide.

Dosage and Method of Administration

A dose of 100 mg. administered intramuscularly every four hours was found to produce a progressive reduction in the blood pressure in all cases.

Subsequently, oral treatment was determined to be satisfactory, and indeed it produced a more constant fall of the blood pressure without the fluctuations encountered when the parenteral route was used. The drug was administered in solution formed by dissolving tablets—0.5 g. in 20 ml. of water. On the first day of treatment 0.25 g. should be given twice, followed by 0.25 g. thrice daily for the next two days, then 0.5 g. thrice daily for two days, the dosage being progressively increased until by the tenth day 0.5 g. is being given four to six times a day—a daily total of 2 to 3 g. It was found that the drug is more effective when given before meals.

Case 1

A woman aged 21 was seen in December, 1949, with dimness of vision and increasingly frequent headaches of over two months' duration. She was then in the third month of her first pregnancy. She had hypertension but no albuminuria, and there was no history of renal disease. Despite the termination of her pregnancy on February 2, 1950, the hypertension increased and albuminuria developed. She was pale, her blood pressure was 220/140, there was no evidence of arteriosclerosis, and the femoral pulses were easily felt. The heart was not enlarged and radiologically was normal in contour. The electrocardiogram was normal. Her vision was 6/36 both eyes; the fundi showed marked papilloedema of both disks, numerous soft exudates, and linear haemorrhages, with classical macular stars. There was fullness of the veins, with nipping at the A.V. crossings, and an A.V. ratio of 1:3.

Urine examination showed an albuminuria of three parts Esbach, occasional red cells, hyaline and granular casts, no pus cells or organisms. The specific gravity was fixed at 1004, with maximum urea concentration of 1.1%. The night volume exceeded the day volume. The blood urea was 115 mg. per 100 ml. A straight radiograph of the urinary tract revealed normal renal outlines, and no calculi were seen; the intravenous pyelogram showed no function up to 22 minutes. The sodium amytal test gave a maximum fall at the fifth hour, the systolic pressure dropping from 230 to 180, and the diastolic from 140 to 115 mm. of mercury.

The patient's progress with rest in bed, sedation, and a salt-free diet, which had been instituted on admission, was disappointing. Over a period of 10 weeks the vision did not improve, the physical findings were unaltered, and the lowest blood pressure recorded was 180/115 mm.

It was decided to use hexamethonium bromide orally. A small dosage was given initially, and within a few days was raised to a total of 3 g. daily, divided into six doses. Her blood pressure fell gradually during the next three weeks and settled to a systolic pressure between 120 and 140 and a diastolic of 80 to 95 mm. The blood urea fell to 70 mg. per 100 ml. Renal function tests showed a maximum concentration of 1018 and a maximum dilution of 1004. Albuminuria remained at two parts Esbach. Vision improved to 6/6 in both eyes; papilloedema disappeared; and fundal haemorrhages and exudates showed absorption and organization.

The patient was allowed up from May 21 and complained of some faintness due to postural hypotension for the first three days. On June 5 hexamethonium bromide was withdrawn, after seven weeks' treatment with it. There was no rise in her blood pressure, which after two months without treatment still varied between 130/95 and 120/75 mm. She was free of all symptoms, and has undertaken work as a nursing orderly in the wards for eight hours a day.

Case 2

This patient, a woman aged 46, was admitted on April 19, 1950, complaining of increasingly severe headaches of four years' duration, with recent transient paraesthesiae in one or more limbs, associated with severe paroxysms of occipital and frontal headaches, and followed by a transient loss of muscle power. She had had four normal pregnancies, the last nine years previously, at which time no hypertension was present. There was no history of renal disease.

On admission her blood pressure was 230/120 mm. The heart was not enlarged clinically, slight radial arteriosclerosis was noted, and the femoral pulses were present. Well-marked papilloedema was seen; the A.V. ratio was 1:2; slight exudates were present, but no haemorrhages. No albuminuria was found; the maximum concentration was 1025, and the minimum dilution of the specific gravity was 1005. Radiological examination of the urinary tract and chest revealed no abnormality. The sodium amytal test gave a maximum fall at the sixth hour—the systolic from 230 to 160 and the diastolic from 130 to 90 mm.

Absolute rest, sedation, a salt-poor low-calorie diet, and xanthine diuretics for three weeks produced no improvement in her condition or fall in blood pressure. On two occasions transitory arm and leg pareses occurred.

Oral treatment with hexamethonium was begun, the dosage being raised to 3 g. daily. Complete relief from all symptoms occurred within six days, her blood pressure falling to between 130/75 and 150/100 mm. She was allowed up, and during the next fortnight complained only of faintness due to postural hypotension. Fundal examination showed disappearance of papilloedema. The blood urea was 20 mg. per 100 ml., and there was no change in renal function. After a further month she was discharged, and attends as an out-patient, receiving a maintenance dosage of hexamethonium.

Case 3

A man aged 39 was admitted on April 20 with retrosternal discomfort and pain radiating down the left arm, occurring at rest and aggravated by effort. He complained also of palpitation and dyspnoea, and suffered from severe headaches. His vision had been failing for the past two months. There was a history of acute nephritis at the age of 20. The blood pressure was 240/120, the heart was slightly enlarged, and there was left ventricular preponderance in the electrocardiogram. Triple rhythm was present. The blood urea was 35 mg. per 100 ml. The maximum renal concentration was 1015 and the maximum dilution 1002. The fall obtained in the sodium amytal test was 240 to 190 systolic and only 140 to 130 diastolic.

After 14 days in bed on a salt-poor low-calorie diet and phenobarbitone, 1 gr. (65 mg.) three times a day, the patient complained of deterioration of vision; increasing papilloedema was observed in addition to numerous linear haemorrhages and exudates.

Hexamethonium bromide was given orally—a total of 3 g. daily. His vision improved, the headache, retrosternal discomfort, pain, and dyspnoea disappeared, and he was allowed up on May 31, his pressure varying between 115/75 and 145/95 with occasional transient variations above these limits. The blood urea was 30 mg. per 100 ml., and the renal function tests were unaltered. After a further month in hospital he was discharged on maintenance dosage. He felt well and was symptom-free.

Case 4

A woman aged 50 was admitted with essential hypertension of 10 years' duration. Cardiac enlargement, moderate arteriosclerosis, and papilloedema were present. Her blood pressure was 230/140 mm.

No improvement was noted during four months of hospital treatment, and on June 14 hexamethonium was given orally, 3 g. daily. In 10 days the blood pressure fell to 160/100 mm. and remained fairly constant. The patient became ambulant and all symptoms were completely relieved.

Case 5

This patient, a man aged 56, developed severe hypertensive heart failure and was admitted on April 24, when cardiac asthma was found to be a prominent feature. There was no history of renal disease. During the next fortnight his blood pressure was constantly 260/155. The heart was clinically enlarged, and radiological examination showed an increase of the transverse diameter of the heart and pulmonary congestion indicating left heart failure. Medium crepitations were present at both bases. Papilloedema was observed. Preliminary treatment without hexamethonium had no effect and the prognosis was grave.

Hexamethonium was given in total dosage of 2.5 g. a day from May 11. From being orthopnoeic the patient became symptom-free and ambulant in 35 days. His blood pressure varied between 140 and 150 systolic and 80 and 110 diastolic. There was no clinical evidence of cardiac enlargement. Radiological examination revealed a transverse diameter of the heart which was within normal limits. A month later he became capable of light exercise without dyspnoea, and he has been discharged on maintenance dosage.

Case 6

A woman aged 49 had been treated in bed for the previous 10 months at home with no relief of her symptoms of dyspnoea on effort and at rest, anginal pain, severe headaches, and failing vision. Her blood pressure on admission was 240/160 mm. There was gross cardiac enlargement, left ventricular preponderance, and triple rhythm. Marked papilloedema and numerous exudates and haemorrhages were seen. She was admitted on

June 14 and treated from the 25th with hexamethonium bromide, 2.5 g. total a day. Her blood pressure fell in 10 days to 170/110 mm. and there had already been relief of dyspnoea, anginal pain, and headache; after a further three weeks she was allowed up, and improvement has been maintained.

Case 7

This patient, a woman aged 41, was admitted on February 15, 1950, with a history of cardiac asthma, severe headaches, and dyspnoea on effort of two years' duration. She had had acute nephritis at the age of 20. Gross heart enlargement was present and triple rhythm. There was early papilloedema with exudates and haemorrhages. Her blood pressure during the next three months in hospital with routine medical treatment was at a constant level of 275/170 mm.

Hexamethonium treatment was begun on June 14 and raised to a total daily dosage of 3 g. Her blood pressure fell to 180/120 mm., and remained at this level. The headaches and dyspnoea disappeared, papilloedema regressed, and the patient could sleep recumbent. After four weeks' treatment hexamethonium was withdrawn. There was no subsequent rise of her blood pressure. She is ambulant and well.

Case 8

A man aged 30 was admitted on April 5 with malignant hypertension, and his blood pressure was found to be 195/130 mm. The symptoms were of four weeks' duration, and during the next two weeks of observation a rapid deterioration in his condition took place, headache, nausea, and vomiting being associated with gross fundal changes and visual failure. There was an albuminuria of four parts Esbach with numerous red cells microscopically and a blood urea of 100 mg. per 100 ml. The intravenous pyelogram showed no function in either kidney after 25 minutes.

Hexamethonium treatment was begun on April 17 in a dosage of 3 g. a day, which produced a steady fall of blood pressure to 130/80 mm. Complete relief of headache followed. The fundal changes regressed, with some improvement in vision. There has been no change in his renal function, and albuminuria averages two parts Esbach.

Hexamethonium was withdrawn on July 9. There was no alteration in the blood pressure for the next month, but a subsequent rise of blood pressure to 170/110 mm. necessitated a further course of treatment with hexamethonium, which has reduced the pressure again to within normal limits, and his blood urea has fallen to 30 mg. per 100 ml.

Discussion

Throughout this series the substitution of normal therapeutic measures other than rest in bed by oral medication with hexamethonium bromide led to an immediate fall in the blood pressure to a level which could readily be maintained by a daily total dosage of 2 to 3 g.

The most striking results were obtained in Cases 1 and 8, young patients with no previous history of renal disease, with symptoms of short duration and rapid progression, and with no arteriosclerosis. Although there was a remote possibility of a remission in Case 1, there can be no doubt about the efficacy of the intervention of hexamethonium in Case 8.

In the presence of long-standing hypertension without a previous history of renal disease, the blood pressure could be reduced to within normal limits or to such levels as were considered desirable clinically. Thus in Cases 5, 6, and 7 gross arteriosclerotic changes were present and reduction of the blood pressure to normal limits was considered inadvisable.

Headache has been abolished, papilloedema has markedly regressed, and vision has improved in every case. All the patients are now ambulant.

Complete relief from paroxysmal nocturnal dyspnoea was observed in Cases 5, 6, and 7, and from angina in Case 3, contrary to the experience of Bjorkenheim (1948) with tetraethylammonium. Clinical and radiological evidence of the return of an enlarged heart to normal size was obtained in Case 5.

Alteration of the balance of fluid intake and output was negligible during treatment, and the volume of urine was slightly increased at first in some patients. It was possible to lower the blood pressure sufficiently to relieve symptoms in patients with chronic nephritis without disturbing renal function.

Hexamethonium was withdrawn in Cases 1, 7, and 8 without an immediate rise in the blood pressure; and, although Case 8 required further treatment, Case 1 still had a stable normal level of pressure after eight weeks. It seems likely that continuous administration may be unnecessary.

During the earlier part of this trial, shortages of hexamethonium led to substitution by pentamethonium bromide and iodide. This drug was found to be less effective in equal dosage, and nausea and tachycardia were troublesome. Hexamethonium is considered preferable.

Side-effects.—Blurring of vision, dry mouth, nausea and heartburn, and constipation were encountered in every case from the beginning of treatment. These side-effects were not severe and disappeared during the first two weeks, but recurred and disappeared with any significant increase in dosage. However, apparent paralytic ileus was encountered in two patients, necessitating withdrawal of hexamethonium for a period of 24 hours and treatment by the administration of a high enema, full dosage being subsequently resumed without complication. It was found necessary to begin treatment with a small dose of the drug, as the administration of a full dose initially produced a circulatory collapse in two patients. Faintness due to postural hypotension was complained of when patients became ambulant, but was of only a few days' duration.

Summary

Eight cases of severe hypertension have been treated with hexamethonium bromide, with a marked lowering of the blood pressure and relief of symptoms. Although experience with this series of patients is limited and the place of hexamethonium in the treatment of hypertension has still to be defined, this preliminary report is recorded because hexamethonium seems to provide a useful method of reducing the blood pressure in severe hypertension, with ready administration and relative freedom from toxicity.

We wish to express our thanks to Dr. J. Gibson Graham and Dr. A. E. Struthers for their encouragement, and to Dr. Thomas Parker for his permission to record these results. We thank Drs. R. Erskine, I. Muir, and N. Murray, house-physicians, for their kind assistance. We are indebted to May and Baker Ltd. for providing the supplies and information which enabled this trial to be undertaken.

EFFECT OF ORAL HEXAMETHONIUM SALTS ON GASTRIC SECRETION

BY

A. W. KAY, M.D., Ch.M.

AND

A. N. SMITH, M.B., Ch.B.

Hall Tutorial Fellow, University of Glasgow

(From the Peptic Ulcer Clinic, Western Infirmary, Glasgow)

Hexamethylene-*bis*trimethyl-ammonium (hexamethonium) iodide (C6) has been shown by Paton and Zaimis (1949) to exert a blocking effect at the synapses of autonomic ganglia. In a previous paper (Kay and Smith, 1950) we have shown that this compound, when given intramuscularly, inhibits the gastric secretion and motility. In the present paper we give the results obtained with the same drug administered by mouth, and also compare the effects of the other halides.

In the first series of experiments we have observed the effect of a single dose of the iodide salt on the gastric secretion; in the second, the effect of repeated administration; and in the third, the comparative effects of equivalent doses of the iodide, bromide, and chloride.

Effect on Spontaneous Gastric Secretion

Ten male patients with duodenal ulceration were selected for study. Cases of peptic ulcer complicated by organic stenosis were excluded, since it was felt that the use of hexamethonium iodide would exaggerate gastric retention. Secretion tests were begun at 9 a.m., after a 12-hour fasting period. In the control test, specimens were aspirated every 30 minutes for a period of three hours. On the following day 500 mg. of the drug was given by stomach tube immediately on removal of the fasting juice. After one hour specimens were aspirated at 30-minute intervals. This method was used for six patients. In the other four, to avoid aspiration of unabsorbed drug retained in the stomach, the first aspiration was delayed until two hours after giving the drug.

At each aspiration the stomach was emptied, and the volume, bile staining, and titratable free hydrochloric acid were noted. All saliva was expectorated. It will be seen from Figs. 1 and 2 that achlorhydria was reached in five patients, being of short duration in three and lasting four hours in the other two. Of the remainder, three patients showed an appreciable fall in the level of acidity. Two, however, showed no significant change. That the reduction of acidity was due to diminished secretion and not to regurgitation of duodenal juice was indicated by the small volume of the fluid withdrawn and the absence of bile.

Effect of a Repeated Dose on Spontaneous Gastric Secretion

In view of the variable results noted above, it seemed desirable to determine if consistent results were obtained in individual patients. With this in view 500 mg. of hexamethonium iodide was administered to four patients on two successive occasions and the results compared with preliminary and final controls. As in the first group, the drug was given after aspiration of the fasting juice. Beginning one hour later, specimens were removed at half-hourly intervals. The results are shown in Fig. 3. It will be

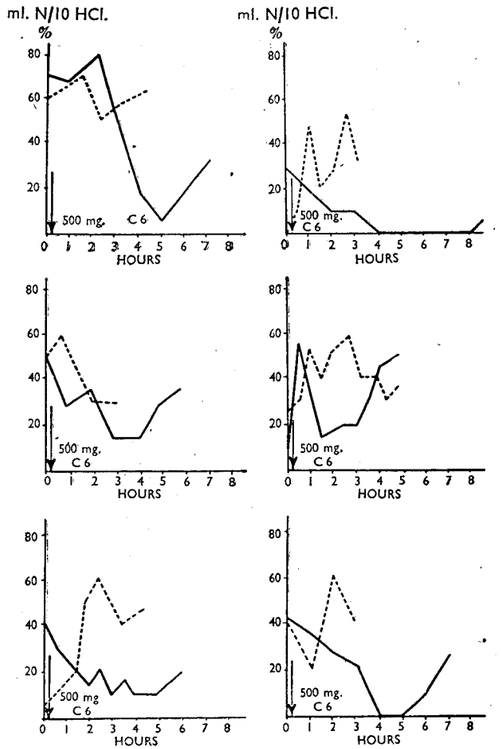

Fig. 1.—Spontaneous gastric secretion. Effect of oral C6, dosage 500 mg. (six cases). Broken line shows control readings.

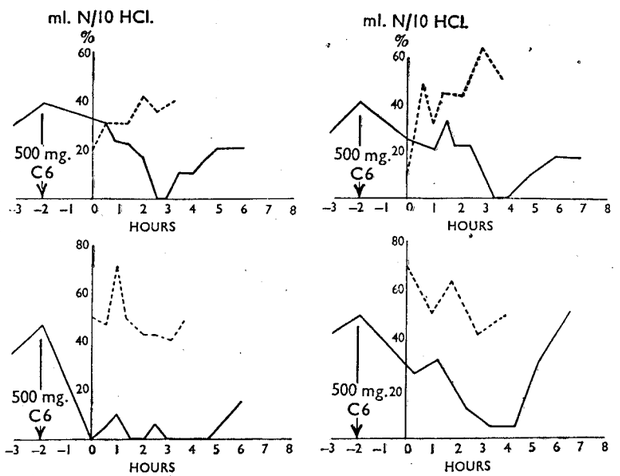

Fig. 2.—Spontaneous gastric secretion. Effect of oral C6, dosage 500 mg. (four cases).

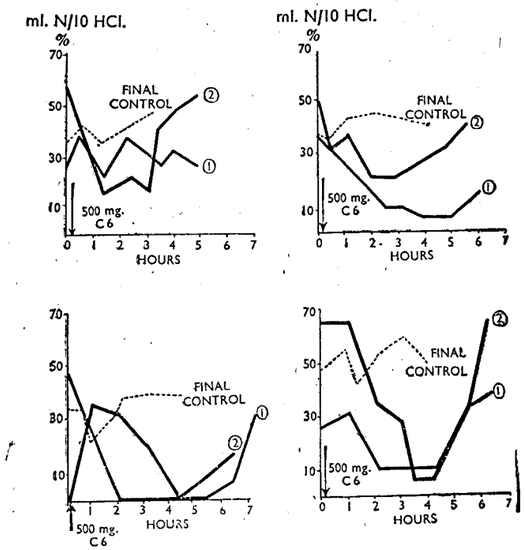

Fig. 3.—Repeated administration with final control.

seen that, while the effects differed in the four individuals, in each of them the successive results were consistent. It will be noted also that there was no evidence of prolonged action of the drug from one day to the next.

Comparison of Hexamethonium Halides

In a further series of six patients the action of equivalent amounts of hexamethonium iodide (500 mg.), hexamethonium bromide (440 mg.), and hexamethonium chloride (340 mg.) was tested on spontaneous gastric secretion. Control tests were performed before and after the test experiments. To avoid fallacies due to possible summation effects, the methonium salts were given in varying order, using all combinations. The tests were made on consecutive days, and in each case the fasting juice was removed, followed by a further specimen one hour later. The drug was then given and repeated aspiration delayed for two hours.

The average figures of the six cases are shown in Fig. 4, from which it will be seen that the iodide appears to give the most effective control of spontaneous secretion, the chloride being the least effective. Results obtained with individual patients agreed with the above finding in four cases; in one case the bromide gave a more satisfactory result, while another was inconclusive.

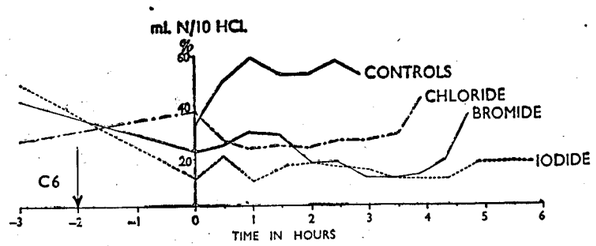

Fig 4.—Comparison of hexamethonium halides: oral administration. Average of six cases.

Observations on Side-effects.—During this investigation hexamethonium was administered on 36 occasions. Observations were made throughout on the frequency and severity of the known side-effects. After 12 of the administrations there was definite impairment of accommodation with resultant blurring of vision, though this was severe in only two cases. There was no visual upset in the remaining 24, but 8 patients complained of heaviness about the eyes; dryness of the mouth was mentioned by three patients; there was a tendency to constipation in several patients, especially in the group receiving hexamethonium on successive days. The sensation of warmth noted after intramuscular injections was not evident after oral administration.

Hypotension

It was found that with the patient supine there was an average drop of 5–10 mm. Hg in systolic and diastolic blood pressure. On standing motionless the fall in blood pressure was increased by 15 mm. Hg. This hypotension, elicited in the above manner, was present from one hour after administration, reached a maximum at two to two and a half hours, and lasted three to four hours. In these circumstances several patients complained of faintness, which was relieved by recumbency. It should be noted, however, that the subjects of this investigation had been fasting for more than 12 hours. It was noted that by taking active exercise faintness was prevented or overcome.

As an experiment under more rigorous conditions in which postural hypotension would be seen at the maximum, the action of hexamethonium was studied in four post-operative cases. They were males, aged 14, 21, 23, and 62 years, and were examined within one week of operation (ruptured appendix, perforated ulcer, inguinal hernia, and appendicitis). The patient aged 21 was ambulant for the first time. In this series particular note was taken of the effect on the blood pressure of standing motionless and of active movements.

Before giving hexamethonium, blood-pressure readings were obtained with the patient at rest in bed, immediately on standing, after standing motionless for five minutes, after walking for five minutes, and, finally, after recumbency for five minutes. Similar observations were made one, two, three, and four hours after 500 mg. of hexamethonium orally. On successive days the drug was given (*a*) after 12 hours' fast, the patient fasting throughout; (*b*) after 12 hours' fast, the administration being followed immediately by a meal; and (*c*) after a meal.

In control observations (without hexamethonium) immediately on standing there was a slight fall of blood pressure (5–10 mm. Hg), which was rapidly compensated by vasoconstriction. After hexamethonium, in two cases a similar fall of pressure occurred, but persisted while the patient remained motionless. In the third (Fig. 5) the fall was considerable (from 100/60 to 65/45). In the fourth there was a transitory severe hypotension with a feeling of faintness. In all cases the pressure rose towards the normal level when purposeful activity was begun. The findings in the man aged 62 are shown in Fig. 5.

When the drug was given on an empty stomach the blood-pressure changes were of the same order, whether the patient was subsequently given a meal or kept fasting, though in the latter state the subjective sensations were severe. When the drug was given after a meal, however, the hypotension on standing was slightly less. This may have been due to delayed absorption, a point which requires further study.

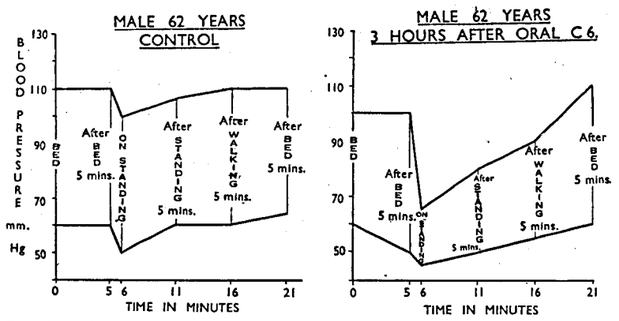

Fig. 5.—Effect of posture and activity on blood pressure before and after C6.

Discussion

Our observations show that hexamethonium iodide given by mouth may depress the acid secretion, but does so less consistently than when administered intramuscularly. In about one-third of our cases the secretion was depressed to the point of achlorhydria, in one-third there was an appreciable lowering, while in the remainder there was no demonstrable effect. Since in this refractory group there were side-effects, including hypotension, the failure cannot be attributed entirely to faulty absorption. The observation that in four cases consecutive experiments gave closely similar results suggests that the failures may be due to individual variations in susceptibility to the drug.

Experimental work has shown that hexamethonium appears to be more effective in blocking the cat's superior cervical ganglion when this ganglion is excited frequently and for a long period than when it is excited briefly and with less frequent stimuli (Paton; personal communication). It seems possible, therefore, that hexamethonium may in some cases depress abnormal ganglionic activity before it interferes with normal function. Thus the gastric effects would be most marked in cases with excessive vagal tone. Indeed, we gained the impression that side-effects such as hypotension were least marked in these cases in which acid secretion was most affected. Thus the drug may act at different sites in different individuals, according to the nature of the predominant autonomic tone.

The three halide salts of hexamethonium have been compared as regards their action on spontaneous gastric secretion. In this small series we gained the impression that the iodide and bromide gave better control of secretion than the chloride. This slight difference in potency may depend on a variation in the absorption of these compounds, though further investigation will be required on this point.

The beneficial effects of parasympathetic blockade are partly offset by the undesirable side-effects resulting from blockade of the sympathetic ganglia, the most notable of which is postural hypotension. The normal drop in blood pressure which occurs on standing is rapidly compensated by vasoconstriction. After oral administration of hexamethonium this mechanism is more or less depressed and postural hypotension is therefore apt to occur, but this can be controlled by muscular activity or recumbency. A feeling of faintness is rare except when standing motionless. The possibility of these symptoms arising is greater in the fasting patients. In general, however, faintness has been an uncommon experience in our series, presumably because standing motionless for several minutes on end is a rare event in everyday life. It is possible that the small risk of faintness could be removed by the use of a long-acting sympathomimetic drug.

Summary

Hexamethonium iodide was given orally to 10 patients with duodenal ulcer—five were rendered achlorhydric, three had a substantial fall in gastric acidity, and in two there was no significant difference between control and test observations.

Comparable results were obtained for each individual when the drug was given on repeated occasions. The effect was not prolonged from one day to the next.

All hexamethonium halides were found to be active in controlling spontaneous gastric secretion. In a small series of cases the iodide and bromide were found to produce a greater fall in gastric acidity than the chloride.

Side-effects, notably postural hypotension, may be present during routine administration of the drug.

Rigorous conditions for an experiment with four patients produced marked hypotension reduced by activity and by the taking of food.

Throughout the investigation a variability of the action of the drug characteristic to the individual was noted.

We are indebted to Professor C. F. W. Illingworth for his advice and helpful criticism throughout this investigation. We wish to acknowledge the interest taken by Dr. W. D. M. Paton, of the National Institute for Medical Research, in this work, and to record our thanks to Dr. N. S. Conway for kind assistance. Our thanks are also due to Mr. Gabriel Donald and the technical staff of the Surgery Department, University of Glasgow, and to May and Baker Ltd. for supplies of hexamethonium salts.

On September 9 President Truman signed a Bill making lawful the call-up of all United States doctors, dentists, and "allied specialists" (including pharmacists, veterinary surgeons, and osteopaths), who are less than 50 years old, for a period of thirty-two months' military service. At the same time the Defence Department has issued a statement to explain in what order doctors will be called. It is intended that the first group will be those who received all or part of their professional training under wartime special training schemes but who had no military service owing to the ending of the 1939–45 war before they qualified. Next come those trained under these schemes but having military experience, those with least service being called first. Finally, all medical officers on the Reserve will be recalled in an order of priority, men trained at Government expense first, those with less than ninety days' active service, then those with less than twenty-one months, then those who had never previously served; and finally doctors who trained at their own expense and have a military record. The officers' Reserve is voluntary, and every medical volunteer gets a pay bonus of $100 (£35) per month, to which the conscript will not be entitled. It is hoped that this, taken with the new call-up, will encourage volunteering to such an extent that it will in fact be unnecessary to apply conscription. The American Services say they need an additional 5,000 doctors and 2,000 dentists this year, and, if all the men trained at least partly with Government aid during World War II but who saw no service can be induced to volunteer, this need will be met. If conscription should prove necessary, it will be administered with the help of a national medical committee which will consider civilian needs in each district; and interns in civilian hospitals will be reserved for a period of twelve months.

CLINICAL ASSESSMENT OF RAPIDLY ACTING AGENTS IN RHEUMATOID ARTHRITIS

BY

C. E. QUIN, M.D., M.R.C.P.

R. M. MASON, M.A., B.M., M.R.C.P.

(From the Arthur Stanley Institute, Middlesex Hospital)

AND

J. KNOWELDEN, M.D., D.P.H.

(From the London School of Hygiene and Tropical Medicine)

The discovery by Hench, Kendall, Slocumb, and Polley (1949) of the therapeutic effects of cortisone in rheumatoid arthritis has stimulated the trial of many other steroids whose action might possibly be similar. Unfortunately the lack of cortisone in this country, with which such substances could be directly compared, has led to considerable difficulty in the interpretation of results. That many therapeutic trials have been carried out using unsatisfactory experimental methods has been strikingly illustrated by the recent controversy over the efficacy or otherwise of deoxycortone and ascorbic acid in rheumatoid arthritis. Some workers (Lewin and Wassén, 1949; LeVay and Loxton, 1950; and others) claim categorically that very remarkable results were being obtained; others (Kellgren, 1949; Spies *et al.*, 1949; Kersley *et al.*, 1950; Fletcher *et al.*, 1950; Copeman *et al.*, 1950) declare equally definitely that their results were negative. Similar claims, though less dramatic, are being made for other steroids lacking an oxygen atom at the 11 position—for example, "pregnenolone" (Davison *et al.*, 1950; Freeman *et al.*, 1950)—but, again, others have failed to confirm these results (Henderson *et al.*, 1950, who quote much unpublished work).

Clinical improvement has been the basis of most claims of therapeutic success. It is necessary, however, to support these claims by the demonstration that such improvement is real, and that it is due in fact to the particular substance administered. Quite apart from normal fluctuations occurring as part of the natural history of rheumatoid arthritis, the psychological effect of giving a new treatment may be considerable, especially as the dramatic effects of cortisone have become widely known. That such effects may be pronounced has been emphasized by Wolf (1950) in a paper entitled "The Effects of Suggestion and Conditioning on the Action of Chemical Agents—the Pharmacology of Placebos."

Our aim has been to adopt methods of assessment of clinical improvement, with special reference to rheumatoid arthritis, which will show conclusively whether or not an apparently beneficial effect is due to the trial substance. A detailed description of the methods used is given. These have been applied to deoxycortone and ascorbic acid therapy as described by Lewin and Wassén (1949), since their claims were both dramatic and precise: improvement was said to occur within minutes of a single combined injection, and this therefore presented the problem of assessment in the simplest possible terms. It is, however, suggested that these methods might be capable of development and modification for other substances which may become available from time to time.

Experimental Methods

The method used involved the clinical assessment of patients suffering from rheumatoid arthritis before and after injection: it was designed to include the following precautions:

Adequate Numbers.—A sufficiently large number was treated to enable a satisfactory statistical analysis to be carried out where necessary.

Placebo Control.—All patients received both test substance and control injection on separate occasions. They were unaware that placebo injections were being used, and the order of injection was statistically randomized.

Observer Control.—The observer was unaware of the nature of the injection given when carrying out the assessment, nor did he have available any record of previous results.

In addition, care was taken to avoid psychological pressure in that patients were told they were not receiving cortisone or A.C.T.H., and that this was simply a scientific investigation into a substance whose effects were not known. It was made absolutely clear that this was an investigation in which they were being asked to co-operate and that it was not part of their treatment.

Since the full assessment of a case of rheumatoid arthritis is a long and tedious business it was necessary to select certain features which would reasonably be expected to be affected if an active agent were used. Such features were both subjective and objective. The subjective phenomena considered were pain and stiffness. Objective measurements were made of joint tenderness, muscle power as measured by the power of grip, range of movement as illustrated by the range of abduction of the shoulder-joint, and the speed of movement by the time taken to walk a distance of 8 yards (7.3 m.), including climbing some steps. While these are by no means complete—and experience will probably suggest other criteria—they cover most of the recognized features of the disability of rheumatoid arthritis.

Joint swelling as such was not measured. We have not established a satisfactory method of doing this, but it would seem reasonable to suppose that any significant reduction in swelling would be manifested by some change in the other features measured. Nor were pathological criteria included, since these have been the subject of careful investigation by others (Bywaters *et al.*, 1950; Dresner *et al.*, 1950), and, as has already been explained, the object was primarily to find out whether clinical improvement took place.

Details of Methods Used

Forty-three patients—33 female and 10 male—were selected for the trial at their routine visits for consultation or treatment. The diagnosis of rheumatoid arthritis was based on the presence of chronic progressive polyarthritis, largely symmetrical, tending to affect the peripheral joints early, with muscle-wasting, constitutional disturbance, and loss of weight, but with no evidence of any specific infective organism. The patients all fell into Stage 1, 2, or 3 of rheumatoid arthritis as defined by Steinbrocker *et al.* (1949). The age distribution, duration of symptoms, and sedimentation rate within three months of the trial are shown in Table I. It will be seen that no case with an E.S.R. below 15 mm. (Westergren) in the first hour was included. Radiographic changes characteristic of the disease were present in all 36 cases in which an *x*-ray examination had been carried out. The experimental nature of the treatment was made clear to all the patients, but few of those

TABLE I.—*Age Distribution, Duration of Symptoms, and E.S.R.*

Total ..	43		43		43

asked refused to take part in the investigation. They were not told what drugs were being used or that control injections of an inert substance would also be given, but it was made clear that they were not receiving cortisone. They were asked not to take aspirin or other analgesics on the days of the injections.

Patients came up in groups of 10 to 12 to be tested and questioned individually by one of us. They were asked whether they had any pain and, if so, whether it was constant or only present on movement. They were also asked whether stiffness was present and, if so, which part of the body was chiefly affected.

In order to elicit joint tenderness, a swollen joint was squeezed between finger and thumb, maximal force being exerted. In the case of proximal interphalangeal joints, which were usually selected, pressure was applied to their lateral and medial aspects. The amount of joint tenderness was graded arbitrarily according to the patient's reaction to this procedure. If the patient said spontaneously or on questioning that the joint was tender, the amount of tenderness was graded as 1; if in addition he winced or grimaced, the grading was 2; if the reaction was more violent and accompanied by withdrawal of the hand, the grading was 3; if no tenderness could be elicited the grading was 0. This grading is rather similar to that used by Hench *et al.* (1950). They, however, describe some six grades of tenderness; our figures are therefore not comparable with theirs.

For testing grip a rolled sphygmomanometer cuff was used. The end of the cuff was sewn firmly to the roll so as to ensure a cylinder of constant size when inflated. The cuff was inflated until a pressure of 50 mm. Hg was registered on the sphygmomanometer. The diameter of the cylinder was then approximately 6 cm. The patient was told to put his elbow on the table with his forearm inclined to an angle of 45 degrees. The cuff was placed in his hand and he was told to squeeze it as hard as possible and maintain the pressure. The height of the mercury column could not be seen by the patient. The pressure which he was able to maintain for two or three seconds was then recorded, the grip being measured in the right and left hand alternately (Kellgren and Janus, 1950—personal communication). Three readings were taken from each hand, and subsequently the mean of these readings was calculated.

The patient was then asked to abduct his shoulder to the fullest possible extent. The arm was not allowed to move forwards, so that true abduction was carried out. The amount of abduction was recorded in degrees, and, though this is a visual estimate without instrumental aid, a considerable measure of accuracy can be obtained.

He was then asked to walk as quickly as possible from one end of the room to the other, some steps being placed in his path. The length of the room was 12 ft. 4 in. (3.76 m.) and the height of the steps 14 in. (35 cm.) (three steps were involved of 6 in. (15 cm.), 8 in. (20 cm.), and 6 in. with no hand rail). The time taken to complete the course was measured with a stopwatch.

After being tested the patient received in a separate room his injection from whichever observer was not doing the assessing on that particular group (22 patients were injected by C. E Q. and 21 by R. M. M.). Numbered envelopes had previously been prepared giving the order of injection, which was randomized. Each patient received a serial number, and the order in which his injections were to be given was determined by opening the corresponding envelope. The nature of the injection was thus concealed from the observer until the group he was assessing had completed the trial.

The technique of injection was as follows: 5 mg. of deoxycortone in 1 ml. of oil or 1 ml. of saline was injected into the muscles of the outer side of the thigh, followed in one or two minutes by 1 g. of ascorbic acid in 10 ml. of aqueous solution or 10 ml. of saline intravenously.

One hour after injection the patient was asked whether his pain was better, unchanged, or worse, and whether his stiffness was less, unchanged, or greater. When the patient reported improvement or deterioration, its extent was graded as "slight," "moderate," or "marked" according to the impression made by his statement. Any other effects from the injections were noted and the tests previously described were then repeated. The assessor was not allowed to see the results of any previous tests when making his assessment. Finally, one week later we noted any improvement or deterioration which had occurred and, in particular, whether the arthritis was better or worse than before the injection.

Results

Subjective Changes.—An analysis of the subjective impressions of the patients following injection is shown in Tables II, III, and IV. In Table II the overall

TABLE II.—*Overall Assessment (Subjective)*

Condition After Treatment Relative to Condition Before	No. of Cases			
	1 Hour After Injection		1 Week After Injection	
	Da/asc.	Saline	Da/asc.	Saline

improvement or deterioration, whether affecting pain or stiffness, is recorded. Pain and stiffness are considered separately in Tables III and IV, and the grading of the responses is shown. It is clear from these tables that there was subjective improvement in many patients, no less than 58% claiming this to be the case one hour after either

Table IV.—*Stiffness*

Stiffness 1 Hour After Treatment Relative to Stiffness Before	No. of Cases	
	Da/asc.	Saline
Better { Marked	—	1
Better { Moderate	11 } 19	6 } 19
Better { Slight	8 }	12 }
Unchanged	23	22
Worse	1	2
Total	43	43

Da/asc. = Deoxycortone and ascorbic acid.

injection. It is also clear from the tables that the test substance was no more effective than saline in this respect. Only one patient showed marked subjective improvement, and this occurred after each injection. One hour after the first injection (deoxycortone and ascorbic acid) he said there was a dramatic relief of his pain and considerable diminution of stiffness. At the end of a week he said that some days he "had been better, some days worse," but, on the whole, slight improvement had occurred. He was then given his control injection of saline, and one hour later said that "almost immediately after the injection there was a glow and complete relief of pain—it was dramatic." The pain had "gone completely" from his hands, and this time a marked relief of stiffness had also occurred. A week later he said that his improvement had been maintained for four days and that he had then relapsed, although not quite to his pre-injection level.

Joint Tenderness.—The degree of joint tenderness of the selected joint at the first assessment was as follows: 4 cases showed grade 1 tenderness only, 26 cases grade 2, and 13 cases grade 3. The wrist-joint was used in 4 cases, a metacarpo-phalangeal joint in 1 case, and a proximal interphalangeal joint in 38 cases. As can be seen from Table V, the numbers of those improved after injection were relatively small and the difference between the effects

Table V.—*Joint Tenderness*

Tenderness 1 Hour After Treatment Relative to Tenderness Before	No. of Cases	
	Da/asc.	Saline
Better by 1 point on scale	8	7
Unchanged	34	32
Worse by 1 point on scale	1	4
Total	43	43

Joint tenderness was measured on a scale: 0 = no pain; 1 = slight pain; 2 = wincing; 3 = wincing and withdrawal.
Da/asc = Deoxycortone and ascorbic acid.

of deoxycortone/ascorbic acid and saline is negligible. No formal tests of significance are required to stress the similarity between the figures.

Grip Test.—The average power of grip in each hand before and after injection, measured in mm. Hg over and above the 50 mm. Hg to which the cuff was inflated, is shown in Table VI, together with the average increase

Table VI.—*Grip Test. Average of Three Readings (mm. Hg)*

	Right hand			Left hand		
	Before Injection	After Injection	Difference	Before Injection	After Injection	Difference
Da/asc.	50	55	+5	47	52	+5
Saline	51	55	+4	48	52	+4

Da/asc. = Deoxycortone and ascorbic acid.

in grip after injection. Table VII gives the frequency distribution of the range of improvement or deterioration Taking both hands together (86 hands, 43 patients), an increased grip was recorded in 65 after deoxycortone/ascorbic acid and in 56 after saline. It will be seen from Table VI that the difference in the average increase in grip after test substance as compared with control amounted to 5−4=1 mm. Hg in favour of the test substance for each hand. Such differences are of no practical significance even if they were technically so. Using a significance test, however, for right hands t=0.433, P>0.6, and for left hands t=0.757, P>0.4. Evidently in this experiment the effect of deoxycortone/ascorbic acid on the power of grip was not significantly different from that of saline.

Table VII.—*Grip Test*

Difference between Grip 1 Hour After Injection and Grip Before Injection (mm. Hg)	No. of Cases					
	Right Hand		Left Hand		Both Hands	
	Da/asc.	Saline	Da/asc.	Saline	Da/asc.	Saline
Better by more than 10	9	11	9	11	18	22
,, ,, 5·1–10	10	9	13	5	23	14
,, ,, 0·1–5·0	14	8	10	12	24	20
Worse by 0·0–4·9	5	8	8	8	13	16
,, 5·0–9·9	3	4	1	5	4	9
,, more than 9·9	2	3	2	2	4	5
Total	43	43	43	43	86	86

Da/asc. = Deoxycortone and ascorbic acid.

Shoulder Abduction.—Patients with a full range of abduction of the shoulders had to be excluded from the analysis of this test since the only change possible would have been a deterioration. Only 24 right shoulders and 26 left shoulders were therefore available in our cases. The average range of abduction of the shoulder-joint in these cases, measured in degrees, is shown in Table VIII.

Table VIII.—*Average Shoulder-joint Abduction in Degrees*

	Right Shoulder			Left Shoulder		
	Before Injection	After Injection	Difference	Before Injection	After Injection	Difference
Da/asc.	109	112	+3	100	106	+6
Saline	102	108	+6	100	105	+5

Da/asc = Deoxycortone and ascorbic acid.

The difference in response for right shoulders was 6−3=3 degrees in favour of saline, and for left shoulders 6−5=1 degree in favour of deoxycortone/ascorbic acid. As already described, these measurements were made without instrumental aid, and such changes are, of course, well within the experimental error of the method. In any case, such differences are of no practical importance and technically not significant (right P>0.4, left P>0.8). Table IX shows the frequency distribution of the range

Table IX.—*Shoulder Abduction*

Difference between Abduction 1 Hour After Injection and Abduction Before Injection (Degrees)	No. of Cases					
	Right Shoulder		Left Shoulder		Both Shoulders

Total	24	24	26	26	50	50

Da/asc. = Deoxycortone and ascorbic acid.
Patients who had a maximum range (180 degrees) before injection of either Da/asc. or saline were excluded from this tabulation. Abduction was measured to the nearest 5 degrees, and the scale of differences therefore is discrete.

of improvement or deterioration, and it reveals that where improvements of 15 degrees or better are considered the figures for deoxycortone/ascorbic acid and saline, taking right and left shoulders together, are identical, in each case 10 shoulders showing this amount of improvement. Again, therefore, the test substance has been shown to be without benefit.

Step Test.—From Table X it can be seen that after deoxycortone/ascorbic acid 30 patients showed an improvement on their time, and after saline 29. One patient had

Table X.—*Step Test*

Saline	14·9	13·3	−1·6

Da/asc. = Deoxycortone and ascorbic acid.

1.3 seconds after test substance and 1.6 seconds after control injection, giving an advantage of 0.3 second to saline. This difference is again without practical or technical significance (t=0.573, P>0.5).

Discussion

As Bywaters *et al.* (1950) have pointed out, the presentation of statistically negative results such as we have shown in the objective tests described does not necessarily prove that the particular treatment is without effect, since the wrong criteria may have been chosen for measurement. However, in this investigation no difference could be detected in the subjective responses to deoxycortone/ascorbic acid as compared with saline: and, in fact, there is a marked similarity between the effects of control and test substances in this connexion.

It has already been shown by Kellgren (1949), Spies *et al.* (1949), and Bywaters *et al.* (1950) on small series of in-patients that deoxycortone/ascorbic acid therapy is without effect in rheumatoid arthritis, but the finding that no less than 58% of the 43 out-patients treated by us showed subjective improvement is of considerable interest. It emphasizes the fact that the strictest control methods are necessary to demonstrate that this is not in fact due to the test substance. It was possible to do this by proper randomization of the control injections, combined with the other precautions described, and it seems probable that these effects are simply due to the psychological effect on the patient of the administration of a new treatment. This may also explain the good results which have been claimed for this treatment.

Conclusions

This investigation indicates that the intramuscular injection of 5 mg. of deoxycortone followed immediately by the intravenous administration of 1 g. of ascorbic acid has no specific therapeutic effect on out-patients suffering from rheumatoid arthritis. This applies to subjective effects as well as the degree of joint tenderness, power of grip, range of shoulder abduction, and speed of walking. It also suggests that the injection of any substance of no therapeutic value whatever may produce a transient subjective improvement in approximately two-thirds of cases of rheumatoid arthritis.

Summary

Forty-three patients with active rheumatoid arthritis have been treated with deoxycortone and ascorbic acid, with saline controls.

Subjective improvement occurred to an equal extent after both test and control injections.

No significant difference could be detected when the results of objective tests with control injections were compared with those in which the test substance was used.

The methods of control and assessment used are described.

Our thanks are due to Dr. W. S. C. Copeman, Professor A. Bradford Hill, and Dr. Oswald Savage for their advice and encouragement, and to the physicians of the Arthur Stanley Institute for allowing us to use their cases. We are also much indebted to Mrs. A. E. White for her help with the injections.

The report of the first session of the Joint I.L.O./W.H.O. Committee on the Hygiene of Seafarers has just been published as No. 20 in the Technical Report Series of the World Health Organization. The committee reviewed some of the main problems affecting the health of seafarers, including such subjects as medical examinations, medicine chests on board ship, accommodation and food supplies on board, hospital treatment on board and in foreign ports, rehabilitation, and social welfare. It was decided that W.H.O. should be asked to investigate the means whereby seamen might be medically examined with a view to preventing the employment of those suffering from active pulmonary tuberculosis. Suggestions were also invited for devising a practical procedure for the medical examination of all new entrants into the service and for ensuring regular periodical examinations thereafter. On the important subject of venereal disease the committee recommended that the attention of Governments be drawn to the importance of maritime nations adhering to the Brussels Agreement of 1924 as an interim measure until a broader instrument, in the form of international health regulations for venereal-disease control, may be established.

FIVE CASES OF PUERPERAL TETANUS (ONE ASSOCIATED WITH ECLAMPSIA)

BY

D. B. JELLIFFE, M.D., M.R.C.P., D.C.H., D.T.M.&H.
A. H. C. WALKER, M.R.C.O.G

AND

STAFFORD MATTHEWS, F.R.C.S.Ed., M.R.C.O.G.

(From the Departments of Medicine and Obstetrics and Gynaecology, University College, Ibadan, Nigeria)

Tetanus is a rare complication of pregnancy, being more often seen during the puerperium. Schneider (1926) collected 109 cases from the literature, and Weinstein and Beacham (1941) reviewed 170 cases of post-abortal tetanus with a mortality of 84%. In tropical countries, especially India, China, and Africa, the condition is undoubtedly more common than these surveys of the literature would indicate.

Tetanus is said to follow abortion more frequently than it does labour at term. Infection often results from criminal interference or operative procedures, as in Case 1. In Cases 2 and 4 there was no such interference so far as could be ascertained, though native medicines are often introduced into the vagina. In Cases 3 and 5 a history of an unsterile procedure at home was elicited.

Clostridium tetani has been isolated from uterine lochia, but was not found in the two cases of the present series investigated bacteriologically. De Lee (1947) records that in Peiping approximately one-third of the population are carriers of the tetanus bacillus, but he does not specify whether this refers to the flora of the vagina or of the intestinal tract.

The incubation period of puerperal tetanus varies from four to twenty-one days (De Lee, 1947). The shorter the incubation period the worse the prognosis. According to Stander (1935) the first symptoms have been known to appear before the completion of labour. In Cases 1 and 4 the incubation period was eight days; in Cases 2 and 5 it was five days; and in Case 3 the first symptom was on the tenth day.

De Lee (1947) states that the incubation period for puerperal tetanus "is shorter than the incubation period in non-pregnant individuals." This is not borne out by the figures for the incubation period for non-puerperal tetanus given by most authors (Whitby, 1938; Brain, 1940; Price, 1946; Cecil, 1947; Harries and Mitman, 1947; Tidy, 1949).

Ibadan is the largest native city in Africa, with a population of over half a million. Living conditions are primitive and a knowledge of hygiene is almost completely lacking. Most of the inhabitants live in crumbling mud-brick houses. Tetanus is common, especially during the dry dusty season, and the portals of entry are often trivial—for example, tropical ulcers, infected "jigger" burrows (*Tunga penetrans*), the umbilical cord in the newborn (Jelliffe, 1950), etc. In India, Rogers (1944) emphasized the importance of dust-contaminated wounds as a cause of tetanus.

A labour managed according to native custom is favourable to the introduction of *Cl. tetani* into the birth canal, as the following brief description illustrates.

At the beginning of labour the patient is removed to the backyard or to a room in a mud house, the floor of which has been prepared by polishing with leaves. When the contractions assume a bearing-down character the patient is placed in a squatting or kneeling position, so that her buttocks are resting on the ground or on her heels and with the vulva touching or close to the ground. She remains in this position throughout the second and third stages of labour. If labour is delayed she may stay in this position for many hours or days, to the extent that lower-limb palsies are not uncommon.

The floor is very apt to be contaminated by goat faeces, which have been shown on many occasions to contain spores of *Cl. tetani*. In addition, Kerrin (1929) found that about 18% of a series of hen faeces examined by him contained *Cl. tetani*. In Ibadan, hens stray inside the houses as commonly as goats.

During the descent of the presenting part, a pad, which is usually a dirty cloth, is placed over the anus in order to protect the perineum, and on occasion native medicines are introduced into the vagina or smeared on the vulva, especially in cases of abnormal labour. After the completion of labour the vulva is cleaned with an unsterile decoction of herbs. This is repeated on the morning and evening of the next day. A torn perineum is similarly treated.

Case 1

An Ibo primipara aged 18 was admitted on March 20, 1950. She was at term and gave a history of having had two fits at about one and a half and two hours before admission. Labour had not begun. She had attended another antenatal clinic, and the pregnancy was reported to have been uneventful until March 16, when marked oedema was found, but she refused admission. Immediately before the first fit she had complained of frontal headache. While being admitted a third eclamptic fit occurred.

On examination the temperature was 99.8° F. (37.7° C.), pulse 88, respirations 22, and blood pressure 130/110 mm. Hg. There was marked oedema of the legs, abdominal wall, and face. Crepitations were heard at both lung bases. Abdominal examination revealed a tense uterus, reaching to the xiphisternum, suggesting hydramnios. Only one foetal heart was heard. Per rectum the cervical canal was felt to be taken up and the position of the head was high mid-cavity. Albumin was not found in a catheter specimen of urine. A modified Stroganoff method of treatment was instituted, using morphine, paraldehyde, and magnesium sulphate, together with a post-partum course of quinine sulphate as an antimalarial.

Eight fits followed in the next 12 hours, five of which were precipitated at short intervals by the onset of uterine contractions, necessitating further sedation and the administration of chloroform. Fifteen hours after admission the urine was found to be solid with albumin. The temperature was 102° F. (38.9° C.), pulse 124, and blood pressure 164/90 mm. Hg. The cervix became fully dilated some 19 hours after admission. After one and a half hours in the second stage, forceps were applied and a fresh stillbirth, weight 5 lb. 2 oz. (2.3 kg.), was delivered. A second foetus was found presenting by the head, but, as it failed to engage on rupturing the membranes, an internal version and breech extraction was performed. This was followed by manual removal of the placenta, which weighed 29 oz. (0.82 kg.) and macroscopically did not seem unduly infarcted. The baby, which weighed 5 lb. 4 oz. (2.4 kg.), has survived.

Next day the patient's temperature was 104.4° F. (40.2° C.), pulse 168, respirations 36, and blood pressure 124/94 mm. Hg. The urine was solid with albumin. Crepitations were not heard at the lung bases. Sedation was continued, together with penicillin, sulphathiazole, and quinine. Her general condition improved rapidly, but she had two further fits at an interval of five minutes, occurring 48 hours after the last fit and 40 hours after delivery. Thereafter the temperature and the pulse settled, the urine contained a trace of albumin, and the blood pressure fell to 108/60 mm. Hg.

The patient seemed to have made an uneventful recovery, when, on the eighth day after delivery at 2.30 a.m., she developed a severe pain in the back of the head and neck.

There were no definite signs. Morphine, ¼ gr. (16 mg.), was given. At 9 a.m. opisthotonos and considerable neck rigidity had developed. The muscles of the abdominal wall were board-like. Kernig's sign was markedly positive. Moderate trismus was present. She was fully conscious. Her temperature was 98.6° F. (37° C.) and the pulse 90. A lumbar puncture showed crystal-clear fluid under no increase of pressure.

Treatment was begun with antitetanus serum, 100,000 units intravenously, together with 100,000 units intramuscularly, sodium amytal, 0.5 g. intramuscularly at 9.30 a.m. and at 1 p.m., and procaine penicillin 1 ml. intramuscularly. At 1.30 p.m. she was much worse. Nuchal rigidity, opisthotonos, and trismus were marked. The body was held in hyperextension. There were no true generalized spasms, but repeated localized spasms of the jaw muscles made swallowing difficult and caused her to bite her tongue repeatedly. Morphine, ¼ gr., was given.

At 4.30 p.m. the patient was drowsy. Spasms were less frequent, her temperature was 99° F. (37.2° C.), and pulse 105. Sodium amytal, 0.5 g., was given intramuscularly. Following this, she slept through the night, and began having localized tetanic spasms only early the next morning.

At 8.30 a.m. on March 29 sodium amytal, 0.5 g., was given intramuscularly, as the patient had become restless and was having frequent generalized spasms. Trismus was very marked, and nasal feeding was started with a Ryle's tube. A vaginal examination showed the fundus uteri to be at the level of the umbilicus. The lochia were noted to be offensive and a high vaginal swab was taken, but *Cl. tetani* was not identified.

At 1 p.m. she had become comatose, although still in hyperextension. Sodium amytal, 0.25 g., was given at 9.30 a.m. and at 12 noon. The temperature had now risen to 104° F. (40° C.) with a pulse of 168. No new physical signs could be found. The lungs were clear. Procaine penicillin, 1 ml. intramuscularly, and quinine dihydrochloride, 10 gr. (0.65 g.) intramuscularly, were given. The temperature continued to rise during the night (107° F. (41.7° C.) at 2 a.m.) despite repeated tepid sponging. The patient did not recover consciousness, and died at 6 a.m. on March 30.

Impression.—A fulminating case of puerperal tetanus, with terminal hyperpyrexia, following eclampsia.

Case 2

A Yoruba woman of about 40 was admitted on January 12, 1950, at 1 a.m. She was a 4-para and gave a history of having aborted spontaneously 10 days before admission, after two months' amenorrhoea. On the fifth day after aborting she developed a stiff neck. Examination showed considerable neck rigidity, together with moderate trismus and rigidity of the muscles of the anterior abdominal wall. Kernig's sign was negative. There were no other abnormal physical signs. Her temperature was 99° F. (37.2° C.) and her pulse 120.

On admission she was given 200,000 units of antitetanus serum intravenously and morphine ¼ gr. This was followed by sodium amytal, 0.5 g. intramuscularly at 9 a.m. and 3 p.m., and phenobarbitone, 2 gr. (0.13 g.) three times a day. On January 13 the patient's condition was rather worse. Generalized spasms occurred if she was disturbed. Neck rigidity was more marked. At 2 p.m. her condition had deteriorated considerably. Generalized spasms were occurring every few minutes. Trismus was pronounced and the recti were board-like. A further injection of sodium amytal, 0.5 g., was given at 3 p.m. At 7.15 p.m. she became restless. The spasms recurred every two minutes or so, and she died at 7.50 p.m.

Impression.—A fulminating case of puerperal tetanus with a short incubation period.

Case 3

A Yoruba woman of about 30 was admitted on March 8, 1950, at 10.30 p.m. She was a primipara and gave a history of having had a normal full-time delivery at home 14 days previously. The delivery was conducted according to native custom with the patient kneeling throughout the later stages of labour. She stated that after expulsion of the placenta something protruded from the vagina (? cervix). Her attendants gave her a sitz bath containing native medicines, replaced the prolapsed tissue with a rag, and applied a dirty pad. Ten days after delivery the patient complained of difficulty in opening her mouth and of stiffness of the neck. Examination showed considerable nuchal rigidity, the neck being held in hyperextension, together with a moderate degree of trismus. The muscles of the abdominal wall were slightly rigid. Kernig's sign was negative. No generalized spasms were observed.

A purulent discharge was the only abnormality revealed by vaginal examination, the involution of the uterus being normal. Bacteriological examination did not show *Cl. tetani*. Her temperature was 99° F. (37.2° C.) and pulse 110. Her tongue was heavily furred and superficial ulceration was present around the edge. She was moderately well nourished, not anaemic, and showed no abnormality in either the respiratory or the cardiovascular system.

Treatment was begun with antitetanus serum, 200,000 units intravenously, sodium amytal, 0.5 g. intramuscularly at 11 a.m. and 5 p.m., and phenobarbitone, 3 gr. (0.2 g.) orally three times a day.

On March 9 the patient was having generalized spasms whenever she was disturbed, but was otherwise sleeping most of the time. Trismus was more marked, so that feeding was difficult. The temperature varied from 99.8° to 100.2° F. (37.7° to 37.9° C.). Sodium amytal, 0.5 g., was given intramuscularly at 5 a.m. and a course of crystalline penicillin was started (100,000 units intramuscularly twice daily). On March 10 generalized spasms were occurring more often, at about half-hourly intervals. On March 12 the fits were rather less frequent. The bowels had not been open since admission, so an enema was given. Fluids were taken fairly well. She was having phenobarbitone, 3 gr. by mouth three times a day.

On March 14 there was considerable improvement, although an occasional spasm of the face and neck occurred. The generalized spasms had stopped. She was able to swallow quite well. The vaginal discharge had also stopped. On March 17 there was considerable residual stiffness, the neck being still held in hyperextension, with rigid abdominal muscles. Absolute constipation persisted, enemas being required every third day. The mouth was clean and she was able to drink easily. Phenobarbitone was reduced to 2 gr. three times a day. On March 21 there had been no recurrence of the tetanic spasms, and the patient slept most of the time. Phenobarbitone was reduced to 1 gr. thrice daily, and on March 24 it was discontinued.

On March 30 there was no hyperextension of the neck, but residual nuchal stiffness was still present. She was able to walk if supported, but was very stiff-legged. Her back was still held in hyperextension and the abdominal muscles were very rigid. She could open her mouth three-quarters of the way and her bowels opened unaided. She insisted on taking her own discharge.

Impression.—A case of puerperal tetanus of moderate severity, responding rapidly to treatment.

Case 4

An Ibo woman aged about 27 was admitted on June 6, 1950, 10 days after the birth of her first child—a normal male infant. She had conducted her own confinement in her house. Labour had been uncomplicated and had lasted only five hours. No native medicines had been administered. Clean rags had been used as a vaginal pad. The patient gave a two-day history of difficulty in opening the mouth and of stiffness of the neck. No vaginal discharge had been noticed.

On examination definite trismus, neck retraction, and cervical stiffness were found. There was no abdominal rigidity or stiffness of the back. Her temperature was 99.5° F. (37.5° C.) and her pulse 100. Vaginal examination revealed no abnormality, the uterus being at the normal stage of involution. Treatment was begun with antitetanus serum, 200,000 units intravenously, sodium amytal, 0.5 g. intramuscularly, phenobarbitone, 2 gr. (0.13 g.) orally three times a day, and a course of crystalline penicillin (100,000 units intramuscularly twice daily).

On June 7 the trismus and neck rigidity had become much more pronounced, though she was still able to swallow. Stiffness of the muscles of the back and the abdomen had developed. There were no generalized tetanic spasms. Treatment was continued with phenobarbitone, 2 gr. four-hourly, and crystalline penicillin, 100,000 units intramuscularly twice daily. During the following week no real change occurred in the patient's condition. She was able to swallow and continued to feed the baby. On June 16 she had improved considerably, the stiffness of the cervical, abdominal, and back muscles having become much less. Phenobarbitone was reduced to 2 gr. three times a day and the penicillin was discontinued.

On June 18 she was able to walk about unaided, though she still had a minimal degree of trismus, neck rigidity, and stiffness of the musculature of the back. She was discharged at her own request.

Impression.—A mild case of puerperal tetanus responding rapidly to treatment.

Case 5

A Yoruba woman aged about 25 was admitted to hospital on June 17, 1950. She was a primipara, having given birth to a normal male child 10 days before admission. The early stages of labour had been easy, lasting only a few hours. Expulsion of the placenta, however, had been incomplete. The patient had then been made to blow into a calabash horn in an attempt to force out the retained portion of placenta. This had been unsuccessful. Attendant relatives had then tried to assist by swabbing out the vagina with plugs of fresh kapok. The woman was not certain whether the remainder of the placenta had been eventually removed or not. No native medicines had been administered during labour. Dirty rags had been used as a vaginal pad.

The patient had been quite well, save for a profuse white vaginal discharge, until five days after delivery, when she developed slight stiffness of the neck and trismus. This had become progressively worse, and on admission the trismus and cervical stiffness had become very severe. Swallowing had become difficult, and in addition she complained of lower abdominal pain and backache.

Examination showed an ill, poorly nourished young woman. Her skin was covered with the pigmented macules of old smallpox. There was marked trismus, neck retraction, and rigidity of the abdominal and back muscles. Her temperature was 101° F. (38.3° C.) and the pulse 104. The gynaecological report (Dr. J. G. Dumoulin) was: "Per abdomen, the fundus is up to the umbilicus and slightly tender; there is no tenderness in the iliac fossae. Per vaginam, a slight greenish-yellow discharge is present. The uterus is bulky and tender. There is nothing abnormal in the fornices. No active gynaecological treatment is required."

Treatment was started with antitetanus serum, 200.000 units intramuscularly, sodium amytal, 0.5 g. intramuscularly at 10 a.m. and 6 p.m., phenobarbitone 2 gr. orally four-hourly day and night, and procaine penicillin 1 ml. intramuscularly daily.

On June 18 the patient had developed full tetanic spasms. These occurred every two minutes. The temperature was 102.5° F. (39.15° C.) and the pulse 120. She was still able to swallow with difficulty. Sodium amytal, 0.5 g., was given at 10 a.m., 2 p.m., and 10 p.m. On June 19 the tetanic spasms had become almost continuous. Sodium amytal, 0.5 g., was given intramuscularly at 6 a.m. At 10 a.m. the temperature rose to 104° F. (40° C.) and the patient became stuporous. She died at 11 a.m.

Impression.—A severe and rapidly fatal case of puerperal tetanus, with terminal hyperpyrexia.

Discussion

It is not the purpose of this paper to discuss the treatment of tetanus, other than to advocate the prophylactic administration of antitetanus serum in the Tropics before undertaking any gynaecological operation, major or minor, and to all obstetrical cases that require intervention. In patients admitted with a retained placenta it is also advisable to give antitetanus serum to the baby in view of the local method of treating the cord before admission.

Tetanus associated with eclampsia seems to have been unrecorded. In Case 1 there was an interval of five and a half days between the last eclamptic fit and the onset of tetanus, from which the patient died two days later. The difference between the two types of fits was striking and clear-cut. Despite the onset of tetanus, the signs of toxaemia of pregnancy did not recur. In addition, the naked-eye and microscopical appearances at necropsy did not reveal any abnormality that could be attributed to eclampsia, from which, therefore, the patient seems to have recovered completely.

The terms "tetanus uteri," "tetanic contraction of the uterus," and "tetany of the uterus," as used by most American authors, are confusing and illustrate the need for greater uniformity and precision in obstetric nomenclature.

It is probable that the incidence of tetanus in Ibadan is much higher than case records indicate, as local women prefer domiciliary confinements and do not readily seek hospital advice for puerperal complications.

Summary

Five cases of puerperal tetanus are recorded, one of which followed eclampsia. The prevalence of tetanus is discussed in especial relation to local primitive conditions. The importance of prophylactic antitetanus serum in obstetrical and gynaecological practice in tropical countries is stressed.

In co-operation with national government, and with Unicef, W.H.O. has launched practical malaria-control projects in four rural areas in India, as well as one in Thailand and two in Afghanistan, since the opening of its regional office in New Delhi in January, 1949. A W.H.O. venereal-disease-control project is operating successfully in North India. Maternal and child-health projects have begun in India and, in co-operation with Unicef, in Afghanistan. W.H.O. is participating with Unicef in yaws-control projects in Indonesia and Thailand. W.H.O. fellowships have enabled 61 doctors and health workers from countries of South-east Asia to obtain advanced training abroad, and a sum of $40,600 has been allotted by W.H.O. to countries in the region for the purchase of urgently needed medical literature and teaching equipment. Assistance has been given to Ceylon in its anti-filariasis campaign, and to Afghanistan in fighting louse-borne typhus. W.H.O. experts in the treatment and rehabilitation of poliomyelitis victims have given training courses in India to local health workers. This W.H.O. regional office for South-east Asia is one of the three regional offices already established by the organization, the other two serving the eastern Mediterranean region and the Americas (Pan-American Sanitary Bureau). In addition, temporary offices for Europe and the Western Pacific are functioning in Geneva and Hong Kong, respectively.

SEVEN CASES OF BARIUM CARBONATE POISONING

BY

GEOFFREY DEAN, M.B., M.R.C.P.

Port Elizabeth, South Africa

Seven patients were given barium carbonate for barium-meal investigations in December, 1948. Pure barium carbonate is a white powder exactly similar in appearance to barium sulphate and is commonly used as a rat poison. It had been placed by mistake in the barium sulphate container at the wholesale premises, and was therefore dispensed instead of barium sulphate in the preparation of the barium cream supplied to the radiologist. The quantity administered in all cases except the fatal one was a glassful, which was later shown to be equivalent to 4.26 oz. (133 g.) of dry barium carbonate. In the fatal case half this quantity was administered.

Case Reports

Case 1.—A healthy man aged 48 swallowed a chicken bone which lodged in his oesophagus. Forty hours later he was sent for *x*-ray examination. He swallowed half a glass of barium cream. The *x*-ray film confirmed the presence of the bone and he was admitted to hospital for its removal. An hour and a half after the barium swallow he was examined by the anaesthetist, who found him fit except for a raised blood pressure, 180/130, which was attributed to nervousness. While his throat was being sprayed with cocaine and adrenaline he vomited. He was given "omnopon," ½ gr. (22 mg.), and hyoscine, 1/100 gr. (0.65 g.). Half an hour later 0.7 g. of thiopentone and 8 mg. of "tubarine" were given. The bone was not impacted and was removed uneventfully. The patient recovered from the anaesthetic, and then started to vomit and purge; this was accompanied by severe griping abdominal pain, tenesmus, and the desire to micturate. He was very thirsty and soon began to complain of heaviness in his limbs and coldness. The vomiting ceased but the diarrhoea continued, he sweated profusely, and his pulse became thready and irregular; his temperature was normal and his mind clear. He was treated with warmth, hot drinks, intravenous glucose saline, nikethamide, adrenaline, and brandy. His pulse became imperceptible, and 11 hours after the operation and 13 hours after the barium he died. At necropsy acid-soluble barium compound was found in the stomach, liver, and kidneys. The equivalent of 2.75 gr. (0.18 g.) of barium carbonate was recovered from the stomach.

Case 2.—This patient was given a full glass of barium cream (equivalent to 4 oz. of barium carbonate). An hour later he started to vomit and had diarrhoea with abdominal colic; his vision was blurred. He was taken to his family doctor, who found him shocked, cyanosed, and sweating, and able to move his limbs only with great difficulty. He complained of heaviness in the arms and legs, he could talk only in a whisper, his pulse was slow and irregular; his mind was clear. I was called in consultation and advised warmth, hot drinks, nikethamide, and a sedative. Eight hours after the barium he was still able to move his limbs only with great difficulty; he had no convulsions. His pulse was 90 and still irregular. An electrocardiogram showed extrasystoles. His blood pressure was 160/100. The reflexes were all present but diminished; the Babinski responses were flexor. Twelve hours later he was improving, but remained in bed in the doctor's house extremely ill for over a week.

Case 3.—A married woman aged about 30 was given a full glass of the cream. Within two hours her face felt stiff and her vision was blurred. A little later vomiting started, followed by diarrhoea and tenesmus. When examined three hours after the meal she was weak, cyanosed, and sweating; her mind was clear, and her pulse was grossly irregular. Her blood pressure was 180/110. An electrocardiogram showed extrasystoles. The muscles of the arms and legs were painful and extremely weak, and she could move only with the greatest difficulty. All the reflexes were present but greatly reduced; there were no convulsive movements. She was immediately admitted to hospital, treated for shock, and given magnesium sulphate—a known antidote for barium carbonate, reacting with it to form insoluble barium sulphate. The weakness of her limbs and irregularity of the heart persisted for nearly a week, but she eventually recovered and was discharged after 16 days in hospital.

Case 4.—A pensioner with hypertensive failure was given a full glass of the cream for a barium meal. Vomiting and diarrhoea started after he returned home. However, he was not so ill as the other patients, perhaps because he had an achlorhydria, or at least a hypochlorhydria, which prevented or diminished the formation of barium chloride in his stomach. Also he took castor oil and, later, Epsom salts. He was admitted to hospital, where I saw him. Two days later he said he felt fitter than for many months. The dyspnoea which had greatly troubled him was much improved; this was considered to be due to the digitalis-like action of soluble barium salts on the heart muscle. Ten days later, however, he had a small cerebral thrombosis, followed after four days by a second which resulted in a left hemiplegia. He gradually recovered, but two months later a fall from his chair resulted in a large extradural haemorrhage and he died within a few days. In this case an elderly man with a weakened myocardium recovered from 4 oz. of barium carbonate; his death may have been indirectly due to the poisoning.

Case 5.—A married woman drank a full glass of the cream for a barium meal. About an hour later she felt as if her face was distorted and her lips were swollen; she complained of double vision. Vomiting, diarrhoea, and tenesmus soon followed. When seen by her family doctor she was cold and collapsed, in a state of shock, with a highly irregular pulse. Several hours later magnesium sulphate was given and she gradually recovered over the course of a few days.

Case 6.—A man was given a full glass of the barium cream and was told to take two teaspoonfuls of Epsom salts in an hour's time to keep the contents of the intestines liquid and so help to outline the appendix. He returned nearly five hours later, having vomited once but otherwise feeling well. In this case the taking of magnesium sulphate had apparently prevented harmful absorption.

Case 7.—This patient left by ship on the same day that he swallowed a glassful of the barium carbonate cream for *x*-ray purposes. He also vomited and had diarrhoea, and was given magnesium sulphate, but no further details are available.

Comment

The quantity of barium carbonate given in a glass of barium cream was estimated by the government analytical chemist at Port Elizabeth. He found that a full tumbler of the cream used contained 4.26 oz. (133 g.) of dry barium carbonate. All six patients who took this amount recovered. In the fatal case it was estimated that the patient, who was given half a glassful of barium cream, took three mouthfuls; this amount was estimated to contain approximately 1.7 oz. (53 g.).

In the stomach barium carbonate is converted by the free hydrochloric acid, if present, into barium chloride; it is absorbed from the small intestine and not from the stomach; there is, therefore, a time lag before symptoms become apparent.

Sydney Smith and Cook (1948) quote two fatal cases of barium carbonate poisoning after the ingestion of 1 dr. (4 g.). Fatal cases have also been recorded after 60 gr. (4 g.) of barium chloride (Blythe and Blythe, 1920; Sydney Smith, 1943) and after 12 gr. (0.8 g.) (Goodman and Gilman, 1941).

The pharmacology of barium has been described by Cushny (1936), who states that its chief action is to strengthen the contraction of all forms of muscle, probably by direct action on the contractile tissue. In this outbreak the effect on muscle greatly predominated over any other action: striated muscle, non-striated muscle, and the cardiovascular musculature were all affected.

In the above cases the first symptom to appear was often a peculiar stiffness about the mouth, accompanied by blurring of vision. This was rapidly followed by salivation, nausea, vomiting, diarrhoea, severe colic, tenesmus, and an intense desire to pass water. Within an hour skeletal-muscle weakness became pronounced and movement was difficult; the legs were weaker than the arms. The typical patient appeared clammy and pale, realized he was desperately ill, and talked only in a whisper; the pulse was extremely irregular, probably owing to very frequent extrasystoles; the blood pressure was raised. Even when *in extremis* the pulse did not become fast, but remained irregular and gradually became weaker. In no case was there convincing evidence of any direct poisonous action on the central nervous system; the mind always remained clear, there were no convulsions or tetanic contractions, the reflexes were diminished but not absent, the plantar responses were flexor, and there was no true paralysis.

Summary and Conclusion

Seven cases of poisoning by pure barium carbonate are described, only one of which was fatal. In this case the barium was followed by heavy sedation and an anaesthetic, which delayed vomiting and purging. The dose administered in all cases was many times that usually considered lethal. The large amount of barium carbonate administered caused rapid onset of vomiting and diarrhoea, which may account for recovery where a smaller dose might have been fatal. Magnesium sulphate, which was given in some cases, proved an excellent antidote. The symptoms were remarkably constant and all of them could be attributed to direct action on muscle. There was no evidence of any effect on the central nervous system: in this respect our views on alimentary barium poisoning should be reviewed; it may be that some of the symptoms described by other authors were due to impurities in the barium.

Finally, I would make the suggestion that barium carbonate, which in its pure form is a white powder, should be coloured by a distinctive dye so that the above mistake does not occur again.

I would like to thank all the doctors concerned with these cases for their help and co-operation in the preparation of this article.

Medical Memoranda

Latent Amoebic Dysentery

The following case is of interest on account of the exceptionally long interval between infection and the development of symptoms, and because the diagnosis of amoebic dysentery was at first missed in spite of considerable investigation. It raises, too, the problem of whether the infection was contracted abroad or was of indigenous origin.

Case Report

The patient, an intelligent man aged 60, had spent much of his early life abroad with the Army. He had had little illness apart from malaria, and, although he had never had injection treatment for dysentery, he had been admitted to Army hospitals three times for diarrhoea whilst on active service in Mesopotamia between 1916 and 1918. He returned finally to England in 1919 and five years later left the Army to become a postman. He remained in good health until January, 1944, when he developed intermittent diarrhoea following the death of his youngest daughter from encephalitis. He lost weight, the diarrhoea continued, and his general condition deteriorated. Six months later he was admitted to a general hospital, where a diagnosis of ulcerative colitis was made. The condition improved following sulphaguanidine treatment, but after his discharge from hospital relapses became more frequent, especially during the winter, and he was compelled to retire from public service in June, 1945.

In the autumn of 1947 he contracted whooping-cough and it was for that reason that I first saw him. He looked extremely ill, very pale, and emaciated, and he had a severe glossitis. Diarrhoea was troublesome, with six to ten motions daily, the stools containing both blood and mucus. He weighed only 8 st. (50.1 kg.).

A blood count showed: haemoglobin, 45%; red cells 4,000,000 per c.mm. I assumed the previous diagnosis of ulcerative colitis to be correct, and therefore gave him a course of sulphaguanidine, followed by oral iron and injections of crude liver and riboflavin.

Two months later the whooping-cough had completely subsided, but the diarrhoea persisted. The possibility of this being a case of amoebic dysentery had by now occurred to me, and he was eventually admitted to hospital on February 2, 1948, for further investigation. Next day a sigmoidoscopy (8 in.—20 cm.) revealed several crateriform ulcers with haemorrhage suggestive of chronic amoebic dysentery. The stools were examined microscopically, and amoebae containing ingested erythrocytes and exhibiting pseudopodial motility characteristic of *Entamoeba histolytica* were observed in two separate specimens. A radiograph of the chest and screening showed the right diaphragm to be raised and the right costophrenic angle to be partly obscured. The white blood cells numbered 8,300, with 86% polymorphs and 1% eosinophils.

A comprehensive course of treatment was instituted combining succinylsulphathiazole, emetine hydrochloride, chiniofon retention enemata, emetine and bismuth iodide capsules, and acetarsol tablets. Vitamin B complex and "fersolate" tablets were given orally, together with a low-residue diet. The response to treatment was most satisfactory. Bowel action became normal after the fifth day of treatment and by the end of one month the patient had gained 28 lb. (12.7 kg.) in weight. By then sigmoidoscopy showed an almost normal mucosa and the stools were negative for *E. histolytica* cysts. A blood count showed: haemoglobin, 75%; red cells, 5,300,000 per c.mm.

Convalescence was progressive and uneventful, and six months later he had regained all but 3 lb. (1.4 kg.) of his normal 12 st. (76.2 kg.) weight, and was able to undertake light work. A year after treatment sigmoidoscopy revealed no ulcers and no *E. histolytica* cysts.

Comment

It seems very improbable that this was a case of indigenous amoebic dysentery, and much more likely that it was a relapse from a previously unrecognized infection contracted abroad. That *E. histolytica* may remain dormant for many years before giving rise to symptoms is well known. Many cases of amoebic abscess of the liver are found up to 30 years after the primary infection. It is much less common for amoebic dysentery to recur after such a long interval of freedom. In this case it is estimated to be 28 years, which so far as I can discover is the longest interval on record. Dobell and Stevenson (1918) described a case diagnosed 34 years after the original infection, but the patient had had subacute dysentery for ten years before their investigation and consequent discovery of *E. histolytica* in the stools.

It may be salutary to recall that Manson-Bahr (1943) states that ulcerative or mucous colitis not infrequently follows amoebic dysentery. Perhaps there are other cases of supposed ulcerative colitis like this one, in which an unrecognized infection of *E. histolytica* is the underlying cause of symptoms.

I am indebted to Dr. Carey Lynch, pathologist, Torbay Hospital, for confirming the presence of *E. histolytica* in the stools.

Angus Everard, M.B., Ch.B.,
Medical Officer, Newton Abbot Hospital.

Two Cases of Paratyphoid Fever Treated with Chloramphenicol

Comparatively few cases of paratyphoid fever treated with chloramphenicol have so far been reported, and there seems to be an impression that paratyphoid infection may be more resistant to chloramphenicol than is typhoid infection (*British Medical Journal*, 1949, **2**, 919).

It is, fortunately, not easy, at any rate in this country and at the present time, to find opportunity of trying out the drug on a large series of paratyphoid infections. If a comparatively large outbreak did occur it might be difficult or even unjustifiable on humanitarian grounds to take strictly alternate cases as controls if, as seems likely, chloramphenicol is potently curative. In these circumstances it may be of interest to report the following two cases of paratyphoid fever (both of type B and Vi phage type 1) recently treated with chloramphenicol.

Case 1

A girl aged 4½ was admitted for investigation on September 1, 1949, in about her tenth day of disease, as a case of continued pyrexia. There had also been malaise, anorexia, headache, stiffness of the neck, and a tendency to several loose motions a day in the three days or so before admission. Examination did not reveal any conclusive physical signs, but toxaemia was fairly marked, the child being pale, limp, and supine, with a temperature of 103° F. (39.4° C.).

Culture of a rectal swab on the day after admission, and a faecal specimen on September 4, gave a growth of *Salmonella paratyphi B*. Blood culture was negative. The Widal reaction was: *Salm. paratyphi B* H, 1 in 500; O, 1 in 250; other groups, negative. There was no history of T.A.B. inoculations. Chloramphenicol was administered from September 4 to 12, a total of 6.25 g. being given, beginning with one capsule (0.25 g.) and following with half a capsule (0.125 g.) every four hours until the course was terminated. The patient's general condition showed clear improvement within 36 hours, but her temperature, though showing marked decline within this period (indeed the first normal reading occurred as early as 40 hours after the drug was first given), did not reach persistently normal levels until the fifth day of the drug. No further positive cultures from repeated faecal specimens were obtained, and she was discharged home on October 8 apparently in very good health.

Case 2

A youth aged 19 was admitted on September 22, 1949, in about the twelfth day of disease. His illness began rather suddenly with diarrhoea, which largely cleared up after about five days; there was no diarrhoea after admission. In the meantime, toxaemia had become increasingly evident, and, when admitted, his tongue was dry and brown, there was a profuse crop of rose spots, and his temperature on the evening of the day of admission was 104° F. (40° C.) and pulse 68.

Blood cultures and faeces gave a growth of *Salm. paratyphi B*. The Widal reaction was: *Salm. typhi* H, 1 in 5,000; *Salm. paratyphi B* H, 1 in 5,000; *Salm. typhi* O, negative; *Salm. paratyphi B* O, negative. There was no history of T.A.B. inoculations. Chloramphenicol was started on September 24 with six capsules (1.5 g.), followed in two hours by six more capsules, then one capsule (0.25 g.) every two hours until September 27, then four-hourly until October 1, and six-hourly until October 3—a total of 21 g. The temperature showed a downward trend inside 24 hours of the drug being commenced, and the first normal four-hourly reading occurred in about 48 hours from the start. It became persistently normal on the sixth day of administration, in spite of a temporary return to somewhat higher levels on the fourth and fifth days. This rise followed and may have been related to a decision not to wait for the temperature to become completely normal before making a reduction in the dosage from 0.25 g. two-hourly to 0.25 g. four-hourly at the beginning of the fourth day of treatment. A bolder dosage policy might, therefore, have resulted in an earlier return to normal temperature. Faecal cultures from the patient were still positive on October 26.

Comment

Toxic reactions that could be attributed to the drug were not observed in either case, and the drug was well tolerated and easily given. There was a strong clinical impression that improvement in the general condition proceeded at a faster pace than resolution of the pyrexia. It is possible that either of these two cases would have improved during the same period without the drug being given. Nevertheless, it is a fact that they both improved in a similar fashion whilst having the drug, and that clinical amelioration was evident within 24 to 48 hours of the drug being started. In the second case, particularly, toxaemia was sufficiently pronounced to have given rise to the fear of a prolonged and stormy course.

Acknowledgment is due to Dr. R. E. Jones, of the Coventry Laboratory of the Public Health Laboratory Service, for bacteriological data.

Joyce W. Brown, M.B., D.P.H.

A scholarship of £100 to £150 will be awarded by the National Association for the Prevention of Tuberculosis to a registered female nurse working at the time of her application in a hospital in Scotland. The scholarship will enable her to spend a period of from three to six months in postgraduate study in hospitals or clinics in (*a*) Scotland, (*b*) England, or (*c*) Scandinavia. Particulars may be obtained from Miss A. J. Weir, Scottish Secretary, N.A.P.T., 65, Castle Street, Edinburgh, 2, by December 1.

Reviews

CHEMOTHERAPY

Recent Advances in Chemotherapy. By G. M. Findlay, C.B.E., Sc.D., M.D., F.R.C.P. Third edition. Volume 1. (Pp. 625. £1 16s.) London: J. and A. Churchill. 1950.

The responsibilities of an author in the "Recent Advances" series vary greatly with his subject. Anatomy, for instance, is comparatively static, and progress in a number of other branches of medicine is not so rapid that a new edition requires more than one or two new chapters and scattered additions and subtractions elsewhere. But the task facing the author of the volume on chemotherapy, of which the last edition appeared in 1939, was truly formidable, and he has met it with such determination that he is expanding one volume into four. Of those which have yet to appear, one will be exclusively on malaria, the third on bacterial, rickettsial, and virus infections, and the fourth on sulphonamides and antibiotics and general principles. In this arrangement it seems that the last volume must involve some repetition of the third, but when it has been carried through the series will be, so far as can at present be foreseen, the only up-to-date account of a form of progress which has already changed the face of medicine and bids fair to transform it into almost a new subject. It may well be that psychiatry and geriatrics will take the leading places in the medicine of the future, the treatment or prevention of microbic infection having become so simple as to take a quite secondary place.

The main subject of this the first volume is protozoal infections other than malaria, and the account of trypanosomiasis naturally occupies most space, next to it in importance coming leishmaniasis and amoebic dysentery. Among minor infections of this kind, trichomoniasis and giardiasis are alone in having almost everyday interest in this country; otherwise the appeal of the greater part of this volume is mainly to the worker abroad. These chapters are prefaced by one on diseases due to "insects," which is mainly about scabies, and another on helminthic infestations, where the author discusses chiefly schistosomiasis and the new work on filariasis resulting from American occupation of the Pacific. He includes an account of the uses of phenothiazine and newer methods of eliminating cestodes and nematodes generally. The volume as a whole is a reminder that, while progress has been much more spectacular against bacteria and protista, medicine has been far from slow in combating animal parasites of all kinds. When they are described and appraised together, the number of effective new drugs available for these purposes is surprising.

The reader will form a deep respect for the author's knowledge of chemistry and pharmacology, and for the industry with which he has collected so great a mass of information about the treatment of such a variety of diseases. He will particularly appreciate the somewhat cynical humour often displayed, and frequent references to the early history of the subject, even extending to the pre-Christian era and attributing the invention of chemotherapeutic aerosols to Tobias. We are reminded in connexion with fleas that they apparently had an aversion to Pepys, and referred to a recent paper in which it is recorded that a certain man's sweat was lethal to ticks: "When they fed on him they fell off dead." It is disappointing that the only illustrations are chemical formulae, and sometimes an assessment of the relative value of the several new drugs described for a single purpose seems lacking. The chapter on amoebiasis was evidently written too early to accord "aureomycin" its rightful place in this connexion, but such omissions are inevitable in any work on so rapidly expanding a subject. The whole book is very fully documented, titles of papers as well as references being given. This volume is in itself a great achievement: its companions will be awaited with keen interest, and even with some anxiety lest this herculean task should prove to be beyond the capacity of a single author.

L. P. Garrod.

IDENTIFICATION OF TUMOUR CELLS

The Cytologic Diagnosis of Cancer. By the staff of the Vincent Memorial Laboratory of the Vincent Memorial Hospital, Boston. (Pp. 229; illustrated. £1 13s.) Philadelphia and London: W. B. Saunders Company. 1950.

All experienced histopathologists practise "cytologic diagnosis" in that they search for, and sometimes find, undoubted tumour cells in various body fluids and secretions. Of recent years there has sprung up a group of enthusiasts in this field who claim to have attained a proficiency much superior to that of other histologists and to be able to identify isolated tumour cells with great accuracy. This book is by such a group. It is essentially an atlas of photomicrographs designed to show the diagnostic features of malignant cells in smears from secretions and effusions. The illustrations are beautifully produced; and, if pictorial evidence capable of settling the doubts of more cautious pathologists were forthcoming, we might expect to find it here. But it is not so; the following grounds for doubt remain.

While some of the figures show indubitable tumour cells which we can all recognize, there are many others—for example, 36, 38, 41, 44, 46, 47, to mention only a few—in which the nature of the supposed tumour cells is at least arguable, and we may wonder if the authors may not be misled by their own enthusiasm. There will be many pathologists who will not agree that irregularity of chromatin, "glazing" of nuclei, wrinkled nuclear borders, and cytoplasmic or nuclear vacuolation are as diagnostic of malignancy as the authors suppose.

The authors give no details about the patients from whom the smears came, so that we cannot judge of the validity of the diagnoses attached to the doubtful pictures. There have been cases recorded in detail by advocates of the method—for example, that of Gates and her colleagues (*Cancer*, 1949, **2**, 838)—in which "malignant" cells were repeatedly identified by "experts" but no tumour could be found subsequently in the surgically removed uterus.

The book gives no statistical evidence of the accuracy of the authors' methods and criteria, because, they say, this is "available in the numerous papers in the literature." The reviewer questions this, on the ground set out in the preceding paragraph, and on the same grounds as did Ferguson (*Cancer*, 1949, **2**, 845), who pointed out that the proportion of false positive misdiagnoses is, on the figures of the enthusiasts themselves, far from negligible, ranging between 5% and 30% of their positive smear diagnoses.

The authors give no evidence that they are well acquainted with tissue pathology; indeed, there is evidence to the contrary. Thus, they say nothing of those cases—far from rare, especially in the cervix uteri—in which competent pathologists have real difficulty in deciding from serial sections of a small lesion whether it is an early cancer or merely a hyperplasia or metaplasia. They say nothing of the fact that not a few malignant tumours consist of well-differentiated cells which, in isolation, do not differ structurally from normal or hyperplastic cells. They say nothing of the great cellular atypism that can occur in non-neoplastic lesions; and one wonders if they are aware that many a regenerative hyperplasia shows much more "malignant" cells (judged by the criteria accepted in this book) than many a carcinoma. Very probably there is room for improvement in the work of some pathologists in their identification of tumour cells in fluids, but this will be achieved only by those with a sound knowledge of histopathology, both of cancer and non-cancer tissues. Purely "cytologic diagnosis" will always suffer from a high proportion of either doubt or error.

Rupert A. Willis.

TELLING THE DIABETIC

Helpful Hints to the Diabetic. By W. S. Collens, B.S., M.D., and L. C. Boas, A.B., M.D. (Pp. 135; 64 figs. 21s. 6d.) Oxford: Blackwell Scientific Publications. 1949.

This is one of those books which invite the patient to co-operate in the treatment of his disease. The nature, symptoms, and principles of treatment are discussed in terms presumably intended to enlighten the sufferer, although it is questionable whether such phrases as "Diabetes is a disease in which the normal process of the utilization of glucose by the cell is impaired because of a disturbance in the function of insulin" would mean much to the ordinary diabetic out-patient. The authors' prose style is based on the principle of avoiding a word of two syllables when one of three is available; thus glucose is never used, but always "utilized"; food is not eaten, but "ingested"; the diabetic does not crave for sugar, but has "an abnormal desire for unusual quantities of sweet and starchy foods."

Food tables are designed for the American larder and are of little help to the diabetic in this country. More than ten pages are devoted to an exposure of the "cures" for diabetes which adorn the advertisement columns of American newspapers, a topic of little interest to the English diabetic. Although the chapters on administration of insulin and urine testing are clear, readable, and excellently illustrated, this book cannot be recommended to diabetic patients in Britain, who are already well served by native authors.

R. Bodley Scott.

INDUSTRIAL TOXICOLOGY

The Chemistry of Industrial Toxicology. By Hervey B. Elkins. (Pp. 406. £2 4s.) New York: John Wiley and Sons. London: Chapman and Hall. 1950.

The author says that this book is an attempt "to treat industrial poisons primarily from the point of view of the chemist and engineer." Any industrial medical officer experienced in the chemical and related industries will know the nature of the problem which he should face but which, not infrequently, he gives up. It is that *he* should learn a great deal of industrial chemistry and that the *chemist and chemical engineer* should be induced to understand the nature of industrial poisonings, acute and chronic, and the way in which co-operation with the medical department can assure good health and happy, productive work. The points of view of doctor and technologist will never be identical, but much can be done to bring them together to the benefit of the worker. For this the doctor must shed his pomposity and his mystery-man state of mind, and the technologist must climb down from his pinnacle of electron shells and thermodynamics.

The author of this book has taken a rather different attitude towards what is needed by the chemist and engineer, for he has given them much useful information on sampling and analytical methods, a valuable chapter on maximum allowable concentrations, and over 180 pages of, in the main, short paragraphs on a large number of elements and compounds of industrial significance. Most paragraphs are preceded by some physical data and a note on harmful effects, as, for example, "Damage to lungs, eyes, skin." Physiology is discussed in two chapters. The references to the literature will probably be more useful than the text.

The dilemma before the author in writing a book of this kind is not underrated, nor is the notable effort made. Perhaps a book on this subject suitable for technologists cannot be written by a single individual. But, if written, it must be much more graphic in precisely the field which the present author says is not his business. Except in the section on analytical methods there is no chemistry in this book, unless giving the empirical formula of a compound is called chemistry; except in the most summary and rudimentary way there is no toxicology. The book is expensive for what it offers. It certainly is not suitable for continuous reading and is hardly authoritative enough for a reference book. But it deserves a place in the chemical factory or laboratory for its collections of useful quantitative data.

M. W. Goldblatt.

BRITISH MEDICAL JOURNAL
LONDON
SATURDAY OCTOBER 7 1950

WOMEN IN MEDICINE

Whether or not one holds with Sir Robert Hutchison[1] that women in men's schools are a disturbing element, the fact must be faced that all the London medical schools, for better or for worse, are now co-educational. The medical schools this week are beginning their new year and are celebrating the event by dining and speech-making. One such speech, by a woman to a woman's medical school, we print elsewhere in this issue. Professor Lillian Penson, who is Vice-Chancellor of London University, usefully reminds her audience that they are part of a university—an idea students who live in the sprawling mass that is London may from time to time forget.

When the Goodenough Committee[2] reported in May, 1944, it drew attention to the difficulties besetting women undergraduates who wished to study medicine in London. While in the rest of Britain medical co-education had for many years been a familiar feature, in London at the time of its report nine out of the fifteen medical schools of London University admitted men students only. At the same time entry to one school—the London School of Medicine for Women, now the Royal Free Hospital Medical School—was limited to women. The Goodenough Committee considered that "in the interests of the public and of the medical profession . . . co-education should become the normal practice in every medical school." And, furthermore, the committee added that the number of women students in any one school should be a "reasonable proportion" of the whole, reason dictating that this should be one woman to every four men. At almost the same time the Senate of London University said that its policy was to open all the London medical schools to men and women on terms of equal opportunity. The matter was clinched when the University Grants Committee said to the medical schools in effect, "No co-education, no grant." By 1947 all the medical schools of London University were co-educational.

As Table I at page 833 shows, in Britain the proportion of women medical students to men in 1938–9 was 1:5.7. The provincial, Scottish, and Welsh universities, which between them accounted for 1,275 out of the 1,930 women medical students in Great Britain, showed the "reasonable" proportion of one woman to four men. In the schools of London University no fewer than 357 of the 551 women medical students were segregated in the London School of Medicine for Women, the remaining 194 being dispersed in King's College (24), King's College Hospital (50), Queen Mary College (4), University College (59), and University College Hospital (57). There were also 38 women undergraduates at the West London Hospital for Women. Taking the figures for London as a whole, there was one woman to every eight men medical students. In the Scottish extra-mural schools (the Anderson College of Medicine and St. Mungo's College, Glasgow, and the School of Medicine of the Royal Colleges, Edinburgh), there was one woman to every nineteen men. But these schools were exceptional, as in 1938–9 over 40% of the Scottish extra-mural students were from foreign countries.

By 1948–9 the total number of women medical students in Britain had risen by 1,001 (2,931 as against 1,930 in 1938–9), while the number of men students had fallen by 756 (10,281 as against 11,037). By that year the proportion of women students to men had risen to 1 : 3.5. This represents an increase of 50% over the figure for 1938–9 (1 : 5.7). In Scotland, Wales, and the provinces there was very nearly one woman student to every three men, while in London the proportion of women (18.9%) was close to the 1 : 4 proposed by the Goodenough Committee. On the debit side of the balance it must be recorded that the West London Hospital for Women, which in 1948–9 had 68 women, has now ceased to recruit undergraduate students, and will in future restrict itself to postgraduate teaching.

If we look more closely at the situation in London, we see from Table II at page 833 that the schools which were co-educational before the war have continued to train about the same proportion of women students. King's College and King's College Hospital taken together averaged 1 : 5.7 in 1948–9; University College and University College Hospital show a slightly higher proportion of women, 1 : 4.7; at Queen Mary College, the figure is a little less, 1:9. But it is the nine naughty schools which formerly were the stronghold of the male that arouse most interest. None of them has yet attained the "reasonable proportion" suggested by the Goodenough Committee. St. Bartholomew's, Charing Cross, and St. George's Hospitals come nearest with one woman to every seven men. Those lagging behind in gallantry are Guy's, the London, and Westminster, where the proportion is less than 1 : 19. Intermediate, with a slightly higher proportion of women than this latter group, are the Middlesex, St. Mary's, and St. Thomas's Hospitals. When the Royal Free Hospital is included, the total proportion of women medical students at London University in 1948–9 falls only just short of the 1:4 recommended in the Goodenough Report. If each school had its reasonable proportion of women there would then be 479 more women medical students in London than at present. Unless extra facilities were provided, this would mean so many fewer places for men—a reflection which may make one question the wisdom of trying to spread the load too widely. At a time when so many students are clamouring at the gates of the medical schools, feminists should take note of the fact that at the Royal Free Hospital, also co-educational, there was last year the very unreasonable proportion of only 1 man to every 93 women medical students.

THE TREATMENT OF RABIES

Having eradicated rabies 50 years ago, we in this country are apt to forget that it still exists in most other parts of the world. No continent is exempt, and even in the United States there are still some 50 human cases annually, as well as many thousands of affected animals. The treatment of the presumably infected human being is thus an ever-present problem throughout the world, as of course is the control of the disease in animals. It was therefore natural that the World Health Organization, at its Second Assembly, should have decided to convene an expert committee on rabies. This committee, which included three representatives from the U.S.A. and one each from England, France, India, and Persia, met in Geneva in April last, and the report[1] of this meeting has now been circulated. It serves as a reminder that much progress has been made in methods of immunization, the general application of which should have valuable results.

Many of the recommendations of the committee are concerned with the method of preparation of the vaccine for the immunization of human beings or dogs. Desiccation, as in the original Pasteurian method, or treatment with phenol has generally been used up to the present as a means of inactivating the virus. There is now strong evidence that a more potent vaccine can be secured when inactivation is carried out by exposure to ultra-violet light. A good account of this method is given by Habel,[2] of the U.S. Public Health Service, himself a member of the committee. Infected brains are emulsified in buffered salt solution by means of a Waring blender and exposed to light from a special lamp in a thin-walled rotating quartz tube. The time required for inactivating rabies virus varies from 0.34 to 0.72 seconds, even though the suspension be as concentrated as 20% —a proof not only of the efficiency of irradiation but of the extraordinary capacity of the Waring blender, now an indispensable laboratory tool for many purposes, to reduce tissues to particles of little more than nuclear size. Habel found the degree of protection afforded by vaccine prepared in this way to be much greater than that conferred by a phenolized vaccine. It is of course very desirable that the immunizing potency of any vaccine used should be ascertained by a standard method, and the method of test described by Habel and Wright[3] forms the subject of another recommendation by the committee. It consists in administering six intraperitoneal doses of vaccine to mice at two-day intervals, followed by intracerebral inoculation with fixed virus, of which test animals receive larger doses than the controls. Owing to variations in the properties of virus used for this purpose in different laboratories, it is proposed to make available a standard challenge virus for use in these tests. The type of vaccine advocated for the prophylactic immunization of dogs is that prepared by cultivation of the Flury strain of virus in eggs, as described by Koprowski and Black.[4] A potency test for this vaccine, carried out in guinea-pigs, is also prescribed.

The most serious drawback of vaccine treatment for rabies in man has been the occasional occurrence of paralysis, due to a demyelinating lesion in the cord. This has always been regarded as a peculiar reaction to some constituent of nervous tissue in the vaccine rather than as an effect of the virus, and therefore there has always been a possibility that this unknown factor could be identified or at least eliminated. Progress in this direction has been made, though the committee considers that further study is called for. It is now said to be possible to detect the paralysis-producing factor by inoculating guinea-pigs with a mixture containing the brain suspension and a suspension of mycobacteria in mineral oil. Furthermore, Bell, Wright, and Habel[5] claim to have removed the factor from a brain suspension previously extracted and inactivated with benzene by the addition of calcium acetate; the washed deposit then constitutes the vaccine, the factor having remained in solution. As the report observes, this danger could also be eliminated by using egg-cultivated virus in place of brain suspensions for preparing vaccines for human use, if this should prove feasible.

Another section of the report discusses the use of immune serum, with or without vaccine, for the treatment of presumably infected persons. On theoretical grounds this should be very effective if given at a sufficiently early stage, but the evidence of its value is conflicting and unsatisfactory. Habel[6] has reviewed this evidence and reported studies of his own of the preparation of immune serum in rabbits, its concentration, and its protective effect in guinea-pigs, mice, and monkeys

[1] The report will be printed as an official document of the W.H.O. Technical Report Series. Copies may be obtained from the World Health Organization, Sales Section, Palais des Nations, Geneva, Switzerland.

when administered after their inoculation with street or fixed virus. It is clear from his results that the degree of protection afforded by serum is greater than that by vaccine, the best results being obtained with the two combined. It has to be remembered in this connexion that post-infection treatment of small animals with vaccine is never very successful, the incubation period being short compared with that in man. Koprowski, van der Scheer, and Black[7] have recently made still stronger claims. The material used was the γ globulin from the serum of rabbits or sheep immunized with vaccine made from the egg-adapted Flury strain and from rabbit-brain fixed virus. This serum neutralized large multiples of a lethal dose of virus when mixtures were injected intracerebrally in mice, and protected the majority of guinea-pigs and hamsters when given 24 hours after bilateral intramasseteric inoculation with street virus. Animals so inoculated and treated with vaccine all died. The serum has also been successfully used in 20 human subjects with either laboratory or street infections, some of a very dangerous nature. The authors made assays of the protective titre of the serum of some of these individuals, with interesting results. In those given vaccine only the titre never exceeded 1 in 6 and was often less than 1 in 2. In one subject given serum as well as vaccine it was 1 in 50 on the day after the serum was given, and 1 in 65, 70, and 55 after 3, 7, and 30 days respectively. This single piece of evidence strongly suggests that such serum gives a high degree of initial protection, which can be maintained by subsequent doses of vaccine. An immediately practical recommendation in the report is that a trial of immune serum should be made in Persia, where rabid wolf-bites, often involving the face, have a mortality exceeding 30% despite treatment with phenolized vaccine. There were 60 such cases last year, and there have been 22 during the first four months of 1950. The report includes a map of Persia showing the air and road routes by which it is hoped that serum may be dispatched to the aid of patients. It is laid down that serum must be given within three days, and that it is not to be used for infiltration of the area of the bite. Alternate cases are also to be given vaccine. Samples of the vaccine used and specimens of serum obtained at different stages of immunization are to be sent to Dr. Habel by air mail for tests of potency and of neutralizing power. If this trial proves feasible its results should be of great interest. The form of the disease is evidently as severe as any known, and the mortality is such that more effective treatment should declare itself unequivocally.

The committee also considered other aspects of diagnosis, treatment, and control. It recommends the intracerebral inoculation of mice or hamsters for confirming the presence of the virus in animal material, and redefines precisely the indications for antirabic treatment. Methods of control in animals are discussed at length; it is suggested that a field demonstration of the use of egg-culture vaccine in dogs should be undertaken in a country where canine rabies is endemic. In view of the recent recognition of the infection in various wild animals other than canines the committee considered that further oecological studies were necessary and also further studies by recently developed methods of the properties of different strains of virus. It is proposed that the committee should meet again next year, and an international conference on rabies is also projected, but is unlikely to take place before 1953.

PREVENTIVE PAEDIATRICS

When a public highway has been in use for a long time it wears into deepening tracks as well as potholes. The authorities may say, rather peevishly, that they are constantly doing repairs, but they ignore the fact that even the best roads need reconstruction from time to time. So it is with other public services, such as infant welfare and school medicine. They have a fine record of progress soundly buttressed by statistics showing a remarkable improvement in child health. Yet Professor Alan Moncrieff has had the courage to challenge them in their strength and to suggest radical changes. In his Dawson Williams Prize Lecture, which is published in the opening pages of this issue, he first discusses the work of infant-welfare centres, applying the test of preventive paediatrics to the diseases and disorders of children. In this respect he feels that the service has somehow failed to provide opportunities for advances in knowledge. The most valuable recent advances in the management of breast-feeding, for example, have come from outside, and the more practical applications of immunization and the trial of the newer antibiotics have been accepted with the reluctance which so often accompanies a too tidy administration. One of the obvious difficulties of criticism is that the infant-welfare services vary enormously from area to area. It is perhaps hardly fair to cite a comment of a prominent M.O.H. as evidence that the service is disloyal to breast-feeding. What is clear, however, is that there are serious gaps in the scheme, especially in its contribution to the early weeks of infant life. There are many lessons yet to be learned about the care of the newborn, and better co-operation is needed between the infant-welfare service, the hospitals, and general practitioners. Professor Moncrieff quotes a comment of the Royal Commission on

[1] *Solving School Health Problems*, 1942, Commonwealth Fund and Humphrey Milford.

Population that "a serious defect in the maternity services is that women are often discharged from hospital on the ninth or tenth day, before they have been taught to handle their babies." This criticism is too frequently true, but the remedy that the health visitor should be on the doorstep to greet the mother on her arrival home surely falls short of the target: the careful training of every expectant mother should begin at the infant-welfare centre long before her first baby arrives. This is the practice of progressive centres, where demonstrations of the everyday duties of motherhood are carried out by health visitors and voluntary workers. Nevertheless, there is a great waste of a health visitor's time in routine work which could easily be done by lay helpers.

On the clinical side Moncrieff is undoubtedly on strong ground when he pleads that the paediatric service in maternity hospitals should provide continuous supervision from birth through infancy. By this means more could be learned about the origins and progress of the common infections of childhood, and also of the so-called defects such as adenoids. The significance of tuberculosis in the early years of life has been slurred over, and it is time for the infant-welfare movement to take up an aggressive attitude. As Moncrieff says, "Surely the early detection of tuberculous infection, the tracking of contacts, the use of B.C.G. vaccine for negative reactors amongst them, could be made a fine co-operative effort between the infant welfare and tuberculosis branches of the health service." There are many other fields, some hardly cultivated at all, in which the welfare centre could help—the promotion of mental health through parent education; an approach by similar methods to sex teaching; and intelligent instruction on the prevention of accidents in the home. Recent studies on infant morbidity indicate a need for the more prompt and efficient care of minor maladies, and of serious illness before it becomes serious. Who is to carry out this treatment? Surely it must be the family doctor in the family home. Moncrieff goes on to say that the medical officers of the infant-welfare centre should logically be the family doctors who will be carrying out the work in the homes. Hitherto, this sensible view has been limited by the element of time and the barrier of competition. The family doctor, working more or less by himself, has in fact found it difficult to arrive at an infant-welfare centre at the scheduled time. Lateness and irregularity of attendance are fatal to the work of a centre. Again, general practitioners have found it embarrassing at infant-welfare centres to treat, or even to examine, the children of other practitioners' patients. Moncrieff says wisely that the health visitor of the future should not be made into a subsidiary social worker: she should in fact receive more training than at present in the nursing of children. In addition, she ought to be trained in educational methods. The family doctor may not have much opportunity to become proficient in this vital subject, yet health education must remain within the province of doctor and nurse because of its ever-changing medical background. It might be reasonable to suggest that the educational work of infant-welfare centres should be undertaken by health visitors and supervised by the medical officer of health and his staff.

The essential structure of the school health service has changed little during the past generation or so, although of course many advances in clinical medicine have been adopted. The most notable progress has been made in the ascertainment and care of handicapped children. A reconstruction of this service is overdue. Nyswander's[1] careful study in the United States exposes the principal weakness of our own system, for she showed that a trained teacher working in harmony with a nurse can detect with great accuracy those school-children who ought to be seen by the physician. If they err, as they will do, on the safe side, no harm is done. The results are wholly beneficial: each child with a suspected defect is examined at leisure by a physician trained in child health instead of being subjected to a dreary routine of superficial inspection. The entire screening system is strengthened, with economy in both man-power and money. The responsibility thrown upon teacher and nurse is a stimulus rather than a burden to them, and it tends to improve co-operation. The school physician on his part is given time for careful, interesting clinical work and opportunity to observe the progress of all the children who suffer from a mental or physical handicap. Most important of all, the parents appreciate the value of thorough examination and gain confidence in the service as a whole. The physician, escaping thus happily from a wilderness of routine inspections, can devote more time to the broader aspects of preventive medicine in his school work.

Moncrieff justly stresses health education, a subject in which every school health officer should be trained, and he urges the importance of bringing him into the teaching programme, both in hygiene and in physical education. There are still many areas in which the school health staff is not consulted on the teaching of hygiene, on sex education, or even on physical training; and there are education authorities which do not give him a voice in the planning of ventilation, lavatories, rooms for drying and changing, and other essential health equipment in schools. This is patently wrong and ought to be remedied without delay. It is no answer to say that some authorities have already adopted the reconstruction which Moncrieff recommends. The time has come for it to be generally accepted.

DRUG ACTION AND SUGGESTION

The clinical trial of a drug may, for obvious reasons, bear little relationship to its effect upon an isolated organ suspended in a standard solution. Clinically the action of the drug can be profoundly modified by numerous factors arising from the vagaries of the intact patient, while in laboratory experiments the effect depends only on the pharmacological action of the drug itself. Those who have attempted to obtain basal conditions for such a clinical test as the B.M.R. will appreciate the difficulties involved, particularly the difficulty of obtaining a basal mental state. Wolf[1] has recently demonstrated the effect of psychological influences on the pharmacological action of drugs in a series of experiments mostly carried out on Tom—his famous modern Alexis St. Martin—who has a large gastric fistula. Wolf has been able to correlate changes in the colour and turgidity of Tom's gastric mucous membrane with measurements of secretion and motility, and he found that the factors apparently of importance in experiments with drugs were the state of the end-organ when the drug was given; the setting in which the drug was employed, including the mode of administration and the effects of suggestion, implicit or expressed; and previously established habits of reaction. Thus urogastrone administered at a time when Tom's stomach was in a normal state usually induced an inhibition of secretion associated with pallor of the mucous membrane. If, on the other hand, it was given when his stomach was turgid and actively secreting, due to a period of frustration, gastric hyperfunction was actually somewhat enhanced rather than inhibited. Further, resentment caused by a hypodermic injection of distilled water greatly increased gastric hyperaemia and secretion. The introduction of 10 ml. of the syrup of ipecacuanha through a Levine tube into the stomachs of two female subjects constantly caused nausea and vomiting, the effect being shown objectively by the characteristic cessation of gastric contractions in kymographic recordings. When, however, a second dose was introduced through the tube, this time with the reassurance that the symptoms would be abolished by it, the nausea subsided and gastric contractions recurred. Doubtless this mechanism operates in any enthusiastic therapeutic regime and is the stock-in-trade of faith healers. In the last of the experiments Tom was conditioned to the administration of neostigmine, to which he invariably reacted with the usual abdominal cramps and diarrhoea and with gastric hyperaemia, hypersecretion, and hypermotility. But when, unknown to him, tap-water, lactose, and even atropine (a direct antagonist to neostigmine) were substituted, identical effects were obtained.

Such experiences confirm what is well known but sometimes forgotten, that the human body reacts not only to physical and chemical stimulation but also to the symbolic stimuli of words and events which have acquired a special significance for the individual. Not only the frequency but the magnitude of the "placebo effects" reported in these experiments was impressive, and they should certainly be taken into account in pharmacological experiments in man and even in the intact animal. Elsewhere in this issue Drs. C. E. Quin, R. M. Mason, and J. Knowelden discuss the difficulty of assessing improvement during the drug treatment of rheumatoid arthritis. When investigating the value of deoxycortone and ascorbic acid injections they found that subjective improvement occurred to an equal extent after both test and control injections, and that when objective tests were used the results obtained with the test substance and the control injections were the same. It is customary to control the clinical trial of drugs with inert placebos when the data to be evaluated are subjective, but when they are objective placebo control is usually omitted. The need for such control is suggested by the fact that placebo effects may be potent enough to cause not only objective changes at the end-organ resembling those attributable to potent pharmacological action but even reversal of the expected action. Thus the familiar difficulty of evaluating the effect of new drugs on patients arises not only from uncritical therapeutic enthusiasm but also from the actual pharmacological effects of "placebo action."

HEXAMETHONIUM

If methyl groups are substituted for hydrogen in the ammonium radical, and if two of the trimethylammonium groups so formed are joined by a chain of six $-CH_2-$ groups, the result is hexamethonium. This was examined in the first place as a substance which might have the properties of D-tubocurarine, but was found by Paton and Zaimis[1] to be much inferior in this respect to decamethonium, which is now commonly used in anaesthesia as a curarizing agent. Hexamethonium was indeed first introduced as an antidote to decamethonium. It has, however, a certain curarizing action which is much more evident at the sympathetic ganglion than at the motor end-plate in skeletal muscle. The transmission of the nerve impulse from the motor nerve to the motor end-plate and likewise the transmission from a preganglionic fibre to a postganglionic fibre in the autonomic system are both believed to be effected through the liberation of acetylcholine, and a curare-like substance which blocks the first transmission should also block the second. D-Tubocurarine is more active at the motor end-plate, while hexamethonium is much more effective at the autonomic ganglion, though both have some action at both sites of transmission. The reports published in this issue by Drs. A. Campbell and E. Robertson on the treatment of hypertension and by Drs. A. W. Kay and A. N. Smith on the effect of hexamethonium on gastric secretion are both based on the property which hexamethonium possesses to block transmission at the autonomic ganglia. The effect on hypertension is due to block in the sympathetic autonomic ganglia, and that on gastric secretion to block in the cranio-sacral autonomic ganglia, if we use Langley's term—that is to say, in the vagal ganglia, which are supposed to exist in the stomach wall.

The sympathetic ganglion is a point in the efferent sympathetic pathway which corresponds to the junction between the upper motor neurone and the lower motor neurone running to skeletal muscle. A block at the sympathetic ganglia interrupts the stream of motor impulses, causing vasoconstriction. Campbell and Robertson have found that daily administration of hexamethonium for a period from one to five weeks brings down the blood pressure and that it remains down when the drug is discontinued. This is a remarkable and hopeful result. The cause of the hypertension is either excessive tone in the arteries or an excess of constrictor impulses from the sympathetic centres. While it is clear that the blood pressure will fall when constrictor impulses are excluded, whatever the cause of the hypertension, it is not clear why the blood pressure does not rise again when the block is removed. Failure to do so suggests that the hypertension is due to some vicious circle, and once this is broken the hypertension disappears.

The action of hexamethonium in diminishing gastric secretion is due to block of the secretory impulses coming down the vagus nerves. Kay and Smith found that when the drug was given by mouth its effect varied in different patients: five out of ten had achlorhydria, three had diminished secretion, while in two there was no effect. They also found that the iodide and bromide salts were more active than the chloride, though it is difficult to see what can be the reason for this. The side-effects do not appear to have been serious in either investigation: when postural hypotension occurred it could be overcome by activity.

AN ACCIDENT IN THE X-RAY ROOM

All who work in radiological departments are well aware of the danger of accidents occurring to those who misuse electrical apparatus, and stringent precautions are taken to guard against disaster. The report appearing on another page by Dr. Geoffrey Dean illustrates a different danger—that is, the accidental administration of a barium compound other than the harmless insoluble barium sulphate for outlining the alimentary tract. Seven patients received a dose of barium carbonate much in excess of doses that had proved fatal in earlier recorded cases. Fortunately only one case was fatal. This patient had less barium than the other six, but was given an anaesthetic soon after: the effect was to prevent the vomiting and diarrhoea which, Dr. Dean believes, were responsible for hastening the excretion of the barium and so saving the lives of the others. The symptoms were similar in all the patients, with the classical signs of salivation, abdominal cramps, vomiting, and purgation. At the beginning of their illness a number of patients noted a peculiar stiffness of the face and blurred or double vision: these symptoms are not described in the standard textbooks and are worth bearing in mind. Early diagnosis in such cases is of special importance, because there is an effective antidote in magnesium or sodium sulphate. Magnesium sulphate was given for another purpose to one of Dr. Dean's patients immediately after the barium, and he escaped all the worst symptoms. The poison had no action on the central nervous system, and, apart from the intestinal disturbances, progressive muscular weakness was the main feature. This is in agreement with the pharmacologists' views on the action of barium—that it affects the muscle fibres rather than the nervous system. Many textbooks mention that convulsions occur in barium poisoning, though one older authority[1] emphasizes that muscular weakness and paralysis rather than contractures dominate the picture of barium poisoning in man.

This accident occurred because the wholesale chemist had put barium carbonate into containers labelled barium sulphate. We are all inclined to accept without question that the statement on any label does in fact correctly record the nature of the contents of the container. Some years ago Keall and his colleagues[2] described three cases of tellurium poisoning with two fatalities among patients given the contents of a bottle labelled "sodium iodide" for retrograde pyelography. The solution was in fact 12½% sodium tellurite, but the authors gave no details about how the mistake was made. There are, of course, many ways in which the wrong contents or the wrong slip of paper might find their way into or on to a container. Some organizations are well aware of this and have established expensive but effective checks to ensure that none but correctly labelled materials leave their premises. If hospitals decide to deal only with such firms they should be prepared to pay the slightly greater cost as the price of safety.

VICTORY MEDAL FOR DIABETES

Dr. Elliott P. Joslin, who celebrated his 81st birthday last June, is known throughout the world as a distinguished veteran in the fight against diabetes. Just over two years ago, as part of his effort to educate diabetic patients in healthy living and to show them what proper care can do, he founded a Victory Medal to be presented to any person who is still free of all vascular disease after a quarter-century or more with proved diabetes. In the 24 months up to June 1, 1950, he had found 20 patients who passed this test, and last year[1] he personally handed one medal to Dr. R. D. Lawrence, who for 20 years has led an active professional life as a consultant in diabetes and is said to have been one of the first people in Britain to receive insulin.

On behalf of the Advisory Committee of the Diabetes Fund of the Boston Safe Deposit and Trust Company, which holds and administers the Medal fund, Dr. Howard F. Root has now invited (see p. 840) the Editor of the *British Medical Journal* to award a bronze Victory Medal in Britain. This gift has been accepted with warm appreciation as a generous gesture of good will from our American colleagues, and the medal is now in the office of the *Journal*. It is hoped to set up a small informal committee to decide how best to award it. The medal, illustrated in Dr. Root's letter, has been designed by Amelia Peabody. It measures 2 inches across, and on the reverse side appear these words: "For life and health through perseverance and scientific medicine."

On October 12, the first degree day of the Michaelmas Term at Oxford, the Osler Memorial Medal will be presented to Sir Ernest Laurence Kennaway, F.R.S., who is an honorary Fellow of New College. The award was instituted in 1925 as a memorial to Sir William Osler, Regius Professor of Medicine at Oxford from 1904 to 1919. The medal is given to the Oxford medical graduate who has made the most valuable contribution to the science, art, or literature of medicine and who has not previously held the award. It is given once every five years only. Sir Ernest Kennaway, who is Professor Emeritus of Experimental Pathology in the University of London, has devoted a large part of his career to cancer research in this country and in the U.S.A.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

THE CARDIOGRAM IN CLINICAL DIAGNOSIS AND PROGNOSIS

I. THEORETICAL CONSIDERATIONS

BY

TERENCE EAST, M.A., D.M., F.R.C.P.

Senior Physician and Physician in Charge of Cardiological Department, King's College Hospital

When the muscle fibres of the heart pass from the resting to the active phase of systolic contraction electrical changes take place. These can be recorded by a suitable instrument. Several types have been used. The string galvanometer makes a photographic record of the greatly magnified movements of an almost invisible fibre. The currents from the heart may be intensified by thermionic valves to work a mirror galvanometer which writes on sensitive paper with a beam of light. The cathode-ray oscillograph may illuminate a fluorescent screen; direct records may be made on special paper by heated points, or traced with ink. The result of all these methods is the cardiogram.

I will consider for a moment the unit—the muscle cell. At rest it is polarized, with a negative charge of anions lining its semi-permeable membrane on the inside, balanced against a positive charge of kations on the outside. When the "stimulus" for action reaches this cell it becomes depolarized, the ions change position, and the cell achieves its one purpose in life—contraction. The process of depolarization is associated with a difference of electrical potential at the ends of the cell, and current flows. Contraction over, repolarization sets in, starting where depolarization began, and again there is a difference of electrical potential and a flow of current, but opposite in sense to that of depolarization. Polarization being complete, current ceases to flow, and there is diastolic rest until the next phase of systolic activity. Any type of electrocardiograph will record these currents.

What has been instanced above must be multiplied untold times when we attempt to conceive the total systolic activity of the syncytium of cells which compose the whole heart muscle. One must remember, too, that the impulse for action passes throughout this mass during a definite interval of time, and that, so far as the auricles are concerned, these impulses are merely simple transmissions through the muscle sheet. But in the ventricles there is a special telegraph apparatus—the Purkinje system—which distributes the impulse as rapidly as possible through these chambers, which are indeed muscular cups. It must also be remembered that the general distribution of the spread of the impulse, considered in three dimensions, is opposite on the two sides, right and left.

Normal Cardiogram: Nomenclature

The apparatus is so arranged that a positive potential will produce a deflection from the base-line (which is spoken of as isoelectric) in an upward direction; a negative potential will give a downward deflection. Hence the direction of deflections is usually spoken of as positive or negative (or upward or downward). It is a fundamental fact that so long as an impulse is travelling towards a recording electrode the potential of that electrode is positive. Similarly when an impulse is receding from an electrode its potential is negative (Fig. 1).

Standardization.—It is now the universal practice to standardize the deflections so that a difference of potential of one millivolt causes a movement of one centimetre.

Auricular Activity.—The electrical potentials developed by auricular systole cause a small deflection, which is always labelled P. As a rule it is positive in standard Leads I and II. It may be negative in standard Lead III. It is shown best by standard Lead II, VR, VF, and V_1. (See below for the explanation of these terms.)

Ventricular Activity.—The impulse reaches the ventricles after a short interval occupied by its passage through the conducting tissues. The first indication of electrical change may be a negative or downward deflection Q. This varies much in size in different leads. Its presence may be physiological merely, or definitely pathological in significance. It is not always seen. It may be followed by a positive deflection R; if Q is wanting this will be the first deflection. It varies much in height for many reasons. After this may come a negative deflection S, again very variable in depth. If the sole deflection recorded be negative there has been some doubt whether it should be called Q or S. It is safest to label it with both letters.

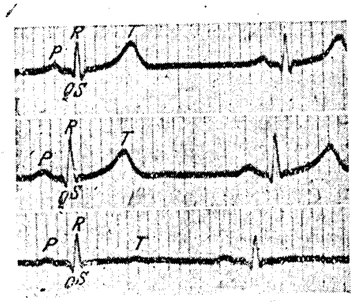

FIG. 1.—Normal electrocardiogram

The QRS complex, as it is called, coincides with the process of activation of the ventricles, or the beginning of ventricular systole. Following this phase, for the instant when all the muscle is in a state of activity, there is no difference of potential anywhere, and the recording curve is at the base-line again. Then that part of the myocardium which first became depolarized starts to become repolarized and for the moment, until repolarization is everywhere complete, there is electrical disequilibrium. This causes a further flow of current through the galvanometer, and a flattened curved wave is recorded which is always labelled T. It is usually positive; in fact, in some leads a negative T can always be regarded as of pathological significance, but in others this is not so. The shape of the wave may be very important and indicate the cause of an abnormal appearance. Sometimes the S–T or RS–T phase is not at the base-line, or isoelectric: it is then said that there is S–T (RS–T) deviation—positive or negative. This may be of great pathological importance in indicating myocardial disease.

It must be remembered that, as in all natural things, the range of the normal cardiogram is wide, and that its limits are by no means clearly defined. Long experience is needed to appreciate these points. The variations in the size and shape of the deflections are considerable, and depend on such causes as the lie of the heart in the chest, the vigour of the heart, the resistance of the skin, and other factors but little understood.

Time Measurements.—All cardiograms show a time scale, usually in 1/5 and 1/25 second. It is convenient to mention here that the interval between the beginning of the wave of auricular systole (P) and the wave of ventricular systole (Q or R) should not normally exceed 0.2 second. The duration of the QRS complex should not normally exceed 0.1 second.

Technique

For many years the standard three bipolar leads from the contacts placed on the arms and the left leg were all that could be offered. Then a fourth lead from the front of the chest in the region of the apex of the heart was added. The potential at the exploring, or precordial, electrode was much higher than that at the distal electrode, which was placed on either the right arm (CR) or left foot (CF), so that the curve was practically derived direct from the region of the heart itself. The next step was to use a variety of precordial contacts, starting with the first position in the fourth intercostal space just to the right of the sternum, the second just to the left of the sternum at the same level, and so on to the sixth in the left mid-axillary line; the fourth position being in the left mid-clavicular line in the fifth interspace. All those were bipolar leads.

The latest development is the introduction of unipolar leads. There are three unipolar limb leads, from the right and left arms and the left leg. It will be appreciated that there is obviously a close relationship between the standard bipolar limb leads and the unipolar limb leads. Lead I records the difference of potential between the right arm and the left arm. The unipolar arm leads record only the electrical potential at each arm.

In the same way standard bipolar limb Lead II records the difference of potential between the right arm and the left leg; and standard bipolar limb Lead III the difference of potential between the left arm and the left leg. The unipolar limb lead from the left leg records only the changes of potential in that limb.

By a similar method unipolar precordial leads have come into use, numbered 1 to 6 (7 and 8 may be added if need be).

The letter V (voltage) has been employed to indicate unipolar contact—VR, VL, VF, for the right and left arms and the left foot, and V_{1-6} for the precordial contacts.

CR and CF were the initials indicating the bipolar precordial (or chest) leads, with the right arm or left foot as the distal electrode, respectively.

This brief survey of the technical side of the nomenclature is needed, partly because the terms may be unfamiliar to many, and also to show that in the past few years a very considerable development in technique has taken place. At present it may be said that the full electrical exploration of the heart requires at least 12 leads, and possibly some six or more at higher levels on the chest. The additional value of oesophageal leads, or of contacts placed on the back of the thorax or on the epigastrium, is still to be assessed. How far the original bipolar limb leads will be retained remains to be seen, and how many of the new ones will be used in the first stages is still uncertain. The introduction of the direct-writing type of cardiograph is a great advantage over the older photographic models; much time can be saved and the use of multiple leads greatly facilitated. It may well be that the simplicity of this technique will enable many or all to be used.

Cardiogram and Position of Heart

The general direction of the spread of the current of activation through the ventricles is downwards and forwards and to the left. Roughly, this is at an angle of about 60 degrees to the horizontal. The direction of this electrical change at any given moment is called the electrical axis.

The lie of the heart in the thorax varies much with a patient's build and with the position of the diaphragm. A person with a long narrow chest will have a vertical heart; a person of stocky build, with wide chest and horizontal rib margins, will have a transversely placed heart. Obesity, pregnancy, and the expiratory phase of respiration will raise the diaphragm and make the heart more transverse. These changes in position alter the appearance of the cardiogram in the standard bipolar limb leads and in the unipolar limb leads.

The expression "left axis deviation" was coined to describe an anticlockwise rotation of the heart's axis in a frontal plane, upwards and to the left. The expression "right axis deviation" describes the opposite, a rotation in a clockwise direction, downwards and to the right. These changes may be caused by the build of the patient or by the phase of respiration. But enlargement of either ventricle also causes them and to a far greater degree than other means. Enlargement of the left ventricle is associated with left axis deviation, enlargement of the right ventricle with right axis deviation. The terms "left and right ventricular preponderance or predominance" were also in vogue to describe these curves.

Cardiogram in Cardiac Enlargement

As many of the features of position and enlargement are closely connected it is convenient to discuss enlargement at this stage, though it is in a sense a myocardial abnormality. The extent to which active hypertrophy of either or both ventricles may produce characteristic curves is very variable. Very often recognizable reliable changes are not seen: on the other hand, if they are present they should be capable of interpretation. In order to find out whether there is hypertrophy of the ventricles one should examine the patient clinically and with the fluoroscopic screen rather than the cardiogram. But there are occasions on which the cardiogram may give useful confirmatory evidence concerning which ventricle is enlarged. This hint is particularly useful in congenital defects.

Considerable increase in size of either ventricle may be present without any modification of the curve; for example, there may be obvious enlargement of the left ventricle from hypertension and yet a normal curve may be obtained. The reason for this is not understood. But once a certain degree of hypertrophy has been reached the characteristic cardiograms are usually seen. In many cases it is possible to gauge the degree of change in the heart by the type of curve. What the causes are, and in what proportion they operate in producing the curves of hypertrophy, is still far from clear. The altered position or lie of the heart in the chest and the increase in the thickness of the ventricular wall are probably the important ones. The most recent trend, due to the use of unipolar leads, is to indicate the position of the heart—horizontal, semi-horizontal, vertical, and so on—and also to refer to any suggestion of hypertrophy.

The right ventricle may influence the change in the curve in the same way as the left; but its relatively smaller normal bulk requires gross increase to produce much effect, so it therefore seems relatively late.

For the most part gross cardiac enlargement is due to valvular disease or hypertension, or congenital defects; less commonly to abnormalities in the pulmonary circulation. The cardiogram will then to some extent help to gauge the degree of deviation from the normal, and so help to assess the gravity of the case. The changes associated with hypertrophy of one or other ventricle give a progressively abnormal type of curve, and so may indicate to which stage the disease has reached.

It must be remembered that in some cases of hypertensive heart disease ischaemic lesions may be present as well. These would increase the gravity of the prognosis. The cardiogram may reveal them.

The cardiogram is quite useless in the early diagnosis of valvular disease, or in the direct diagnosis of valvular disease at all; only indirectly, by indicating ventricular hypertrophy, may the curve suggest that a defect in the function of a particular valve may be the cause of it.

UNIVERSITY VENTURES OLD AND NEW*

BY

LILLIAN PENSON, LL.D., D.Litt., Ph.D.

Vice-Chancellor of the University of London; Professor of Modern History in the University of London

All university education, and indeed all education and all activities of universities, could be brought under my title. For, whatever can be said for or against the educational process, it is a constant series of ventures—often over seas which are unknown and therefore uncharted. Which of them shall I choose?

There is first the venture of doing things for the first time. Some of you may well feel that you have a special claim to inclusion here. It is your first year in the school or your first year of a new and different part of your course. I can assure you, however, that these particular types of venture do not stop here. I claim a special place in this category myself—by asserting that few people so often do strange acts for which they feel at best only partly qualified. I should like to warn you of this in case any of you are thinking of becoming vice-chancellors. The things may be different, but the process remains the same.

But it is of collective rather than individual ventures that I want mainly to speak—appropriately enough to a world where emphasis is growing on the importance of collective action or, if you prefer it, combined operations. The use of the last term will in itself be enough to show that collective action is in the last resort the action of individuals. The antithesis is an unreal one. Somewhere in all collective action there is someone who is making a decision. Frederick the Great once said that he disliked councils because they were always timid. One of the problems of the modern world is to secure that this is not true. Individual responsibility and individual initiative are, when it comes to the point, essential to all organizations, large or small. That cannot need emphasis in a medical school which has, at least in its associated hospitals, so many examples of the individual idiosyncrasies of the members of the human race.

We start, then, with the knowledge that these corporate activities of ours are at heart the activities of individuals. And I am choosing at random. The first I would call the venture of choosing and finding the subjects of academic study. We have been on the whole conservative in this country in our attitude to university education. Some countries have gone further than we have in the direction of including among the courses which could be taken for university degrees a number of forms of training which are training for a particular type of post, and it may well be that there will be further pressure upon us in this country. No one would in fact be prepared to say that subjects should be excluded because they are useful. We are driven to the harder task of defining what we mean in a positive form. What are the characteristics which entitle a subject to be put on the right side of the line? Perhaps the nearest that we can get to it is to say that every subject which should be included contains in it an unlimited possibility of development by research. This on the whole is a good approximation to the truth, for it implies something which I believe to be fundamental to undergraduate study, that what is being studied is something which is constantly changing and which therefore holds out a promise in the future which no undergraduate can hope to reach.

It is true that one of the difficulties of all university education at the present day—and I imagine that this applies to the faculty of medicine just as much as to any other—is that the body of knowledge already obtained is so great that it is necessary to go a very long way before even a glimpse is caught of the knowledge of the future. So far as undergraduates are concerned this situation has obvious drawbacks. We all maintain, those of us who teach in universities, whatever our subjects may be, that we are doing or trying to do something more than impose upon the memories of our students masses of detailed information which indeed is all recorded in numerous textbooks which are available to them. Yet in our candid moments we have all to own that a good memory can carry an undergraduate a very long way.

This brings me to another of the several ventures which are included under my title—the venture which must be of necessity a combined effort on the part of the university teacher and the man or woman who is being taught. This is the venture of seeing beyond the factual information which it is essential to impart or absorb to the as yet unproved or unascertained items of knowledge which lie beyond. It is a venture which requires above all an effort of faith, and I should be prepared to prophesy that a great many of you who are now beginning your university career will find a good many moments, if you take what I have said seriously, when you wonder whether it is anything but moonshine.

If this is a venture of faith and the most constant of all the ventures with which we are concerned; it is nevertheless only one of the many differing things which can be brought under my heading. I should like to refer in the first place to some matters with which I have been concerned.

During the war—and I am not concerned for the moment in dealing with the reason—there was a greatly increased sense of purpose in relation to a totally different aspect of governmental activity: the welfare of colonial peoples. It is difficult to give a date to this development, but roughly speaking it came with the middle period of the war, although of course its history could be traced back to the pre-war era. It will be enough for the moment to refer to the decision in 1940 to grant a substantial sum of money by parliamentary action to what is technically described as "Colonial Development and Welfare." One of the results of this policy has been the establishment of a number of new university institutions in the colonial areas. A commission was appointed in August, 1943, to inquire into this matter: "To consider the principles which should guide the promotion of higher education, learning and research and the development of universities in the colonies. . . ."

*Inaugural address at the opening of the 1950–1 session of the Royal Free Hospital School of Medicine, delivered at B.M.A. House on September 29.

Ventures Overseas

I was a member of this commission, and shared with a number of other people, therefore (there were sixteen of us in all), the task of making recommendations on this subject. I am glad to say that it was one of the commissions—of which, whatever the general public may think, there are many—which led to some practical results. Roughly speaking it may be said to have led to two main classes of results: to the transformation into universities or university colleges of certain institutions which were already in existence—for example, the colleges in Singapore have since been transformed into the University of Malaya, and two institutions in Africa which were not at the time of university status at all—Makerere College in Uganda and Gordon Memorial College, Khartum—have been transformed into university colleges; that is one group of results. The second is the founding of new university colleges—two of them in West Africa at Ibadan in Nigeria and Accra in the Gold Coast, and the other in the West Indies in Jamaica. I am not going to venture to speak of this last, much as I should like to do so; Professor Lucas Keene knows it well, and has contributed so much of value to it that it would be impertinence to say much in her presence. Nor shall I refer to Nigeria, which I have never visited, while Professor Killick has. All these are ventures which, like all other actions or series of actions that can be included in that term, are acts of very considerable faith on the part of those who carry them out. The institutions which I know best, at Khartum and in Jamaica, belong to the two different categories which I have mentioned; they have a great many other differences as well.

The College of Khartum is essentially a Moslem institution in a predominantly Moslem country. There are no religious tests and there are in fact now a few Christian students. The majority of the staff is Christian, but, as is appropriate in a Moslem country, the outlook of the College is strongly affected by the predominant religion. The weekly holiday is on Friday and not on Sunday. There is not yet a mosque attached to the College, but the new buildings which are envisaged will include one. This affects perhaps the study or teaching in certain faculties, but does not alter materially the fundamental characteristics of university institutions. Another interesting characteristic is the fact that the Anglo-Egyptian Sudan is far more completely a socialist State than the Britain of to-day. The effect of this fact is that practically every occupation which is open to the students of the College is in government service of one kind or another. It is thus more difficult to maintain that university education in the Sudan is something more than training for a particular occupation. Another element in the situation is to a large extent common to all these new institutions. It is the difficulty of making it clear that a university course is something other than the successful passing of appropriate examinations. This difficulty is the greater because in all these regions, where only a very small minority of school-boys or school-girls can possibly hope to reach the stage at which they could enter a university institution, the passing of examinations looms very large in the educational system. At almost every stage of their early education they have to face a competitive examination upon the results of which they keep or lose their place on the educational ladder. By the time, therefore, that a student reaches a university college he has almost inevitably become imbued with the idea that what matters is a successful climbing of the next particular step.

No student in London whose private interests lie in art or in music can legitimately complain if provision is not made at his own particular institution. The opportunities not only in other parts of the university but in London as a whole are so great that his difficulty is rather a matter of choice than anything else. He may well, and of course often does, complain that with all these opportunities he lacks time to take advantage of them, and thus it comes about that, while in these new university ventures overseas the chief need is to provide for something which will interest and stimulate students outside their compulsory curriculum, in our own case the parallel need is rather to see to it that everybody has time to take advantage of some of the many opportunities which at present exist.

There is naturally something exciting in these university ventures in distant countries which is lacking in our own problems. There is something exciting for visitors to these regions simply because the countries themselves are in so many ways different from our own. There is a measure of excitement from the point of view of the peoples themselves. Colleges necessarily live there in a blaze of publicity which is fortunately lacking, for example, in London. To a very large measure the hopes of the peoples for self-government are tied up in the progress of the college: their national pride is involved in its success.

University Education for All

Nevertheless, most of our university activity here could be brought in one form or another under the heading of a venture. This is perhaps particularly true in our own day, since there has been such spectacular development in university education in the past hundred years. Most of the modern universities in England have grown to maturity in that period, and we ourselves in London only celebrated our centenary fourteen years ago, and our older colleges, though some of them are older than the university itself, are for the most part the product of the nineteenth century. What is interesting as we look back upon this historical record is that there were a number of differing influences which went to make the different university institutions and indeed the university itself. If we reflect upon these factors and try to pick out one thing above others which characterizes the movement as a whole, I think it would be the attempt to provide university education of one kind or another for virtually all comers. The absence of restrictions upon first creed—it is difficult to think that only a hundred years ago that was a matter of burning importance—and later on race or sex is one way of bringing out this insistence upon a universal opportunity. We have at the same time to realize that in our age also there are ventures to be faced almost, if not quite, as important as those which were involved in the great university development of the nineteenth century. In almost every respect our outlook on university affairs needs to be adjusted to the new circumstances of our own age. The great ideal for which I have said our own

university stood, the provision of opportunities for university education for all those who by one means or another could achieve it, has a new bearing when so much of university education is achieved not by individual unaided effort but by the grant of support in one form or another by the State. This is one of the main problems facing universities at the present time, and our new venture of the mid-twentieth century is perhaps above all to find a way of reconciling two things—the great tradition to which we are almost without exception devoted, the freedom of universities and, within measure, of students in universities, and the necessity of finding some proper method of determining the proportion of people, and indeed the actual persons, in the population who should be enabled to enter upon a university life. There is no easy answer. It is easy to adopt phrases such as "service to the community" or "the good of the community," or even the older phrase of "equal chances for all," but none of these is satisfactory as a solution of the practical problems with which we are all faced.

It is undoubtedly true in university as in other aspects of life that there is a danger lest the matters which are of concern for the future should be decided almost wholly by people who by the mere passing of time belong largely to the past. I am not, however, so far removed from my own generation as to think that the younger anyone is the better their judgment. There is a great deal to be said for that peculiar, as it seems to us, constitution which is one of the many which were invented by the fertile brains of French revolutionaries which divided the population into the young and the old rather arbitrarily at the age of 40 and gave to the young the duty of formulating ideas and to the "ancients" the duty of criticizing them and the power to prevent any of them from being put into action. It embodied at any rate one fundamental principle, that in all developments which could possibly be brought under the word which I have used in my title it is necessary to blend together the old and the new, and to give some opportunity, however small, to the trying out of new ideas.

MIDDLESEX HOSPITAL MEDICAL SCHOOL

The annual dinner of the Middlesex Hospital Medical School was held at the Savoy Hotel on September 28. Mr. E. W. Riches presided over a record attendance, the number of covers laid being greater even than at the dinners before the second or the first world war. The principal guests included Lord Webb-Johnson, the presidents of the three Royal Colleges, the regius professors of Oxford and Cambridge, the principal of the University of London, the medical directors-general of the Royal Navy and the Royal Air Force, the secretary of the Ministry of Health, the chief administrative officer of the North-west Metropolitan Regional Hospital Board, the mayor of St. Marylebone, and the medical officer of health to the London County Council.

The chairman said that among the former Middlesex men who had died during the past year was Warwick Deeping, the novelist, and mentioned that when one of Mr. Deeping's novels was filmed Middlesex men took part "to ensure accuracy of technique." It was unusual for a hospital to have two of its members knighted in the same year, and he congratulated Sir Harold Boldero, dean of the school, and Sir Harold Graham Hodgson. Another tribute was the institution by the Royal Australasian College of Surgeons of a Gordon-Taylor Prize. He announced that the *Archives of Middlesex Hospital* would be revived in 1951. Many of them, he continued, had been a little critical of the increase of administrative and clerical staff under the National Health Service, but, with a total population at Middlesex of about 2,500, the administrative staff formed about 8%. With the ratio of nurses to patients now approximately 1:1, and bearing in mind the vast services rendered apart from treatment, the percentage did not seem to be excessive. The new department of physiotherapy at the Middlesex, opened during the year, was agreed to be one of the best of its kind. In the medical school, the first two women students of Middlesex—Verity Wills and Jean Shanks—had qualified.

Responding to the toast of "The Hospital and School," the dean, Sir Harold Boldero, declared, "We are prepared to back youth at the Middlesex." After welcoming Professor Walls as the new professor of anatomy, Sir Harold turned to the increase in facilities in the clinical years at the school. They were grateful to their friends at the Central Middlesex Hospital, and in particular Dr. Joules, for an arrangement whereby students would go to that hospital for a portion of their clinical period. They were also beginning to develop their associated hospitals for teaching purposes—the Soho Hospital for Women, in gynaecology, and Harefield Sanatorium, for tuberculosis.

Mr. R. W. Gilliatt, as Senior Broderip Scholar, in a further and admirable response to the toast, referred to the ex-Servicemen who had returned to complete their training after the war; the first of these had qualified during the past year. Mr. D. H. Patey, in proposing the health of the chairman, mentioned that among those present was the chairman's daughter, herself a student at the hospital.

KING'S COLLEGE HOSPITAL

SIR LIONEL WHITBY ON THE ADVANCE OF MEDICINE

At the opening of the 121st winter session of King's College Hospital Medical School on September 29, with Mr. J. B. Hunter presiding, the scholarships and prizes were presented by Sir Lionel Whitby, regius professor of physic, University of Cambridge.

Sir LIONEL WHITBY said that King's College was one of the younger generation of great teaching hospitals, having been founded not in the eighteenth but in the nineteenth century. It was founded by churchmen, three years after University College, largely to counteract that seat of learning where no religious instruction was given. There had been three hospitals, two on the Strand site, and the present magnificent building on Denmark Hill, opened in 1913. At the time of the foundation of the hospital the practice of medicine was just about to pass from the empirical to the rational phase. Before that time there had been only one outstanding contribution to the control of disease—also a brilliant piece of empiricism—Edward Jenner's successful cross-immunization experiment with cowpox.

The council of the hospital was wise enough in 1877 to create an additional chair of clinical surgery and to invite Joseph Lister to join the staff. Nowadays there was no part of the body which could not be explored with complete freedom from the bogy of sepsis. From Lister's time until now there had been an epoch-making transition from the empirical to the rational, or from the pharmacopoeial to the specific. There had grown up an immense accumulation of knowledge of the habits of parasites and of the complex science of immunology. Not much more than 50 years ago most of the drugs in medicine were used—with much art and some skill and a certain measure of success—only for the alleviation of symptoms. There was little or no knowledge of their action on the primary cause of the disease. The advances in rational therapy had yielded a rich dividend.

It was remarkable to read the lives of men who had, so to speak, a foot in both eras. One such was his famous predecessor at Cambridge, Clifford Allbutt, of whom Sir Humphry Rolleston said that during his 89 years he witnessed changes in medicine which were never likely to be equalled. That, of course, was no longer true, for the speed of the advance had greatly quickened since Allbutt's death in 1925. Allbutt was born before the introduction of anaesthesia. He saw the development of bacteriology, immunology, antiseptic and aseptic surgery, the creation of the nursing profession,

astonishing progress in public health and preventive medicine, the discovery of *x* rays, radium, and vitamins, the beginnings of cardiology, biochemistry, endocrinology, and specialisms in many spheres.

The rapid evolution of medicine in this century had had a great impact upon its central figure, the patient. A man must now have many doctors and not just one, and because of the volume of ancillary examinations which were deemed necessary a serious illness was beyond the purse of the average person. This fact had hastened the institution of a State medical service, and in all civilized countries some form of subsidized service was developing. The British experiment had shown the fantastic cost of making everything free. In a case no more serious than pyrexia of unknown origin, which in due course might cure itself, the cost of establishing the diagnosis and determining whether the case was amenable to modern chemotherapy, and whether it was likely to be a menace to anyone else, was something like £50; while a case requiring thoracoplasty for tuberculosis might involve, before the job was completely finished, an expenditure of as much as £1,000. All were familiar with the formidable cost of such preparations as penicillin and streptomycin, yet in the interests of humanity these must not be withheld on economic grounds. It would obviously be a travesty of justice were such treatment available only to a few rich people.

The public had become aware of the notable advances in medicine. Not that the information given to them by the lay press was always accurate. He found himself being sometimes surprised by his own ignorance of the latest advances of medicine when these were mentioned to him by a lay friend who had skimmed an article in some publication or other. Indeed, the doctor who wished really to keep up to date would be well advised to subscribe, not only to the orthodox medical journals, but to the *Reader's Digest*, *Life*, and similar publications. (Laughter.)

The intervention of the State in medicine had been occasioned by war. The tremendous events of the last 50 years had forced the State first to interest itself in public health and then to extend its interest to the individual. But it was a remarkable fact that no sooner was the cure of one disease accomplished than another took its place. Moreover, in the enthusiasm of the sulphonamide era it was thought that such a disease as gonorrhoea had been brought under control, but now it was known that the organism was rapidly able to adapt itself to such drugs. The same thing might happen in due course with penicillin. Chronic disease, the degenerative processes which crippled and disabled in later life, and the activity of the malignant cell were not yet comprehended, much less controlled.

In conclusion Sir Lionel Whitby declared that individualism had done so much for medicine in the past that were it to be extinguished, either by State service or by regulations of any kind, or by too much insistence on plans and planning, then the future advances in medicine would never reach the high achievements of the past.

MEDICAL STUDENTS IN GREAT BRITAIN

In the two tables on this page the numbers of medical students in training during the last pre-war academic year (1938–9) have been compared with those in 1948–9. Table I shows the overall picture in Great Britain, and Table II deals with the medical schools of London University. In both tables clinical and preclinical students are considered together.

The rise in number of women medical students, as shown in these tables, is discussed in a leading article at p. 822.

TABLE I.—*Total Clinical and Preclinical Medical Students in Great Britain in the Academic Years 1938–9 and 1948–9*

	Men		Women		Total		Percentage Women	
	1938-9	1948-9	1938-9	1948-9	1938-9	1948-9	1938-9	1948-9
London:								
(1) Schools of University	4,513	4,096	551	888	5,064	4,984	10·9 / 100 } 11·5	17·8 / 85 } 18·9
(2) West London Hospital for Women*	—	12	38	68	38	80		
Universities in provinces and Wales	2,879	3,337	708	1,104	3,587	4,441	19·7	24·9
Scotland:								
(1) Universities	2,336	2,836†	567	871†	2,903	3,707†	19·5 / 4·8 } 14·8	23·5
(2) Extra-mural schools	1,309		66		1,375			
Totals	11,037	10,281	1,930	2,931	12,967	13,212	14·9	22·2

* The West London Hospital for Women no longer admits new undergraduate medical students.
† This figure includes returns from the Anderson College of Medicine and St. Mungo's College, both in Glasgow, and from the School of Medicine of the Royal College in Edinburgh. These schools were classified as extra-mural in 1938-9; and at that time over 40% of the undergraduate medical students at these schools were from foreign countries.

TABLE II.—*Total Clinical and Preclinical Medical Students in the Schools of London University in the Academic Years 1938–9 and 1948–9**

Medical School	Men		Women		Total		Percentage Women	
	1938-9	1948-9	1938-9	1948-9	1938-9	1948-9	1938-9	1948-9
Charing Cross Hospital	122	146	—	21	122	167	0	12·6

PREMATURE BABY UNIT

A unit for premature babies was opened on October 1 at the Obstetric Hospital, University College Hospital, London. The unit consists of two nurseries, each with six cots, and in addition an isolation nursery with two cots. One of the nurseries, called the "hot" nursery, is heated by electric wall-panels thermostatically controlled to 75° F. (23.9° C.). Here piped oxygen is available for each cot from a bank of oxygen cylinders outside the unit. The other, or cooler, nursery has the normal hospital heating, and the temperature will vary by a few degrees so that the babies can gradually become acclimatized. Babies under 4 lb. (1.8 kg.) in weight will be started in the "hot" nursery, and then, when they become able to control their own temperature, will be transferred to the other, while larger babies will be able to begin in the cooler nursery.

Some of the cots are fitted with a "perspex" lid, converting them into oxygen tents while affording the nurse a clear view of the child. One cot has an oxygen cylinder attached, and is for carrying the newborn babies from the delivery room. Between the two nurseries is the sister's duty room, where mothers who live near can come and feed their babies. There is also attached to the unit a milk-kitchen where foods are made up and sterilized. Breast-milk from the baby's mother will be used if possible, and in addition there is a breast-milk bank where the milk is stored in the frozen state. A coloured chart, marked for every half-hour of the twenty-four, indicates to the nurses the feeding times of all the babies.

The unit is intended to take not only babies born in the hospital but, up to about half its accommodation, babies born outside. Babies weighing less than 5 lb. (2.27 kg.) who are in need of special care which cannot be provided at home can be admitted by arrangement with the children's house-physician at University College Hospital. A specially constructed cot, with an oxygen cylinder, enables the baby to be brought by ambulance or car without need for any special attention to the atmosphere of the vehicle. A member of the premature-baby-unit staff will collect the baby by ambulance at any time of day or night from anywhere in the London area.

There are two other premature baby units in London, but this is the first to be constructed in a London undergraduate teaching hospital.

The physician responsible for the unit is Dr. Bernard Schlesinger, and the staff consists of a sister-in-charge and eight nurses, five day and three night. Sister E. M. Edwards achieved a record low mortality (8.1%) with an improvised premature baby nursery during the war. Of the babies born in the Obstetric Hospital about one in every sixteen is premature, and with the premature baby the danger of dying during the first month of life is twenty times greater than for the full-term baby, so that more than half the babies who die are premature, and die from causes directly related to prematurity. It is believed that this special care, with a trained staff available to handle and feed the babies, and the provision of extra warmth and oxygen, may result in halving the mortality.

KNOCKSHINNOCH COLLIERY DISASTER

The Scottish Secretary of the B.M.A. has received the following letter from the divisional medical officer of the National Coal Board in Scotland:

At last week's meeting of your Colliery Practitioners' Subcommittee I made some remarks about the excellent response the Knockshinnoch Castle Colliery disaster had elicited from the medical profession round about. Although we are writing to each doctor who helped us, I think it fitting that I should send you, as representing the medical profession in Scotland, a written appreciation of the doctors who helped.

The event at Knockshinnoch Castle Colliery, New Cumnock, created a potential or actual demand on doctors for the space of some 60 hours, and throughout that time we had a ready response not only from the local general practitioners but from the staff of the hospitals and from other doctors many miles away. This involved, in some cases, a stay of a couple of days at the colliery and a long spell underground—a stout effort for some who had no previous experience of mines.

I must say that although I expected willing help I was not quite prepared either for the number of helpers or for the extent of their help. Also worthy of note was the very smooth collaboration of all the doctors concerned. I assure you it is a great comfort to us, and must be to all our men, to know that in a crisis we can count on receiving such assistance.

I have not singled out any individuals, since any distinction, where all gave of their best, would be invidious, but I attach a full list of our helpers.

The Secretary of State for Scotland has also sent his thanks to the medical and nursing staff of Ballochmyle Hospital for the way they transported and treated 98 patients from the colliery.

Correspondence

A Secret Remedy for Cancer

SIR,—I am a week late in congratulating you upon your excellent leading article in the *Journal* of September 16 (p. 663). I do so now because my letter in response to an invitation from *Picture Post* to give them my opinion on their article was not published by them. This was not unexpected, as in it I observed that I had "rarely, in a long experience, known a reputable journal do such a great disservice to the community."—I am, etc.,

London, W.1. HORDER.

Distinction Awards

SIR,—Mr. R. S. Murley does Lord Moran less than justice in his comments in your issue of September 23, p. 726, on the meetings called by Lord Moran in the North-west Metropolitan Region to discuss the whole question of distinction awards. I am sure that this is only because Mr. Murley was not present at the meeting and is incompletely informed about what went on, since it seems fair to assume that the meetings were conducted on the same basis as one held in the South-eastern Metropolitan Region at which I personally was present. At this meeting it was made abundantly clear that Lord Moran, so far from delegating his responsibilities, was in fact putting in a tremendous amount of time and work in order to discharge those responsibilities to everybody's satisfaction. He intimated that, although the Distinction Awards Committee had an enormous amount of information available about consultants, it would be helpful if subcommittees elected in the various regions by the local consultants would give the Central Awards Committee their views on which consultants should become the recipients of distinction awards. He did not demand that a subcommittee should be formed, but hoped that it would be. Those of us present were not compelled to form the committee then and there, and we could have called further meetings to discuss it, or have carried out the election of the committee in any way which we saw fit. It seems, therefore, quite unfair to blame Lord Moran for his attempt to gain further information which might make the decisions on these distinction awards fairer than otherwise, and if Mr. Murley has any complaint of the manner of his own election to the local subcommittee, surely it should be addressed to his colleagues who attended the meeting and elected him?

While Mr. Murley may be on firmer ground when complaining of the shortness of the time allowed for these subcommittees to deliberate, he is on less firm ground in complaining that his subcommittee has to make "decisions of so great importance." In fact his committee is not being asked to make any decision at all, but is simply being asked for its opinion. It is being asked to provide one facet of evidence and not to allot the distinction awards; and it must surely be inferred that those at least of his colleagues who elected him must consider that Mr. Murley already has sufficient knowledge of his colleagues' ability and qualifications to be able to express an opinion on them. Viewed in this light, the length of time remaining for deliberation may not seem too short after all.

Mr. Murley further states that the consultants are entitled to ask for as just a method as possible of selection. At the meeting at which I was present, Lord Moran made it abundantly clear that the Central Distinction Awards Committee was making unusually exhaustive investigations in its efforts to make the selection fair, and that this request for the opinions of local subcommittees, albeit perhaps a little tardy, was only intended to round off the evidence so that so far as was humanly possible no one could feel that any claim of his to distinction had been overlooked.

On the question of the distastefulness of his task, Mr. Murley must, I think, have felt that it was distasteful to him largely because it is a new and unfamiliar task, but the principle of choice underlying this task is nothing new, and I have little doubt that Mr. Murley has on numerous occasions sat in judgment without a qualm upon, admittedly, a junior colleague when deciding his fitness for an appointment.

This brings us, I think, to the whole kernel of the acrid discussion which has gone on about distinction awards. Mr. Murley says that the only true reward for distinction is distinction, but it would be ignoring the facts of the situation to pretend that a certain, shall we say, financial improvement was not prone to accompany distinction in the old days, and it would be ignoring human nature to pretend that this fact did not influence those who chose medicine as a profession. I, no less than Mr. Murley, have viewed the whole question of distinction awards with distaste and misgivings, but in the light of the above consideration it seems fair to crystallize the problem down to one simple question: Is it worse to accept a financial award for distinction when it is judged by one's own colleagues on the fairest basis that they can devise, than to accept that award piecemeal when it is based upon the estimate patients have of one and which they show by their willingness to pay private fees? Quite honestly I cannot see that there is very much in it. On the one hand, patients may be somewhat gulled by plausible and smooth-mannered doctors; on the other, Central Awards Committees, no matter how conscientious, are very likely to make errors of judgment and overlook deserving individuals. Looking at it from this point of view, it was with some relief that I heard Lord Moran say that the whole point of the system of distinction awards was to preserve an incentive by which to draw able men into the profession when, as it seemed, the rewards of private practice are likely steadily to dwindle.

If there is any substance in the argument that the awards are to take the place of the financial rewards of private practice, it is obvious that hard facts make it necessary that the system of awards shall be started as soon as possible, and it should be remembered that we are, after all, free at any time to change and modify the system of selection and the size of the awards in any way that we think right. We are even free, as a magnificent gesture of renunciation, to hand the money all back again.—I am, etc.,

Shorne, near Gravesend. O. J. VAUGHAN-JACKSON.

SIR,—Dr. R. S. Murley's timely letter (September 23, p. 726) on this subject underlines the profound disquiet existing throughout the consulting side of the profession. Even more disturbing is the disclosure of the almost complete apathy shown towards the subject as a whole when four consultants of the forty entitled to attend turned up at the local meeting called by Lord Moran. Whenever this topic has arisen at any hospital committee meeting I have attended during the past fifteen months the same lack of interest, coupled with ironic expressions of derision, has been evinced. The root of this attitude lies in the generally held conviction that the non-teaching hospital men have been sold out to their teaching hospital colleagues as a deliberate act of "Divide and rule" by the Minister, a feeling which is emphasized whenever the activities of the selection boards for new appointments in our area come up for discussion.

It is conceded by most of us that inevitably the Service will become organized on lines similar to those existing in the medical side of the armed Forces, and that it is more tactful to restrain public expressions of criticism where these seem unlikely to influence the trend of events. The dry rot has set in. It is definitely not wise to become an overt malcontent.

Dr. Murley invites attention to the "indecent haste" characterizing Lord Moran's present activities. His area was given four weeks to organize the required form of assistance to the awards committee, which "has to complete its work by the middle of October." My hospital group was invited to meet Lord Moran for the same purpose on October 5! Mid-October was then less than ten days off! Would any self-respecting consultant in this area feel it worth the time involved in allocating an evening for so nebulous a purpose; or even worth while putting pen to paper to criticize so patent a device to clothe exclusive and arbitrary decisions with the more pleasing robes of democratic participation and acquiescence? Last August the awards committee made use of a similar strategy in the S.W. regional area when they arbitrarily excluded all those consultants appointed after appeal regrading from participation in routine merit award consideration, the reason given being

that there had been "insufficient time available to their office staff" to include the recently arrived new names on their typewritten duplicated list. They found two months insufficient for this purpose. No one in the area bothered to protest.

It is obvious that the merit awards committee can do what it likes, that it likes doing it, and that it need apprehend no spirited organized attempt to question its findings, or the details upon which such findings are based in any individual case. The Minister will continue to expect two men doing exactly the same type of clinical work to accept utterly different rates of remuneration side by side in brotherly amity. One will secure the "rate for the job," the other "the distinction of his own distinction."

The worst feature of the matter is that the awards are for life and pensionable. Surely at the outset of a new and necessarily experimental State medical scheme its organizers ought not to saddle the country with irrevocable financial commitments of this controversial type and magnitude. If the awards are to be made at all, they should be for maximum periods of three to five years, non-pensionable, renewable by further re-election, and coupled with a system of outright lump sum awards from time to time (in the manner of the Nobel prizes) for unquestioned contributions to the advance of medical science. —I am, etc.,

London, W.1. LIONEL M. GREEN.

Improving the Medical Curriculum

SIR,—I wish to congratulate you, first of all, on an exceedingly interesting educational number of the *Journal* (August 26), which is well worth and demands the attention of all those interested in medical education. Having as long ago as 1933 advocated a special course of education for those students intending to enter general practice, I was particularly interested in those articles dealing with that side of medicine. I have in the past advocated four things which I thought would improve the work of the general practitioner: the development of treatment centres, now known as rheumatic clinics; the provision of centres for clinical pathology, *x*-ray investigations, and physiotherapy for the general practitioner; the association of general practitioners with the work of hospitals; a special pre-graduate course for general practitioners. The first rheumatic clinic was developed at my suggestion by the Kensington division of the London County branch of the B.R.C.S. as long ago as 1922. There seems to be general agreement about my second and third points, and somewhat unexpectedly I now find support for my fourth proposition.

I feel that I somewhat light-heartedly suggested a special course of instruction for students intending to engage in general practice; the subject is obviously a very complicated one, but I still think I was right. But we must first decide what form this special education is to take. I do not feel that wholesale condemnation of previous methods such as characterizes Dr. Donald Johnson's article (p. 493) will advance us much. Unless medical education deteriorated much from the standards of 25 years before Dr. Johnson's time I cannot think many of his criticisms are or were justified. Of course our ideas of education have evolved and are still evolving, but I think much of the student's failure to benefit from instruction lies at the student's door. I am sure much of my failure could be attributed to myself.

Still considerable improvements in medical education are attainable, but we must make up our minds what these should be. It has been suggested that a general practitioner should take part in the teaching. Probably a sound suggestion, but what is he or she to teach? So far the role assigned to him seems to be little more than instructor in the necessary deportment towards patient and relatives. The Syracuse Medical School (U.S.A.) makes the student take an interest in one patient, not only studying him in hospital, but investigating his home surroundings and conditions. The general-practitioner teacher could give much useful instruction here.

I am no educationist, but, stepping in where angels fear to tread, I suggested in a memorandum to the conference of representatives of the Universities, Royal Colleges, and the Society of Apothecaries, met to consider the medical curriculum, that the prospective general practitioner should be taught thoroughly the common diseases, relying on the consultant for the rarer diseases, yet having fuller instruction in such of these latter diseases as throw light on organic function—e.g., osteitis fibrosa cystica due to overfunctioning of those little-understood parathyroid glands. With his curriculum thus modified the student should receive fuller instruction in such subjects as dietetics, balneology and other forms of physical treatment, psychology, and industrial medicine.

These are my views, but the whole subject is beset with difficulties. Nevertheless it behoves us to decide what alterations, if any, are desirable.—I am, etc.,

London, W.8. HAROLD H. SANGUINETTI.

"Dramamine" and Sea-sickness

SIR,—Your recent observations (*Journal*, September 23, p. 719) again champion hyoscine against the antihistamine drugs in the treatment of motion sickness. Recently, I took an appointment as a ship surgeon for a short period. I tried out the routine suggested by Dr. F. K. Beaumont in a letter to the *Journal* (1949), **2**, 1473. This was to take an "antergan" 100 mg. tablet at night and "phenergan" 25 mg. tablets t.d.s. I was very much impressed with the results obtained using these antihistamine drugs in treating sea-sickness among the passengers. Also for the first time I avoided being sea-sick myself.

It seems to be difficult to produce statistical evidence that these drugs are more efficacious than hyoscine, but from my own observations I feel very convinced that the proof of this pudding is in the eating. It would be interesting to know if Dr. Beaumont, who, I believe, is ship surgeon in the *Queen Elizabeth*, still prefers the antihistamines to hyoscine. —I am, etc.,

London, W.2. M. F. BETHELL.

SIR,—As an off-shore cruising addict and a thoroughly bad sailor I have for many years tried the current remedies for sea-sickness, from "mothersil" to hyoscine, with and without amphetamine. The trouble with all I have previously used has been that, taken over a period of days, the side-effects—dryness, anorexia, and loss of visual accommodation—have been almost as trying as the original complaint. In other words they have been effective for short periods but not for long.

This summer, however, over a period of several days I used "dramamine" in conditions which would ordinarily have prostrated me, and found it to be, for me at least, the answer to a sailor's prayer. I say "prostrated" advisedly—my variety of the complaint being that while horizontal I am perfectly comfortable, but when vertical I am anything but. With dramamine I could eat normally, stand my watches without undue somnolence, and, except for slight but not unpleasant dryness, felt no side-effects at all.

There are probably many individual types of sea-sickness, as there are of most allergic troubles, and the remark at the end of your annotation on Professor J. H. Burn's interesting article (September 23, p. 691), that hyoscine is best, may hold for the group of such troubles taken as a whole, but in my own case it certainly does not.—I am, etc.,

Beccles, Suffolk. C. GRANTHAM-HILL.

Antihistaminics and Nocturnal Frequency

SIR,—After reading Professor J. H. Burn's interesting paper on the pharmacological action of antihistamine compounds in the *Journal* (September 23, p. 691), I am prompted to record that I have found these substances to be effective in relieving some patients suffering from nocturnal frequency of micturition, which is usually due to prostatic enlargement. My attention was first drawn to this therapeutic use of antihistamine drugs by my colleague, Mr. Ian Robin. He had occasion to prescribe "anthisan" to a middle-aged man suffering from rhinitis; his patient noticed that after taking this drug not only were the symptoms of rhinitis relieved, but his sleep was no longer disturbed by a troublesome frequency of micturition from which he also suffered.

Subsequently I have prescribed "benadryl" to six unselected patients suffering from frequent nocturia; three derived relief. In one of the latter cases the patient after taking the drug declined to undergo an operation for prostatectomy to which he had previously agreed, for the frequency of micturition had greatly diminished, seemingly as a result of medication. Admittedly, one cannot draw any definite conclusions from such few cases, but I hope after a more extensive and carefully controlled trial with antihistamine substances that these compounds will be found to be useful in relieving the troublesome bladder symptom of nocturnal frequency.—I am, etc.,

London, W.1. VALENTINE SWAIN.

Infection by Syringe

SIR,—I was greatly interested in the paper by Dr. R. J. Evans and Professor E. T. C. Spooner (July 22, p. 185), your annotation on the subject (p. 204), and the three subsequent letters from Sir Alexander Fleming and Drs. G. Bousfield and R. R. Hughes (August 5, pp. 365 and 366). There are two points arising out of this paper and correspondence which I think merit further attention. The first is the renewed support given to the use of hot oil as a sterilizing agent by Sir Alexander Fleming, since there has been a wide fluctuation of opinion on the value of this method of sterilization in recent years. In 1941 an M.R.C. committee advocated the sterilization of syringes by drawing up oil at a temperature of 120°–130° C. with inversion of the syringe. It was stated that 160° C. should not be exceeded. In 1940, however, Bigger and others had written, "We have proved experimentally that the drawing up of boiling oil into the barrel of a syringe fails to sterilize it if sporing organisms are present even in small numbers," and in 1945 a special M.R.C. committee condemned the use of hot oil for syringe sterilization, stating that "even vegetative organisms dried on the glass are not uniformly destroyed." In 1946 Rogers (as Sir Alexander has pointed out) again recommended the method and put forward experimental evidence of the efficiency of oil at 120°–140° C.

I became personally interested in this question, since I had been in the habit of using hot oil for resterilization of syringes between injections until the report of Bigger and his co-workers came to my notice. In 1945, therefore, I carried out a series of experiments in an attempt to evolve a method by which hot-oil sterilization could be made effective.

My experiments were interrupted and showed no promise of success, so the work was never published. Since, however, it supports the conclusions of the special M.R.C. committee and it appears contrary to the subsequently published findings of Rogers, I propose to summarize it briefly here before attempting to reconcile these opposing views.

My approach to the problem was influenced by two considerations: the first that heating by hot oil is a form of application of *dry* heat, the second that any contaminant gaining admission to a syringe while in use will be in a watery environment. In this connexion it should be noted that it was "vegetative organisms *dried on the glass*" (my italics) that were stated to have survived the experiments carried out by the members of the special M.R.C. committee, and that in his letter Sir Alexander Fleming refers to *the boiling of the water in the needle* as the means of destruction of pathogens in the latter when it is dipped in oil at 150°–160° C. for 10 seconds. I therefore carried out parallel experiments on wet-contaminated and dry-contaminated syringes. In other tests 0.1–0.2 ml. of water was introduced into the contaminated syringes before hot oil was drawn up. The intention in these last tests was that the water should be boiled by the entering oil and the steam so produced become the effective bactericidal agent.

Experiments were carried out on these lines at various temperatures and for different periods of exposure. The number of times oil was admitted and expelled was varied, and tests were made with and without inversion of the syringe. The contaminant used was *Staph. pyogenes*, and it was proposed to employ *B. subtilis* later if success was achieved against the former species. *B. subtilis* was in fact never used, however, as, even with oil temperatures up to 170° C. and moisture present, all staphylococci in the syringe were not killed, and cultures of saline and bicarbonate solutions used to wash out the treated syringes were positive.

In order to reconcile these differences it is, I suggest, necessary to give separate consideration to *primary* and *secondary* contamination and to the requirements for sterilization of articles exposed to either. Primary contamination might be defined as the type of contamination liable to follow exposure to general internal and external contact with bacteria or other infective agents. The term secondary contamination could suitably be applied to the entry of such agents into, or via, the needle of a sterile syringe, following its use for making an injection. Primary sterilization to overcome primary contamination must therefore be capable of destroying organisms on the side of the piston and on that part of the inner surface of the upper end of the barrel of the syringe which remains in contact with the piston even when it is withdrawn to the limit possible while in use. These areas cannot come into direct contact with any fluid drawn up into the syringe. Their sterilization by means of the heat of such a fluid must be brought about indirectly through the piston. For this to be effective is a practical impossibility. A metal piston heated to such a degree will become jammed—or crack the glass barrel. A glass plunger would never reach an adequate temperature throughout owing to poor conductivity. It follows that primary sterilization by the drawing up of hot oil into an assembled syringe must be unreliable.

In the case of secondary sterilization after injection of the contents of a previously sterilized syringe, however, conditions are very different. Here any secondary contamination which may have occurred will be limited to the needle or distal end of the barrel of the syringe. Organisms will be suspended in fluid. Contaminants will thus come into immediate close contact with the hot oil introduced, so that their destruction when the temperature of the latter is adequate should be ensured.

The different results obtained by Rogers and myself may be subject to explanation on such lines. In my experiments contamination of the side of the piston and upper part of the interior of the barrel was ensured. In Rogers's first three observations contamination appears to have been produced by aspiration. Whether aspiration contamination is of primary or secondary type (as defined above) might well depend on the degree to which the interior of the syringe can be made wet, and this in turn be limited by the presence of a film of oil. It appears that Rogers maintains his syringes in an oily state. It is therefore suggested that the nature of contamination produced and adequately dealt with in his first experiments resembled secondary contamination in that the inaccessible parts of the syringe remained bacteria-free. When he used a method involving frank primary contamination, it seems that the separate parts of the syringe were treated by immersion in the oil.

The second point which seemed to me to call for attention concerns the distance up the needle lumen which may be contaminated before its removal from the syringe, following injection of an infected tissue or cavity. If, as seems unlikely, however, the greater length of the needle is internally contaminated failure of sterilization by merely dipping the needle in hot oil (Sir A. Fleming) or flaming a platinum one (annotation) might possibly occur, since heating of the distal portion of the infected column of fluid might drive the upper portion still containing viable organisms upwards towards, or into, the syringe. The upper limit of internal needle contamination might be investigated by contaminating needles on the lines described by Dr. Evans and Professor Spooner, cutting off with a sterile cutter various lengths of different needles while still in place on the syringes, injecting the sterile contents of the syringe through the needle butt into a suitable medium or animal, and noting the length of needle which has to be removed for the syringe contents passing through the butt to remain sterile.

To avoid the complicating factor of external contamination the needle might be treated by the external application of a volatile disinfectant, insoluble in water and active against the contaminant (e.g., ether for coliform bacilli). The needle might if necessary be sealed before such treatment with, for example, sterile paraffin.

In conclusion: The methods suggested by your correspondents for control of backward contamination can be experimentally tested. It would, I suggest, be most valuable if this were done by experiments on the lines of those described by Dr. Evans

and Professor Spooner and preferably by them. Only then can a final judgment be given on the best method of preventing such backward contamination of a syringe and its contents.—I am, etc.,

Fayid, M.E.L.F. G. T. L. Archer, Colonel, R.A.M.C.

Sir,—With reference to the article by Drs. R. J. Evans and E. T. C. Spooner on the transfer of infection by syringes during mass inoculation (*Journal*, July 22, p. 185), I wonder if the method adopted by me about 20 years ago during a cholera epidemic in Bombay might overcome the difficulty of the infected needle. After each inoculation two or three drops of the vaccine were expelled into a kidney-tray and rejected, and the needle was dipped at once into hot "vaseline" kept over a bunsen flame and maintained at between 160° and 170° C. The vaseline tends to make the needle puncture easier and less painful.

Changing the needle after each injection will be a surer way of ensuring sterility, but when one had to inoculate nearly 300 medical students and an equal number of nurses in the course of an afternoon, besides the routine laboratory work, the time factor was a consideration.—I am, etc.,

Bombay. P. A. Dalal.

Mortality in Bleeding Peptic Ulcer

Sir,—The discrepancies in the mortality rates reported from Newcastle and Aberdeen (see *Journal*, July 15, pp. 133, 138, 153) are interesting and important. Is the low mortality at Newcastle representative for the district, or is it exceptional to Dr. A. G. Ogilvie's wards? In view of the comments of a previous correspondent I will not present a burden of statistics, but I have looked up the death rate from peptic ulcer in Aberdeen and in Newcastle in the Annual Reports published by the Registrar-General and it is clear that there is little between the two cities. It is, therefore, unlikely that Dr. Ogilvie's experience is representative of Newcastle as a whole. I think the excellence of his figures is due to two reasons. First, while not professing to be particularly interested in gastroenterology, he has been particularly vigilant of emergencies admitted to his wards—a time-consuming task which nevertheless pays good dividends with patients with bleeding ulcer, particularly when under 70. Secondly, he has been distinctly lucky in having so few admissions over 70. In the Central Middlesex Hospital 20% of my admissions with haematemesis and melaena are over 70, and in this age group there is a mortality of at least 30%, a heavy statistical millstone. Ogilvie and Spencer had only 2% of patients over 70, and it is likely that the old decrepit bleeders, whom we know so well in this district hospital, do not find their way to his teaching wards.

Haematemesis and melaena form an appreciable part of the emergency work of all hospitals, and the varying mortality figures reported suggest that there may still be scope for improvement in management. At St. Mark's Hospital there is an admirable custom of reviewing the work of the hospital every three to six months, and the meeting is attended by all members of the consulting staff. It would be entirely feasible for members of the staffs of hospitals to review certain groups of admissions, such as haematemesis, at intervals and agree on lines of treatment, particularly in regard to indications for operation. Moreover, periodic review of cases might stimulate extra interest and vigilance for these patients—so necessary in preventing the patient from reaching anoxaemic levels, and so necessary for selecting the right case for operation without undue delay. Such reviews might help to reduce the mortality of mass hospital statistics to the lower figures to be found among series reported by interested individuals.—I am, etc.,

London, N.W.10. F. Avery Jones.

Amplifying Heart Sounds

Sir,—I read with interest and surprise the annotation (*Journal*, September 2, p. 567) on phonocardiography. The reproduction of the heart sounds and murmurs through a loudspeaker, though practised by some workers, can never be really satisfactory. The frequency response of a loudspeaker is far from ideal. The high frequency components of the sounds tend to be projected forward in a narrow beam and the low frequency ones tend to escape sidewards unless special precautions are adopted. Those near the sound reproducer hear the sounds as of a quality and intensity different from those further away. The quality of the sounds as perceived by the ear is modified by the physiology of hearing, as a study of Fletcher and Munson's normal threshold curves of audibility shows. The reverberation effects due to the acoustics of the room further complicate matters. Unless special precautions are taken the microphone picks up the amplified sounds coming from the loudspeaker and these are further amplified. This means that acoustic feedback is set up and the amplified sounds tend to be further distorted. As a matter of fact they may eventually be replaced by a howl whose pitch depends upon the characteristics of the microphone, the sound amplifier, the loudspeaker, and the distance between the loudspeaker and the microphone. It is no wonder that the average auscultator rejects these distorted sounds as being a faithful reproduction. The ear is very tolerant to bad reproduction, but there is a limit to what even it can stand.

It is rather unfortunate that the annotation suggested that a loudspeaker may be used and did not mention that multiple moving-coil headphones are the method of choice for teaching purposes. The degree of faithful reproduction obtained by this method is greater than by any other. There is the added advantage that the patient is not upset by hearing his own amplified heart sounds. It is possible by adjusting a frequency control to enable the auscultator to obtain the degree of pitch and quality of the acoustic stethoscope, but from a purely scientific point of view it would appear to be fundamentally unsound to deteriorate a method which is capable of improved reproduction to the level of a stethoscope which was originally invented a hundred years ago. It seems that the auscultator should learn to hear the heart sounds truly, and that the method should not be debased to the level of his previous experience. Tone controls can be justifiably used to accentuate wanted sounds or murmurs, but it is very desirable that the auscultator should know the exact physical effects of what he is doing. The loudness of the sounds as heard through the headphones can be governed by a tone-compensated gain-control which helps to correct certain deficiencies in the human hearing.

I note that the annotation states that a loudspeaker may replace the recording apparatus of the phonocardiograph. I would suggest that the words "may replace" should not have been used but rather the words "may be used with." It is highly desirable that a subjective method like auscultation should be simultaneously correlated with an objective method such as phonocardiography.

The annotation states that it is very difficult to obtain faithful reproduction by this or other mechanical devices, and indeed, however faithful the reproduction, the method seems to be of very limited value. This, I would suggest, is untrue. It is also untrue that there can be no effective substitute for the practice of the close personal application of the acoustic stethoscope. Since the acoustic stethoscope is nothing more than a hearing-aid, and an obsolete form at that, I suggest that it should be replaced by a properly designed electronic stethoscope. It is also desirable that the auscultator should have his audiogram done and that the electronic stethoscope be suitably adjusted to compensate for any defects in his hearing.

The best method is the one introduced by myself, which incorporates a double-beam cathode-ray oscilloscope with a fluorescent screen of long afterglow. The method permits the direct, instantaneous, and constant viewing of two phenomena such as the phonocardiogram and electrocardiogram, the phonocardiogram and electrical-sphygmogram, etc., without the necessity of photographic registration and consequent delay in developing film. At the same time the heart sounds can be heard through moving-coil headphones by one or many auscultators. The logarithmic, stethoscopic, and linear phonocardiograms are easily recorded. It is possible with this method for a group of students to hear and see the sounds produced by the heart, including those not audible to the human ear with the ordinary stethoscope, as well as the sounds and murmurs reasonably amplified which he should be able to hear with the simple stethoscope. At the same time they give visible evidence of the correlation of these sounds with the various phases of the cardiac cycle. The simultaneous seeing and hearing of the same phenomena by the teacher and student is an advantage, as the student's immediate attention can be drawn to the feature commented upon by the teacher. The traces on the long afterglow screen provide identifying characteristics of the murmurs and sounds—so that the auscultator will know for what to listen. The auscultator associates the traces with their sounds and quickly recognizes the sounds within his own particular auditory limits by hearing alone. Not the least advantage is the saving of the instructor's time and the patient's strength.

It is necessary for the advancement of phonocardiography that it should develop in a favourable climate of opinion. Manufacturers, physicists, and medical research workers will be chary of producing suitable instruments if the view expressed in the annotation is typical of the reaction of the profession to these new advances.—I am, etc.,

Johann Mikulicz-Radecki: A Reply

Sir,—Sir Gordon Gordon-Taylor was quite justified in referring to Johann von Mikulicz-Radecki as a German surgeon rather than a Polish patriot as Dr. Galewski does (*Journal*, September 9, p. 630).

Johannes von Mikulicz-Radecki was born in Czernowitz on May 18, 1850, which was at that time the capital of the Austrian county Bukovina and a German-speaking city. Hence a Rumanian chauvinist might claim Mikulicz-Radecki as a Rumanian. His father was born in Sniatyn, which is in Eastern Galicia, and since this region is now under Russian domination the Russians will probably be delighted to claim Mikulicz-Radecki as a Russian surgeon. Some, however, regard Mikulicz-Radecki, because of his origin, as a Ukrainian.

All this meant very little at a time when these regions belonged to Austria, and it may be claimed that Mikulicz-Radecki was a typical Austrian, not only because of his origin and the civilization to which he undoubtedly belonged, but also because of his own personal character. He was not affected by nationalism and nationalistic politics, and was deeply interested in music, which earned him the first interest of Billroth, his Viennese teacher in surgery. Furthermore, Mikulicz-Radecki's father was an Imperial Councillor, and this title would have never been conferred or accepted if he had been a rebel, which Dr. Galewski claims him to have been. It is of interest that at that time the Austrian Empire maintained two Polish universities, whereas neither in the German nor in the Russian part of Poland was any such university in existence. Furthermore, Mikulicz-Radecki was educated exclusively in German-speaking schools although there were numerous Polish-speaking schools at his disposal in Austria.

After Mikulicz-Radecki had graduated he was appointed by Billroth and quickly rose to be his second assistant, next to Wölfler. Soon afterwards he received the lectorship of the Viennese medical faculty and the title of *Dozent* was conferred on him. This did not involve his leaving the faculty; on the contrary, he would have lost the title if he had left the faculty. Furthermore, he was appointed director of the surgical department of the Viennese Poliklinik. The professorship in Graz was not withheld because he was a Polish national but because Wölfler was his senior. It is of interest that in Austria even a Pole could become a prime minister (this actually happened), and there were a number of Polish cabinet ministers quite apart from numerous high officials both in the civil service and at Court.

When Mikulicz-Radecki was offered the chair at Cracow he was quite embarrassed because did not have sufficient command of the Polish language. He had to acquire it. He was even regarded as a stranger in Cracow for some time, and not until later did he receive the public recognition which was intended to prevent him from accepting an invitation to Königsberg, in Prussia. Actually Mikulicz-Radecki went gladly to Germany, where he had much wider opportunities for work. He was later on invited to Breslau from Königsberg, and at Breslau his clinic was so well endowed that he refused a subsequent invitation to become Gussenbauer's successor in Vienna. Mikulicz-Radecki developed a carcinoma while living in Breslau and he died on June 5, 1905. In view of his lifelong teaching in German-speaking universities in Vienna, Königsberg, and Breslau, and because of his membership of the Deutsche Gesellschaft für Chirurgie, he may be regarded as a German surgeon just as much as the Swiss Kocher or the Austrian Finsterer. These facts can be found in the *Wien. klin. Wschr.*, 1905, **18**, 67, *Zbl. Chir.*, 1905, **32**, No. 26, and in textbooks on the history of medicine.—I am, etc.,

London, W.1. Albert W. Bauer.

Infection from the Bite of a Bear

Sir,—Human infections with organisms of the *Pasteurella* group occurring in this country are perhaps sufficiently rare to merit recording the following case.

A man aged 41, an animal-trainer, was admitted to the County Hospital, Hereford, on September 29, 1948, suffering from wounds to his right hand caused by the bite of a bear three days previously. Lacerations were present on both palmar and dorsal surfaces and had been previously sutured. The hand was swollen and the wound on the dorsum was discharging. The temperature was 100.9° F. pulse 88, and respiration 20 per minute. No lymphangitis or adenitis was present. Sutures on the dorsum were removed and treatment commenced with penicillin, 50,000 units three-hourly by injection; sulphathiazole 2 g. followed by 1 g. four-hourly was also given for 48 hours.

A swab taken from the wound on admission showed, in the direct film, pus with Gram-positive cocci and occasional Gram-negative short bacilli. Cultures, on blood agar plates, gave a profuse growth of alpha-haemolytic streptococci and a Gram-negative cocco-bacillus, both sensitive to penicillin (by paper disk method).

The wound continued to discharge. A further swab taken on October 8 showed, in the direct film, pus with a few Gram-positive cocci and small Gram-negative cocci and bacilli. Cultures yielded a pure growth of a Gram-negative cocco-bacillus, sensitive to penicillin. In spite of continued penicillin, the wound was slow to heal and was twice explored and drained (on October 20 and November 4). A further swab taken on October 30 yielded *Staphylococcus pyogenes* insensitive to penicillin. Penicillin was then discontinued and sulphadiazine given until November 12. By November 18 the wound was healed and finger movements good apart from some difficulty in opposing the little finger to the thumb.

The further investigation of the organism twice isolated from the wound showed the following characters. A 24-hour culture on blood agar yielded flat, 2 mm. diameter, shiny, translucent, convex, non-haemolytic colonies, under both aerobic and anaerobic conditions. Films from this showed a small Gram-negative cocco-bacillus with filaments up to 10-15 μ. In broth cultures a turbidity with a thick deposit was produced. Growth was poor on nutrient agar and slow in peptone water. Fermentation reactions: acid in glucose, mannite, sucrose, xylose, slight in maltose, no change in lactose, litmus milk, or salicin. No liquefaction of gelatin or serum was produced. The organism was non-motile and produced indole in peptone water. Mice inoculated with a suspension of a 24-hour Loeffler slope culture were unaffected.

The organism appeared, therefore, to be an avirulent strain of *Pasteurella septica*. Group II,[1] belonging to the group of organisms causing pasteurellosis or haemorrhagic septicaemia of fowls and mammals. Previous cases have been described following cat and dog bites,[2] some being complicated by osteomyelitis. Occasional cases have developed pleurisy or meningitis. Organisms of this group are said to be widely distributed,

being frequently found in the upper air passages of normal cattle, horses, swine, sheep, dogs, and cats, and less frequently in the intestinal tract. It is somewhat surprising, therefore, that they are not more frequently found in wounds from animal bites.

I am indebted to Dr. Pat Brown, medical superintendent of the County Hospital, Hereford, for permission to use the case notes, and to Dr. M. E. Morgan Thomas, of the Central Public Health Laboratory, who performed the animal inoculations, for help in identification of the organism.

—I am, etc.,

Hereford. W. H. J. Baker.

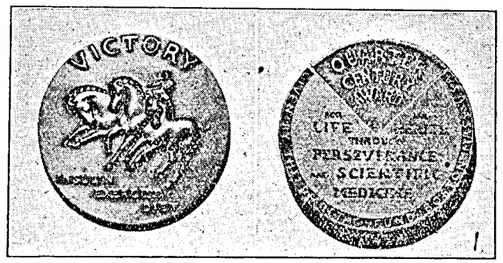
Preventing Wastage of Stored Blood

Sir,—It is obviously desirable to eliminate avoidable wastage of stored blood. In consequence of the spoiling of bottles of whole blood due to refrigeration faults we decided to install refrigerator alarm systems in a group of general hospitals after consultation with the regional blood transfusion service. The basic idea is by no means new, but the system does not appear to be widely used. The electrical alarm system is so arranged that any potentially dangerous deviation from normal storage temperature causes a bell to ring continuously in the porter's lodge. The alarm signal can be stopped only by operating a switch on the refrigerator. Out of normal laboratory hours, one of the previously instructed porters on duty deals with the fault if he is able. If not, he consults a member of the hospital blood transfusion laboratory, who takes appropriate action. A common fault is simply the failure to close refrigerator doors after the removal of blood. The alarm systems have cost approximately £70, but already over the past few months we have probably saved 200 bottles of blood.—I am, etc.,

Sheffield. E. K. Blackburn.



Diabetes without Vascular Disorder after 25 Years

Sir,—On reading the letter concerning vascular changes in diabetes by Dr. G. M. Wauchope in the *British Medical Journal* (August 5, p. 368) I am impressed by her careful statements about a persistent high blood sugar and the relation of diabetes to vascular changes. It is important to emphasize that a persistent high blood sugar means that a harmful and disturbed condition of metabolism is present in the body cells and apparently that the cells particularly concerned in the structure of the arteries, arterioles, and capillaries are vulnerable to this disturbed metabolism.

At the annual meeting of the American Diabetes Association held at San Francisco on June 24, 1950, Dr. E. T. Bell, of Minneapolis, compared the pathology of 1,200 diabetic patients at necropsy with the pathology of 49,000 non-diabetic patients examined in the last 30 years in the pathological laboratory of the University of Minnesota. He pointed out the extraordinary frequency of arteriosclerotic lesions in the coronary arteries, the legs, and the kidneys in diabetics, especially when the diabetes was of long duration. He noted that arteriolar disease of advanced degree illustrated by the Kimmelstiehl-Wilson lesions is 100 times as common in diabetics as in non-diabetics.

In an analysis of 250 young diabetic patients by H. F. Root, R. H. Sinden, and R. Zanca (*Amer. J. digest. Dis.*, 1950, **17**, 179) we have summarized the results of careful *x*-ray examinations of these young patients after having diabetes 10 to 29 years. Few escaped some evidence of calcification or some retinal haemorrhages. Nevertheless we were able to show that young diabetic patients whose diabetes began under 30 years of age could be divided into two groups at the end of 20 years. Those who had practised fair control of diabetes showed retinal haemorrhages in only 18% of the series, whereas those whose diabetic control had been grossly irregular in spite of taking insulin showed retinal haemorrhages in 85% of the group.

A Quarter-century Victory Medal (illustrated below) is now offered by the Diabetes Fund (chairman, advisory committee, Dr. Elliott P. Joslin) at the Boston Safe Deposit and Trust Company in Boston to any diabetic patient who, having had proved diabetes for 25 years, is still free from *x*-ray evidence of calcified arteries, retinitis, albuminuria, hypertension, or other degenerative changes. Already 20 patients have won this medal. It would

be desirable for anyone who sees many diabetic patients living for more than 25 years without vascular complications to provide *x*-ray and chemical evidence of freedom from such changes in order that such a patient might receive the Victory Medal which is to be deposited in your editorial office.

One of the Quarter-century Victory Medals is being sent in the hope that you will be kind enough to give it to any diabetic patient proved to have true diabetes mellitus for more than 25 years who at the end of that time shows roentgenograms of the legs, the pelvis, and a lateral film of the abdominal aorta to be free from calcification, and who has no albuminuria, hypertension, retinitis, or other degenerative disease.—I am, etc.,

New England Deaconess Hospital, Boston, Massachusetts. Howard F. Root.

*** The kind offer of a Victory Medal referred to by Dr. Howard F. Root is discussed in an annotation at p. 827.—Ed., *B.M.J.*

POINTS FROM LETTERS

The Roots of All Evil

Dr. A. Lewis (London, W.9) writes: Your correspondents, Drs. Lennox Johnston and F. C. Morgan (September 9, p. 630) would be far less likely to find themselves in a minority crusade if they were a little less sweeping in their assertions. Few doctors could fail to join them in a campaign against *excessive* smoking, nor could many fail to agree that the inhalation of tobacco smoke is unlikely to do good to any kind of cough whatever its aetiology. But how far are Drs. Johnston and Morgan justified in announcing that failure to get rid of tobacco is probably the main cause of failure to get rid of tuberculosis? The pathogenicity, infectivity, and chronicity of tuberculosis depend on several factors, and the extent to which these may be affected by smoking may not be so great as they would have us believe. . . . Not satisfied with this, Drs. Johnston and Morgan go on to argue that, because of its bad effect on tuberculosis (which most of us admit) and because of other ill effects of excessive smoking, *all* tobacco smoking could (and should) be abolished to the advantage of the community. Perhaps it could. But it is only one of the so-called "evils" with which a civilized community indulges itself. I feel, for instance, that a strong case could be made against tea. . . . I have no doubt that Drs. Johnston and Morgan could if they tried bring a good case on a sound scientific basis for the abolition of kissing. But if they charged all who failed to join them with promiscuous lasciviousness they could hardly be surprised if their accusations were met with ribald cries of "Whack ho!". . . Until Drs. Johnston and Morgan can show that a little of what I fancy does me harm I hope the world will still find me willing to appreciate anything from a pipe and a glass of beer to a Havana cigar and a vintage brandy.

Congenital Malformation and Disease

Dr. Charles Schiff (London, E.8) writes: Dr. Paul Wood's St. Cyres Lecture (*Journal*, September 16, p. 639, and September 23, p. 693) is entitled "Congenital Heart Disease." Since faulty wording is apt to lead to faulty thinking, it is surely not pedantic to point out that the Lecture deals with various kinds of congenital heart malformation and not with disease.

Obituary

S. ROODHOUSE GLOYNE, M.D.

Dr. S. R. Gloyne, consulting pathologist to the London Chest Hospital and King Edward VII Sanatorium, Midhurst, died in London on September 25.

Stephen Roodhouse Gloyne studied medicine at Leeds University and the Middlesex Hospital. He graduated M.B., Ch.B. in 1906, took the D.P.H. from St. George's Hospital in 1908, and proceeded M.D. in 1909. He became pathologist to the London Chest Hospital in 1911, and remained on the staff of that hospital until his retirement two years ago. It was at St. George's Hospital that he met Mr. A. W. Smart, who joined him as senior laboratory technician in 1920, a partnership which lasted nearly 30 years. Gloyne was a recognized authority on the pathology of respiratory diseases, especially industrial diseases of the lung. With the late Dr. Burton Wood he reported on the effects of asbestos dust on the lungs, and he was made a member of the Medical Board for Silicosis and Asbestosis. He was also well known for his work on tuberculosis, being president of the British Tuberculosis Association in 1938. When the Thoracic Society was formed he was made a vice-president. In 1948 he was awarded the Weber-Parkes Prize by the Royal College of Physicians.

Dr. E. H. Hudson writes: "Old Gloyne" was a term of endearment by which Stephen Roodhouse Gloyne was known among his intimate friends and numbers of visitors from all parts of the world. His silver hair belied him—he was not old. His mind and actions were young, and he enjoyed youth's company. His unfailing cheerfulness and sage wisdom made many seek his counsel and seek his advice in committee too. A Yorkshireman, of Quaker upbringing, he was, as one would expect, a warm-hearted, generous character. His real attachment to Victoria Park seems to date from the 1914–18 war, when owing to the shortage of medical staff he came to live in the hospital and combined the duties of pathologist and resident medical officer. He became part and parcel of the hospital, and it is impossible to think of the two apart. He had a happy knack of making visitors feel at home, both in the hospital and laboratory, and if he saw a new resident ill at ease he would immediately break the ice and make him feel he was no foreign body. In the common-room at the hospital, where most of us will remember him, he had his special after-lunch seat at the end of the sofa, which we always left for him. At these times art, politics, cricket, literature, and medicine were all subjects for discussion, and all took part. He was a keen cricketer and a member of the M.C.C.; a true Yorkshireman, he followed his county with great interest. When war came again in 1939, with the staff sadly depleted through the deaths of Chandler and Burton Wood, Gloyne shouldered fresh responsibility. He was a moving spirit in preparing a country branch at Camberley for evacuation of the main hospital. When the hospital was badly bombed in 1941 his laboratory received a direct hit, and he saw a life's work disappear in a night; all his museum specimens, so laboriously gathered, all his personal papers, section blocks, and his new microscope of which he was so proud, vanished. He immediately organized a highly efficient temporary laboratory which is still functioning, and in spite of his great personal loss and anxiety he placed his country house at the disposal of the matron as a rest centre for the nursing staff. Gloyne was a most lovable man. He was a scholar with a great appreciation of beauty. We knew him to be a fine pathologist, and we shall always remember his merry infectious laugh.

H. de CARLE WOODCOCK, M.D., F.R.C.P.Ed.

Dr. H. de Carle Woodcock, who devoted a great part of his career to developing the tuberculosis service in Leeds, died on September 5 in Leeds aged 89 years.

Herbert de Carle Woodcock received his medical education at Leeds and Edinburgh Universities, at the Middlesex Hospital, and at the Johns Hopkins Hospital, Baltimore. He qualified in 1885 and soon afterwards went into general practice in an industrial part of Leeds. He continued his medical studies, however, taking the English Conjoint qualification in 1889, the D.P.H. in 1901, and the M.R.C.P.(Edinburgh) in 1911. In 1911 also he graduated M.D.(Durham), and in 1918 he became a Fellow of the Royal College of Physicians of Edinburgh. It was while he was in general practice that his attention was directed to the growing menace of tuberculosis and to the urgency of the need to alleviate the suffering of the victims and save from infection those who had to live in close contact with them, often in poverty and squalor. A crusade was started, and the Leeds Association for the Prevention and Cure of Tuberculosis was founded at the end of the last century. A public appeal for funds made it possible for two small sanatoria and a dispensary to be built. Woodcock, of course, was a member of the honorary medical staff, and into his self-appointed task he put his whole heart and soul, visiting sanatoria in Europe and America and acquainting himself with all the current literature. In Edinburgh, where Dr. Robert Philip had opened the first tuberculosis dispensary in Great Britain, he spent a considerable time, gaining valuable experience. He was constantly thinking out new methods of treatment, some of which still survive. In the first world war Woodcock brought his skill and judgment to the problems connected with recruitment and the treatment of infected men discharged from the Forces. He also took a leading part in founding a tuberculosis society for ex-Service men. When the Leeds Association for the Prevention and Cure of Tuberculosis was taken over by the corporation, Woodcock continued, as chief clinical tuberculosis officer, to devote much time to the work. He was an active member of the National Association for the Prevention of Tuberculosis and was president of the Tuberculosis Congress in 1929. He retired from active practice in 1934, when his sight failed.

J. J. J. writes: Dr. Woodcock built up a large practice in Leeds, and established himself so firmly in the affections of his patients and the public in general that long after he had left the district in which he practised his name remained a household word. As the tuberculosis work grew he found that he had to devote himself entirely to it and abandon general practice. This meant severing his connexion with many old patients and friends and giving up a lucrative source of income, but to a man with his burning zest no sacrifice was too great. He was interested in many branches of social work, indeed in anything that would build up a resistance against "the enemy" he had sworn to defeat. A convincing speaker, a clear and original thinker, and a facile writer, he could be a charming companion and conversationalist. His knowledge of general as well as medical literature was extensive. Besides many articles in magazines and newspapers he was the author of a book, *The Doctor and the People*, which gave a fascinating picture of life in

a working-class district. In his home life he was extremely happy; he kept open house in his younger days, and was never happier than when he had young people around him. The staff of the Leeds Dispensary loved him as a father and would do anything to serve him. He treated them with the greatest generosity. Progress in science owes much to the pioneers. They get very little recognition, at least from their own generation, and no reward. Woodcock was a pioneer, one of a number who in the first half of this century blazed the trail in the field of tuberculosis in this country. He laboured better than he knew, and his successors have entered into his labours.

A. E. N. writes: I had known Dr. Woodcock for nearly 50 years. This was a privilege which I appreciated increasingly as the years went by; and especially so for the last 20 years when old age and blindness had severed for him the normal contacts of a physician. It was then that the essential qualities of his mind stood out undisturbed by the daily cares of competitive work. There are few who wholly escape the mental rigidities of the eighth and ninth decades of life. Dr. Woodcock was one of them. As the years rolled on a larger proportion of each day was spent in sleep, but when awake he was wholly so—as mentally agile in current affairs, in literary discrimination, and in philosophical outlook as ever he had been. Though completely blind for over 10 years, he could seize on the character and mental outlook of a stranger within a matter of minutes from the time of his first introduction. After a single reading to him of an hour's essay or treatise he had summed it up in detail and made a close estimation of its value.

Dr. JAMES STEWART JOWETT LEE died suddenly at his home in Belfast on August 3. He studied medicine at Queen's University, Belfast, and graduated M.B., B.Ch. in 1920. He took the D.P.H. in 1922. Before going into practice Dr. Lee was senior demonstrator in physiology and demonstrator in pathology at Queen's University. A member of the Ulster Medical Society and the British Medical Association, he was keenly interested in the work of the Association in Belfast. During the air raids on Belfast in 1941 he did excellent work in a first-aid post in one of the most heavily damaged areas of the city. James Lee was a good doctor, and his tragically sudden death came as a great shock to his patients and colleagues in North Belfast. He leaves a widow and three young children.—F. W. M.

Dr. RINGLAND GILMORE BOYD, senior assistant medical officer of health for Gloucestershire, was killed in a road accident on August 17. He was a member of a well-known family in County Derry, Northern Ireland, and was educated at Coleraine Academy and Queen's University, Belfast. He graduated M.B., B.Chir. in 1941, and after joining the R.A.M.C. he served with distinction in Africa, Sicily, and Italy. He was awarded the Military Cross in 1942. After attaining the rank of lieutenant-colonel, he was demobilized in 1947. Returning to Belfast, he took the D.P.H. and entered the public health service as an assistant M.O.H. in Manchester. Later he moved to Gloucestershire, and was appointed senior assistant county medical officer as recently as last April. A very skilful tennis player, Boyd had many successes in tournaments in Gloucester, Cheltenham, Cirencester, and Ledbury. He won the tennis championship at Gloucester last year and again this year. He was also an outstanding badminton player. He had charm without being effusive, and great ability with modesty. He had also a strong belief in the principles of freedom, honourable human relationships, and justice. As a sportsman he was outstanding, and as a friend loyal and dependable. He was highly thought of by senior and junior colleagues, and it is a tragedy that he should be killed on the road during the ordinary course of his duties after having withstood the perils of active service in war.—J. K. M.

Dr. JACQUES DE FOURMESTRAUX, director of the surgical clinic at Chartres, was killed recently in a road accident. We are indebted to Mr. H. W. S. Wright for the following appreciation:

British surgeons who are members of the French and British Associations of Surgeons will share with their French colleagues the sense of loss which comes to European surgery with the death of Jacques de Fourmestraux. Those who attended the French Congress of Surgery in 1947 will remember its president, and those who were at the Association of Surgeons meeting in London in 1946 and Oxford in 1947, and at the International Congress in London in the same year, will recollect a massive, dark Frenchman, hair brushed back, with a dark upturned moustache. At first sight perhaps a cheerful farmer up from the country, but then one glance at his kindly, intelligent, widely set apart eyes above the firm chin and humorous mouth showed that here was no ordinary man. He was born in 1879, and after a brilliant career in Paris, where he was a pupil of de Picqué and de Berger, his sense of adventure led him away from Paris to Chartres, where he organized a surgical clinic which might well be the envy of many university towns. He was a general surgeon in the best and highest sense of the word, and his writings range over the whole realm of surgery. I think he was the first man in Paris to suture a wound of the heart, an operation which he performed in 1905. He was, moreover, an authority on the history of French medicine and the author of a standard work on the history of French surgery. At home de Fourmestraux was a sort of uncrowned king of Chartres. From cathedral and cottage, from *préfecture* and farmhouse, they all came to seek his help. No trouble was too small for his consideration, and no call on his wisdom and sympathy ever went unanswered. Above all things he had a genius for friendship, and no one with whom he shared his greatness of heart and spirit will ever forget him. I sat with him last June for an hour in a café in Brussels; he talked with wisdom and wit about the origin of place names in central France, about speed in surgery, about his farm, and then, with a far-away look which seemed to come from the past and go towards the dim horizons of the future, he said with great delight: "At last I have managed to get a suite of rooms in my clinic for any surgeon who cares to come. I like to have young people visit me nowadays; I think that is the best way I can help. The world is too complicated for one man to do much." Our sympathy goes out to his wife and his family.

A memorial service for the late Dr. Herbert Morley Fletcher, who was senior consulting physician to St. Bartholomew's Hospital, will be held in the church of St. Bartholomew-the-Great on Wednesday, October 11, at 12.30 p.m.

Medical Notes in Parliament

Smoke Abatement

Mr. F. LONGDEN raised, on September 19, the problem of smoke abatement. He recalled that the Minister of Health had said in 1949 that he contemplated introducing no legislation on the subject. But from Birmingham, which had some 6,000 factories with more than 24,000 chimney-stacks, the chief medical officer told him that in 1948–9, of two standard atmospheric-pollution-deposit gauges, the central one had recorded a total deposit of 330.9 tons per square mile, while a similar gauge on the south-west boundary in West Heath had recorded a total deposit of 191.5 tons per square mile during the year. The inspector of factories for Birmingham told him that the insoluble deposits consisted mainly of mineral matter, grit, ash, soot, and tar, while the soluble deposits were mainly of sulphates, chlorides, calcium, and sodium salts. In the opinion of the inspector about 60% of the pollution was from industrial sources. Every medical officer must know that the effects on health must be bad, particularly in the matter of lung troubles such as bronchitis, pneumonia, and cancer. There was a need for more powers for local authorities to employ inspectors and for stricter control and severer penalties for deliberate evasion. The Birmingham inspector referred to pollution caused by emission of fumes from processes such as brass casting, aluminium melting, scrap-metal recovery, and enamelling ovens. He himself had worked in an iron foundry where fumes got into the nose, eyes, and lungs. He asked whether, if legislation could not be contemplated, there could not be more intense investigation and administration to reduce this waste of health and wealth.

Dr. BARNET STROSS, as a medical man, remarked that there was something to be said for the contention that the higher incidence of carcinoma of the bronchial tubes now found in elderly people might result from the tarry deposits inhaled from the atmosphere.

Mr. A. BLENKINSOP, replying for the Ministry of Health, said local authorities had fairly wide powers and in most cases controlled emission of black smoke. Over pollution from chemical works the Ministry of Health had direct responsibility under the Alkali Acts and could take direct action. Local authorities were active in using their powers, but were often defeated by the general anxiety to secure full production. The Ministry of Health with the Ministry of Fuel and Power, was doing all it could to secure training in better stoking and to secure more efficient plant. Powers had been taken in some towns to provide for smokeless zones where, after proper notice, it would be a punishable offence to create smoke. As these smokeless areas were gradually extended, some steady improvement would be seen.

National Service

When asked on September 19 whether National Service men due to enter a university in October would be exempted from a further six months' service under the National Service Act which had become law on the previous day, the Minister of Labour said arrangements had been made for the early release of the men concerned. Applications should be made through the ordinary Service channels. These men would be discharged at the end of their 18 months' service and would not be liable for another six months' service.

In reply to another question, he said that all men attending for medical examination under the National Service Acts were asked to give the Medical Board full details of their medical history. Any certificates from general practitioners or consultants that a man might produce received full consideration.

Welfare Foods.—The stocks of welfare foods in distribution in the United Kingdom at the end of the July accounting period, 1950, were: National dried milk, 3,987,000 tins against 2,959,000 tins in 1945; cod-liver oil, 2,485,000 bottles against 1,955,000 in 1945; vitamin A and D tablets, 585,000 packets against 405,000 in 1945; and orange juice, 6,830,000 bottles against 4,184,000 in 1945.

Universities and Colleges

UNIVERSITY OF MANCHESTER

Dr. Kathleen V. Lodge has been appointed demonstrator in pathology.

Dr. Stanley Wyatt (lecturer in occupational health), Dr. G. W. Boden (assistant lecturer in radiotherapy), and Dr. J. K. Craig (demonstrator in physiology) have resigned the posts indicated in parentheses.

UNIVERSITY OF SHEFFIELD

At a Congregation held on September 23 the following degrees were conferred.

M.B., CH.B.—H. Bailey, Patricia T. Ferraro, W. E. Freeman, L. G. Gordon, Shelagh Hannath, E. A. Johnson, F. E. Neal, N. L. Sarkar, J. D. Warren.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

Dr. Philip S. Hench, of the Mayo Clinic, Rochester, U.S.A., will deliver the inaugural Walker Trust Lecture entitled "The Effect of Cortisone and A.C.T.H. on Rheumatic Diseases" in the Hall of the Faculty (242, St. Vincent Street, Glasgow) on Monday, October 16, at 4 p.m. Admission is by ticket, which may be obtained free of charge on application to the secretary of the Faculty.

No. 37

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended September 16.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each Infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1950 (a)	(b)	(c)	(d)	(e)	1949 (Corresponding Week) (a)	(b)	(c)	(d)	(e)

* Measles is not notifiable in Scotland, and the returns are therefore an approximation only.

† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

‖ Includes puerperal fever for England and Wales and Eire.

¶ Primary pneumonia no longer notifiable in Eire.

EPIDEMIOLOGICAL NOTES

Poliomyelitis

Notifications of poliomyelitis in the week ending September 23 were: paralytic, 268 (291); non-paralytic, 151 (187); total, 419 (478). The figures for the previous week are in parentheses. For the second successive week there has been a decided fall in the total number of cases. Non-paralytic cases were 36% of the total during the week under review.

Decreases were fairly widespread, but were more marked in counties heavily affected earlier in the year. Stafford and Gloucester had 13 fewer cases than during the previous week; Worcester 11 fewer and Warwick 10 fewer. Material increases were shown in Kent and Northumberland with 9 more cases each. Surrey had an increase of 7 cases and Lancashire one of 6 cases.

The uncorrected notifications for the corresponding week in 1947, 1948, and 1949 were 594, 73, and 295 respectively. Total uncorrected notifications for 1950, up to and including the week under review, were 6,023. The corresponding figures for 1947, 1948, and 1949 were 6,192, 1,361, and 3,284.

Discussion of Table

In *England and Wales* a fall occurred in the number of notifications of whooping-cough 596, measles 36, and acute poliomyelitis 35; a rise was reported for scarlet fever 92, acute pneumonia 26, and dysentery 10.

The largest variation in the local trends of scarlet fever was a rise of 27 in Yorkshire West Riding. A decline in the incidence of measles was reported throughout the country; the outstanding exceptions were rises in Lincolnshire 184 (due to a big outbreak in Spalding U.D.) and Yorkshire West Riding 76. The largest returns of diphtheria during the week were those of Bootle C.B. and Birmingham C.B., with 4 notifications each. The largest falls in the notifications of whooping-cough were from Warwickshire 75 and Middlesex 67, and the most notable exception to the general downward trend was a rise of 20 in Staffordshire.

The chief centres of dysentery were Lancashire 55 (Droylsden U.D. 11, Great Harwood U.D. 10); Leicestershire 49 (Leicester C.B. 42); Yorkshire West Riding 32 (Shipley U.D. 10, Bradford C.B. 7); Durham 14 (South Shields C.B. 8); Surrey 13 (Coulsdon and Purley U.D. 10); and London 10.

The chief features of the returns for acute poliomyelitis were a rise in the South-west counties of 13 and a rise of 12 in Worcestershire. The largest returns were from Lancashire 35 (Liverpool C.B. 15, Manchester C.B. 13); Gloucestershire 31 (Bristol C.B. 25); Staffordshire 30 (Rowley Regis M.B. 4); London 29 (Islington 4, Southwark 4); Warwickshire 25 (Birmingham C.B. 14, Coventry C.B. 7); Middlesex 24 (Harrow U.D. 4); Yorkshire West Riding 24 (Sheffield C.B. 7, Leeds C.B. 4, York C.B. 4); Durham 23 (distributed over 15 areas); Essex 16 (Walthamstow M.B. 4); Worcestershire 16 (Dudley C.B. 5); Devonshire 15 (Newton Abbot R.D. 4); Dorsetshire 14; Kent 14 (Orpington U.D. 5); Lincolnshire 12 (Grimsby C.B. 5); Nottinghamshire 11 (Nottingham C.B. 4); Southampton 11 (Bournemouth C.B. 4); Leicestershire 10; and Somerset 10.

In *Scotland* a fall occurred in the number of notifications of whooping-cough 125 and measles 16; a rise was recorded for scarlet fever 21. The notifications of scarlet fever fell by 10 in the Western area, but a small rise occurred in the other areas. The largest returns of dysentery were from Glasgow 39, Stirling county 20, and Edinburgh 12. Very little change occurred in the geographical distribution of acute poliomyelitis; the largest returns were from Glasgow 16, Fife county 11, Dundee 7, Lanark county 7, and Edinburgh 4.

In *Eire* decreases were recorded in the number of notifications of measles 36 and whooping-cough 33; a rise of 10 occurred in the notifications of diarrhoea and enteritis. A fall in the incidence of measles and whooping-cough was general throughout the country, while the rise in diarrhoea and enteritis was confined to Dublin C.B.

In *Northern Ireland* a rise of 13 occurred in the number of notifications of measles, and a fall of 12 was reported for whooping-cough. An increase of 10 was recorded for the notifications of acute poliomyelitis. The largest returns for acute poliomyelitis were from Antrim county 8, Down county 7, Belfast C.B. 5, and Armagh county 3.

Week Ending September 23

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 771, whooping-cough 2,935, diphtheria 38, measles 2,673, acute pneumonia 260, acute poliomyelitis 419, dysentery 170, paratyphoid fever 9, and typhoid fever 3.

Medical News

W.H.O. Mission to Korea

The World Health Organization has appointed a special mission to Korea to assist in the administration of health and relief programmes for the civilian population. The director of the mission, Dr. W. H. Crichton, C.I.E., has already left to assume his new post. He will be assisted by five public health teams composed of medical officers and sanitary engineers now being recruited by W.H.O. in Europe, South America, and the United States. The W.H.O. mission to Korea will be put at the disposal of the unified command and will assist the South Korean Ministries of Public Health and Social Welfare. The mission will help to reorganize health services for the population and assist in relief programmes and in the control and prevention of communicable diseases.

Neurosurgical Congress in Bologna

Dr. A. J. H. Hewer, consulting anaesthetist to the Middlesex Hospital, visited Italy between September 26 and October 3 to read a paper on anaesthesia with special reference to neurosurgery at a congress of neurosurgeons at Bologna. The visit was sponsored by the British Council.

Visits to Finland

Professor R. Cruickshank, of the Wright-Fleming Institute, St. Mary's Hospital, London, gave three lectures for the British Council in Finland between September 17 and 21. At the University of Helsinki he spoke on "The Chemotherapy of Tuberculosis," to the Society of Pathologists in Helsinki on "The Epidemiology and Control of Whooping-cough," and to the medical faculty of the University of Turku on "Modern Antibiotic Therapy."

Another visitor to Helsinki, during the fortnight September 11 to 26, was Miss E. M. Crothers, general superintendent of the Queen's Institute of District Nursing, who lectured and demonstrated on home nursing methods at the invitation of the Finnish State Medical Board.

Visit to Yugoslavia

Dr. Marc Daniels, of the M.R.C. Tuberculosis Research Unit, spoke in Belgrade and other Yugoslav centres on "The Chemotherapy of Tuberculosis" and "The Epidemiology of Tuberculosis" between September 22 and October 6 on behalf of the British Council.

Vellore Christian Medical College

The Golden Jubilee celebrations of the Christian Medical College at Vellore, South India, are being celebrated in London on October 12. The college has recently been granted permanent affiliation to the University of Madras, and is the only Christian medical college in India and Pakistan where men and women can take the M.B., B.S. degree. It is also the only university school of nursing in South India. The hospital has 468 beds, with a staff of 60 doctors and 120 nurses, and it offers a complete medical service. A valuable side of the hospital's work is its rural medical service: mobile dispensaries go out weekly, treating on each trip up to 300 patients. At present there are over 160 students in the medical school, which has many Europeans on the teaching staff. At a medical meeting, which is to be held in the Caxton Hall, Westminster, on October 12 at 5.30 p.m., the chair will be taken by Sir George McRobert, former professor of medicine, Madras College, and speakers will include Sir Henry Holland, C.I.E., and Drs. J. Donald Ball and Leela Chacko. A coloured film showing the work of the college will be shown before the medical meeting at 5 p.m. Application for afternoon tea tickets should be addressed to the Secretary, "Friends of Vellore," Annandale, North End Road, London, N.W.11.

R.C.O.G. Dinner

The annual dinner of the Royal College of Obstetricians and Gynaecologists was held at the Dorchester Hotel on September 29, when the president of the College, Professor Hilda Lloyd, was in the chair. The large number of distinguished guests included the Lord Mayor of London, Sir John Anderson, and the vice-chancellor of the University of London.

In proposing the health of the College, Sir John Anderson said it gave him special pleasure to be invited as the chief guest, because as chairman of the Postgraduate Medical Federation he was concerned with advanced medical education. Responsibility for higher medical education was shared between the universities and the royal colleges. The federation was encouraging the recognition by the universities of a series of specialist institutes for postgraduate teaching. One of these was the Institute of Obstetrics and Gynaecology, founded in 1948 and based on the Hammersmith Hospital, Queen Charlotte's Maternity Hospital, and the Chelsea Hospital for Women. Co-ordination of these activities was met by a representation of the colleges on the governing body of the Postgraduate Federation and also by the establishment of a joint board. The Royal College of Obstetricians and Gynaecologists was responsible for the standards of consultants in these subjects, and its sphere extended to all parts of the Commonwealth. It had no responsibility comparable with the older colleges for undergraduate training. Through its diploma of membership the College had influenced higher medical education substantially in respect of clinical practice. Referring to finance, Sir John observed that the colleges had to depend on their own resources. So long as this was the case they could claim a degree of independence not consistent with reliance on Exchequer grants. Such independence was important and valuable, and he hoped that the time was not far distant when the College could command resources comparable, in relation to their needs, to those at the disposal of the older colleges.

In response, Professor Hilda Lloyd welcomed new fellows and members, and in particular those from the Dominions. She referred appreciatively to the three years of office held by Sir William Gilliatt and the work he had done to raise the status of the College. Their facilities for research were restricted for lack of funds. But they were making some headway. £60,000 had been raised by the appeal fund organized by the College. Sir Arthur Sims and his family had given funds to establish a Commonwealth Travelling Professorship tenable every other year. The Bernhard Baron trustees had given £10,000 towards travelling scholarships. These gifts had brought their funds within the region of £100,000. Professor Hilda Lloyd mentioned that the Royal College of Obstetricians and Gynaecologists now had a seat on the G.M.C. They also had regional councils in New Zealand, Canada, and Australia.

The health of the guests was proposed by Mr. G. F. Gibberd and responded to by Dr. W. Russell Brain, the president of the Royal College of Physicians.

King's College Hospital Medical School

The annual dinner of King's College Hospital Medical School was held at Claridge's Hotel on September 30 with Sir Cecil Wakeley, P.R.C.S., in the chair. The toast to the medical school was proposed by Dr. Lawrence Dulake, who spoke as a general practitioner looking back on the value of the training given to him. The main object of a medical school was to turn out good doctors—not special kinds of doctors. The medical school, in fact, concentrated on basic training. When the speaker was a student he and his contemporaries thought the curriculum was good, but he believed it was far better to-day. In his experience psychosomatic disturbances accounted for 60% of the G.P.'s work, and it would be a great step forward in the training of students when full emphasis was given to psychiatric considerations. Dr. Dulake expressed confidence in the future of King's, which was safe in the hands of the present staff and of the King's men and women who were scattered about the world. In his reply Mr. Harold Edwards, the dean of the medical school, said that the intake of students was still rising. With three London University gold medallists they had had a fine year of academic successes. The need for more beds was as great as ever, and at last there did seem to be some hope that building would be begun. In proposing the health of the chairman, Dr. F. S. Cooksey said that Sir Cecil Wakeley was the ninth old King's man to be president of the Royal College of Surgeons. His contributions to surgery, to his medical school, to the Royal Naval medical service, and to his own great college were outstanding. Sir Cecil Wakeley, replying, said that it was just after the first world war that the first lecture by a G.P. was given to King's students. On the whole he thought that the clinical acumen of physicians in the Victorian age was probably better than it is to-day. In some important things the student did not now acquire the knowledge his predecessors acquired 20 or 30 years ago. He earnestly hoped that it would never be the common practice in this country for students to be examined by their own teachers only. This would not be for the good of the profession.

COMING EVENTS

Lectures on Ophthalmology

A series of four lectures on ophthalmology began in the Department of Ophthalmology of the University of Glasgow on October 4, when Dr. Fergus Campbell spoke on "Experimental Corneal Lesions." Further lectures will be given on October 11, 18, and 25, details of which will be published in the "Societies and Lectures" column of the *Journal*.

Fellowship of Postgraduate Medicine

The Fellowship of Postgraduate Medicine, 1, Wimpole Street, London, W., has arranged a concentrated practical week-end course in the "Rheumatic Diseases" with clinical lectures, practical demonstrations, and ward rounds at the Rheumatism Unit, St. Stephen's Hospital, Fulham Road, London, S.W., on Saturday and Sunday, October 7 and 8. The programme is as follows: October 7, 10 a.m., introductory address by the Rt. Hon. Lord Amulree, "The Social and Economic Aspects of the Chronic Rheumatic Diseases"; 11 a.m., Dr. Peter Bishop, "The Endocrine Aspects of the Chronic Rheumatic Diseases"; 12 noon, Dr. Philip Ellman, "Rheumatoid Disease—its Widespread Clinical Manifestations"; 2 p.m., Dr. Francis Bach, "The Management of the Rheumatic Patient"; 3 p.m., Dr. Francis Bach and the medical registrars, demonstration of methods of physical treatment and rehabilitation; 4.30 to 5.30 p.m., Dr. E. G. L. Bywaters, "Pathology of the Chronic Rheumatic Diseases." October 8, 10 a.m., Dr. Philip Ellman and the medical registrars, ward round with demonstration of cases; 11.15 a.m., Dr. Philip Ellman, "Joint Lesions in General Medicine"; 12 noon, Dr. David Shaw, "Psychiatric Factors in the Chronic Rheumatic Diseases"; 2 p.m., Mr. Timbrell Fisher, "Orthopaedic Aspects of Rheumatic Disease and the Prevention and Treatment of Deformities"; 3 p.m., Mr. Timbrell Fisher, demonstration of cases and treatment by manipulation (if cases are available); 4.30 to 6 p.m., lantern lecture by Dr. Grace Batten, "The Radiological Diagnosis of the Rheumatic Diseases." The fee for the course, open only to members of the Fellowship of Postgraduate Medicine, is £2 12s. 6d. payable in advance to the Fellowship of Medicine. Lunch will be provided at the hospital and is included in the fee.

British Postgraduate Medical Federation Lectures

The series of lectures on "The Scientific Basis of Medicine" arranged by the British Postgraduate Medical Federation will begin on Tuesday, October 10, and will continue until Tuesday, March 20, 1951. Lectures will be given at 5.30 p.m. on Tuesdays and Thursdays at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, W.C.

Admission is free without ticket. The programme for the period October 10 to December 21 will be found in the advertisement columns. Details will be published in the "Societies and Lectures" column of the *Journal* week by week.

Royal Institute of Philosophy

The 1950–1 programme of lectures of the Royal Institute of Philosophy has been arranged as follows: October 13, 20, and 27, and November 3, a course of four lectures on "Synoptic Philosophy (A Philosophy of Nature)," by Mr. G. J. Whitrow, D.Phil.; November 10, "Aristotle's Doctrine Concerning the Connexion of Soul and Body," by Mr. W. F. R. Hardie; November 17, "The Notion of an Imperative in Morality and Elsewhere," by Professor C. D. Broad; November 24, "The Nature of Aesthetic Experience," by the Earl of Listowel; January 26 and February 2, 9, and 16, a course of four lectures on "The Philosophy of Mind and Value," by Mr. A. J. T. Wisdom; February 23, "The Nature of Religious Knowledge," by the Very Rev. W. R. Matthews (Dean of St. Paul's Cathedral); and March 2, "The Function of Art in Civilization," by Mr. Stanley Spencer. The lectures will be delivered at University Hall, 14, Gordon Square, London, W.C., at 5.15 p.m.; they are open to the public, and tickets of admission may be obtained, free of charge, from the director of studies of the institute.

Neurological Diseases in Children

The Institute of Child Health (Hospital for Sick Children, Great Ormond Street, London, W.C.) in conjunction with the Institute of Neurology (National Hospital, Queen Square, London, W.C.) has arranged a series of 10 lectures on "Neurological Diseases in Children" to be given at the Institute of Neurology, National Hospital, on Mondays from October 16 to December 18 at 5 p.m. There is a fee for the lectures, and tickets will be issued in advance. Details will be published in the "Societies and Lectures" column of the *Journal* week by week.

27th General Hospital

A reunion dinner of the 27th General Hospital will be held at the Eccleston Hotel, Eccleston Square, London, S.W., on Saturday, October 21, at 6.30 for 7.15 p.m., when Lieutenant-Colonel Colin Wilson will preside. Tickets (inclusive) £1; informal dress. Inquiries should be addressed to Dr. L. S. Potter, B.M.A. House, Tavistock Square, London, W.C.1.

I.B.P. Medical Group Conference

The Medical Group of the Institute of British Photographers is holding a one-day conference on Saturday, October 28, 1950, at the Polytechnic, Regent Street, London, W.1, which will include a demonstration of cavity photography by Mr. F. Wardlaw, of Manchester, a lecture-demonstration on "Autostereoscopic Photography and Radiography," by Mr. L. P. C. J. Dudley, and the showing of two films, one on "Carcinoma of Fauces Treated by Beam-directed *X* Rays," by Mr. J. Larway, of Sheffield, and the other on "Examination of the Cervical Lymph Nodes," presented by Dr. Peter Hansell, of the Westminster Hospital. The conference is open to all interested in medical photography, and tickets (price 12s. 6d.) can be obtained from the secretary, Institute of British Photographers, 49, Gordon Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Friday

Royal Medical Society, 7, Melbourne Place, Edinburgh.—October 6, 8 p.m., "*The Use of Radioactive Isotopes in Science and Industry*," inaugural address by Sir Edward Appleton.

Monday

Edinburgh University.—At Surgery Lecture Theatre, University New Buildings, Edinburgh, October 9, 5 p.m., "*The Indications for Surgery in Peptic Ulcer*," Macarthur postgraduate lecture by Mr. Norman C. Tanner.

Institute of Ophthalmology (University of London), Judd Street, London, W.C.—October 9, 5.30 p.m., "*The Anatomy of the Ocular Muscles*," by Dr. F. Stansfield.

Institute of Psychiatry, Maudsley Hospital, Denmark Hill, London, S.E.—October 9, 4.30 p.m., lecture-demonstration for postgraduates by Dr. E. Stengel.

Medical Society of London, 11, Chandos Street, Cavendish Square, London, W.—October 9, 8.30 p.m., annual general meeting; 8.45 p.m., "*Occultism in the Days of Lettsom*," pres.dential address by Dr. A. H. Douthwaite.

●Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C.—October 9, 5 p.m., "*Surgery of the Pancreas*," by Professor C. F. W Illingworth; 6.15 p.m., "*The Nodular Breast*," by Mr. Hedley Atkins.

●Royal College of Surgeons of England: Faculty of Anaesthetists, Lincoln's Inn Fields, London, W.C.—October 9, 10 a.m., "*Blood Transfusion*," by Dr. H. F. Brewer; 11.30 a.m., "*Lumbar Puncture and Spinal Anaesthesia*," by Dr. H. W. C. Griffiths; 2.30 p.m., "*Blood Transfusion*," by Dr. H. F. Brewer; 4 p.m., "*Lumbar Puncture and Spinal Anaesthesia*," by Dr. H. W. C. Griffiths.

Tuesday

British Postgraduate Medical Federation.—At London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, W.C., October 10, 5.30 p.m., "*Scientific Method in Medical Research*," by Sir Henry Dale, O.M., F.R.S.

Chelsea Clinical Society.—At South Kensington Hotel, 47, Queen's Gate Terrace, London, S.W., October 10, 7 for 7.30 p.m., "*Plastic Surgery and the Arts*," discussion to be opened by Mr. Adrian Hill and Mr. Henry E. Blake.

Edinburgh University.—At Surgery Lecture Theatre, University New Buildings, Edinburgh, October 10, 5 p.m., "*Operative Methods in the Treatment of Peptic Ulcer*," Macarthur postgraduate lecture by Mr. Norman C. Tanner.

●Institute of Dermatology, Lisle Street, Leicester Square, London, W.C.—October 10, 5 p.m., "*Eczema and/or Dermatitis*," by Dr. J. E. M. Wigley.

London University.—At Westminster Medical School (Meyerstein Lecture Theatre), Horseferry Road, Westminster, London, S.W., October 10, 5.30 p.m., "*Nature and Properties of Certain Metalloprotein Enzymes*," by Professor D. Keilin, F.R.S.

●Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C.—October 10, 5 p.m., "*Congenital Abnormalities of the Foot*," by Mr. John Bruce; 6.15 p.m., "*Intracranial Suppuration*," by Sir Hugh Cairns.

Epstein; 11.30 a.m., "*The Circulation During Anaesthesia*," by Professor E. A. Pask; 2.30 p.m., "*Principles of Anaesthetic Apparatus*," by Dr. H. G. Epstein; 4 p.m., "*The Circulation During Anaesthesia*," by Professor E. A. Pask.

Royal Medical Society, 7, Melbourne Place, Edinburgh.—October 13, 8 p.m., "*Diseases of the Cotton Industry*," dissertation by Dr. J. G. E. Smith.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Macphail.—On September 11, 1950, at Queen Charlotte's Hospital, to Dr. Margarett Macphail (formerly Hutchinson), wife of Dr. D. S. Macphail, a daughter.

Parkes Bowen.—On September 23, 1950, to Sheila (formerly Robinson), wife of Dr. David Parkes Bowen, a daughter—Penelope Susan.

Whitehouse.—On September 20, 1950, at Ashleigh, Gosforth, Newcastle-upon-Tyne, to Joan (formerly Tully), wife of Dr. Dennis Whitehouse, a brother for Peter—Michael David.

DEATHS

Abercrombie.—On September 30, 1950, at Plymouth, Massachusetts, Peter Henderson Abercrombie, M.D., of Putney Hill, London, S.W., aged 83.

Ball.—On September 25, 1950, at University College Hospital, London, W.C. Cecil Glyn Ball, M.B., B.S., C.P.H., of 213, Everton Drive, Stanmore, Middlesex, aged 30.

Edington.—On September 23, 1950, at 21, Brunswick Square, Penrith, Daniel Charles Edington M.D.

Ferguson.—On September 27, 1950, Robert Ferguson, M.D., of Albury Nook, South Eden Park Road, Beckenham, Kent, late of Ongar, Essex, aged 81.

Garner.—On September 16, 1950, at "Brookfield," Irlam Road, Flixton, Manchester Charles Garner, M.D., aged 75.

Gloyne.—On September 25, 1950, Stephen Roodhouse Gloyne, M.D., D.P.H., of 190, Chiltern Court, London, N.W.

Harris.—On September 16, 1950, at the London Hospital, Charles Harris, L.R.C.P.&S.Ed., D.P.H., of 44, Carden Avenue, Patcham, Brighton, aged 65.

Humphery.—On September 22, 1950, at Stradbroke Priory, near Diss, Norfolk, Geoffrey Per y Humphery, M.B., C.M., Brevet Lieutenant-Colonel, R.A.M.C., retired, aged 83.

Jarratt.—On September 19, 1950, at 14, St. James' Road, Bridlington, Yorks. Alfred Kaye Jarratt, M.B., C.M., aged 82.

Leech.—On September 19, 1950, at Chadlington House, Victoria Park, Manchester, Ernest Bosdin Leech, M.D., F.R.C.P., aged 75.

Leys.—On September 15, 1950, at "Culdearn," Grantown-on-Spey, Morayshire, John Leys, M.D., aged 85.

Purslow.—On September 20, 1950, at 65, Sir Harry's Road, Edgbaston, Birmingham, Charles Edwin Purslow, M.D., aged 89.

Rawlence.—On September 17, 1950, following an operation, Harold Ernest Rawlence, O.B.E., M.D., F.R.C.S.Ed., of Stoford House, Stoford, near Salisbury, Wilts.

Swyer.—On September 21, 1950, at the Queen Mary Hospital, Millbank, London, S.W., James Edward Swyer, M.R.C.S., L.R.C.P., Colonel, A.M.S.

Walters.—On September 16, 1950, William James Walters, M.R.C.S., L.R.C.P., of 185, Whitehall Road, Gateshead, late of Bryn Road, Swansea, aged 59.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Diastolic Murmurs

Q.—*How can the "innocent" diastolic murmur be diagnosed, and what is its significance?*

A.—Strictly speaking, there is no such thing as an innocent diastolic murmur. There are functional diastolic murmurs which are innocent in the sense that they do not denote valve disease; on the other hand, they may indicate something even more serious. For example, practically all pulmonary diastolic murmurs are functional and depend upon dilatation of the pulmonary artery and valve ring. A functional aortic diastolic murmur occurs in about 10% of cases of severe hypertension for similar reasons. A functional mitral diastolic murmur may be heard in patent ductus arteriosus, ventricular septal defect, and occasionally in thyrotoxicosis, and signifies a greatly augmented mitral blood flow. There is no difference in the timing and quality of such functional murmurs from those due to organic disease of the valve, but the clinical circumstances are different. The correct diagnosis is thus arrived at only after a full consideration of all the features of the case, not just by auscultation alone.

A soft respiratory murmur may occasionally be heard in diastole at the left sternal border, and this of course is innocent. It is difficult to hear, varies with respiration, and may have an unusual relationship to the second heart sound as compared with intracardiac murmurs. A soft pericardial friction rub in diastole may also be mistaken for a diastolic murmur.

Prickly Heat

Q.—*What is the modern specific treatment, if any, for prickly heat?*

A.—There is no truly specific treatment for prickly heat. The most important thing to do is to supply animal or vegetable fat to the epidermis. This is best done by rubbing in daily ung. adipis lanae hydrosi. The second thing is to use a mild antiseptic to kill the invading staphylococci. Brilliant green is the least irritating and can be incorporated in the ointment, but its staining properties make it objectionable to use. An alternative would be to swab once daily with a 1:1,500 solution of mercury perchloride. Anything that removes the natural grease from the skin must be avoided; soap should not be used more than once daily. Swabbing with alcoholic solutions is to be condemned.

Testing Visual Acuity in a Small Surgery

Q.—*I have a surgery which is not 6 metres (19.7 ft.) long, and I wish to use my Snellen's test-type card. Can you please tell me: (1) Is a mirror-image card available so that I may put the card 13 ft. (3.97 m.) from the mirror and the patient 7 ft. (2.14 m.) from the mirror? (2) Is there any simple way of reading my test-type card at a distance of 13 ft., instead of at 20 ft. (6.1 m.), and expressing the result in the standard way?*

A.—(1) Special types are made by the dispensing opticians who supply ophthalmic apparatus, with letters reversed for reading in a mirror. The results are satisfactory, but in a few cases a psychological effect is produced which makes the record of visual acuity a little inaccurate. In some cases it is possible to put a window fairly high up on the wall facing the patient with the usual test-types attached high up on the opposite wall in the adjoining room or passage, the card being moved by cords from the examiner's position. By this means it may be possible to get the full 6 metres.

(2) No. But the visual acuity at 13 ft. can be recorded fairly correctly as 4/12 and 4/18, etc. These figures, however, cannot accurately be converted to, say, 6/18 or 6/24.

Barbiturates and Loss of Memory

Q.—*Is it common for patients taking nightly doses of "seconal" ½ gr. (194 mg.) or "sodium amytal" 3 gr. (32 mg.) over long periods to suffer from some degree of loss of memory? If so, what is the best alternative treatment?*

A.—It is not common for patients taking seconal or sodium amytal in the moderate doses mentioned to suffer from disturbances of memory. These barbiturates are relatively short-acting ones, and have no cumulative effects even if taken for prolonged periods, provided the renal function is not profoundly depressed. The best alternative hypnotic to barbiturates is chloral hydrate in a dose of 10–20 gr. (0.65–1.29 g.) well diluted.

Amphetamine during Lactation

Q.—*Is there any contraindication to the use of an amphetamine preparation in a nursing mother as an aid to weight reduction? Would the milk contain sufficient of the drug to cause the baby to be restless? Is there any objection to starting the course of amphetamine at the beginning of lactation?*

A.—A nursing mother should not use an amphetamine preparation as an aid to weight reduction. It is very likely that the drug would enter the milk and that the baby would be restless and wakeful. To start the course of amphetamine at the beginning of lactation is the worst time, for then the baby is most easily upset.

Excessive Libido

Q.—*What is the best method of reducing the libido of a healthy man, aged 23? There has been no relief with carbromal 10 gr. (0.65 g.) given in the afternoon, nor with phenobarbitone 1 gr. (65 mg.) t.d.s. and butobarbitone 1½ gr. (97 mg.) at tea-time. My patient fears that the frequency with which he indulges in intercourse is undermining his health.*

A.—It would appear that the patient is asking that his libido should be reduced because he himself believes that the frequency of intercourse is "undermining his health." In other words, the patient and not the doctor is deciding that treatment is necessary. Whilst it is reasonable to give stilboestrol to a patient with phthisis who has a haemoptysis after having intercourse, this treatment is not indicated in the present case. Normal intercourse does not undermine a patient's health, and excessive intercourse only makes him tired. The right treatment here is to get rid of the patient's fears and not of his libido.

Immunization of Allergic Children

Q.—*What is the best procedure to adopt in immunizing children who give a history of asthma and similar allergic conditions?*

A.—The important point is that these children should be immunized with preparations which do not contain serum. They can be immunized with alum-precipitated toxoids in the usual way.

Methyl Bromide and Ethylene Oxide Poisoning

Q.—*Methyl bromide and ethylene oxide are both extensively used for the fumigation of stored products. What is the immediate first-aid treatment to an operator who has been exposed to either of these gases? What are the physiological changes and pathological findings in cases of poisoning?*

A.—The concentrations of methyl bromide and ethylene oxide commonly used for fumigation are so small that poisoning from inhalation of the vapour is unlikely to occur. Wyers (*Brit. J. industr. Med.*, 1945, **2**, 24) describes the causes of poisoning from methyl bromide; he points out that careless handling of the materials and failure to appreciate the risk of poisoning are common among workmen. Men engaged in fumigating should work in pairs, and not singly. Protective clothing must include masks and gloves, and rooms should be thoroughly ventilated after fumigation. Periodic medical examination of workers assists in detecting early symptoms and in drawing attention to possible sources of exposure. Workers who experience symptoms such as headache, smarting of the eyes, loss of appetite, abdominal discomfort, or numbness of the feet should be removed at once from further exposure and kept at rest in bed under close observation for several days. Delayed symptoms, including visual disturbances such as difficulty in focusing and amblyopia, apathy, drowsiness, and epileptiform attacks, may occur from 2 to 16 hours after exposure, and death from pulmonary oedema has occurred after 48 hours. There is no specific treatment once these symptoms have developed. Liquid methyl bromide causes burns with marked vesication, redness and swelling of the superficial layers of the skin. Washing in weak sodium carbonate solution, by decomposing the methyl bromide, may help to prevent skin lesions. Chlorbutol ointment relieves the pain of burns.

Little is known about the physiological effect of methyl bromide. There is an increase of non-volatile bromide in the blood (normal 0–1.5 mg. %) and in the cerebrospinal fluid. Methyl bromide cannot be detected in the tissues, and there is no evidence of a cumulative effect nor of acquired sensitivity to it. Necropsy reveals congestion and cloudy swelling of the kidneys and liver, congestion and oedema of the lungs, and oedema of the brain with perivascular haemorrhages (Clarke *et al., Brit. J. industr. Med.*, 1945, **2**, 17).

Ethylene oxide is not particularly toxic to man. It is an irritant gas and causes irritation of the eyes and nose with blood-stained watery discharge from the nostrils. In experimental animals the principal changes at necropsy are found in the respiratory system (Fairhall, *Industrial Toxicology*, Baltimore, 1949, p. 341). In high concentrations the irritant properties of ethylene oxide give warning of its presence. First-aid treatment consists in removal from exposure, rest in bed, and observation for 48 hours until the risk of delayed pulmonary oedema is past.

Corona Diaphragmatica

Q.—*A transverse row of venules is frequently seen running across the front of the chest wall, more usually on the left. Each venule runs more or less vertically, and the condition suggests some obstruction to the deep veins at the level of the diaphragm. What is the significance of this condition?*

A.—A band of dilated superficial venules, embracing the thorax at a level roughly corresponding with that of the diaphragmatic attachment, is commonly seen in males above middle age. It has been termed the "corona diaphragmatica." This phenomenon is compatible with health and does not indicate venous obstruction or any other disease process.

Antihistamine Drugs and Peptic Ulcer

Q.—*Is anything known about the value of antihistamine drugs in the treatment of peptic ulcers?*

A.—Unfortunately the antihistamine drugs have the effect of increasing rather than decreasing the amount of acid secreted by the stomach. This has been studied by Doran (*Lancet*, 1947, **2**, 490) and by Deutsch (*Klin. Med., Wien*, 1947, **2**, 1113). In one of Doran's patients with a duodenal ulcer there was a huge increase in the acidity of the fasting contents after 300 mg. of "benadryl" had been administered. It has been shown that benadryl does not protect guinea-pigs against the development of ulcer after the implantation of histamine in beeswax (Crane *et al., Amer. J. digest. Dis.*, 1947, **14**, 56).

A STUDY OF CORTISONE AND OTHER STEROIDS IN RHEUMATOID ARTHRITIS*

BY

W. S. C. COPEMAN, M.D., F.R.C.P.
Physician-in-Charge, and Physician to Arthur Stanley Institute, Middlesex Hospital, and Hospital of St. John and St. Elizabeth

OSWALD SAVAGE, M.R.C.P.
Assistant Physician, and Physician to Arthur Stanley Institute, Middlesex Hospital

P. M. F. BISHOP, D.M.
Endocrinologist, Guy's Hospital and Chelsea Hospital for Women

E. C. DODDS, M.V.O., M.D., F.R.C.P., F.R.S.
Director, Courtauld Institute of Biochemistry, Middlesex Hospital

B. GOTTLIEB, M.D., M.R.C.P.
Senior Physician, St. Mary Abbots Hospital

J. H. H. GLYN, M.B. **A. A. HENLY, Ph.D.** AND **A. E. KELLIE, Ph.D., A.R.I.C.**
(From the Rheumatism Department, West London Hospital)

Soon after Hench, Kendall, Slocumb, and Polley (1949) announced their preliminary results in treating active rheumatoid arthritis with 17-hydroxy-11-dehydrocorticosterone ("compound E"), hereafter called "cortisone," two of us (W. S. C. C. and O. S.), with others, had an opportunity of visiting the Mayo Clinic and seeing for ourselves the remarkable and rapid results obtained with this substance. It was at once obvious that owing to the difficulties and high cost of production cortisone would not be available for some time in this country even for a limited clinical trial on a research basis.

Consequently the present group was formed with the object of testing, with concurrent metabolic studies, other steroids which were more readily available, and of devising methods by which improvement in rheumatoid arthritis could be assessed in therapeutic trials of any substances which might be thought to have a cortisone-like action.

On the occasion of a second visit to the Mayo Clinic by one of us (O. S.) a small supply of cortisone was made available to us at the instigation of Dr. Philip Hench.

The present report deals with the results of the administration of cortisone to five patients suffering from rheumatoid arthritis and 35 patients treated with other steroids.

Methods

In this condition, in which the severity of the disease may fluctuate from day to day and criteria of activity depend to a large extent on the patient's own account of his pain and disability, assessment of improvement is notoriously difficult. Moreover, in addition to the normal variations which occur as a part of the natural history of rheumatoid arthritis, the psychological effect of giving a new treatment may be very considerable, as has recently been shown by Quin, Mason, and Knowelden (1950).

After discussion with Professor Bradford Hill it was decided to "screen" certain steroids by giving them to a small number of patients and assessing the results. In the event of a significant improvement occurring a second therapeutic trial was to be set up, in which the effect of the steroid would be compared with that of an inert substance indistinguishable from it in appearance, so that neither the patient nor those responsible for administering the injections and assessing the clinical results should know which compound was being given. The two substances, however, would be labelled in such a way that they could be identified in Professor Bradford Hill's department.

This latter method of trial was used in the case of cortisone on five patients who had previously received one of the other steroids; cholesterol was employed as the inert substance. Dr. J. Knowelden, lecturer in medical statistics at the London School of Hygiene and Tropical Medicine, working in Professor Bradford Hill's department, kindly handled this part of the trial.

The cases selected were patients suffering for more than six months from polyarthritis of the rheumatoid type, with symmetrical involvement of the peripheral joints, and tenderness, restricted range of movement, loss of weight, anaemia, and a raised erythrocyte sedimentation rate (E.S.R.). Cases with radiological evidence of minimal joint destruction were chosen so that restoration of full joint movement was still theoretically possible.

Patients were admitted to hospital for the trials and were all volunteers. They were not necessarily confined to bed, and in some cases they returned home for a part of each day so that they were able to judge for themselves whether there was improvement in their ability to carry out domestic duties. Patients were selected from out-patients attending the West London Hospital and the Arthur Stanley Institute of the Middlesex Hospital, and were admitted to the West London Hospital, the Hospital

*This study was aided by grants from the Medical Research Council, the Empire Rheumatism Council, and the Dan Mason Research Foundation of the West London Hospital.

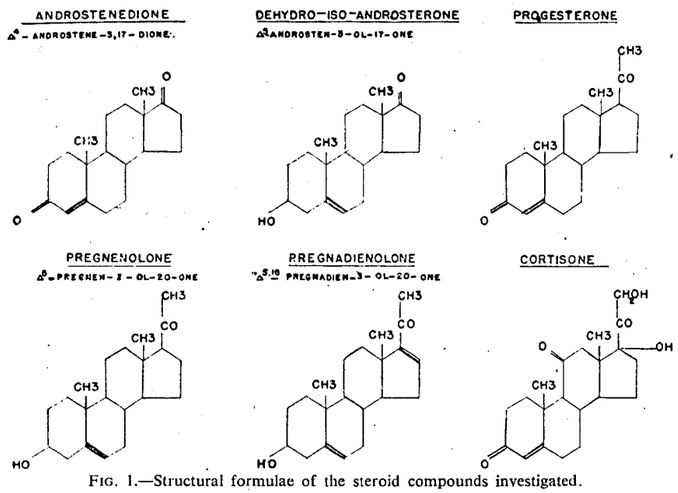

FIG. 1.—Structural formulae of the steroid compounds investigated.

of St. John and St. Elizabeth, or St. Mary Abbots Hospital. Each section of the metabolic studies was, however, carried out in the same laboratory in each case.

Each ten-day trial followed a period of observation in hospital of at least a week, during which a full assessment was carried out, as well as during and after the trial period.

Assessment of Effect

The following criteria were used in assessing the results of the trials:

1. Answers to standard questions were recorded on a "Wirek" magnetic wire recorder, so that the whole interrogative interview could be reproduced at a later date for consideration by both observer and patient. The following are examples of the standard questions used: "How long does it take you to dress?"; "Can you dress fully without assistance?"; "How many tablets do you take daily to relieve the pain?"; "How many times nightly do you wake up with pain?"

2. Repeated examination by the same observer of joints for tenderness on firm pressure, swelling, and range of movement; the results being charted as follows: "1" is recorded when firm pressure over a joint gives rise to pain; "2" when it causes the patient to wince; "3" when the affected limb is in addition involuntarily withdrawn.

3. The grip test.—A blood-pressure cuff is folded up and sewn together into a suitable shape to be gripped in the palm of the hand and is inflated to 30 mm. Hg. The patient is then asked to squeeze it as tightly as he can, and the pressure recorded on the manometer is noted. The mean of three grips with each hand is taken.

4. Certain functional tests using most of the joints of the body, such as walking, climbing a standard set of steps, putting on a coat, getting up and down from a chair. These movements were timed, and could be assessed simply as "positive" or "negative." The tests most often repeated are those which the patient can just accomplish, because they most clearly demonstrate the degree of disability. They may vary from case to case.

5. Patient's own assessment.—During the period of observation patients were taught to assess their own condition from day to day, taking "100" as the "base-line" condition before the trial began. Subsequent figures above 100 indicated deterioration, whereas those under 100 denoted improvement.

6. Certain haematological studies, such as the erythrocyte sedimentation rate, the eosinophil count, and the haemoglobin percentage.

7. Filming certain standard movements before and after therapeutic trials in some cases.

8. Metabolic studies.—In selecting the urinary estimations to be undertaken in the present study it was decided to confine the investigations to those which were reported to have yielded significant results in the early published work on cortisone. These were: (1) 17-ketosteroids, estimated by the method of Callow, Callow, and Emmens (1938). (2) Pregnanediol, determined by a modification of the method of Sommerville, Gough, and Marrian (1948) in which the second and third reprecipitations from aqueous ethanol were replaced by washing with petroleum ether. (3) Corticoids, estimated by the periodic acid oxidation method, using a procedure similar to that described by Corcoran and Page (1948). The conditions of the hydrolysis and extraction were rigidly standardized in order to obtain comparable results. (4) Uric acid. (5) Creatinine. (6) The uric acid/creatinine ratio. Metabolic studies were undertaken on six patients receiving progesterone (Fig. 2), four patients receiving pregnenolone (Fig. 3), two patients receiving dehydro-*iso*-androsterone (Fig. 4), three patients receiving androstenedione, one patient receiving pregnadienolone, and four patients receiving cortisone (Figs. 5 and 6).

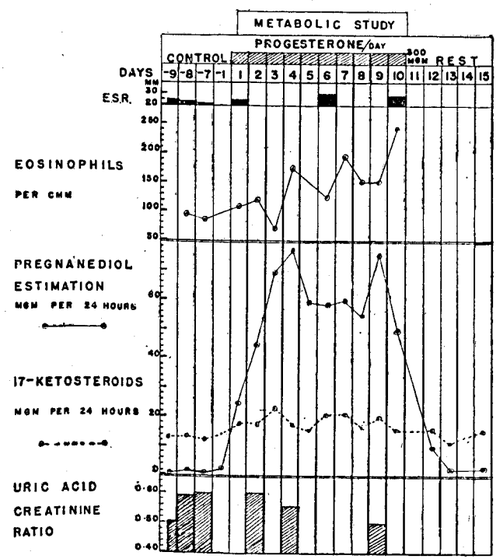

FIG. 2.—A metabolic study of a therapeutic trial with progesterone.

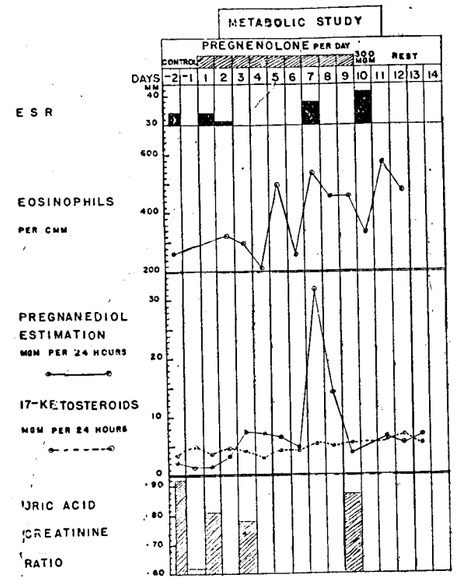

FIG. 3.—A metabolic study of a therapeutic trial with pregnenolone.

Materials

The steroid compounds investigated, other than cortisone, were androstenedione, dehydro-*iso*-androsterone, progesterone, pregnenolone, and pregnadienolone. Their structural formulae are shown in Fig. 1.

It was decided to use high doses of each steroid because it had been shown by the original workers at the Mayo Clinic that only high doses of cortisone would produce results in rheumatoid arthritis. The compounds were in most cases dissolved in ethyl oleate, and the chief factor limiting dosage was the volume of injected oil that the patient could tolerate.

Results

The accompanying Table is a summary of the results of administration of cortisone and other steroids in 40 cases of active rheumatoid arthritis.

Androstenedione.—Six patients were given 100 mg. daily for ten days. There was no clinical improvement in any case. The metabolic study showed a rise in 17-ketosteroids excretion. The uric acid/creatinine ratio showed a steady rise during the administration of androstenedione, but with all the other compounds this ratio fluctuated in a manner which did not indicate any significant trend.

Dehydro-iso-androsterone.—This compound was administered to four patients in daily doses of 300 mg. Slight transient improvement was recorded in one case only. Fig. 4 shows the results of a metabolic study. The increased output of 17-ketosteroids will be noted.

Progesterone.—Twelve patients (ten women and two men) were treated with 300–500 mg. daily for ten days. In every case there was a marked rise in sedimentation rate during progesterone administration. Only in the following case was any improvement seen.

Case 1.—A married woman aged 55 had been disabled with rheumatoid arthritis for six years. Five days after the injection of 300 mg. of progesterone daily she showed marked improvement, being able to run up and down the ward and raise her arms in a way she had been unable to do for three years. The improvement was maintained on 500 mg. daily until the end of the trial period, but when the inert control substance was administered she relapsed to her former state. No improvement occurred during a further period of treatment with 300 mg. of progesterone daily.

This suggests that progesterone is not so effectively metabolized in rheumatoid arthritics as in normal individuals. In this connexion it is of interest that the pregnanediol output was low (13.5 mg./24 hours) in the first period of progesterone administration, when there was marked improvement, and much higher (45 mg./24 hours) during the second course of progesterone, which proved ineffective. It seems possible that the progesterone was being more efficiently utilized during the first course of administration, and that this coincided with the beneficial effect.

Fig. 2 shows a metabolic study performed during a therapeutic trial with progesterone.

Pregnenolone.—No improvement was recorded in the eight cases of the present series. Fig. 3 shows the results of a metabolic study. There was no significant change other than an unexplained rise in the pregnanediol excretion on the seventh day. The E.S.R. rose during treatment.

Results of Administration of Cortisone and Other Steroids in 40 Cases of Rheumatoid Arthritis

Substance Used For Ten Days	No. of Cases	Improvement			No Apparent Effect	Toxic Effect Sufficient to Stop Treatment	Made Worse
		Dramatic	Marked	Slight			
Progesterone (300-500 mg./day)	12		1		8	2	1
Pregnenolone (100-300 mg./day)	8				8		
Androstenedione (100 mg./day)	6				6		
Dehydro-*iso*-androsterone (300 mg./day)	4			1	3		
Pregnadienolone (200 mg./day)	5				3	2	
Cortisone (Day 1, 300 mg., Day 2, 200 mg. Day 3-10, 100 mg.)	5	4	1				

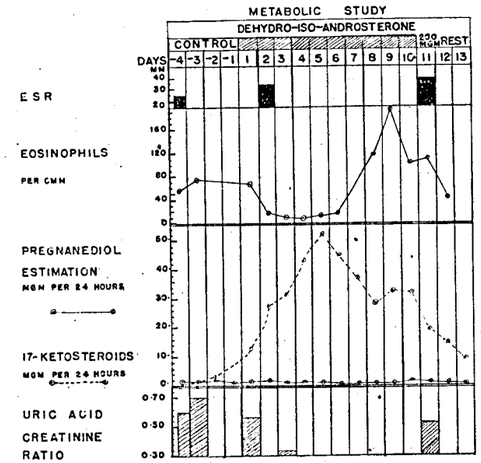

FIG. 4.—A metabolic study of a therapeutic trial with dehydro-*iso*-androsterone.

Pregnadienolone. — This substance was administered in arachis oil in doses of 200 mg. daily for ten days to five patients. In two cases the injections had to be discontinued because of urticarial reactions. In no case was there any improvement.

Cortisone

Five patients were given cortisone and the inert substance, the materials being labelled so that the observers did not know which was the active and which the control compound. After the clinical results had been assessed it transpired that cholesterol had been given first in three cases and cortisone in the remaining two: 300 mg. was administered on the first day, 200 mg. on the second day, and 100 mg. daily for the following eight days.

In all five patients the E.S.R. fell significantly during the cortisone trials. There was no marked rise in haemoglobin percentage in any case, though all the patients were anaemic. The number of eosinophils was considerably diminished throughout the trial (except in one case in which they rose on the eighth day), though they did not disappear completely. There was a sharp rise when cortisone administration was discontinued. In the two cases in which 17-ketosteroids were repeatedly estimated the level rose when cortisone was given, returning to normal subsequently. Similarly, the urinary corticoids rose during treatment, sometimes to three or four times the original level. Less than 2% of the administered cortisone was excreted in the urine as "corticoid" (that is, formaldehydogenic neutral lipid). This agrees with the findings of Sprague *et al.* (1950).

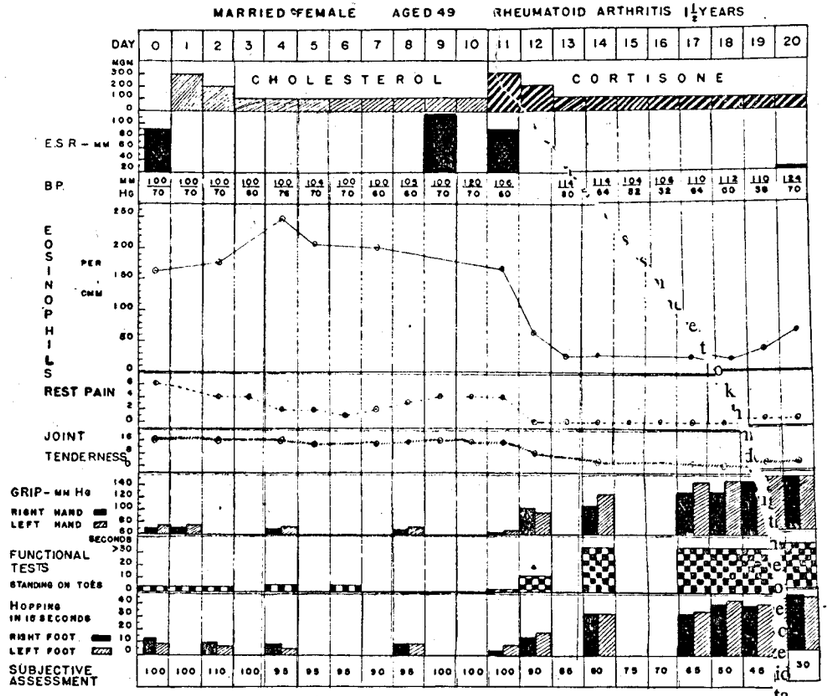

FIG. 5.—Showing the continued improvement throughout a trial with cortisone. (Case 2.)

Four patients gained from 2 to 4 lb. (0.9 to 1.8 kg.) in weight in ten days. There was marked increase in uric acid excretion; in one case the figure rose from 95 mg./24 hours to 429 mg./24 hours on the first day, and to 618 mg./24 hours on the second day of cortisone administration. The urinary creatinine figure rose from 699 mg./24 hours to 968 mg./24 hours on the second day.

All five patients receiving cortisone were women—two of the pre-menopausal, and three of the post-menopausal age. The treatment did not interfere with the menstrual cycles of the former or induce uterine bleeding in the latter.

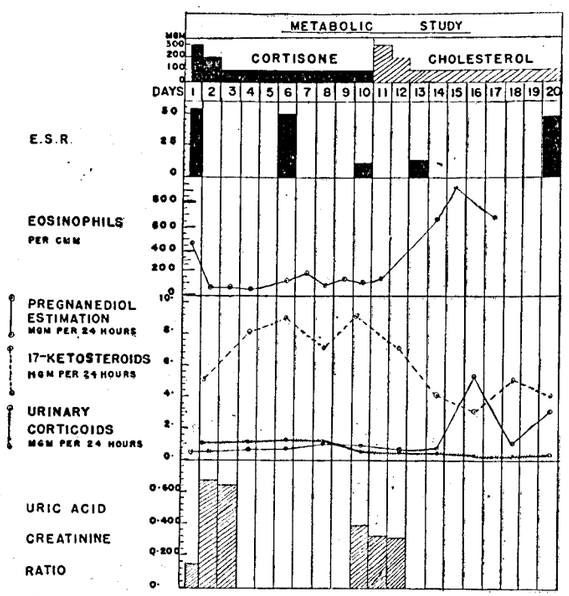

FIG. 6.—A metabolic study of a therapeutic trial with cortisone. (Case 4.)

Case 2

A married woman of 49 had suffered for one and a half years from rheumatoid arthritis, starting in the feet and gradually spreading to the knees, hands, and shoulders with development of nodules on the fingers. She was unable to do her cooking or housework, could not put on her dressing-gown unaided, or hold a cup of tea with one hand. She was taking 10 tablets of codeine daily and was awakened each night with pain. In the previous six months the erythrocyte sedimentation rates were repeatedly found to lie between 50 mm. and 60 mm. in one hour (Westergren). Previous trials with two other steroids had failed to help her.

The response to cortisone was dramatic. On the second day of administration she could hold a pot of tea with one hand and slept throughout the night; on the third day she could put on her dressing-gown unaided. After this she was allowed to go home each day and found she was able to cook

and undertake housework without pain, though it tired her to do so. Fig. 5 indicates the continued improvement throughout the trial.

One month later the residual improvement was considered to be about half as much as she had attained during the course of cortisone therapy, although the E.S.R. had risen to 54 mm. in one hour within a week of discontinuing the injections.

Case 3

An unmarried woman aged 41. The onset, seven months previously, had been febrile with rapid deterioration, and at the beginning of the therapeutic trial she was completely bedridden and in constant pain. The E.S.R. while she was attending as an out-patient was 100 mm. in one hour (Westergren) and had fallen to 60 mm. in one hour after she had been in hospital three months. She had failed to improve while receiving the cholesterol injections, but the improvement with cortisone was dramatic. After receiving 300 mg. on the first day she no longer complained of pain at rest, and on the third day she could get out of bed unaided and stand for a minute. Her grip improved from 60 to 140 mm. Hg with the right hand. The E.S.R. fell from 60 mm. to 20 mm. in one hour during the course of cortisone injections, and she assessed her improvement at 50% at the end of the 10-day course.

A month later she retained half the improvement she had shown during treatment and the E.S.R. had risen to 42 mm. in one hour.

Case 4

An unmarried woman of 55 had suffered from rheumatoid arthritis for three years with a gradual onset involving the knees and spreading to the hands, wrists, elbows, ankles, and shoulders. Previous therapy and steroid trials had failed to help her. She showed marked "ganglionic" swellings at the interphalangeal and wrist joints and could raise her arms only with difficulty. She could walk fairly well, but had been unable to take a bath without assistance for two years. The interphalangeal, wrist, elbow, shoulder, knee, and foot joints were tender on pressure and the E.S.R. had remained at 50 to 60 mm. in one hour each week for the previous two months.

The response to cortisone was dramatic. By the third day she had no pain at rest and the joints were less swollen and no longer tender. On the seventh day she could extend her arms above her head 20 times in one minute, and on the eighth day she took a bath without assistance. During the period of observation she had been unable to jump, but on the tenth she could do so 40 times in one minute. The E.S.R. fell from 54 to 11 mm. in one hour during the trial. She assessed her improvement as 60%.

A month later she had completely relapsed and the E.S.R. had risen to 50 mm. in one hour within 10 days of cortisone being discontinued. The metabolic study is shown in Fig. 6.

Case 5

A married woman aged 38 had suffered from rheumatoid arthritis for three and a half years, starting during her fifth pregnancy involving the hands, wrists, ankles, and feet, with mild joint pains. These became severe three months after parturition and progressed rapidly. She lost 2½ st. (15.9 kg.) in weight, and for the last nine months had suffered from lassitude. She took an hour to dress herself and was unable to carry out most of her household duties, such as holding plates and work involving kneeling. The fact that the E.S.R., which had been 40–50 mm. in one hour for the previous four months, had dropped to 17 mm. just before the trial, however, suggested that the condition might be entering a stage of remission.

The response to cortisone was dramatic, but not as rapid as in the three previous cases. On the second day she no longer complained of pain at rest and most of the tenderness had disappeared, but she did not consider herself much improved until the third day, when she could kneel for the first time without pain. After the fourth day she improved more rapidly, and by the tenth day she could climb on to her bed easily and unaided. The grip of her right hand had strengthened from 100 to 200 mm. Hg and the left hand 90 to 185 mm. Hg. The E.S.R. fell from 17 mm. to 6 mm. in one hour. She assessed her improvement as 50%.

During the subsequent 10-day course of cholesterol injections she retained about half the improvement she had achieved, although the E.S.R. rose again to 23 mm. in one hour. A month later she retained the same degree of improvement, although the E.S.R. had risen further to 43 mm. in one hour.

Case 6

An unmarried woman of 30 had suffered from mild rheumatoid arthritis for four and a half years. Though she was able to continue her clerical work she complained of marked stiffness on rising and a chronic effusion in the left knee. The interphalangeal, metacarpo-phalangeal, and wrist joints and the left knee and mid-tarsal joints were tender, and she was taking an average of 10 codeine tablets daily. The E.S.R., which had fluctuated between 16 mm. and 60 mm. in one hour during the last year, was 20 mm. at the beginning of the clinical trial.

The response to cortisone was marked but not dramatic. The left knee was no longer painful at rest and the wrist-joint tenderness was less, although it did not entirely disappear. The effusion in the left knee subsided. She assessed her own improvement as only 30%, in spite of the fact that she was able to go up and down a flight of steps in eight seconds at the end of the trial, whereas previously it had taken her double that time.

A month later she had retained all her improvement and the E.S.R. was 12 mm. in one hour.

Discussion

Progesterone

Sommerville, Marrian, Duthie, and Sinclair (1950) found that rheumatoid arthritics of both sexes excrete an unusually high proportion of intramuscularly administered progesterone in the urine as pregnanediol. This suggests inadequate metabolism of progesterone, and the observation in one case of the present series, that the pregnanediol excretion was higher when the progesterone proved clinically beneficial than later when it failed to reproduce clinical benefit, would support this contention. Alexander and Duthie (1950) reported five cases treated with progesterone in doses lower than those used in the present study, with no improvement.

Pregnenolone

Davison *et al.* (1950) reported improvement in cases of rheumatoid arthritis and ankylosing spondylitis with 300 mg. daily and also in lower dosage. They noticed clinical improvement within a week, with reduction in the E.S.R., and claimed that, although pregnenolone is less rapidly effective than cortisone or adrenocorticotrophic hormone (A.C.T.H.), it appears to be free from toxic effects and is cheap and easy to make. Ishmael *et al.* (1949) reported promising results in various rheumatic conditions, including rheumatoid arthritis, with 100 mg. daily. Freeman *et al.* (1950) claimed good results with pregnenolone by mouth in daily doses of 500 to 700 mg. Stock and McLure (1950) obtained objective improvement in three cases out of ten treated for two weeks with 200 mg. daily. Guest *et al.* (1950) treated 17 cases, of which only one showed improvement.

It was impossible to detect any improvement in the eight patients given pregnenolone in the present series.

Pregnadienolone

This compound has a double bond between C_{16} and C_{17}. It seemed possible, therefore, that it might give rise to a metabolic derivative in which the double bond had been converted into a hydroxyl substituent at the 17-carbon atom, such as is found in compound E and "compound F." It did not prove effective, however, in clinical trial.

Cortisone

Mason, Myers, and Kendall (1936) reported on the physiological activity of the crystalline compound E which they had isolated from the adrenal cortex. The same compound was also isolated by Wintersteiner and Pfiffner (1936) and by Reichstein (1936).

The metabolic effects of this and other cortical compounds have been reviewed by Venning (1948). Recently the results of metabolic studies on patients with rheumatoid arthritis treated with cortisone have been published by Sprague *et al.* (1950). Carlisle (1950) has summarized its clinical uses.

In the original series of 14 patients studied at the Mayo Clinic (Hench *et al.*, 1949) all responded dramatically with loss of stiffness, pain, and tenderness, and improvement in articular and muscular function, often within 48 hours. Sedimentation rates decreased within one or two weeks. Every patient except one relapsed when treatment was discontinued.

Boland and Headley (1949) reported the results of treating eight cases of rheumatoid arthritis with cortisone. In five the disease was severe and the initial dose of 300 mg. was followed by 100 mg. daily for seven days. All improved "rapidly and remarkably" except for one diabetic patient, who improved more slowly but also relapsed more slowly when the drug was withdrawn. Lower doses (50 mg. daily for 10 to 15 days) were given in the three less severe cases, and by the end of the course the clinical manifestations had subsided almost completely and the sedimentation rate was normal. No side-effects were noted.

Hench *et al.* (1950) reported a further series of 21 patients. Improvement was either "marked" or "very marked" except in one case in which it was only moderate. According to these experienced workers the sequence of events is usually as follows: decreased stiffness and aching; diminished tenderness and swelling within the first 12 to 48 hours; complete relief of pain and sometimes swelling during the first week.

Freyberg (1950) recorded 17 cases treated with cortisone with uniformly good results, which could be maintained with 100 mg. three times a week.

Boland (1950) reviewed the literature concerning 160 cases of rheumatic disease, mostly rheumatoid arthritis, which had been treated with cortisone. In rheumatoid arthritis results have with very few exceptions confirmed the dramatic findings of Hench *et al.* (1949).

Side-effects can best be avoided and clinical remission maintained by giving 200 mg. of cortisone on the first day and subsequently 100 mg. daily until the clinical symptoms and E.S.R. subside (usually in two to eight weeks). Dosage is then gradually reduced to the lowest level that will control the condition.

The present study records the results of the first European clinical trial of cortisone in the treatment of rheumatoid arthritis, and each of the five patients treated has shown unequivocal response which completely confirms the claims of the American workers.

Eosinophils.—Most authors (Thorn *et al.*, 1950) report that whereas with A.C.T.H. there is complete disappearance of eosinophils starting about six hours after the first injection, with cortisone there may be no significant eosinopenia. In the present series there was a marked diminution in eosinophils, which was maintained while cortisone was administered.

Side-effects

Side-effects consisting in sodium retention, leading to oedema, alkalosis, glycosuria, acne, hirsutism, striae, and the rounding of the face seen in Cushing's syndrome, have occasionally been recorded after prolonged cortisone therapy. With the recent tendency to use lower maintenance doses, however, they occur less commonly, and according to Baehr and Soffer (1950) are more likely to be seen during the treatment of such acute conditions as disseminated lupus erythematosus than in rheumatoid arthritis. Boland (1950) suggests that they should be referred to as "signs of hyperadrenalism" rather than as "toxic effects."

Freyberg (1950) has encountered no serious complications in a series of 17 patients treated with cortisone, some for as long as 160 days. Hench *et al.* (1950) reported mild and reversible side-effects in eight out of 21 patients treated for periods of up to seven months; in four patients the side-effects were pronounced.

Treatment had to be discontinued in the present series on four occasions (see Table)—in two cases because of an urticarial reaction, presumably to the vehicle, and in the others on account of severe pain at the site of the injection. No side-effects occurred in any of the cases treated with cortisone, although a careful watch was kept for signs of oedema, rounding of the face, acne, glycosuria, and hypertension.

The psychological reactions of the patients were interesting; all were delighted with their improvement, but none was unnaturally excited or displayed euphoria or exhibitionism. This may be because they were warned, as had the patients receiving the other steroids, that there was a ten-day supply only for each of them and that it would therefore be necessary to discontinue treatment at the end of that time even if improvement occurred.

Summary

Forty patients suffering from rheumatoid arthritis have been submitted to clinical trials with cortisone and five other steroid compounds.

The following criteria were used to assess the effects of these compounds: (1) Recorded interviews before, during, and after treatment. (2) Filming of certain movements in selected cases. (3) Assessment of joint tenderness and range of movement. (4) Functional tests such as walking, climbing steps, putting on a coat, and mounting a chair. (5) Personal assessment of improvement by the patient. (6) Eosinophil counts, erythrocyte sedimentation rate, and haemoglobin determination. (7) Urinary 17-ketosteroid, pregnanediol, and "corticoid" estimations.

Cortisone was used in five cases, with cholesterol as a control substance. Although it was not known at the time of administration which compound was being used, the dramatic clinical effects of cortisone were immediately obvious.

The other steroid compounds employed were androstenedione, dehydro-*iso*-androsterone, progesterone, pregnenolone, and pregnadienolone. These proved ineffective, except in one case treated with progesterone in which there was a remission of symptoms, which was not repeated when a second course was administered.

We wish to acknowledge the valuable assistance given to us by the following pathologists and biochemists and their assistants: Dr. H. E. Archer, West London Hospital; Dr. A. G. Signy, St. Mary Abbots Hospital; and Dr. R. G. L. Waller, West London Hospital.

The materials used in these trials were generously supplied by the following firms, whose scientific directors we should like to thank for their interest and co-operation: Cortisone by Dr. J. M. Carlisle, of Messrs. Merck and Co., Rahway, N.J., U.S.A.; progesterone, androstenedione, dehydro-*iso*-androsterone, and pregnenolone by Sir Jack Drummond, F.R.S., of Boots Pure Drug Co., Ltd.; and pregnenolone and pregnadienolone by Dr. B. M. Merriman, of British Drug Houses Ltd. Other substances, including material for controls, were kindly supplied by the following firms: Messrs. Allen and Hanburys Ltd., Bayer Products Ltd., Benger Laboratories Ltd., Ciba Laboratories Ltd., and Roche Products Ltd.

A "Brochure of Instruments and Accessories for Radio-isotope Applications" has just been issued by the Scientific Instrument Manufacturers Association (of Great Britain, Ltd.) in collaboration with the Atomic Energy Research Establishment, Harwell. It is likely to be a useful booklet for all interested in employing radio-isotopes in their work, since it is in effect a directory to all instrument manufacturers, to consultants capable of advising in work of this kind, and to the suppliers of radio-isotopes (at Harwell and at the Radiochemical Centre, Amersham), as well as providing a short discussion on the kinds of instruments to be employed in different situations. Thus Geiger-Müller counters may register either the total radiation they receive in a given time or the rate at which they receive it; they may be sealed off or have an arrangement for introducing the substance to be assayed for radioactivity actually into the counter tube. Scintillation counters contain phosphors which sparkle as gamma rays strike them, and a device for counting the flashes. Ionization chambers measure in a given time the total radiation due to nuclear particles striking the atoms of gas in the chamber. Several kinds of instruments are available for health monitoring. A small direct-reading ionization chamber set in a fountain-pen-like cylinder measures the cumulative exposure to radiation of the person who wears it in his pocket. A hand-and-foot monitor looks something like a weighing-machine, on which the person under examination stands. Under its platform are two G.-M. counters, which measure the radiation from dirt on the shoes, while at arm height are pockets into which the hands can be thrust to have their radioactivity assayed by further adjacent counters. Two frisking probes are counters attached to the sides of the machine by long flexible leads. It is interesting to note that no less than six different firms make G.-M. counters, and eight produce monitoring instruments. In addition to the official isotope information office at Harwell there are also three private firms of consultants in this field of work. Copies of the brochure can be obtained free of charge from the publishers.

INSULIN AND E.C.T. IN TREATMENT OF RHEUMATOID ARTHRITIS

REPORT ON A PILOT SERIES OF CASES

BY

G. D. KERSLEY, M.D., F.R.C.P.
L. MANDEL, M.B., M.R.C.P.
M. R. JEFFREY, M.B., M.R.C.P.
M. H. L. DESMARAIS, M.R.C.S., L.R.C.P., D.Phys.Med.

AND

E. BENE, M.D.

(From the South-west and Oxford Regional Rheumatism Research Unit, Royal National Hospital for Rheumatic Diseases, Bath)

Insulin has been used as a "tonic" and as a method of increasing weight in rheumatoid arthritis for a number of years (Copeman, 1931). The more recent theories of the part played by the pituitary adrenal mechanism in this disease have suggested another reason for this type of therapy. Cannon *et al.* (1924) found that insulin hypoglycaemia provoked the liberation of adrenaline, and since then evidence has been produced which is claimed to show that the adrenal cortex can be stimulated in this way, either directly in hypophysectomized animals or indirectly by stimulation of the pituitary with liberated adrenaline (Langecker, 1928; Miller *et al.*, 1941; Godlowski, 1947). It seemed that this explained the benefit obtained from insulin shock therapy and electric convulsion therapy (E.C.T.) in many mental disorders. Moreover, it had been noted that the combination of rheumatoid arthritis and epilepsy was extremely rare. On the suggestion of one of us (M. H. L. D.) it was decided to treat a pilot series of cases of active rheumatoid arthritis with insulin hypoglycaemia and a second series with E.C.T., and observe the clinical and biochemical results.

Methods and Techniques

All patients were suffering from active rheumatoid arthritis, and in addition to insulin therapy all received the same basic regime of treatment, which included rest splints, remedial exercises, and physiotherapy. Treatment was not begun until patients had had two weeks' basic physical treatment in hospital.

The method used was based on the modified insulin technique as described by Sargant and Slater (1948). Attempts were made to induce hypoglycaemic reactions every morning for five days each week, leaving Saturday and Sunday free of treatment. Treatment was carried out over a period of three or four weeks. A good hypoglycaemic reaction was indicated by marked flushing and sweating, weakness, drowsiness, and tremor. The reaction was normally interrupted three hours after the dose of insulin by a meal containing 16 oz. (454 g.) of mashed potatoes flavoured with an egg, or other suitable breakfast dish, together with bread-and-butter, jam, porridge, and sugared tea. Only if the patient went into sopor or coma, or had convulsions, was hypoglycaemia interrupted earlier by intravenous glucose. This had to be carried out in four patients (Cases 21, 23, 30, 33).

Patients were assessed clinically every week, before, during, and just after treatment, and also at varying periods after treatment was completed. The assessment included observations on the general feeling of well-being, mental outlook, subjective pain (including rest pain),

stiffness, swelling, range of movement, deep hyperalgesia, in addition to functional ability—e.g., ability to dress, shave, brush the hair, walk, use a knife and fork. Patients were also weighed weekly before, during, and after treatment, before breakfast, and after emptying the bladder and, if possible, bowels.

In view of the rapid increase in weight during and the decrease after treatment, fluid balances were performed latterly before and after treatment.

During the week before starting treatment, estimations of sedimentation rate (E.S.R.), haemoglobin, haematocrit, fasting blood sugar, and serum potassium were carried out. Urinary uric acid and creatinine levels were estimated on a 24-hour specimen in all cases and 17-ketosteroids in 8 cases (Nos. 8, 10, 17, 18, 23, 24, 25, 26). In addition the basic level of circulating eosinophils was ascertained under strict standard conditions (see below), together with changes of such levels in response to injections of adrenaline and A.C.T.H.

During treatment, on the first day on which the patient showed a good hypoglycaemic reaction, similar controlled estimations of eosinophil counts, serum potassium, blood sugar, and urinary uric acid and creatinine levels were carried out. The same tests were repeated during the week following completion of treatment.

The "activity index" referred to in Tables I and II represents an attempt to give a numerical value to the activity of the disease. The index is derived from four factors—change in weight, E.S.R., haemoglobin levels, and degree of pain at rest. These are graded on a three-point scale, as explained in a previous paper (Kersley *et al.*, 1950).

Blood sugars were estimated by the method of Folin and Wu, and urinary uric acid and creatinine by Folin's method.

TABLE I

Case No.	Age and Sex	Duration of Disease (Years)	Duration of Treatment (Days) Total	Effective	Min. Dose Insulin to Produce Hypoglycaemia (Units)	Clinical Degree of Hypoglycaemia	Clinical Change	Change in Activity Index

Clinical change: − = Deterioration. 0 = No change. + = Slight improvement. ++ = Marked improvement.

During the latter period of these observations total neutral 17-ketosteroids were estimated in the urine by the modified method of Callow *et al.* (1938), where creatinine levels of the 24-hour urine specimens were constant.

Serum potassium estimations were carried out by the method of King (1946). These tests were done before treatment was started (fasting) and on the first day of definite clinical hypoglycaemic reaction, both at 10 a.m. (at the height of hypoglycaemia) and at 3 p.m. (when the eosinopenic response was maximal).

Circulating eosinophils were counted by the Randolph (1949) technique, four improved Neubauer chambers being used. Three o'clock was chosen for the time of the second eosinophil count because we ascertained by preliminary observations that the maximal eosinophil depression occurred about that time, the figure varying little between 2 p.m. and 3.30 p.m. The count was thus made about 4½ hours after the ending of hypoglycaemia by breakfast. The counts are given in Table II. In addition to the counts observed, the 3 p.m. figure was expressed as a percentage of the 10 a.m. value (columns 3 and 6); the ratio of the "hypo. day" to the "control day" represents the true depression consequent upon hypoglycaemia. Cases 1–4 did not have an adequate control estimation; all of them, however, showed considerable eosinophil depression after hypoglycaemia.

Results and Observations

Of 40 cases (17 male and 23 female) in whom treatment has been completed, 22 (55%—6 male and 16 female) showed marked clinical improvement, 9 (22.5%—6 male and 3 female) showed slight clinical improvement, and 8 (20%—4 male and 4 female) showed no significant change. One patient (Case 20) deteriorated (see Tables).

In most cases in which there was marked clinical improvement, such improvement occurred after the first week's treatment (shortly after a hypoglycaemic reaction was obtained) and continued throughout the whole course. Improvement was pronounced in all aspects, especially in general feeling of well-being and mental outlook, with loss of malaise and increase of appetite, lessening of pains in joints (including rest pain), and deep hyperalgesia. The general impression was that the joints of the upper limbs improved more than those of the lower limbs, and that joints more recently affected showed an earlier and more marked response than the others.

In those patients only slightly improved, improvement affected some joints but not others, and the patient's condition often varied throughout treatment. Although there was frequent subjective improvement, objective change was not significant.

Of the 8 patients in whom there was no change, one (Case 7) had had treatment for only nine days, when therapy had to be stopped because the hypoglycaemia was causing her to become mentally confused and irrational; in another (Case 17), though the pains in the upper limbs improved very slightly, the knees flared up during treatment.

All patients showed a gain in weight. The mean initial weight for men was 133 lb.—range 105–170 lb.— (60.3 kg.; range 47.6–77.1 kg.) and for women was 111 lb.—range 78–165 lb. (50.3 kg.; range 35.4–74.8 kg.). The mean increase in weight for men was 7 lb.—range 1–15 lb.—(3.17 kg.; range 0.45–6.8 kg.) and for women 6 lb.—range 2–11 lb.—(2.72 kg.; range 0.9–4.99 kg.).

All the 22 cases showing marked clinical improvement had quite definite and pronounced hypoglycaemic reactions

clinically. Of the 9 cases which had slight clinical improvement, 4 had marked, 3 had moderate, and 2 had slight hypoglycaemic reactions. Of the 8 cases which showed no significant clinical change, 5 had marked, 2 had moderate, and 1 had no hypoglycaemic reaction.

Of the 22 cases which showed pronounced clinical improvement, 15 had had the disease for three years or less and 7 for over three years. Those patients with slight or no clinical improvement fell equally into these two duration groups.

There was no obvious change in the sedimentation rates during treatment.

Of 39 cases, 14 (36%) showed an increase of more than 1 g./100 ml. Hb, 3 a decrease of more than 1 g./100 ml., and 22 a change of less than 1 g./100 ml. No consistent significant alteration was observed between the haemoglobin levels estimated at maximum hypoglycaemia and 4½ hours later.

As these cases were not under continuous treatment in a metabolic ward, it was considered that any change in the urinary uric-acid/creatinine ratio of less than 40% might be fallacious. Only 11 cases (27.5%) had an increase of more than 40% during the course of treatment. Of these 11 cases, 8 had marked clinical improvement.

Satisfactory total neutral 17-ketosteroid estimations were made in only 8 cases, which is obviously an insufficient number from which to draw conclusions; but it is perhaps of interest that those cases which showed clinical improvement had either a reduction or no change in ketosteroid levels.

The most striking biochemical result of all these investigations was the almost constant decrease in serum potassium levels during hypoglycaemia and an increase in these values 4½ hours later in all cases. In 34 cases the potassium level was lowered during hypoglycaemia by amounts ranging from 0.8 to 9.4 mg./100 ml.; in one case the value was unaltered and in another case it rose by 3.3 mg. (Cases 34 and 20 respectively). In the cases showing a fall the mean control value was 19.8 mg. and the hypoglycaemic value 15.9 mg., the mean fall being 3.9 mg./100 ml. (20%). The lowest figure recorded was 13.0 mg.

At the time of maximal eosinopenia (3 p.m.) the mean potassium level had risen to 20.9 mg.—i.e., 1.1 mg. above the control value. Some increase above the hypoglycaemic level was present in every case: in 13 cases the control value was exceeded by more than 1 mg./100 ml., the highest figure recorded being 27.5 mg.

U.A./Cr. ratio: 0 = Unchanged; + = Increased. * Brought forward from Table I.

Lowering of the fasting blood sugar level, by amounts ranging from 12 to 66% of that level, was achieved in all of the 36 cases examined. Contrary to expectations, little correlation was apparent between the degree of eosinophil depression and either the percentage depression of blood sugar relative to the fasting value or the absolute values for blood sugar obtaining during hypoglycaemia.

A wide variation in susceptibility both to the hypoglycaemic action of insulin and to the eosinopenic action of hypoglycaemia was apparent. In Case 37, for example, a fall in the blood sugar from 82 to 28 mg./100 ml.—a drop of 66%—produced only a 24% reduction in eosinophils whereas in Case 27 a fall in blood sugar from 80 to 68 mg./100 ml. produced an eosinophil depression of 76%.

Of the 36 adequately controlled cases, 34 showed a depression of eosinophils following hypoglycaemia; 26 of these had decreased by 50% and 15 by more than 75% at the 3 p.m. count.

Comparison of the 10 a.m. figures for control and "hypo." days showed that there was no consistent change in eosinophils during hypoglycaemia.

Of the two patients who failed to show any depression of eosinophils, one (Case 32) never had a good hypoglycaemic reaction clinically, although his insulin dosage was raised to 116 units. Nevertheless, on the last day of treatment his eosinophils did in fact fall from 483 at 10 a.m. to 211 at 3 p.m.—a true depression of 55%. Unfortunately, the blood sugar was not estimated. The other patient (Case 15) showed a considerable spontaneous decrease of eosinophils during the control day, a decrease materially unaltered by clinically adequate hypoglycaemic reactions. Case 32 showed only very slight clinical improvement, and Case 15 none whatever.

The Adrenaline Test

The effect upon circulating eosinophils of 0.3 mg. of adrenaline hydrochloride, given subcutaneously in the front of the forearm, was estimated by comparing the change produced after four hours in the number of eosinophils with that occurring spontaneously over a similar period on a previous control day.

The patient remained in bed until the completion of the test. A normal breakfast was given at about 7.30 a.m. and then no food until lunch at 12.30 p.m. Eosinophils were counted at 12 noon and again four hours later, the adrenaline injection being given immediately after the first eosinophil count on the appropriate day. The 4 p.m. figures were expressed as a percentage of the 12 noon value, comparison of these percentages revealing the change produced by adrenaline.

Thirty-nine cases were tested in this way, the results being as follows:

Eosinophil depression	>50%	30–49%	<30%
Men (17 cases)	7	2	8
Women (22 cases)	6	5	11

Thus half of both the male and the female cases showed an insignificant change (leading article, *Lancet*, 1950, **1**, 1042), about one-third gave the response stated to be normal by Recant *et al.* (1950), and the remainder showed a distinct but less than normal depression.

Of the 22 patients showing marked clinical improvement, 21 had an adrenaline test performed before therapy was instituted. Of these, 8 showed a positive reaction (eosinophil depression >50%), 9 showed a negative reaction (eosinophil depression <30%), and 4 showed a doubtful positive reaction (eosinophil depression 30–49%). Of the 9 patients showing a slight clinical improvement and the 8 patients showing no change, 4 had a positive reaction, 10 a negative reaction, and 3 a doubtful reaction. The patient who deteriorated had a positive reaction. There does not seem to be a correlation, therefore, between the adrenaline test results and the degree of clinical improvement.

The eosinophil count varies very considerably in the same person from day to day and in the course of the day, and we are well aware that a procedure involving only one control and one test day cannot be highly accurate. It was hoped, however, that this relatively crude test would prove of value in distinguishing those patients who would respond well to therapeutic hypoglycaemia, but it has not done so. Furthermore, no correlation was found between the adrenaline test and any of the laboratory tests carried out.

There is a suggestion that the cases giving a negative adrenaline reaction show a smaller increase in weight and that a smaller proportion of them achieve a satisfactory depression of eosinophils than occurs in the adrenaline-positive cases, but the test certainly does not decide which patients will respond well to insulin therapy.

A.C.T.H. Test

The effect of A.C.T.H. upon circulating eosinophils was estimated in 10 patients before treatment, the conduct and timing of the test being exactly the same as for the adrenaline test except that a dose of 12.5 mg. A.C.T.H. was injected intramuscularly after the first eosinophil count. This small dose was used partly to stretch our supply to its maximum, but also to ascertain whether any considerable variation in individual susceptibility to the eosinophil-depressing action occurred, and, if so, whether the "sensitive" group would respond better to insulin therapy than the insensitive.

Of the 10 patients tested, 6 showed a depression of 50% or more of circulating eosinophils after four hours (of these, 4 had a marked clinical improvement and 2 showed no clinical change); 2 a depression between 30 and 50% (both these patients showed only slight clinical improvement), and 2 no significant change (one with marked and one with slight clinical improvement). One of the cases with a negative A.C.T.H. reaction and both cases with a doubtful positive had negative adrenaline reactions; the other negative A.C.T.H. case did not, unfortunately, have an adrenaline test. Of the 6 showing positive A.C.T.H. reactions 3 cases had negative, 1 case had a doubtful positive, and 2 cases had a positive adrenaline reaction.

From the above it is obvious that our results show no correlation between the adrenaline and A.C.T.H. reactions or between either of these and the clinical progress of the cases.

Clinical Follow-up of Patients

Of the 40 patients, up to date 25 have been followed up for periods varying from four weeks to four months.

Of those showing marked clinical improvement (16 of the 25), 10 (Cases 1, 13, 14, 18, 19, 23, 24, 25, 27, 29) maintained their improvement for four to six weeks after completion of treatment. The remaining six (Cases 2, 3, 9, 26, 28, 31) relapsed after periods varying from two to five weeks after completion. Of these, Case 2 was given a second course of insulin lasting one week, 13 weeks after the first course, with slight improvement only. In the following week she was given one dose of insulin with little change, and shortly after this she developed gastro-enteritis followed by attacks of spontaneous hypoglycaemia, during which time her arthritis again improved. This case will be the subject of a further communication later.

Of those showing slight clinical improvement (5 of the 23), 3 patients (5, 11, 21) maintained their improvement for five weeks, whereas 2 patients (8, 16) relapsed within two weeks of the completion of treatment.

Further clinical follow-ups are proceeding.

Electric Convulsion Therapy

Altogether 11 patients were treated with electric convulsion therapy combined with curare. The technique employed was, after premedication with morphine and atropine, to give 0.5 g. of thiopentone sodium combined with, or followed immediately by, 2 mg. of D-tubocurarine chloride per stone (5.2 kg.) body weight, intravenously. After an interval of 2–2½ minutes an electric shock was given in a dose of 120 or 130 volts for 0.3 second. In 4 patients, as a control, the above technique was used, omitting the actual electric shock in the first instance.

In 2 cases only one shock was given. In one there was no significant change, but in the other there was considerable improvement in the patient's general feeling of well-being and mental outlook, together with reduction of pains in his joints, especially the feet. He could walk without pain and could stand on his toes, a thing he had been unable to do for the past 18 months. This improvement was noted on the evening of the day of therapy and lasted for three weeks, but then his symptoms recurred.

In 2 cases two shocks were given at an interval of five days. In one there was no significant change; the other improved shortly after the first shock, only to relapse again after three days, and after the second shock there was considerable deterioration in the patient's condition in all aspects.

In 1 case three shocks were given at weekly intervals. Considerable improvement was noted on recovery from the shock, and this lasted six days. After the second shock there was again improvement, but much less in degree and lasting only three days. No significant change occurred after the third shock.

In 2 cases two shocks were given at an interval of five days, followed by six more shocks on alternate days over a period of two weeks. One of these cases improved after the first and second shocks, relapse occurring in each instance after 24 hours. After the remaining shocks, however, the patient showed progressive slight improvement of the pains in the joints of the upper limbs, but those in the knees remained unchanged. The improvement noted after completing the course of E.C.T. continued for the next three and a half months, with a slight temporary relapse about six weeks after completion of treatment. The other patient also improved after the first and second shocks, relapsing in each instance after three to four days. Again after the remaining shocks the patient progressively improved, with no relapse, regarding both her general health and the pains and stiffness. This improvement had lasted 10 weeks when she was last seen.

In 3 cases eight shocks were given on alternate days over a period of three weeks following one control. In one patient there was no significant change; in another, slight improvement was seen after the last three shocks, but this was maintained for only two weeks; the third patient progressively improved throughout treatment and continued to do so even more significantly during the next two months, at the end of which time the patient was symptomless and felt extremely well generally, with minimal physical signs.

In 1 case six shocks were given on alternate days over a period of two weeks following one control. Treatment was not continued, because of the development of thrombophlebitis in the arm vein. This patient showed no significant clinical change.

Thus of all the 11 patients treated with E.C.T., 3 showed marked clinical improvement, 3 slight clinical improvement, and 5 no significant clinical change. The average number of shocks given was five.

No significant drop in the number of circulating eosinophils was observed five hours after E.C.T.

Discussion

Arising out of our findings there are a few points worthy of some discussion. Although it was recognized that small doses of insulin had been used for many years for increasing weight, the constancy, magnitude, and rapidity of the increase with the larger doses employed in this series were quite remarkable. This increase was observed even in the worst cases, which had been deteriorating continuously for a year or more in spite of all treatment, including gold, transfusions, etc. Obviously the psychological effect of this weight increase must be considered in the assessment of subjective improvement. In the week after treatment was discontinued about half the cases showed a loss of part of the weight gained. In view of this, fluid balances were charted for the week before and the week after treatment in the last 14 cases treated. During treatment the hypoglycaemic sweats made any balancing of intake against urinary output quite useless. Even without obvious sweating it was realized that the results might be fallacious, as borne out by Talbott's (1943) observations on a paradoxical increase in weight coupled with diuresis in certain phases of gout, explained by him as due to changes in insensible perspiration. It was thought, however, that even this rough test might give some evidence whether water retention played any part in the very rapid changes in weight.

Before receiving insulin treatment all the patients except one showed a positive fluid balance, whereas after treatment 10 of the cases showed a negative and only 4 a positive fluid balance. Of the 10 showing a negative fluid balance 6 had a loss in weight of 1–3 lb. (0.45–1.36 kg.), 3 had a gain in weight of 1 lb., and in one the weight did not change in the week following treatment (Table III). Observations on fluid balance are continuing.

One fluid ounce = 28·4 ml. One pound = 0.37 kg. * Average daily figure.

In spite of the high percentage of cases that showed marked clinical improvement, usually starting in the first week, there were no consistent changes in the E.S.R. during the period of observation. This is not in conformity with the findings of Godlowski (1949) in his single case.

The uric acid excretion was significantly increased in only 11 cases, but this is not surprising in view of the comparatively small average increase in uric acid found by Sprague *et al.* (1950) even on administration of 200 mg. of cortisone.

The changes in the serum potassium were the most constant of all the biochemical findings in our series. The reduction of potassium at the height of hypoglycaemia is well recognized (Cantarow and Trumper, 1945), but the rise 4½ hours later, at the point of eosinopenia, is worthy of notice. Sprague found that a drop in potassium was the most constant biochemical finding of any in treatment with cortisone or A.C.T.H.

The absence of correlation of eosinopenia with clinical progress is of interest, as is the constancy of the fall of eosinophils with insulin but absence of change with E.C.T. The suggestion that insulin hypoglycaemia acts by stimulation of the pituitary through the production of adrenaline is borne out neither by the response of the patients to adrenaline—which showed little correlation with their response to insulin—nor by our previous indifferent results when 5 cases of rheumatoid arthritis were treated with adrenaline in oil (unpublished). It seems, however, that direct stimulation of the adrenal cortex, as has been shown to occur in hypophysectomized animals, is more likely;

or the synergic action of insulin and endogenous cortisone may be a factor in our results (Henderson *et al.*, 1950).

It is stressed that the use of insulin hypoglycaemia should not be looked upon, at all events at present, as a new treatment for rheumatoid arthritis. This is only a report on a pilot series of cases, which require further control and follow-up. Further information is being sought on such problems as potassium excretion, fluid retention, correlation of results with A.C.T.H.-sensitivity, and the value of intermittent treatment.

Summary

Forty cases of active rheumatoid arthritis have been treated five times weekly for either three or four weeks with insulin hypoglycaemia.

Twenty-two of these cases showed marked clinical improvement, nine slight improvement, eight no change, and one deteriorated.

Ten maintained their marked improvement and three moderate improvement six weeks after completion of treatment.

In cases showing definite improvement, this usually began within a week of starting treatment.

All cases increased in weight, some remarkably.

The serum potassium was lowered in 34 out of 36 cases at the height of hypoglycaemia, and had risen again in all cases four and a half hours later, at the time of maximal eosinopenia —in 13 significantly above the control value.

Urinary uric acid excretion was significantly raised in 11 cases during treatment, but there was no increase in the neutral 17-ketosteroids in the eight cases in which these were estimated.

The sedimentation rate was not significantly changed.

Fourteen cases showed an increase and three a decrease of more than 1 g./100 ml. in haemoglobin.

Thirty-four cases showed a significant fall in circulating eosinophils four and a half hours after maximal hypoglycaemia. There was no marked correlation, however, between the degree of fall and the degree of hypoglycaemia or the clinical improvement. There was very little correlation between the eosinophil depression produced by adrenaline or A.C.T.H. and either the clinical response or the degree of eosinopenia following hypoglycaemia.

Eleven cases were treated by E.C.T. with an average of five shocks each. Three showed marked improvement, three slight improvement, and five no change.

No significant fall of eosinophils was found as the result of electric convulsion therapy.

We would like to thank Dr. Tyndall, of Messrs. Organon, Ltd., and the Medical Research Council for donations of A.C.T.H., the Empire Rheumatism Council for financial assistance in laboratory expenses, and Drs. J. B. Bennett, T. Northover, R. Pearson, L. Scott White, and J. Thoresby for their help and suggestions; also the nursing and secretarial staff of the unit.

THE EFFECT OF CORTISONE ON THE CARDIOGRAM IN CHRONIC ADRENAL INSUFFICIENCY*

BY

WALTER SOMERVILLE, M.D., M.R.C.P.

Senior Registrar, Cardiographic Department, Middlesex Hospital; formerly Assistant in Medicine, Peter Bent Brigham Hospital, Boston, U.S.A.

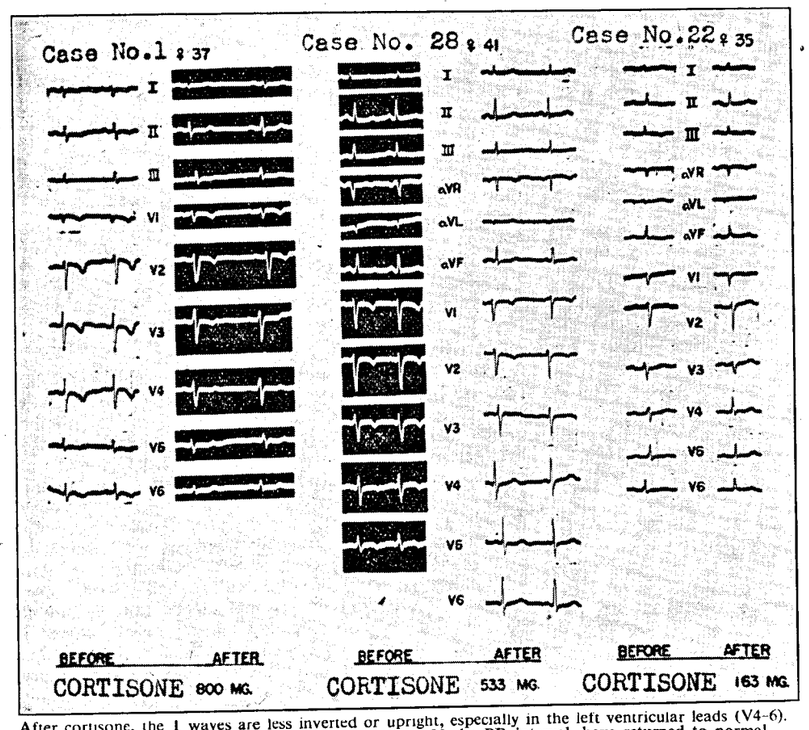
The beneficial effects of cortisone (17-hydroxy-11-dehydrocorticosterone) on chronic adrenal insufficiency (Thorn, Bayles, Massell, Forsham, Hill, Smith, and Warren, 1949) suggested that the cardiovascular system, which is often involved in this condition, might take part in the improvement. In a typical and severe case the heart is smaller than normal, the blood pressure lower, and the cardiogram shows non-specific abnormalities. These are, in order of frequency, abnormally flat or inverted T waves, prolonged QT interval, low voltage, prolonged PR or QRS interval, and depressed ST segment. On the other hand, the cardiovascular system, including the cardiogram, may be normal (Somerville and Levine, 1950).

Present Series

This series comprises 11 patients (3 males and 8 females) with proved chronic adrenal insufficiency treated with cortisone under the direction of Dr. George W. Thorn. The ages ranged between 14 and 55 years. All had been treated previously with replacement therapy for periods of 2–28 years (average 9 years). The cardiograms of six patients showed one or more of the abnormalities mentioned above. In five instances the cardiograms were normal. The clinical and metabolic changes following cortisone therapy in these patients have been reported elsewhere (Thorn, Forsham, Bennett, Roche, Reiss, Slessor, Flink, and Somerville, 1949).

Cortisone was given by intramuscular injection in total doses of 163 to 850 mg. over periods of 5 to 18 days. In three instances cortisone pellets were implanted subcutaneously and the dosage was estimated from the predetermined rate of absorption of the pellets. Several of the patients were given additional replacement therapy in small amounts, but from previous experience with such measures in these patients no effect was expected on the cardiovascular system.

Table showing changes Occurring in the Cardiogram during Cortisone Therapy



Case No.	Cortisone: Dose (mg.)	Cortisone: Period of Admin. (Days)		Cardiogram: Low Voltage	Cardiogram: Prolonged PR	Cardiogram: Prolonged QT	Cardiogram: Depressed ST	Cardiogram: Abnormal T	Result

Note.—Abnormalities persisting after cortisone may have been, in part, residue of recent pericarditis.

* From the Medical Clinic of the Peter Bent Brigham Hospital and the Department of Medicine, Harvard Medical School, Boston, U.S.A.

Results

The changes noted in the cardiogram during cortisone therapy are summarized in the Table. Four of the six abnormal cardiograms improved and two were unchanged. Improvement was represented by flat or inverted T waves becoming upright (see Fig.); shortening of a prolonged PR interval (one case) or QT (corrected) interval (one case). The five normal cardiograms were unchanged.

After cortisone, the T waves are less inverted or upright, especially in the left ventricular leads (V4–6). In Case 28 the corrected QT interval, and in Case 22 the PR interval, have returned to normal.

The duration of the cardiographic improvement after cortisone is uncertain. In one patient the cardiogram had partly regressed towards its original abnormal state two months after cortisone was discontinued. Throughout the observation period and for several weeks before cortisone was given this patient had been receiving small supportive doses of "percorten." In two other patients treated with cortisone pellets inserted subcutaneously the improvement was still present after two to five months.

The heart size, expressed in terms of the transverse diameter determined radiologically, was measured in six patients before and after cortisone therapy. In four the size of the heart increased, in one (normal at the beginning of treatment) it decreased, and in one it was unchanged. In no instance was the size increased beyond normal, and in general the greatest increase was observed in those patients in whom the heart size was smallest when cortisone therapy was instituted.

Changes in blood pressure were not remarkable. In two patients there was a slight increase. No significant alteration was noted in the remainder.

Discussion

The nature of the changes in the cardiovascular system in chronic adrenal insufficiency which give rise to the abnormal cardiogram is unknown. Thorn, Dorrance, and Day (1942) suggested that deficiency of adrenocortical carbohydrate-regulating factors might be responsible, since the cardiogram is usually abnormal in those patients who are unable to fast for 24 hours without a steady fall in blood-sugar levels or severe hypoglycaemic reactions. Cortisone and other 11, 17-oxysteroids are the most active carbohydrate-regulating adrenocortical steroids, and their administration increases the threshold at which hypoglycaemic symptoms occur (Thorn, Koepf, Lewis, and Olsen, 1940). The improvement in four of the six abnormal cardiograms in the present series may be thus explained in part. Yet normal cardiograms may be found in many patients with chronic adrenal insufficiency in whom deficiency of adrenocortical carbohydrate-regulating steroids may be demonstrated by the eosinophil reaction to the A.C.T.H. test described by Thorn, Forsham, Prunty, and Hills (1948). Therefore other factors must exist which lead to cardiographic abnormalities and which are influenced by cortisone, but at present they are unknown.

An increase in heart size following cortisone therapy is in itself unlikely to account for the cardiographic improvement. The incidence of normal and abnormal cardiograms was almost identical whether the heart size was normal, above normal, or below normal in 131 observations on 71 patients with chronic adrenal insufficiency (Somerville and Levine, 1950).

Perera *et al.* (1950) remarked on slight improvement in the cardiogram of a single patient with chronic adrenal insufficiency treated with 400 mg. of cortisone over a period of five days. Commenting on the small increase in blood pressure which they noted, these authors suggested that cortisone may act as a pressor substance in the absence of the adrenal cortex. In the present series cardiographic improvement occurred without changes in blood pressure.

Abnormal cardiograms recorded in acute rheumatic fever have reverted to normal in the course of cortisone therapy. Hench, Slocumb, Barnes, Smith, Polley, and Kendall (1949) have described instances in which prolonged PR intervals, ST segment deviation, and abnormal T waves returned to normal 7–26 days after the beginning

of cortisone therapy. No remarkable effects were noted by these workers on heart size or blood pressure, but in three cases tachycardia was replaced by bradycardia. The dosages of cortisone used were considerably greater than in the present series; on reducing the daily dosage from 200 mg. to 100 mg. the heart rate increased to normal levels. Hench and his associates offered no explanation of the cardiovascular action of cortisone.

Summary

Cortisone was administered to 11 patients (3 males and 8 females) with chronic adrenal insufficiency.

The drug was given by intramuscular injection or pellet implantation in doses of 163 to 850 mg. over 5 to 18 days.

All patients had been treated previously by various forms of replacement therapy.

The cardiograms in six of the patients showed the abnormalities often encountered in chronic adrenal insufficiency—namely, abnormal T waves or prolonged PR or QT intervals. In the remaining five patients the cardiograms were normal.

After cortisone therapy four of the six abnormal cardiograms improved, and two were unchanged. No effect was noted in the five normal cardiograms. The improvement was still present in one patient five months after the treatment was stopped. In two others in whom cortisone pellets had been implanted cardiographic improvement was maintained over a two-months observation period. The cardiogram in one patient had partly regressed two months after cortisone was suspended.

The way in which cortisone influences the cardiogram in chronic adrenal insufficiency is unknown.

This study was aided in part by a grant from the National Heart Institute, United States Public Health Service (Grant No. H-446).

The Ministry of Health has advised local authorities to make certain changes in the record cards for diphtheria immunization and vaccination. The Ministry suggests that the cards should be of postcard size with the address to which they are to be sent printed on the reverse. Immunization cards should be white and vaccination cards green. Some local health authorities have included on the cards a form of consent to be signed by the parent or guardian. This appears to be unnecessary where the vaccination or immunization is done by a practitioner at the instance of the parents in the ordinary course of his practice, and the Minister feels that it should be omitted. Other arrangements should be made when formal consent may be required for inoculations done at a local health authority centre. Among other changes suggested is a provision on the new card for the practitioner simply to indicate whether any unusual or general reaction or other sequelae to vaccination have occurred. Practitioners should be allowed to use rubber stamps in giving their name and address on the cards.

FURTHER OBSERVATIONS ON THE AGE OF THE MENARCHE

BY

DAGMAR C. WILSON, M.D., M.R.C.P., F.R.C.O.G. D.P.H.

(From the Laboratory of Human Nutrition, University of Oxford)

AND

IAN SUTHERLAND, M.A., D.Phil.

(From the Institute of Social Medicine, Oxford)

In an earlier paper (Wilson and Sutherland, 1949) data collected from nine secondary schools in Oxford and Oxfordshire were used to study the onset of menstruation in relation to height and weight. In the first part of the present paper an analysis similar to the earlier one is made for seven schools elsewhere in the South of England, and the two sets of findings are compared. In the second part, serial records of height and weight, kept as a routine by two schools, are studied to see what information they give of growth processes in the adolescent girl.

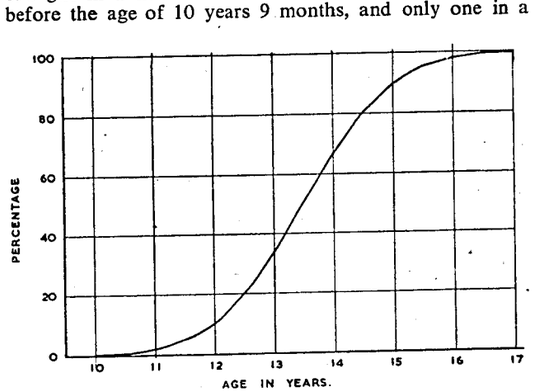
First Investigation

The new data were obtained from five day schools and one boarding-school in Dorset and from one day school in Essex. The information consists of the ages, heights, and weights of 1,707 girls attending these schools in the summer term of 1949, together with a record of whether or not menstrual periods had started. Similar data were available for comparative purposes for 1,284 girls attending eight schools in Oxford and Oxfordshire in the autumn term of 1948.* In the case of children whose menstrual periods had already begun, the age at the menarche was also requested. But since it is possible to determine the average age of the menarche without using this extra information (which may not be fully reliable), it has been necessary to use it in only one analysis (Table III). In both surveys, children attending day schools were excluded if they had not been resident in the area for at least three years preceding the menarche or the date of the inquiry, whichever occurred earlier.

Age of the Menarche

A criticism of most studies relating to this subject is that they depend upon the girl's memory of her age at the menarche, and experience has shown that this cannot be wholly trusted even a short while after the event. A close examination of our data for Oxford and Oxfordshire shows certain discrepancies which may well be due to faulty memory. For this reason a different method of calculating the average age of the menarche, known technically as probit analysis, has been adopted. It can be used when, as in this instance, the age-range of the girls questioned is the same as that in which menstrual periods usually begin —namely, 9 to 18 years. Only two pieces of information are required from each girl—her present age and whether or not her periods have started—and these can both be recorded with a high degree of reliability.

Table I summarizes the findings concerning the age of the menarche in five groups of schools. In the day schools in Essex and in Dorset the average age of the menarche was 13.4 years, in the Oxford and Oxfordshire schools



*Information from one of the nine schools previously studied had to be discarded because it related only to those girls who had attained the menarche.

TABLE I.—*Average Age of the Menarche in Four Groups of Schools (Calculated by Probit Analysis)*

Group of Schools	No. of Schools	No. of Children	Mean Age of Menarche (Years), with Standard Error	Standard Deviation of Age of Menarche (Years)
Dorset (day) ..	5	1,151	13·38 ± 0·05	1·14
Essex (day) ..	1	155	13·38 ± 0·14	1·04
Oxford and Oxon (day)	8	1,284	13·61 ± 0·05	1·26
Dorset (boarding)	1	401	13·89 ± 0·11	1·13
All day schools ..	14	2,590	13·490 ± 0·037	1·191

it was 13.6 years, and in the Dorset boarding-school 13.9 years. The differences in mean age are slight, but statistically significant. The standard deviations range from 1.04 years to 1.26 years, but these variations are unimportant. Since the girls at the boarding-school represent the children of well-to-do parents, these findings suggest that there may be a relationship between sexual maturity and social background.

It is of interest to mention also that the data from each group of schools are consistent with the hypothesis that the age of the menarche follows a "normal" frequency distribution; this finding is a by-product of the probit analysis. This is true in particular of all the day-school girls, 2,590 in number, for whom the mean age at the menarche was 13.49 years, with a standard deviation of 1.19 years. In view of the large experience upon which these figures are based, they can probably be regarded as a reliable standard for day-school girls in the South of England. This standard indicates, for example, that only one girl in a hundred will menstruate for the first time before the age of 10 years 9 months, and only one in a hundred after the age of 16 years 3 months. The Graph presents this standard experience in the form of a curve, which shows at each age the percentage of girls who have attained the menarche.

Graph showing percentage of girls who at a given age have attained the menarche (standard based on 2,590 girls).

Height and Weight

The girls were divided into those who had already passed the menarche and those who had not, and were then subdivided by age. Table II presents the mean heights and weights in the various schools for six of the resultant groups of children. Several important points emerge.

In the first place the figures for the 13-year-old girls in the middle of the table indicate that in each group of schools height and weight are substantially greater among those who have attained the menarche than among those of the same age who have not. This confirms one of the findings of the earlier paper.

Secondly, the table enables comparisons to be made between girls at the four groups of schools. Both before and after the menarche there are interesting differences in mean height and weight. The greatest values occur throughout at the boarding-school in Dorset and the lowest (with one or two minor exceptions) in the Dorsetshire day schools. These findings suggest that there may be differences, due to social factors, in adolescent height and weight as well as in the attainment of the menarche. There appear to be two possibilities to investigate. The first is that there is an inherent relation between the attainment of the menarche and absolute height and weight, which might account for the social pattern. The other is that no such relation exists, and that differences in physique between social groups arise independently of any differences in the onset of menstruation. The present study offers some further evidence on this matter.

TABLE II.—*Mean Heights and Weights of Certain Groups of Schoolgirls*

Age when Measured (Years)	Group of Schools	No. of Girls	Mean Height (in.)	Mean Weight (lb.)
Girls who had not passed the menarche				
11–	Dorset (day)	66	57·9	84·3
	Essex	18	58·1	87·3
	Oxford and Oxon	158	58·0	84·3
	Dorset (boarding)	8	60·9	93·8
12–	Dorset (day)	193	59·1	87·7
	Essex	25	60·0	94·1
	Oxford and Oxon	220	59·4	87·2
	Dorset (boarding)	33	60·3	96·1
13–	Dorset (day)	112	60·7	94·3
	Essex	16	59·7	91·6
	Oxford and Oxon	151	60·9	93·0
	Dorset (boarding)	40	62·0	104·3
Girls who had passed the menarche				
13–	Dorset (day)	151	62·3	112·8
	Essex	15	61·0	110·6
	Oxford and Oxon	132	63·0	118·3
	Dorset (boarding)	28	64·3	119·9
14–	Dorset (day)	210	63·0	115·6
	Essex	33	64·0	122·0
	Oxford and Oxon	203	63·6	116·7
	Dorset (boarding)	48	64·3	125·4
15–	Dorset (day)	186	63·9	120·9
	Essex	22	63·9	122·0
	Oxford and Oxon	165	64·3	121·7
	Dorset (boarding)	60	65·2	129·6

Metric equivalents: 1 inch = 2·54 cm.; 1 lb. = 454 g.
In order to keep the table within a reasonable compass only those groups containing the largest numbers of children were included. However, the conclusions drawn from the table apply equally to the whole body of data.

TABLE III.—*Mean Heights and Weights in Two Groups of Day Schools According to Age When Measured and Recollected Age at the Menarche*

Age at Menarche (Years)	Age when Measured (Years)	Group of Schools	No. of Girls	Mean Height (in.)	Mean Weight (lb.)
12–	13–	Dorset	78	62·3	112·5
		Oxford and Oxon	63	63·3	118·8
	14–	Dorset	46	62·9	119·0
		Oxford and Oxon	51	63·6	122·9
13–	13–	Dorset	57	62·3	110·1
		Oxford and Oxon	56	62·7	117·8
	14–	Dorset	116	63·1	115·6
		Oxford and Oxon	92	63·5	115·4
	15–	Dorset	66	63·9	119·8
		Oxford and Oxon	68	64·6	124·0
14–	15–	Dorset	59	63·4	117·8
		Oxford and Oxon	39	64·5	116·1

The age groups included in this table are those containing the largest numbers of children.

It will be noticed from a comparison of Tables I and II that in the schools with the taller and heavier girls the menarche tends to occur later than in the schools where the girls are shorter and lighter. This is just the opposite of what would be expected if girls who grow rapidly attain sexual maturity earlier—the usual suggestion. But although this correlation supports the view that there is a relation between the attainment of the menarche and absolute height and weight, the analysis in Table III indicates that there is no causative connexion between the two sets of figures. In this table are compared the height and weight of Oxford and Dorset girls who were at the same stage of sexual development—that is, who had the same recollection of their age at the menarche and were the same age at the time of study. The comparisons show that the Oxfordshire girls are superior in height and weight; these differences in physique must therefore be independent of the attainment of the menarche. In other words, the second possibility is the correct one: absolute height and weight are not determining influences upon the age of the menarche.

Second Investigation

The data for the second part of the study were recorded by the medical officers of two boarding-schools, one in Sussex and the other in Yorkshire. They consist of serial measurements of height and weight, made at the beginning and end of each school term, together with a note of the occurrence of the menarche. Records were available for 202 pupils who left the Sussex school in the years 1936 to 1948, and for 87 who left the Yorkshire school in the years 1947 to 1949.

The advantage of serial records is that they enable the changes in height and weight of the *individual* to be studied in relation to the age of the menarche. The years particularly worthy of study are those immediately preceding the menarche, during which time marked height and weight changes occur. Such a study would probably suggest a method of predicting at what age a girl will attain the menarche, and this would be of great value to parents and others concerned with education in health and sex. Unfortunately the majority of the present series of measurements are post-menarcheal because of the age range covered by the schools. It was therefore decided to study the four years after the menarche. Even over this limited period of time it was not possible to follow an unchanging set of individuals, since some girls entered school after the menarche and others left within four years of its attainment. But despite these drawbacks the data do reveal certain points of interest about growth during this period.

There are considerable differences between the girls at the two schools. The mean ages of attainment of the menarche, with their standard errors, were 13.11±0.09 years among the girls from the Sussex school and 13.82±0.14 years among the girls from the Yorkshire school. This difference is statistically significant. Further, the girls at the Sussex school were at each age taller and heavier than those at the Yorkshire school (Tables IV and V). It is worth noting in passing that these findings cast doubt upon the suggestion that the age of the menarche tends to be greater in children of the more favoured social and economic groups. At the Sussex boarding-school the average age of the menarche is in fact less than at any day school included in this study, while the social status of the girls there is certainly no lower than at either of the other boarding-schools, in each of which the average age of first menstruation is later by about nine months.

Because of the differences between the Sussex and Yorkshire schools the data for each had to be analysed separately,

despite the small numbers of pupils involved. At each school the children were divided into three "maturation" groups according to age at the birthday before the menarche (9–12, 13, or 14–17 years). The progress of each group in height and weight (and also in an index of body-build based upon these two measurements) was then followed, first, according to the interval in years from the menarche, and, secondly, according to actual age Each average was based upon as many measurements as were available in the records.

Weight

The findings on weight are summarized in Table IV. As might be expected, the mean weights for each "maturation" group rise both with increasing interval from the menarche and with increasing age, and by the end of the period of study the weights are approaching a stable level.

But the most interesting information in Table IV is obtained from a study of its rows. The upper half of the table permits a comparison of girls at the same stage of sexual maturity, but of different ages, while the lower half enables girls to be compared who are the same age but differ in sexual maturity. At the Yorkshire school, for example, the mean weights one year after the menarche were 110.3 lb. in the first maturation group, 114.6 lb. in the next, and 121.7 lb. in the last group—that is, in the girls who were measured at the oldest age. Thus weight at this stage of maturity is influenced by age. On the other hand, the comparison of girls aged 14 shows that the mean weight was 118.7 lb. in the first maturation group, 114.6 lb. in the next, and only 108.5 lb. in the last group—that is, in the girls who were measured at the earliest stage of sexual maturity. Thus weight in girls of this age is influenced by the stage of sexual maturity. These examples are typical of the experience in each school, with

slight exceptions towards the end of the period of study. Thus, so far as girls are concerned, weight in adolescence depends not only upon age but also upon the stage of sexual maturity.

Height

The mean heights are summarized in Table V. As with mean weight, the measurements tend to reach a stable level by the end of the period studied.

However, the comparisons of the three maturation groups show a rather different pattern. The measurements in the upper half of the table indicate that at each stage of maturity height is influenced by age. Those in the lower half suggest that at the beginning of the age-period 13 to 17 years there is a slight tendency for those maturing early to be tall, and at the end a slight tendency to be short, in comparison with those maturing late; but this pattern is much less clear-cut than that in the upper half of the table. Thus between the ages of 13 and 17 the height of girls is influenced almost exclusively by age; the stage of sexual maturity exerts little additional influence.

Body-build

So far height and weight have been considered in isolation, but together they can give a rough indication of body-build. The measure used here is the height (in inches) divided by the cube root of the weight (in lb.). It is accurate enough for the purposes of this study to calculate this fraction for each group of measurements from the mean height and the mean weight, and this avoids the laborious procedure of calculating the measure of build for each pair of measurements and then averaging the results. The figures are presented in Table VI.

TABLE VI.—*Body-build (Mean Height in Inches Divided by Cube Root of Mean Weight in lb.) of Children at Two Schools According to Age at the Menarche*

Interval Since Menarche (Years)	Age at Menarche

* Fewer than 10 measurements—value omitted.

The values at the Sussex school are slightly higher than those at the Yorkshire school. For each maturation group the measure of build falls with increasing age and with increasing interval since the menarche. That is to say, girls become progressively heavier for their height during this period—a finding which would be expected from the outward physical changes in girls in the course of sexual maturation. It would be of interest to know if the same is true of boys. In the valuable study by Richey (1937), records for boys as well as girls were available, but unfortunately no analyses analogous to those in the upper half of Tables IV, V, and VI were made.

When a comparison is made as before between the three maturation groups of children in each school, a pattern different from that of height or weight is revealed. In the first two years following the menarche there is no apparent relation between build and age. For example, one year after the menarche the measure of build is approximately 12.9 or 13.0 at each school, whatever the age of the children when measured. In the third and the fourth year after the menarche there is a slight tendency for those who matured early to be shorter for their weight than those who matured late. But on the whole, body-build in the first few years after the menarche is not influenced by age. The lower half of the table confirms that the stage of sexual maturity in girls of the same age exerts a considerable influence on build. Among those observed at 14 years of age in the Yorkshire school, for example, the measure of build varied from 12.8 in those who matured early to 13.1 in those who matured late. The figures thus make it clear that at the time of the menarche build is independent of age, and that, during the following two years at least, girls become heavier for their height to an extent which is also independent of their age.

These analyses indicate that it is convenient to regard growth in the adolescent girl as being of two types. One is the normal physical growth with age, and superimposed upon it are changes specifically arising from the processes of sexual maturation. The findings of this study suggest that between the ages of 13 and 17 height is practically unaffected by the processes of sexual development as such; on the other hand, as a consequence of weight changes, body-build (as measured in this study) seems to be determined solely by the processes of maturation for at least two years after the menarche.

Summary and Conclusions

This paper describes two separate studies into the onset of menstrual periods in relation to height and weight.

In the first study data were available for nearly 3,000 school-girls within the age range 9–18 in the South of England. Using only two pieces of information from each girl—her present age and whether or not her periods have started—a standard statistical technique known as probit analysis enables the average age of the menarche to be estimated with a known degree of accuracy. It should be noted that this is a particularly suitable technique for use in surveys of this (and other) aspects of sexual maturation, as it requires a minimum of information and does not depend on the girl's memory of her age when her periods first started. It is suggested that the ages of attainment of the menarche in the 2,590 day-school girls may be regarded as a standard for the South of England. This standard indicates that only one girl in a hundred will start her periods before the age of 10 years 9 months, and only one in a hundred after the age of 16 years 3 months. One-half will menstruate by the age of 13 years 6 months. There were interesting differences in average height, weight, and age at the menarche between different groups of girls. Despite an apparent correlation, it is shown that the differences in height and weight were not a determining influence upon the age of the menarche.

In the second study serial height and weight records were available for 202 girls from one boarding-school and 87 from another, and were studied to see what light they shed upon the processes of growth. The findings show that growth in the adolescent girl may be regarded as of two superimposed types—normal physical development with age, and growth specifically related to the process of sexual maturation. In the age period 13 to 17 years height changes are practically independent of sexual maturation. But because of changes in weight, the body-build, measured as the height divided by the cube root of the weight, develops independently of age for at least two years after the menarche. During this period girls become heavier for their height. It is unfortunate that the records do not permit an analysis at younger ages; a study of the years preceding the menarche would not only give a more complete picture of growth processes but should suggest a method of predicting

when the menarche will occur in an individual. This would be of great value to parents and others concerned with education in health and sex.

We are indebted to the educational and medical authorities in Dorset, Essex, Oxford, and Oxfordshire for their help in obtaining the necessary data for the first part of this study. It is a pleasure to thank Mr. P. H. Leslie for his advice. We also wish to thank the medical officers of the boarding-schools in Sussex and Yorkshire for their readiness to make available to us the medical records of those who had left school, and for their interest in the study.

FATAL CASE OF ACUTE PORPHYRIA IN A NEGRO

BY

C. A. WIGGINS, M.B., Ch.B.

House-physician, St. James' Hospital, Balham

Acute porphyria has been reviewed in several papers since 1945. Abbott and Evans (1946) found that nearly 300 cases had been described since Günther's first case in 1911. Pyrrole metabolism is reviewed by Dobriner and Rhoads (1940) and by Welcker (1945). The following are the main clinical points.

Porphyria is a disorder of metabolism of the respiratory pigments (haemoglobin, myoglobin, cytochrome oxydase, etc.). "Acute" porphyria is almost certainly a chronic disorder, with acute episodes superimposed (Gray, Rimington, and Thomson, 1948). Barbiturates, sulphonal, sulphonamides, "trional," arsenicals, phosphorus, or lead may precipitate an attack (Dobriner and Rhoads, 1940), but there is no hard-and-fast distinction between the toxic and idiopathic varieties (Discombe and D'Silva, 1945).

Roth (1945) states that psychic episodes may occasionally precipitate an acute attack, and that the siblings of these patients are often hysterical or psychotic. Porphyrins are excreted in abnormal quantities during attacks and often between attacks; the usual finding is uroporphyrin III or coproporphyrin III, but Gray (1950) says, "It has never been possible to correlate the varied clinical features with any definite pattern of porphyrin excretion." He had a case in which the colourless porphobilinogen was predominant. Characteristically the urine is a red or brown colour and darkens further on standing. Hare and Wilmore (1948) quote Waldenström's epithet "la petite simulatrice" and his remark that hysteria is often suspected. Davies (1949) finds that barbiturates are given to the majority of these patients.

The acute form is commoner in women—3:1 (Abbott and Evans, 1946). The age of onset is 20 to 45 (Davies, 1949). Symptoms may be mainly abdominal, or mainly nervous, or combined abdominal and nervous as in the classic type. There may be a prodromal period of lassitude and mental disorder, and the onset is with colicky abdominal pain, nausea, vomiting, constipation, leucocytosis, tachycardia, and a rise in blood pressure; while hypotension is common in the later stages. Sometimes the pain is in the form of dysmenorrhoea. Attacks of jaundice are not infrequent and may obscure the significance of dark urine, and it is worth noting that an apparently positive Ehrlich aldehyde test is given by porphobilinogen in the urine (see below).

In nearly half the cases neurological symptoms occur, which may include confusion, delirium, convulsions, or amaurosis. Characteristically there is a polyneuritis, which may fluctuate in severity, affecting the limbs, especially the proximal segments, with or without cranial nerve and sphincter involvement. Pain and paraesthesias are common, but objective sensation is usually relatively spared. With neurological involvement the mortality is about 75% (Berg, 1945; Petrie, 1948). Subsequent attacks may occur in those who survive (Gray, Rimington, and Thomson, 1948).

Case Report

The patient, a male native of Lagos, Nigeria, aged 30, had been in London for six months preparing for examinations in accountancy. He was admitted on April 13, 1950, with the history of inconstant shortness of breath for some years, related sometimes to physical and sometimes to emotional strain. He was a hard worker, conscientious, and ambitious, but lacked self-confidence. He had worn spectacles for some weeks. Seven weeks before admission he again complained of dyspnoea, and doubted his ability to pass his examinations. After a week he complained of central abdominal pain with nausea, vomiting, and constipation, and was admitted to another hospital from which he went home against advice after three weeks.

A week later a reassuring talk relieved his symptoms, but next day he had anorexia, paraesthesias, and pains in the limbs, followed by hallucinations, insomnia, and irregular behaviour. This sequence of events strongly suggested hysteria, and he was given 3 gr. (0.2 g.) of butobarbitone at night. After this he became clear mentally, but noticed a gradual onset of weakness in all limbs. He became incontinent of urine, and was admitted to this hospital. Specific inquiry later revealed that he had had red urine on occasions for some years and for most of the last six weeks. His parents, two sisters, and three brothers had always been well, and had never mentioned similar discoloration. No siblings had died. He knew of no white ancestry.

On examination he was markedly wasted and dehydrated. He was febrile, 99.6° F. (37.55° C.). There was bilateral conjunctivitis with mucopurulent exudate. His tongue was furred, his mouth was dry, and his breath foul. The buccal mucosa and teeth were normal. The abdomen was lax and retracted, and slightly tender in the right iliac fossa, with a nodule of faeces in the left iliac fossa. The liver and spleen were not palpable. The heart and lungs were normal, the pulse was 130, and the blood pressure 115/75. Although correctly orientated and otherwise rational, he thought that there was "somebody under the bed lifting it up and down." Visual fields were full by confrontation. There was slight weakness of the left fifth cranial nerve, his voice was very weak, and his speech a little slurred and difficult to understand. His neck was normal but the trunk muscles were weak. There was a flaccid tetraplegia, almost complete at the hips, shoulders, knees, and elbows, with very little power at the distal joints and with a coarse irregular tremor when movements were attempted. All tendon-jerks were present, the knee-jerks being very feeble. The plantar responses were normal. Sensation to pin-prick was slightly impaired over the forearms and hands; light touch, position sense, and vibration sense were normal. There was a burn from a hot-water bottle on the right calf; elsewhere the skin was normal. Tenderness was increased in the calves. He was incontinent of urine. The white cells numbered 6,000 (polymorphs 62%, lymphocytes 30%, monocytes 8%).

On the first day after admission his blood pressure was 140/100. Examination of the urine revealed: acid, a trace of protein, no Benedict reduction, no casts, cells, organisms, bile salts, or bile pigments. A blood count showed: red cells, 4,850,000; Hb, 97%; white cells, 21,000 (polymorphs 88%, lymphocytes 12%). On the second day the urine was seen to be brownish red and was then found to contain porphyrins. By this time his voice had sunk to a whisper. The weakness of the fifth cranial nerve had increased; both knee-jerks and

the left ankle-jerk were absent. His blood pressure was 120/80. On the fourth day the facial muscles were mildly affected. The sclerotics were a yellowish brown colour, but the serum bilirubin was 0.4 mg. per 100 ml.; the direct van den Bergh was negative.

On the sixth day he was generally weaker and there were paradoxical respiratory movements. Coarse rales appeared in the chest, and breathing became slow and irregular before he died. During the six days his pulse rate varied from 118 to 150, average 130. There was continued pyrexia, higher in the last 36 hours, average 100° F. (37.8° C.). On the day before death a blood count showed: red cells, 4,130,000; Hb, 84%; white cells, 13,800 (polymorphs 79%, eosinophils 20%, monocytes 1%). On the last day the blood urea was 156 mg. per 100 ml.; blood sugar 129 mg. per 100 ml.; Wassermann reaction and Kahn test negative; serum alkaline phosphatase 6 K.-A. units; direct van den Bergh positive; serum bilirubin 0.8 mg. per 100 ml. Total serum protein was 6.56 g.%—albumin 3.02 g., globulin 3.54 g.

Post-mortem Examination

This was carried out 20 hours after death by Dr. N. Orchard, to whom I am indebted for the following report.

"Lungs: marked congestion and oedema. Stomach: mucous gastritis and numerous petechiae in the mucosa. Spleen: deeply congested with very prominent follicles. Liver: firm, slate-blue in colour, with numerous small greyish-yellow areas. Kidneys: traces of foetal lobulation; capsule stripped easily; deeply congested, but a slate-blue colour evident. Brain and cord: oedematous.

"The following organs were of slate-grey or bluish colour: visceral and parietal pleura and peritoneum, myocardium, psoas and rectus abdominis muscles, liver, kidney, most of the jejunum, the caecum, and the proximal half of the ascending colon. The following were of an unusual yellow-orange colour: pancreas, cerebellum, omentum, peritoneal fat, and the sternal, vertebral, and iliac marrow. The following fluoresced with a pink or red colour in ultra-violet (Wood's) light: liver, kidneys, omentum, psoas and rectus abdominis muscles, myocardium, pericardium, aorta, costal cartilage, and sternal marrow.

"Histological abnormalities were as follows:—Right optic nerve: marked round-cell infiltration, the myelin sheaths being intact. Anterior horn cells: marked chromatolysis at all levels of the cord. Cerebellar Purkinje cells: severe degeneration. Liver: polygonal cells loaded with greyish, granular pigment. Kidneys: congested. Lungs: oedematous, congested, with early bronchopneumonia."

Biochemical Findings

The urine when freshly passed was a red-brown colour and darkened considerably on standing. The Watson and Schwartz modification of the Ehrlich aldehyde test was positive (see below). A quantity of urine was collected over a period of some days and sent for biochemical examination. I am greatly indebted to Dr. L. Ellis for his report, as follows.

"The urine was a deep port-wine colour and did not obviously darken further on standing. Using a direct-vision spectroscope, the urine showed two absorption bands in the green closely resembling the bands of oxyhaemoglobin and a band at the junction of the green and the blue. About 15 ml. of urine was acidified with a few drops of glacial acetic acid and shaken thoroughly with about 10 ml. of tertiary amyl alcohol. After centrifuging, the upper alcohol layer showed the same absorption bands and gave a brilliant pink fluorescence under the ultra-violet lamp. It would seem that the porphyrins were excreted as metallo-porphyrins (see Chandler, Harrison, and Rimington, 1939).

"For further differentiation a specimen of urine was acidified with a few drops of glacial acetic acid, and extracted with several quantities of ether until the ether layer showed no further spectroscopic evidence of the presence of porphyrins. This indicated that all coproporphyrin had been extracted. The urine layer was then extracted with amyl alcohol and the alcohol layer separated. This layer now contained the uroporphyrin. The ethereal extract was evaporated down to the same volume as the amyl-alcohol extract and the two extracts were compared under the ultra-violet lamp and spectroscopically. It seemed obvious that, while there appeared to be quite a fair amount of coproporphyrin, uroporphyrin was present in some excess."

Discussion

The diagnosis of acute porphyria seems to be substantiated on the sum of the findings recorded. The clinical course of the illness was in accord with the usual (albeit variable) symptomatology, and there were two further points which are not included in the introduction. Hare and Wilmore (1948) were "impressed by the degree of cachexia and debilitation" in one of their cases. Davies (1949) noted a yellow-brown tint in the sclerotics not due to bilirubinaemia.

Roth (1945) mentions the temporary or protracted attacks of amaurosis which may occur, and in his cases neither ophthalmoscopic nor post-mortem microscopical abnormalities were detected to account for the symptom. My patient made no specific complaint about his vision, and no history was obtained whether he had had intermittent amaurosis, but it may possibly be significant that he had recently worn spectacles. Equally problematical is the significance of the other early symptom—namely, the shortness of breath accompanying emotional strain.

Degeneration, pigmentation, and fluorescence of organs have been recorded. To summarize Roth (1945), the commonest central-nervous-system changes are parenchymatous degeneration in the peripheral nerves, the anterior horn cells (and to a lesser extent the posterior horn cells), the cerebellar Purkinje cells, the cerebral cortex, and the sympathetic ganglia. The changes are more marked in the peripheral nerves and lower segments of the central nervous system.

Abrahams, Gavey, and Maclagan (1947) found a striking bluish black discoloration of both rectus abdominis muscles, parts of the psoas muscle, and peritoneum, with red fluorescence under ultra-violet light in the costal cartilage, sternal marrow, rectus muscle, small intestine, and elsewhere. Prunty (1946) found ultra-violet fluorescence (microscopically) in the liver, renal tubules, costal cartilage, and parts of the central nervous system. In his case, however, the pigment granules in the liver parenchyma were of two kinds—large golden-yellow granules and small red-orange granules. It is usually agreed that acute porphyria is commoner in those of Scandinavian descent (Discombe, 1948), and there is evidence that it may be transmitted as a Mendelian dominant. If this is so, the occurrence of a case in a West African negro makes it possible that it may occur in the American negro, but, judging by the literature of both countries, it is rare. A brief survey revealed only one other case, that of Schneck (1946) in the United States, and he could find no other cases. It may be said, however, that his case, although suggestive, was not proved, for at no stage were porphyrins detected in the urine or elsewhere.

Finally, it is worth repeating a point stressed by many authors, that the diagnosis should be considered and the urine examined in any patient with obscure mental, nervous, and/or abdominal symptoms. The simplest test is that of Watson and Schwartz (1941) for porphobilinogen. Mix equal parts of urine and Ehrlich's aldehyde reagent, add a few millilitres of chloroform, and shake. Urobilinogen gives a red colour soluble in the chloroform layer, but porphobilinogen gives a red colour which remains in the aqueous layer.

Summary

A case of classical acute porphyria occurring in a West African negro is described. Post-mortem and biochemical findings are included. The literature is briefly quoted.

I am indebted to Dr. A. Kahan, under whose care the patient was admitted, for permission to publish the case and for his encouragement and advice; to Dr. N. Orchard for the post-mortem report and the preliminary detection of porphyrins; to Dr. L. Ellis, biochemist to the Lambeth Group Laboratory, for his report on the urine findings; and to Dr. J. Olu-Mabayoje, who had known the patient for many years, for his help with the history.

FOLLOW-UP OF RHESUS-NEGATIVE PRIMIGRAVIDAE

DEVELOPMENT OF RHESUS IMMUNIZATION

BY

W. WEINER, M.D.

Director, Regional Blood Transfusion Service, Birmingham

AND

JEAN L. HALLUM, B.Sc., M.D., D.C.H., M.R.C.O.G.

Obstetrician, Sorrento Maternity Hospital, Birmingham

Rhesus immunization in the first pregnancy has been found only very exceptionally, apart from patients who had previously received a transfusion of rhesus-positive blood. Few authentic cases of rhesus immunization of the first-born child have been mentioned in the literature (Boorman, Daley, and Dodd, 1947).

It has been suggested that the immunizing stimulus is provided during labour by a small "blood transfusion" given to the mother by the foetus through the breakdown of the syncytial placental layer. During the second pregnancy small "booster doses" of foetal blood reaching the maternal circulation stimulate antibody formation further, and the "full-blown" picture of rhesus immunization develops. The assumption that the first pregnancy or labour provides the first antigenic stimulus seems to be necessary to explain the development of antibody formation during the next pregnancy, in which presumably identical conditions obtain with regard to the placental barrier as in the first pregnancy.

Stratton (1943) has shown that the rhesus factor can be discovered on the foetal red blood cells at the eleventh week of development, but it seems improbable that such an immature foetus could provide enough antigenic material to produce antibodies in the maternal serum. Occasionally, however, antibodies are discovered in the early weeks of a second pregnancy. The following case illustrates this point.

A married woman aged 25 had her first baby on February 23, 1948. The infant, of 30 weeks' gestation and weighing 2 lb. 15 oz. (1.33 kg.), was born spontaneously. Serological investigations were performed on the mother at the ninth and twenty-seventh weeks and eight days after delivery. The result of all three investigations was Group B rhesus-negative, the serum containing no anomalous antibodies.

The patient became pregnant again in September, 1948. The first specimen of blood investigated early in January, 1949, at 16 weeks' gestation, showed definite signs of rhesus immunization by containing blocking anti-rhesus antibodies of fairly high titre (1 : 32). Several repeat investigations gave essentially identical results, and on May 3 a baby suffering from haemolytic disease of the newborn was born. She weighed 4 lb. 7 oz. (2 kg.). Despite a blood transfusion of rhesus-negative blood, she died of kernicterus at the age of 7 days. The diagnosis was confirmed at necropsy (Dr. Baar).

It was thought advisable to follow up a number of primigravidae after delivery, for a comparatively long period, to see whether any antibody formation followed delivery and whether the antibody could be proved to be present by routine serological methods. If the assumption is correct, that the primary immunizing dose is given during labour or afterwards, one could hope to find antibodies in sera of exceptionally good reactors without a further stimulus having been applied.

The investigation was undertaken on 62 primigravidae who were all seen antenatally and delivered at Sorrento Maternity Hospital, Birmingham. They were also followed up post-natally there. The serological investigations covered determination of the blood group, rhesus type, and investigation for antibodies in the serum. The latter was done by means of saline- and albumin-suspended cells, ten of which were rhesus-positive and two rhesus-negative. All the sera were also tested by means of the indirect Coombs test. The cord blood was also investigated. This investigation included the group and rhesus type and, from 1948 onwards, the direct Coombs test. Consecutive rhesus-negative primiparae were selected, and only those excluded who produced a rhesus-negative infant. The post-natal investigations were undertaken at various intervals. In most, the second specimen was obtained about eight days after delivery, and in no case were anomalous antibodies found. Several patients were followed up further at intervals up to two years. Two patients developed anti-rhesus antibodies. Their clinical and serological details follow.

Case 1

A woman aged 24 was delivered of a healthy, normal, full-term baby on October 20, 1947. This baby showed no icterus or other sign of haemolytic disease. His blood type was Group A rhesus-positive.

Further specimens were investigated from the mother, and approximately two years later the following results were obtained: The cells were confirmed as Group O rhesus-negative, the serum agglutinated strongly rhesus-positive albumin-suspended cells and did not agglutinate rhesus-negative cells. An indirect Coombs test with rhesus-positive cells was positive. Three weeks later a further specimen gave identical results. The serum was tested with a large battery of fully typed cells and agglutinated every sample cell which contained the D antigen. The titre of the antibody was found to be fairly low (1 : 2) against CDe/CDe and cDE/cde. At the same time a specimen of blood from the patient's husband was investigated and found to be Group A rhesus-positive (most likely genotype CDe/CDe).

It was obviously important to find out whether the patient had at any time between the delivery and the follow-up investigation been pregnant. This seemed impossible. She had attended a welfare centre regularly. Husband and wife confirmed the use of birth control (by male sheath) because they did not desire a second child until they no longer had to live in the same house as a relative suffering from pulmonary tuberculosis.

The patient gave a history of regular menses and had received no injections of any kind either ante- or post-natally, and had never received a transfusion.

Case 2

A woman aged 22 was delivered of a living healthy, full-term baby on September 19, 1948. The infant showed no signs of haemolytic disease of the newborn. The infant's blood type was Group A rhesus-positive.

The maternal serology antenatally was Group A rhesus-negative, the serum containing no anomalous antibodies. A specimen of blood obtained on the eighth day after delivery gave identical results. A further specimen, however, obtained on June 22, 1949, gave definite evidence of the presence of a potent anti-rhesus antibody, again acting more strongly on albumin-suspended rhesus-positive cells. The titre was moderately high (1 : 8). The serological behaviour of the antibody was typical, no reaction occurring unless the test cells contained the D antigen.

This patient had shown no sign of a further pregnancy, her menses having been regular since the cessation of lactation three months after delivery. She had received no injections ante- or post-natally or transfusions at any time of her life. Her husband was Group O rhesus-positive and most likely genotype CDe/cde.

Discussion

The serological findings in these two cases are clear-cut and indicative of rhesus immunization. The fact that the antibody reacted better with albumin- than with saline-suspended cells might perhaps be due to its comparatively low titre. We share with several other workers the experience that sometimes an "albumin" antibody can change into a saline agglutinating antibody just before delivery. The contention, therefore, that a blocking antibody is always a sign of hyperimmunization might perhaps be open to discussion.

It is difficult to understand why antibodies in these two patients developed so late after delivery. In both, the antigenic stimulus must have been the first pregnancy, and, so far as can be established, there was no further antigenic stimulus. That antibodies can develop to a stimulus a long time after its first application is a not uncommon experience in immunology—for example, undulant fever. Further investigations are in progress to elucidate this problem in greater detail. As a practical application of our findings, if they can be confirmed on a larger series, it might perhaps be advisable to investigate for the presence of anomalous antibodies the sera of all primiparae contemplating a second pregnancy.

Summary

In a follow-up of 62 rhesus-negative primiparae with rhesus-positive babies, two were found who, after intervals of two years and of nine months respectively, had developed anti-rhesus antibodies in their serum without a further intervening pregnancy or other antigenic stimulus.

We are greatly indebted to the technical staff of the Blood Transfusion Service in Birmingham and to Sister Lyons, of Sorrento Maternity Hospital, for the valuable help they have given in testing the many specimens and in following up the patients.

MONGOLISM IN ONE OF TWINS

BY

T. H. CROZIER, M.D., F.R.C.P.

Assistant Physician, Royal Victoria Hospital, Belfast

AND

W. A. B. CAMPBELL, M.D., M.R.C.P.Ed.

Assistant Paediatrician, Royal Belfast Hospital for Sick Children

Graham (1950), reporting a case of mongolism in one of twins, drew attention to the comparative rarity of such cases in the British literature. The largest series so far published seems to be that of Warner (1949), who collected 101 cases from the literature and recorded one further case in which an older sib was also a mongol. Of these 102 sets of twins, one child was affected in 82 cases and both children in 20.

It is well recognized that there is a considerably increased incidence of congenital cardiac defect among mongols. Wylie (1949) quotes 22 examples in a series of 138 mongols (16%); Benda (1947) states that up to 75% of mongols dying in the first two years of life have a congenital cardiac defect, as have 35% of those surviving. Post-mortem records of the Hospital for Sick Children, Great Ormond Street, yielded evidence of congenital cardiac abnormality in 28 of 63 mongols (Evans, 1950). While various malformations are encountered, persistent ostium atrio-ventriculare commune is especially apt to be associated with mongolism (Abbott, 1936). Robinson (1941), in a series of 39 cases of this defect collected from the literature, states that about one-half of these were in mongols. Taussig (1947) emphasizes the likelihood that a mongol presenting signs superficially resembling ventricular septal defect, and without cyanosis, is suffering from persistent atrioventricularis communis. There were, however, only four examples of this in Evans's series, the commonest anomaly being in fact ventricular septal defect.

Case Report

Helen B. was born on November 20, 1949, at full term, the first of twin girls. The mother was aged 35; her health was good during pregnancy, apart from a cystocele which was troublesome during the first trimester. The father's age was 36. The family and personal histories of both parents were, so far as is known, good. There are two older (normal) daughters, now aged 4 and 7 years. Helen was delivered as a vertex, and the second (normal) twin as a breech; each weighed approximately 5½ lb. (2.5 kg.) at birth. A suggestion of mongoloid physiognomy was noted in Helen at birth, but was discounted to some extent by the medical attendant because

of a strong family resemblance between the infant, the father, and the two elder children.

From birth breast-feeding was difficult, and soon became impossible; she was given expressed breast milk for four weeks, and afterwards a mixture of cows' milk and water was substituted. She never thrived so well as her twin, and on first examination weighed only 9 lb. (4.1 kg.), as against 12 lb. (5.4 kg.). The mother noticed that she was less lively than her twin, was easily made breathless, and sometimes "went blue." She vomited slightly from birth, but at the time of first attendance this was not causing any anxiety.

The child was examined in the out-patient department of the Royal Belfast Hospital for Sick Children on January 20, 1950, when the diagnosis of mongolism was confirmed and its significance explained to the mother. The accompanying photograph was then taken.

She was again brought to the out-patient department on January 28 with a history of severe vomiting of a projectile type. On examination the pylorus was easily palpable and thought to be thickened. In view of the presence of a systolic murmur to the left of the sternum a chest radiograph was taken, which showed considerable generalized enlargement of the heart. A dietetic regimen and "pylostropin" tablets were used until admission could be arranged, but at the time of admission (January 31) she was vomiting as copiously as ever. Surgical treatment of the pylorospasm was decided upon, despite the known multiple hazards present.

Mr. J. A. W. Bingham opened the abdomen by a right transverse rectus-cutting incision under "soneryl"–atropine–vinyl-ether anaesthesia on February 2. Bleeding was slight and the blood dark. Before the peritoneum could be incised the heart stopped suddenly. Cardiac massage, artificial respiration, and oxygen inhalation produced only transient response.

Post-mortem Examination

At the post-mortem examination, carried out by Dr. R. J. Marshall, a poorly nourished female infant with the typical facies of mongolism was seen. The heart was considerably enlarged: normal epicardium; ductus arteriosus closed; the great vessels entered and left the heart in normal arrangement. The right auricle was much enlarged, and the wall markedly trabeculated. The interauricular septum was thin, terminating in a crescentic free edge just proximal to the auriculoventricular ring. The septum was fenestrated, and the foramen ovale closed. Anterior and posterior valve cusps were present, but were abnormal in that they continued uninterruptedly across the septal defect, the distal halves serving as mitral cusps.

The right ventricle was also markedly enlarged, and there was gross defect of the interventricular septum, which was rudimentary and present only at the apex of the organ. The ostium between the edges of the auricular and ventricular septa measured 2 by 1.5 cm.; thus there was virtually a common ventricle, the right half of which was larger than the left.

The stomach and duodenum were essentially normal in size and shape, and, although the pylorus was somewhat thickened, no congenital hypertrophy was noted. The lungs showed patchy interstitial pneumonia with mononuclear infiltration of the alveolar walls and comparatively little alveolar exudate. The liver and spleen showed the persistence of haemopoietic tissue.

Summary

A case of mongolism with persistent ostium atrioventriculare commune in one of twins is recorded. Pylorospasm with intractable vomiting, inanition, and death under anaesthesia exemplify the precarious hold on life which is the inheritance of most mongols. The nature of the cardiac anomaly was such as to preclude lengthy survival in any event.

We are indebted to Dr. P. P. Jackson for the obstetrical details, and to Mr. D. Mehaffy, A.R.P.S., for the photograph.

Medical Memoranda

A Vestigial Tail

Many cases of children born with a tail have been reported in the last seventy years, but very few in the English literature. The following is the description of one.

Case Report

The patient first attended hospital on May 11, 1949, at the age of 11 months. He had been born with a tail-like appendage, but his mother had not sought advice before, as she thought that nothing could be done until the child had dispensed with napkins. However, the increase in size of the tail at last made her come to hospital. There was no family history of any like anomaly. The child was a firstborn, the pregnancy and delivery had been without incident, and the child had developed normally since birth. There were no bowel or urinary symptoms. On examination he was found to be a healthy normal child, apart from his caudal appendage. The tail was attached to the right posterior anal margin (see illustration) and could be freely moved by the child. It was extensile and when fully pulled out measured just over 3 in. (7.5 cm.). When released it would contract, curl on itself, resembling the tail of a pig, and then relax and flick from side to side.

Photograph showing the vestigial tail at 11 months.

No bone or cartilage could be palpated in the tail. It was covered with normal skin. The anus freely admitted the examining finger, and the sphincter was of normal tone. *X*-ray examination of the pelvis showed no bony abnormality.

On May 26 the tail was excised by an incision encircling the base. The wound was soundly healed eight days later.

The specimen was reported on as follows: "A finger-like process 7 cm. in length and 1.5 cm. in diameter at the base. It was covered with hair-bearing skin and its core consisted mainly of fibro-fatty tissue with a small eccentric nodule of 'cartilaginous' consistency. *Microscopy*:—The external lining was of epidermis with normal skin appendages. Most of the core was formed of striated muscle bundles. Also present were fat, fibrous tissue, blood vessels, and nerves."

Comment

Bartels (1884) traced 116 recorded observations on tails in man. He found references as far back as the writings of Pliny, and stated that tailed races at one time or another had been reputed to have lived in South America, Asia, Africa, and Western Europe. Harrison (1901) reviewed the occurrence of tails in man and reported a case very similar to the one recorded here. R. J. McNeill Love (1934), in describing a case, suggested that such an abnormality might well be left in the hope that the bearer could use it later to earn his living in a circus.

In the 14–16 mm. embryo the caudal region shows a well-marked tail projecting beyond the cloaca—the proximal part containing vertebrae, the distal part without vertebrae. The latter is termed the caudal filament, and it seems that it is the persistence and growth of this structure which gives rise to a tail.

I wish to thank Mr. Charles Donald for permission to publish this case, Dr. Martin Bodian for the pathological report, and Professor J. D. Boyd for his interest.

Chorion Carcinoma after Ectopic Gestation

The debt which diagnostic acumen owes to previous experience is too great to be assessed, and it must be accepted that he who would diagnose a condition not previously met is at a grave disadvantage; if, furthermore, he is unaware that such a condition exists, then the handicap will be so overweighted that the issue may well be decided before he can come to the aid of his patient.

That chorion epithelioma follows on hydatidiform mole is well known; that it may follow on normal pregnancy or abortion is taught, though few will have met it; therefore, that it may follow an ectopic pregnancy is a reasonable enough supposition. When, however, one estimates how extremely rarely chorion epithelioma follows normal pregnancy, and then estimates the rarity of ectopic as compared with normal pregnancy, when one adds to that the ease with which ectopic pregnancy is diagnosed, and the satisfactory extirpation which surgery achieves, one becomes prepared to accept the statement that chorion epithelioma after ectopic gestation is a very rare condition.

Rufus Thomas (1934) records a case, reviews the literature (the bibliography is appended), and states that "the number up to date would appear to be at least thirty-six." Walsh (1935) records a case and states that "Szathmary collected 1,412 cases of chorion epithelioma, of which 6.6% followed ectopic gestation"—that is, approximately 94 cases. Dafoe (1939) adds two more cases, the second of which is remarkable in that the patient survived, though metastases had occurred and the Aschheim–Zondek test was still positive one month after excision of the chorion-epitheliomatous tube. Smith and Werthessen (1941) record a case which presented with a hard nodular mass above the pubis and an exfoliative mass around the urethra nine months after an ectopic gestation.

To these few cases one more is published in the hope that a surgeon finding his patient deteriorating after the operation for ectopic gestation will not assume, as I did, that it is due to his own lack of skill or fortune until an estimation of the urinary gonadotrophins has been made and the more deadly possibility has been excluded.

Case Report

The patient, aged 41, had her last regular menstrual period from August 12 to 16, 1948. Clotted blood was passed for four days from September 26—that is, after six weeks' amenorrhoea. She had had nausea, heaviness of the breasts, and frequency of micturition, and complained of an ache in the buttocks and pains ("like labour pains") in the abdomen.

On examination on October 26 no sign of activity could be found in the breasts; the abdomen was tender. The vagina showed the heliotrope discoloration of pregnancy, the uterus was retroverted, and there was a small tender swelling in the left tube. A diagnosis of ectopic gestation was made and the patient was admitted to hospital.

Laparotomy was performed on November 1. The abdomen was opened through a transverse suprapubic incision. The left broad ligament was filled with a clotted haematoma 6 in. (15 cm.) in diameter. The uterus showed some hypertrophy. The right ovary was stuck to the floor of the pouch of Douglas. The left tube and ovary and broad ligament tumour were removed. As bleeding was troublesome the uterus was also removed, the better to secure the main vessels. Bleeding was thereby for the most part satisfactorily controlled, and the application of a piece of "oxycel" gauze produced haemostasis, whereupon the abdomen was closed. Convalescence was uneventful.

In early January, 1949, the patient stated that she had been feeling fairly well until a week previously, when she had had aching pains in the pelvis and thighs and had been sick, and complained that the bowels had become "lazy."

The findings now were: "a thickening in the pelvic floor on the left side amounting almost to a tumour (N.B., blood clot; bleeding; oxycel)." Later in the month the findings were more definite. However, in view of the extensive nature of the first operation so recently performed it was decided to palliate, and if an abscess should form to drain it through the pouch of Douglas. A month later, however, the issue was forced by the patient developing general peritonitis.

The peritoneum was opened and drained, and the haematoma opened. Stinking greenish blood clot was removed, and blood began to well up. The only way to arrest it was by packing. This was done, and on removal of the pack faecal material followed, intimately mixed with blood. Thereafter her condition was wretched indeed, but with the aid of penicillin and repeated transfusion she lived, steadily losing ground, wasting away, but never despairing.

From time to time there was a suggestion of icterus, and about three weeks before she died an intractable cough began. Occasionally frothy sputum was produced but more often nothing at all. Clinical findings in the chest were absent, and skiagrams showed no evidence of growth. A diagnosis of malignant disease, probably chorion epithelioma, was now made, and this was confirmed 48 hours later by the Friedman test. The patient was perfectly conscious to the end and not in pain. She died, unaware that she was dying, of inanition, blood loss, and exhaustion from coughing.

Necropsy revealed a necrotic mass in the pelvis which had eroded the sigmoid colon. The liver and brain were free from metastases. The lungs were very pale and the cut surfaces were uniformly stippled with bright-red dots about 1 cm. apart.

Sections taken from the uterus, tube, and ovary at the time of the original operation showed no evidence of chorion epithelioma. Sections taken at the post-mortem examination revealed the presence of actively dividing chorionic tissue in the pelvic veins and in the lungs.

Reviews

NON-GONOCOCCAL URETHRITIS

Non-Gonococcal Urethritis, including the Genital Manifestations of Local and Systemic Diseases and Infestations of the Urinary Tract with Protozoa, Metazoa, and Fungi. By A. H. Harkness, M.R.C.S., L.R.C.P. (Pp. 424; 167 illustrations, 73 in full colour. £2 12s. 6d.) Edinburgh: E. and S. Livingstone. 1950.

It is a real pleasure to read such a scholarly book as this. It consists essentially of a full critical review of the literature together with the author's own experiences and views. Few will deny that Dr. Harkness has made a thorough investigation of this subject, and even if they do not share his opinions these must be treated with respect. Many readers will be amazed at the mass of detail contained in this book and at the multiplicity of possible causes of non-gonococcal urethritis, but there can be no doubt that this condition presents a far greater problem than gonorrhoea and is responsible for a large proportion of attendances at V.D. clinics. Perhaps the most attractive section is that on Reiter's disease, but every line of the book should be read by the venereologist who hopes to complete his education.

The author insists that keratodermia blennorrhagica is not due to the gonococcus, and he is prejudiced against the complement-fixation test for gonorrhoea. Admittedly this reaction is seldom positive nowadays in patients treated with penicillin, because all the organisms are usually destroyed before there has been time for antibody production, but there does seem to be a case for its use in such conditions as epididymitis, arthritis, and salpingitis, where it is almost always positive when the gonococcus is the causal agent.

This book is a veritable mine of information on a subject about which most practitioners know very little. There are 167 beautiful illustrations, 73 of which, in colour, could hardly be improved. There is a full bibliography set out under subjects at the end of each chapter, and an author index in addition to the general one. The book is well produced and clearly printed. Many of the opinions expressed are open to criticism, but the author writes with authority and every venereologist will profit by a careful study of its contents.

T. E. Osmond.

CORONARY DISEASES

Les Maladies des Coronaires. L'Infarctus du Myocardie; l'Insuffisance Coronarienne. By Ch. Laubry and P. Soulié. Second edition. (Pp. 618; 299 figures. 2,400 francs.) Paris: Masson. 1950.

The publication of the second edition of this book is an important event in cardiology. The seven years that have passed since the first edition came out have witnessed the new impetus given to research by the ending of the war and, in the present instance, by the Liberation. It is therefore not surprising that this treatise comprises a formidable body of new work; but what is remarkable is that, though knowledge in so many aspects of the subject has grown rapidly and there is a time-lag in all the stages between writing and final publication, the authors have succeeded in presenting so up-to-date a volume.

Comprehensiveness has its drawbacks as well as its merits. Detail may blur the vital outlines. Writing of the prodromal symptoms of cardiac infarction, the authors refer to an "intense asthenic state," to extrasystoles, to transient unexpected dyspnoea, to fleeting pains, and to palpitations. It might be better to stress the fact that such symptoms were put in their proper "functional" place some decades ago, and that it is more important for them to be kept in this perspective than to risk raising false suspicions of myocardial disease by according them a possible portentous significance.

This monograph states clearly the current concept of the cardiographic establishment of ischaemic myocardial disease. In effect, there are three recognizable phases: (1) ischaemia, (2) an ischaemic lesion short of necrosis, and (3) cardiac infarction with necrosis. Electrical analysis of the posture of the heart, of the heart in the frontal plane and the sagittal plane by standard and unipolar derivations, and by vectorcardiography and calculations of ventricular gradient complete the electrical assessment of a myocardial lesion.

While this work deals comprehensively with theory, there is a wealth of clinical material and of symptomatology critically expounded with the realism and insistence on first principles characteristic of clinical medicine in France. On the subject of treatment the authors maintain a conservative view. While accepting this, it is not easy to understand the cursory dismissal of anticoagulants in the therapy of cardiac infarction. But this is a current topic and possibly the authors should not be held to views expressed perhaps a year ago (publication date January, 1950).

Professors Laubry and Soulié have defined the current outlook on coronary syndromes in a masterly fashion. It is manifest that their own labours and researches are intimately interwoven in the fabric of modern cardiological knowledge. Moreover, since there is no other treatise on this subject of comparable value and authority in any language, it cannot be neglected by any student or practitioner of cardiology.

K. Shirley Smith.

SKETCH OF OSLER

Osler as a Gastroenterologist. By Felix Cunha, M.D. (Pp. 57. £1 5s.) San Francisco, California. Copyright by Felix Cunha. 1948.

Those fortunate enough to have met Osler find pleasure in any book which adds to their knowledge of him, or which gathers together material about a particular field of his activities. Dr. Joseph H. Pratt's *A Year with Osler*, published last year, belongs to the former category, Dr. Cunha's publication to the latter.

The probable reactions of those who never met Osler are more difficult to assess, for he was a personality as well as a great physician, teacher, and writer, and how far a personality can survive death varies with the individual and with circumstances. Perhaps with this in mind, Dr. Cunha has not confined himself to Osler as a gastroenterologist, but has, by appropriate introduction of other details, to some extent brought Osler himself back into being. He has also reprinted Osler's rare first publication, "Christmas and the Microscope," London, 1869. The combination has resulted in an interesting sketch of a past era and of a prominent person in it, and at times such a sketch can convey the atmosphere of a period more successfully than a detailed, full-scale account. The price of the book is, unfortunately, high in comparison with its length and will dissuade some would-be purchasers.

K. J. Franklin.

SOCIAL MEDICINE

Social Medicine: Its Derivations and Objectives. Edited by I. Galdston, M.D. (Pp 294. 22s.) London: Geoffrey Cumberlege. 1949.

In 1947 the New York Academy of Medicine invited a number of eminent doctors to take part in a discussion of social medicine; the papers contributed have now been edited by Dr. Iago Galdston and published by the Commonwealth Fund. After reading the book converts to this new gospel may find themselves wishing that its admirable but elusive doctrine could be formulated in more precise terms. Social medicine, it appears, embraces a very wide field, which includes for the moment epidemiology, preventive medicine, medical economics, and the social complications of illness; it leans towards psychiatry and nutrition.

The difficulty, which paradoxically is crystallized by the diffuseness of the matter in this collection of papers, is that the term social medicine is currently used in two quite different senses. In the first place many people use it in reference to a personal exposition of the humanitarian or preventive traditions: it is better to prevent than to cure; the doctor should consider patient as well as illness, family as well as patient, community as well as family. These and many other ideas are included, and it is in this general sense that most of the contributors to the conference of the New York Academy have written. Secondly, and more specifically, since 1943 social medicine has been used in Great Britain as the title of a number of university departments. It would be unrealistic to expect these departments, which must be judged by the quality, number, and uniqueness of their research publications, to give direction to all the good-natured observations which have appeared under the broad banner of social medicine.

A few words of consolation for the general reader, who by now no doubt has become reconciled to the fact that no definition of social medicine acceptable to all tastes is forthcoming: no branch of science was ever established in debate, and when questions of definition are taken too seriously research workers may find themselves merely discussing what they would be doing if they were doing anything at all

T. McKeown.

MEDICAL RESEARCH

Research in Medical Science. Edited by David E. Green, Ph.D., and W. Eugene Knox, M.D. (Pp. 492. £2 8s.) New York: The Macmillan Company. 1950.

The title of this book is not fully informative. It contains articles on growing points of medical research by 26 distinguished contributors, including among British workers Burnett on viruses, Hogben on the methodology of medical genetics, and D. D. Woods on micro-organisms and vitamin research. The range of subjects includes research on psychiatry, by Karl A. Menninger, which reads like an apologia, and biochemical problems in sanitary engineering. Material is up to date to the end of 1948 and early 1949, and the book is well printed and produced. There is no index. It is difficult to review a book of this kind or to envisage the audience to which it will appeal, an audience which is already well served by journals and reviews. The individual articles are excellent, but they will remain inaccessible to most readers. Moreover, I think many of us find that we do not get as much out of reading a variegated book of this kind as from reading a monograph or textbook confined to a single field.

TREATMENT OF RHEUMATOID ARTHRITIS WITH STEROIDS

Eighteen months have elapsed since Hench and his colleagues[1] at the Mayo Clinic published their first report on the results obtained by treating cases of rheumatoid arthritis with the steroid "compound E," which was isolated by Kendall in 1936 from adrenal cortex and since named cortisone. Although the rheumatic diseases are notorious for the frequency with which dramatic successes have been claimed for various forms of treatment, it was immediately apparent that here was something really revolutionary both in its concept and in the consistency of its success.

During the past year tremendous efforts have been made in many parts of the world to find a cheaper and more plentiful substitute for cortisone, the supply of which is limited by the scarcity of raw material—namely, ox bile—and the complexity of the chemical steps by which the cholic acid of the bile is converted to cortisone. Callow[2] has recently described a search for alternative raw material among plants in Nigeria. But, despite the extreme shortage of supplies of the drug, confirmation of the Mayo Clinic results was rapidly forthcoming from many experienced clinicians in N. America. Investigators in this country had to content themselves with minute quantities adequate for animal experiments on a small scale but quite insufficient for any kind of clinical trial. It will therefore come to most as a pleasant surprise that, thanks to the kindness of Dr. Philip Hench, at least one group of investigators here—Drs. W. S. C. Copeman, Oswald Savage, P. M. F. Bishop, Professor E. C. Dodds, and Drs. B. Gottlieb, J. H. H. Glyn, A. A. Henly, and A. E. Kellie—has been able to study the therapeutic effects of cortisone at first hand. The results of this first clinical trial in Europe are published in the opening pages of this issue. Of the five patients treated—each for ten days—four responded in the same dramatic fashion as Hench's original patients, and the clinical improvement in the fifth case is described as marked.

At the outset of such an investigation as this the difficulty had to be faced of determining criteria for assessing response to treatment in a disease so variable in its manifestations and so unpredictable in its course as rheumatoid arthritis. A substance like cortisone, the therapeutic response to which is so unequivocal, is obviously invaluable as a yardstick with which to compare all other forms of therapy. Copeman and his colleagues have therefore wisely used the opportunity presented by this gift of a small quantity of cortisone to study its effects on patients and to compare them with those of several other related steroids, for some of which strong claims have already been made. Thus Davison and his colleagues[3] have described excellent results obtained with pregnenolone, and Henderson and his colleagues,[4] reviewing the conflicting results obtained with this steroid, concluded that further trials were justified. When compared with cortisone, however, it is apparent that its therapeutic effects are negligible. The London group of investigators also used androstenedione, dehydro-*iso*-androsterone, progesterone, and pregnadienolone in their comparative study, and found no evidence of clinical improvement with androstenedione, pregnenolone, or pregnadienolone in six, eight, and four patients respectively. A moderate response was seen in one of the twelve cases treated with progesterone (but this could not be repeated when the patient relapsed) and a slight response in one of the four cases treated with dehydro-*iso*-androsterone. These results are in complete agreement with those of the Mayo Clinic workers. In a recent review by Polley and Mason[5] the therapeutic activity of a large series of steroids and adrenal extracts was compared with that of cortisone. The only substances with activity comparable with that of cortisone were "compound F," adrenal extracts containing compounds E or F in adequate quantities, and pituitary adrenocorticotrophic hormone. From the large series of steroids studied it became apparent that antirheumatic activity was possessed only by steroid derivatives of corticosterone with the following attributes: a double bond between carbon atoms 4 and 5, an oxygen on carbon atoms 3 and 20, an oxygen or hydroxyl group on carbon 11, and a hydroxyl group on carbons 17 and 21. Any single deviation from this essential structure resulted in complete loss of the activity.

Of particular value in the London group's study of the steroids was the development of a method for the clinical assessment of rapidly acting agents in rheumatoid arthritis. The method of choice in such trials is for both the assessing clinicians and the patient to be ignorant of the nature of the substance under trial in the individual case—that is, whether the test substance or control material is being administered. By this means Quin, Mason, and Knowelden, whose paper was published in last week's *Journal*,[6] were able to show that the therapeutic effects of deoxycortone and ascorbic acid could be exactly matched by injections of saline, and it might reasonably be suggested that had similar controls been used by others the world-wide polemic that has arisen round this subject could have been avoided. Fortunately this first trial of cortisone in this country is free from such criticism.

Also in this issue of the *Journal* we publish the results of a different type of treatment for rheumatoid arthritis. Dr. G. D. Kersley and his colleague at Bath have attempted to stimulate endogenous adrenocortical activity by the induction of insulin hypoglycaemia in forty cases and by electric convulsion therapy in eleven cases. It is obvious that with both these types of treatment the methods of test described by Quin, Mason, and Knowelden cannot be applied. Neither insulin hypoglycaemia nor E.C.T. can be given without at least the patient being aware that something unusual has occurred. In assessing Kersley's results, therefore, allowance must be made for the psychological effect of any new therapy, whatever its real value. Nevertheless, the clinical improvement in 22 of the 40 patients treated by insulin hypoglycaemia is encouraging. From a comparison of these results with those obtained by injections of adrenaline in oil the authors conclude that hypoglycaemic stimulation of the adrenal is not mediated by adrenaline. They suggest rather a direct stimulation of the adrenal cortex, or possibly a synergistic action between insulin and endogenous cortisone as postulated by Henderson.[7]

Despite the enormous volume of work that has been directed towards solving the problem in the past year and a half we appear to be as far as ever from understanding the mechanism by which cortisone produces its truly remarkable effects upon the rheumatic and related "collagen" diseases, though Selye's[8] theory of the general adaptation syndrome has stimulated much discussion of the subject. There is no evidence of any primary failure of the adrenal cortex in these conditions, no indication from a study of the patient as a whole of any adrenal hypofunction. Should not the conclusion be, therefore, that the fault lies not in the adrenal cortex but at the peripheral sites of activity of these hormones? If that be so, greater knowledge of connective tissue metabolism may well throw light on this excessive demand for cortisone by the connective tissues of the rheumatoid subject. Equipped with this additional knowledge clinicians will be closer not only to an understanding of the true aetiology of rheumatoid arthritis but also to a more physiological type of therapy.

A SECRET REMEDY FOR CANCER

We publish elsewhere correspondence between the Minister of Health and Mr. D. Rees Evans, whose treatment of cancer with a secret remedy has been described for the supposed benefit of the public by *Picture Post*. This was the subject of comment in a leading article in the *Journal* of September 16. What little comment there has been in the Press generally has been singularly uninformed. One wonders what the Press would have said if a medical man claimed to have a secret remedy for the cure of tuberculosis and at the same time intimated that such a cure could be effective only in his hands.

Mr. Bevan has appointed a strong independent committee to consider Mr. Rees Evans's claims to have discovered a treatment for cancer—namely, Sir Robert Robinson, O.M., the President of the Royal Society; Sir Alexander Fleming; Sir Ernest Rock Carling; and the Secretary of the Medical Research Council, Professor H. P. Himsworth. Mr. Bevan expresses the hope that Mr. Rees Evans will accept the offer, and adds this: "I must ask that you on your part will agree to abide by any decision which they may reach and, furthermore, that you will be prepared to submit to the committee, should they require it, full details of your materials and methods and will no longer insist that these can be disclosed only during the actual treatment of patients."

Some may doubt whether the evidence presented by *Picture Post* on behalf of Mr. Rees Evans would justify a serious inquiry by eminent scientists into the effects of a secret remedy which in one form or another has been in the hands of the Evans family for something like fifty years. We think it is a pity that on behalf of the public the Minister of Health did not see fit to condemn outright the use of a *secret* remedy for the treatment of such a serious condition as cancer. Even if the remedy produced some benefit, secrecy in the treatment of a disease with such a heavy mortality is unpardonable. Whether Mr. Rees Evans is medically qualified or not is completely beside the point. The director of the most important medical research institution in this country, for example, has no medical qualification. We should have felt a little more reassured if Mr. Bevan had insisted more pointedly upon the necessity for a full disclosure of the nature of the secret remedy before making this concession to popular clamour. Mr. Evans now says: "... I am perfectly willing to submit to the committee ... whatever they may ask concerning my materials and methods." Could he not have made this offer years ago to a properly accredited research organization, and shared then with mankind the benefit, if any, of a remedy he has hitherto kept secret?

LIMITS TO S.H.M.O. GRADE

An important statement on senior hospital medical officers by the Ministry of Health, sent in the form of a circular to hospital boards, appears in the *Supplement* at page 162. It should go far to allay much of the dissatisfaction that has been felt about this grade. The decisions were taken by the Ministry after full discussion with the Joint Committee representing consultants and specialists, and the committee itself sought the views of organizations representing certain specialties before giving its opinion to the Ministry. The principal change is that the grade of S.H.M.O. has been strictly limited. In future there will be no S.H.M.O. posts in general medicine, general surgery, obstetrics and gynaecology, cardiology, dermatology, otolaryngology, neurology, neurosurgery, plastic surgery, and thoracic surgery. A large part of consultant practice has therefore been defined where only consultant posts may be offered. Only when a suitable candidate cannot be found to fill a consultant post in these specialties should the hospital board consider whether the duties can be rearranged so that the field of applicants may be extended—for example, to part-time consultants. But if this policy fails, the vacancy may be readvertised as a S.H.M.O. post.

The S.H.M.O. posts will be retained in the limited circumstances described in the circular. For instance, obstetric posts at antenatal and post-natal clinics, and in maternity departments which are under the general supervision of a consultant, may still have senior hospital medical officers appointed to them. Other posts in the same category include those in orthopaedics primarily concerned with non-operative work, paediatric posts at welfare centres and other posts chiefly concerned with child welfare, posts in geriatrics below the rank of head of a large department, and, in ophthalmology, posts primarily concerned with non-operative work, such as refraction.

In the specialty of anaesthetics the circular makes clear that hospital establishments should include an adequate complement of widely experienced anaesthetists of consultant status, but, in addition to this staff and to trainees, some hospitals may appoint assistant anaesthetists in the S.H.M.O. grade. Similarly, in departments of pathology, radiology, and radiotherapy a full complement of consultants and trainees will be required, but there may also be a need for a few senior hospital medical officers in certain circumstances. The Ministry draws attention to general practitioners' being appointed to S.H.M.O. posts in some specialties, particularly anaesthetics, geriatrics, and paediatrics. Hospital boards are specifically adjured not to establish any consultant or S.H.M.O. post in a specialty not mentioned by the Ministry without first obtaining the Ministry's approval. The circular includes detailed instructions on future appointments and revision of the present establishments.

The statement is a welcome approach to the delicate problems of the S.H.M.O. grade, and the members of the Joint Committee are to be congratulated on having impressed the profession's views so clearly on the Ministry. Much anxiety will be removed when these new arrangements are put into effect.

ROSEOLA INFANTUM

Roseola infantum is a common but little-known infectious disease of young children which has received too little attention in the past. Many medical men are unfamiliar with it, and it is usually unrecognized. The principal reasons for this regrettable state of affairs are inadequate instruction of medical students in the features of the disease and scanty references to it in medical literature. Even textbooks on infectious diseases often fail to describe it adequately and to emphasize its importance, and several recent papers[1-3] on the subject are therefore welcome. This exanthem is a relatively benign disease and seems usually to occur sporadically. In the U.S.A. the condition is generally known as exanthem subitum, and it has also been called "sixth disease." Berenberg, Wright, and Janeway[1] believe that "there is increasing evidence that exanthem subitum is probably the most common febrile exanthem under 3 years." This may seem an extravagant claim to some, but there is no doubt that roseola should always be considered in the differential diagnosis of an unexplained high fever or a morbilliform eruption occurring in early childhood.

The peak incidence is in the second year, and 95% of the patients are aged between 6 months and 3 years. It occasionally occurs in the newborn and in school-children, but rarely in adults. The incubation period is 8 to 15 days. Fever is usually the first sign to attract attention: it is remittent, and temperatures of 102° F. (38.9° C.) to 105° F. (40.6° C.) are the rule; it usually persists for three to five days and ends more often by crisis than by lysis. There is remarkably little, if any, malaise in most cases, but restlessness and irritability may be observed when there is high fever. Older patients occasionally complain of headache and abdominal pain. One of the characteristic features of the disease is the late appearance of the rash; its eruption either coincides with the end of the pyrexia or follows within a day or two. The rash is rose-pink and consists of small discrete macules which fade on pressure. It is almost indistinguishable from the rash of rubella, but its distribution is less widespread; it predominates on the trunk and neck and may appear on the proximal parts of the limbs, but the face usually escapes. The eruption usually persists for 24 to 48 hours and fades completely without residual pigmentation. Occasionally it fades within two to four hours. Its fleeting nature in some cases, and its absence from the face, account for the ease and frequency with which this clue to the diagnosis is overlooked. Slight enlargement of the posterior cervical lymph nodes is a constant feature, though it is easily missed, and catarrhal pharyngitis and mild otitis media are often found. A few of those affected are acutely ill. Febrile convulsions are the commonest complication, but they are seldom serious. No fatalities have ever been reported, but Berenberg and his colleagues believe that the patient may occasionally die in the acute stage before diagnosis is possible and that this disease may sometimes be a cause of sudden death in infancy. The blood picture is characteristic. There is a slight neutrophilic leucocytosis on the second day, but this is rapidly followed by a neutrophilic leucopenia, with a consequent relative lymphocytosis, which appears on the third day. The neutropenia is most obvious towards the end of the febrile period, when the total white-cell count may fall below 2,000 per c.mm. The white-cell count usually returns to normal within a week.

The differential diagnosis of roseola is important. The outstanding features of the disease are the age incidence and the time relation of the fever and the rash. In the acute febrile stage it is most often thought to be acute pharyngitis, otitis media, or pneumonia, and because of the height of the fever chemotherapeutic or antibiotic drugs are often unnecessarily administered. When the rash appears it is often mistaken for a toxic rash or miliaria, or, when drugs have been given in the acute stage, for a drug rash. Drug rashes may take any form but seldom resemble roseola in either distribution or appearance. Though roseola may be mistaken for rubella because of the similarity of the rash and greater familiarity with the latter disease, there are several distinguishing features. The rash in rubella is more widespread and usually involves the face, and the macules frequently coalesce. Rubella may also be distinguished by the absence of a high temperature, the early appearance of the rash during the febrile stage, the occurrence of cases in epidemics, and the higher average age incidence. Measles, scarlet fever, and infectious mononucleosis should all be considered, though they seldom cause difficulty in diagnosis.

The infectious nature of roseola is not as apparent as that of the other exanthemata, because the youth of the patients diminishes the opportunities for epidemic spread; but the occurrence of outbreaks in children's institutions,[4 5] and even in nurseries for the newborn,[5] proves its infectious nature. The causal organism is almost certainly a filterable virus, but none has yet been isolated. One attack confers permanent immunity. Berenberg and his colleagues believe that infection with the roseola virus may be almost universal in the first three years of life. They base their hypothesis on the following grounds: first, widespread dissemination of the infective agent, largely by numerous adult carriers; secondly, universal susceptibility after disappearance of the congenital passive immunity conferred by the mother's specific antibodies; and, thirdly, the presumed existence of atypical modified forms of the disease such as occur in other virus diseases. Such epidemiological features would account for the sporadic occurrence of roseola and the usual absence of known exposure to cases. Treatment is symptomatic and consists chiefly in administering antipyretic drugs and tepid sponging. Anticonvulsant drugs such as phenobarbitone should be given to children who are known to be subject to febrile convulsions.

PREGNANCY AND PULMONARY TUBERCULOSIS

The effect of pregnancy on pulmonary tuberculosis affords a subject for perennial discussion, the most recent being at the Annual Meeting of the B.M.A. in Liverpool last July.[1] This is, of course, a serious medical and social problem, for Schaefer[2] has pointed out that, while the incidence of phthisis in pregnancy is of the same order as heart disease, it is at least four times more lethal a combination. Radiological examination of the chest should therefore be a routine practice in pregnancy. The view generally held to-day has been well summarized by Turner,[3] who states that in a minority of cases pregnancy is a direct cause of deterioration; in another and probably larger minority it exerts a beneficial effect, while in the majority it has no obvious influence on the disease. Turner, however, goes further than most when he claims that the onset of phthisis or reactivation of quiescent infection is most likely to occur in the first four months of pregnancy and in the first four weeks after labour. Obstetricians admit that the physical exertion of labour, especially if prolonged, may be harmful. In fact Schaefer advises resort to elective caesarean section in primigravidae with far-advanced disease or when labour appears likely to be prolonged. But gynaecological pathologists would not in the main support Turner's theory that aggravation in the early months might be due to the implanting ovum disturbing endometrial tuberculous follicles, thereby allowing direct entry of tubercle bacilli into the blood stream.

Turner has also suggested that oestrogen exerts a beneficial and chorionic gonadotrophin an adverse effect on tuberculosis, and that the high level of circulating chorionic gonadotrophin is responsible for the aggravation of the disease and thus for the peak incidence in early pregnancy. In support of this last point he puts forward figures showing that the survival rate is appreciably higher when early abortion occurs spontaneously than when therapeutic abortion is performed. This may be so, but the reason given—namely, that spontaneous unlike therapeutic abortion is likely to be accompanied by a diminution in the chorionic gonadotrophin and an increase in the oestrogen levels—is open to question. Most of the recent papers and discussions indicate that therapeutic abortion is becoming less widely practised and that when it is performed the deciding factor is more often social than strictly medical. Although a truism, it is worth repeating that the best results are to be obtained when the tuberculosis and the pregnancy are treated concomitantly and adequately. In this connexion it appears that neither streptomycin therapy nor thoraco-

4 *Brit. J. Tuberc.*, 1946, **44**, 10.
5 *J. Bone Jt Surg.*, 1950, 32-B, 307.

plasty is contraindicated in pregnancy. When well-equipped maternity units are provided in sanatoria many present difficulties will be overcome.

At Black Notley Hospital, in Essex, a maternity unit for tuberculous women was opened in 1937, and more than 300 patients have now had their confinements there. Cohen[4] has discussed the treatment of those suffering from pulmonary tuberculosis, and more recently Wilkinson[5] has investigated the effect of pregnancy on 32 married women with skeletal tuberculosis, most of whom were treated at Black Notley. He concluded that no serious harmful effects have been caused by pregnancies going to full term. Some time must elapse before additional special units can be opened, and meanwhile co-operation between obstetrician and physician should be close, and the practice of setting aside in maternity hospitals a number of beds for tuberculous pregnant women should be encouraged and extended.

DISTINCTION DENIED

An unfortunate anomaly by which certain consultants are debarred from receiving one of the distinction awards is discussed in a letter at page 887. Apparently some consultants who hold contracts with hospital boards in the Health Service to work unpaid and in an honorary capacity are not eligible for distinction awards. A ministerial ruling on the matter has been given in a document sent to members of hospital boards and others, and it states that "consultants who hold only *unpaid* appointments in the hospital service cannot be eligible for awards (with the exception of some clinical teachers and research workers). The purpose of the distinction awards system is to select consultants for the higher rates of remuneration, and it is therefore inapplicable to consultants who are not remunerated."

Though the financial harm to the consultants concerned is obvious, our correspondent indicates that these consultants are anxious on other grounds. A distinction award is from its description a hallmark of distinction. The names of those holding them are not to be published, but the secret cannot be kept long, for the administration of them is itself enough to distribute the knowledge widely. It will soon become known in a hospital, or a hospital group, that a certain consultant has not received an award; some people will know why, but others may not. Again, there is some healthy rivalry between hospitals, particularly between those renowned for the skilful and original work of their staffs. If one hospital has 20 men with distinction awards and another only 15, invidious comparisons are bound to be made. The future selection of consultants for higher awards from among those holding lower awards is apt to be vitiated if the choice is disproportionately small in a hospital where there is a high number of consultants eligible on merit for holding the lower awards, but debarred by this ruling from doing so.

Since these honorary consultants hold contracts with their hospital boards, there seems to be no administrative objection to paying them the awards and thereby conferring what they are more concerned about—the label that indicates their colleagues consider them worthy of distinction. Alternatively, they could be given the distinction, and the money could be put to other purposes.

Consultants who do part-time paid work are eligible for a fraction of the distinction awards proportionate to their paid work. It may be argued that, since the fraction of the award diminishes in accordance with the amount of paid work done, therefore a man who does no paid work is not eligible at all. But this overlooks the fact that a man doing unpaid work does so many sessions a week—work for the Health Service and sessions which can be counted. The amount of the award could be given proportionately to the amount of unpaid work done. To withhold distinction awards altogether from these people, some of whom are known to be outstanding men in the profession, is an incongruity that should be examined.

THE PATIENT'S NEEDS

"The hospital, grey, quiet, old. . . . These corridors and stairs of stone and iron, cold, naked, clean—half-workhouse and half-gaol." So William Henley wrote of the Old Infirmary, Edinburgh, in 1873. Although present-day patients have no reason to be so unflattering about their hospitals they still have some grounds for complaint about their environment and the routine to which they are subjected while undergoing treatment. This has found expression in Miss Olive Matthews's booklet *Hospital Improvements*.[1] She has studied 24 hospitals in England, Holland, Southern Rhodesia, and South Africa, and has been able to list, from the patient's viewpoint, the most irksome details of hospital life which are usually completely outside the thoughts of the medical staff.

Her critical eye strays from bedside lockers to occupational therapy, from clothes cupboards to the view from the patient's window. She finds the conventional locker ill designed, usually containing a jumbled-up mixture of food, soap, cigarettes, and books. She recommends a small open trolley like a dinner-wagon with sets of shelves which would give easier access for the patient who used it and the nurses who had to clean it. Bed-tables should be in the form of a bridge on wheels that pushes over the bed, and preferably equipped with a centre book-rack.

The author condemns the screens perpetually carried round from bed to bed by the nurses, and favours curtains on runners from the ceiling, which transform a ward in a minute into a collection of cubicles. Most patients in a hospital ward fortunately do not feel particularly unwell—they are recovering or being investigated. Their main enemy is boredom, and the hours pass like milestones to a tired walker. Miss Matthews is anxious that a library service should be available in all hospitals and that patients should have no difficulty in buying their morning newspaper, and she is ready to praise the occupational therapist. Visitors, the finest antidote to boredom, should be admitted daily, preferably in the evening, for then is more convenient for the visitors and lightens a particularly heavy few hours in the patient's day. For those who have become permanent residents in hospitals, and who have no relatives or friends to visit them or write to them regularly, she suggests a voluntary service of pen friends to write to their adopted patient not less than once a month. "The amount of satisfaction given," she says of such letters, "is out of all proportion to the effort made."

Miss Matthews particularly dislikes (and so, it appears, does the irrepressible G.B.S.) the early-morning wash, which has become good-humouredly accepted as an inescapable unpleasantness of ward routine; but why, she asks, should it be an unmovable rite? The occurrence that determines the time of washing early in the hospital day is the arrival of the medical staff between 9 and 10 a.m. There is so much work to be done in the ward before that time that washing the patients is usually the duty of the night nurses. If the doctors could be persuaded to come later or the nurses' hours of duties rearranged the patients could sleep longer. Would this reorganization be worth while? Miss Matthews is emphatic that it would.

The modern hospital has private charity and the Poor Law as its ancestors: they have left their image stamped on their descendant. Entering a hospital is to most patients a crisis in their life and an experience of great disquietude. Some of the suggestions made by Miss Matthews for making the patient more comfortable, bodily and mentally, are impossible without adding to hospital budgets. Many require simple common sense and kindness from hospital staffs, and should therefore have no obstacle to their immediate fulfilment.

INDUCED BACTERIAL ANTAGONISM

More than 25 years ago Schiller and others claimed to have shown that bacteria can be "induced" to form antibiotics by feeding them on the other species which these substances are to attack. Superficially the well-known work of Dubos, which led to the discovery of gramicidin, might be supposed to exemplify this process, although the mechanism concerned was almost certainly selective and not adaptive. This subject, which is clearly of great importance, has been thoroughly restudied at Oxford by Savage and Florey.[1] They copied the methods of Schiller and others as far as possible, but applied them more thoroughly and stringently, as well as devising a new method of their own. In the first place the chosen "antagonists" (*B. licheniformis* and *Proteus vulgaris*) were cultivated on agar containing no source of nutriment except cells of the "victims" (*Bact. coli* and *C. xerosis*). During repeated transfers on this medium growth improved, the antagonists having evidently learned to utilize the victims as nutriment and in some cases developed the capacity to lyse them. Nevertheless no antibiotic was developed. The living cells of the victims were unaffected, as judged by tests in streak and cylinder plates, except that *B. licheniformis* continued to form the same small amount of a substance inhibiting the growth of *C. xerosis*. Results were of the same nature when *Proteus* was cultivated serially in a suspension of tubercle bacilli containing diminishing traces of peptone as the only other source of nutriment. Finally, an ingenious mechanism was devised for making regular additions of a suspension of *Bact. coli* to a culture of *Proteus*, with the aim of keeping the latter continuously in the logarithmic phase of growth: this was equally without effect in inducing antagonism.

These experiments do not prove that there is no such thing as induced antagonism, since it may be objected that the wrong species were chosen, but they make it seem very probable that earlier work in which this phenomenon is supposed to have been demonstrated was in some way faulty. They make it clear for the first time that capacity to use bacterial cells as nutriment or to lyse them may exist or even be developed in another species unaccompanied by the formation of any substance which affects the living cell of the victim. This was perhaps to be expected. Antibiotics are not enzymes, and when they cause lysis this is a secondary and not the primary effect. What might, from a study of the older literature, have seemed a promising way of evolving new antibiotics is now less likely to engage the time of other workers unprofitably.

RELIEF OF MUSCLE SPASM IN POLIOMYELITIS

So-called "muscle spasm" in poliomyelitis is a complex problem. Denny-Brown[1] considers that three varieties of the condition must be considered: one is contracture, one is a response to the meningeal reaction, and yet a third type is a transient increase of stretch reflexes. Some exponents of hot-pack methods of treating muscle spasm believe that by relieving it they are minimizing the degree of paralysis and even assisting some form of regeneration of nerve to occur. There is no firm evidence in support of these views, but nevertheless the relief of spasm seems very desirable if only to alleviate pain and to facilitate the all-important early passive movements. There is of course no point in treating "spasm" when there is none, and many cases of poliomyelitis show little or none of this abnormal muscle sensitivity. Further, the muscles with prolonged spasm are those which will not be paralysed, but by their unopposed action are liable to develop shortening and contracture. Many drugs have been used in recent years for the relief of muscle spasm. Among these may be mentioned curare and neostigmine, but these have not become popular. Recently Smith and his co-workers[2] have advocated the use of sympatholytic drugs such as "priscoline" and report its use in 663 cases of acute poliomyelitis. It seems from this report that the treatment was symptomatically often beneficial, though it caused vomiting in over 500 cases. Patients with bulbar and respiratory paralysis were not included in the series. Unfortunately the method of testing the value of the drug was somewhat uncritical, and the authors made no attempt to record the duration and severity of muscle spasm in an untreated series. Their method of dosage was to push the drug until flushing was noted, and this flushing dose was then repeated every three hours during the day and every four hours at night throughout the patient's stay in hospital. This intensive method may be necessary, but a trial of different methods of administration is needed. In conclusion these workers rightly emphasize that no treatment is known to influence the effect of the virus on the nervous system. It was also a disappointment that Denny-Brown in his electromyographic studies found no reason to believe that there is regeneration of nerve fibres in poliomyelitis.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

THE CARDIOGRAM IN CLINICAL DIAGNOSIS AND PROGNOSIS

II. PRACTICAL APPLICATIONS

BY

TERENCE EAST, M.A., D.M., F.R.C.P.

Senior Physician and Physician in Charge of Cardiological Department, King's College Hospital

There are two main clinical uses of the cardiogram. The first is in the diagnosis of disorders of rhythm, and the second is in the detection of disease of the myocardium. Rhythm disorders may sometimes be due to myocardial disease.

The Patient with a Cardiac Arrhythmia

In the matter of the arrhythmias the cardiogram gives final and complete diagnosis in almost every case. For the most part the standard bipolar leads suffice, unless special study of auricular activity is called for, when the precordial lead from either edge of the sternum or the unipolar lead from the left foot (VF) will show it well. Oesophageal leads are useful in this respect too.

The common arrhythmias can usually be fairly easily diagnosed at the bedside, with unaided senses, if their nature is properly understood and a careful history is taken. This should not be outside the competence of the general practitioner.

A bradycardia may cause difficulties, but, should the vagus be the cause, there is always exercise or atropine to show it (Fig. 2). A regular tachycardia of, say, 150 may

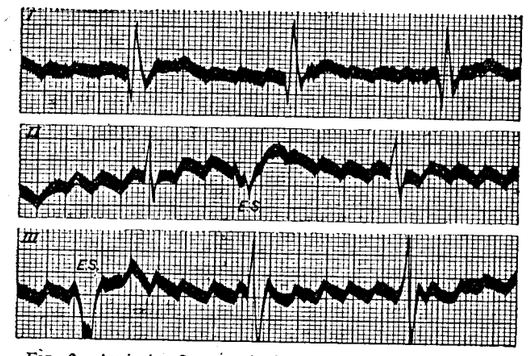

FIG. 2.—Auricular flutter. Auricular rate 250. As usual, the flutter oscillations appear only in two leads. The ventricular rate is slow, 55, owing to complete heart block, and irregular from extrasystoles (E.S.). Q_1 suggests past anterior myocardial infarction.

cause difficulties. Here, again, the vagus comes in useful owing to the increase in its tone that can be caused by pressure on the carotid sinus, a most valuable clinical procedure. The premature beat should rarely fail to be diagnosed.

Heart block may be undiagnosable in any stage in some cases. The minor grade of incomplete heart block can be detected only by measuring the P–R interval. The dropping of beats can usually be diagnosed by auscultation, but some are very difficult if many beats are dropped and the conduction times are varying. The changeless bradycardia of complete block is usually easily diagnosed, but pronounced bradycardia is not always present, and premature beats may complicate the picture.

Delay of conduction in the ventricles is usually caused by block of either branch of the bundle of His. This may be due merely to local disease or, more usually, may be an indication of widespread trouble. The defect cannot be certainly diagnosed clinically, but there may be suggestive clinical evidence of asynchronous ventricular contraction. Not that this is always due to bundle-branch block, for instead of pathological tardy activation of one ventricle it is possible to have physiological prior activation of one ventricle. But it is safe to conclude that any delay in the spread of the impulse from auricle to ventricle, or within the ventricle, is mostly due to disease.

Auricular fibrillation should rarely be missed, but if the rate is slow there may be difficulty, as the variation in spacing is so slight. If there is any doubt at all a cardiogram should be taken (Fig. 3), for mistaken diagnosis may have serious consequences. There are a number of rare and curious disturbances of function—often harmless yet of academic interest and a joy to the expert, which he would be sorry to miss—that may be stumbled on in this way.

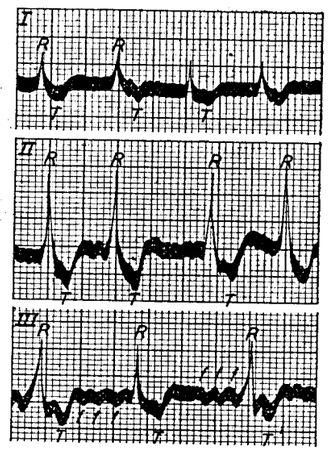

FIG. 3.—Auricular fibrillation. Note fibrillary waves in Lead III, inversion of T in all leads by digitalis, variation in the shape of the T waves.

Unfortunately, an arrhythmia may be transient and capricious, and therefore it may not be recorded because the heart's action may be normal at the time of examination. Sometimes very long records are needed for its full elucidation. But the history taken by the expert may give, or very nearly give, the diagnosis even when no disturbance of function is present.

The study of the arrhythmias depends on the fact that the cardiogram shows the site at which any impulse started, the course which it followed, and the time taken in its spread. These three pieces of evidence provide all the information available for diagnosis. If the source and the course of the impulse are abnormal, the form of wave in the cardiogram will be abnormal. The circus movements of the impulse in the auricle or ventricle are well demonstrated by suitable leads. Here systole (and its P wave) is abolished and the fibrillation or flutter waves are substituted. The prognosis will to a large extent depend on the nature of the arrhythmia. Some types are trivial and

some are grave in their significance; their importance depends to some extent on their association (the company they keep). By this I mean the question of the presence of any underlying disease in the heart. This may be apparent clinically, or the cardiogram may reveal it when hitherto unsuspected.

The solution of a curve of arrhythmia is usually simple. Occasionally it may be very difficult even to the most expert. Long study of cardiograms makes one realize that the repertoire of the tricks a heart may play is almost inexhaustible.

Myocardial Disease

Lesions of the heart muscle may provoke symptoms of inefficiency by causing undue breathlessness on exertion; the age, habits, weight, and personality of the patient, the physical efficiency of the breathing apparatus, and the possibility of anaemia must be fully considered. Clinical examination may reveal no abnormal physical signs at all, and every lead of the cardiogram may be perfectly normal, and yet the heart may not be healthy. It must be emphasized once again that normal curves do not exclude disease. On the other hand, a supposedly healthy person—for example, an elderly candidate for life assurance—may be shown cardiographically already to have silent lesions which will cause trouble in the future. The strict correlation between pathological curves and pathological states in the heart muscle is often far from close. Disease found at necropsy may not have changed the cardiogram materially, nor may examination of the myocardium reveal the cause of an abnormal curve. The microscope may show but little in a heart that has actually failed.

Probably the closest correlation is to be found in lesions of an ischaemic nature, when they are large enough. Cardiac ischaemia usually causes the clinical symptom of the typical substernal pain, and here, again, careful attention to the patient's story of his symptoms is probably 70% of the diagnosis. Indeed, I must stress that this applies to the full diagnosis in any patient supposedly suffering from heart disease.

To approach the subject more closely, a few general principles may be briefly touched on. In the auricles disease is not of great importance. The two chief disturbances of auricular function—the circus movements of fibrillation and flutter, and auricular paroxysmal tachycardia—have no constantly recognizable pathological changes associated with them. Rarely, the auricular wave may be modified by auricular enlargement (better detected by screening) or by infarction.

If it is in the ventricles that the morbid changes are to be sought. Here disease may be widespread or local. Toxic, metabolic, and biochemical causes may underlie the former, and local ischaemic changes due to vascular disease may produce the latter. The morbid process may interfere with the spread of the activating impulse for contraction, which is now regarded as a process of depolarization, or with the process of repolarization that succeeds it, restoring the cells to a condition ready for the next systolic contraction. These defects are reflected in the first part of the ventricular complex (QRS) for the former, and in the T wave or RS–T interval in the latter. But the range of the normal variations for the ventricular complex is very wide. As already stated, the position of the heart in the thorax, depending on various degrees of rotation about possibly three axes, modifies the curve a great deal, and much experience is needed to say that this or that curve is within normal limits.

The best way to proceed with this discussion seems to be to select certain clinical types of case and to show how the practitioner may be helped by the cardiogram, and also to mention, perhaps chiefly for interest, some conditions in which the abnormal cardiogram provides indication about the degree to which the heart may be involved.

It must be emphasized that the cardiograph is not a penny-in-the-slot machine which produces the diagnosis complete. The cardiogram is only one detail in the clinical picture—its importance can be assessed only by seeing the picture as a whole. The full significance of any curve is appreciated only if the complete clinical background is known. In order to make a diagnosis a thorough knowledge of the individual under investigation is necessary. The art of prognosis depends on the accurate assessment of the significance of as many relevant points in any given case as possible, viewed from experience of as many cases of that sort as possible. A prognosis that hangs on one peg will soon fall. The cardiogram is only one relevant peg, on which too much weight must not be hung.

Diagnosis of Angina Pectoris (Transient Myocardial Ischaemia)

The history is the important thing in making a diagnosis. If there are already pathological changes in the heart muscle the cardiogram may show abnormal features. A normal curve will not exclude the diagnosis. It is known that curves taken during the pain may become abnormal temporarily, so some workers have deliberately tried the effect of provoking pain by exertion to see whether the curve becomes abnormal. Another method is to make the patient breathe air with a low concentration of oxygen (these practices have not become popular in this country); even then the pain may be felt and the curve remain normal. There is also some risk. And quite healthy persons may produce abnormal curves in such conditions.

Diagnosis of Myocardial Infarction

Experimentally, the cutting off of the blood supply to some of the myocardium caused changes in the cardiogram in a few moments. These may disappear if the circulation is restored. Myocardial infarction is an irreversible process. Occlusion of a coronary artery very soon produces a change in the cardiogram. The type of abnormality which results goes through progressive phases. These may be extended over some length of time, from hours to days: as a rule they are quite typical and are easily recognized.

By means of multiple unipolar leads it is often possible, when the infarct is in the front of the left ventricle, to map out its extent. Antero-septal, anterior, and antero-lateral types can be recognized. It may be possible to determine whether the whole thickness of the wall of the ventricle is involved. To be able to gauge the degree and extent of the damaged area in this way is obviously very important. As the changes pass through progressive phases it is possible to say whether the infarct is new or old. Thus it may be determined that infarction has occurred in a patient who has given no clear history that it has happened in the past. Some infarcts develop without pain and may be overlooked in consequence. Some ischaemic changes are gradual and symptomless. The cardiogram, as already indicated, enables the site of the infarct to be located (Fig. 4). Those which form at the back of the heart are less accessible. The unipolar lead from the left foot (and, as a result, standard Leads II and III) usually shows them. Oesophageal leads may be useful in detecting these lesions, but they are not easy to employ.

More than one infarct is sometimes located. To be able to estimate fairly accurately the extent and degree of the

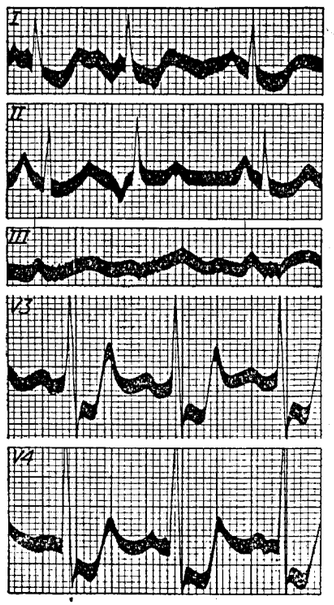

Fig. 4.—Infarction of lateral wall. There is depression of S-T interval in Leads I and II and deep depression of ST junction in V_2 and V_4. Auricular premature systoles are present in Leads I and II.

The taking of serial curves is often very useful in certain types of abnormality. In these a return to normal may be noted. The curves are not typical of infarction, and information about the transient pathological state underlying them is meagre, but there is reason to suppose that in these patients, who have suffered attacks of cardiac pain, the prognosis is much better than in those in whom irreversible disease in the form of infarcts has developed.

But in all these cases of ischaemic disease the prognosis will depend, first, on the after-effect of any one lesion on the cardiac efficiency, and, secondly, on the unknown chances of another attack. In addition, all the other pertinent factors peculiar to each individual case must be considered—his personality, body build, family history, age, and so forth. The value of the cardiogram in prognosis in most of these patients is relatively small. The cardiogram tells nothing about cardiac efficiency or the liability to failure.

Toxic and Metabolic Disorders

After an infectious illness some patients develop cardiac symptoms. These are usually of the type associated with effort syndrome—fatigue, palpitation, tachycardia, breathlessness—and may be regarded as a general lowering of ability to undertake exertion. How far a toxic myocarditis may exist as a pathological entity in such cases is open to question. But there is no doubt that in some instances there may be an abnormal appearance in the T wave of the ventricular complex, or of the RS-T interval. This is a sign of some importance. There is little doubt that in course of time the normal appearance will be resumed, but if such indications of an unhealthy state in the myocardium are discovered, there is definite need for care and restriction of activity on the part of the patient as long as they persist. In these cases a cardiogram may provide useful information.

infarct may be helpful in prognosis so far as that particular lesion is concerned, but the value is often limited. There may at times be surprisingly good recovery from large lesions.

On the other hand, small lesions may not affect the curve, or not to the extent to enable a precise diagnosis to be made. One may, in fact, find large ischaemic lesions at necropsy in cases in which cardiograms had shown very little abnormality. A negative finding, as in other instances, may not exclude pathological changes, and the clinical side of the diagnosis must predominate.

Under this heading one must also refer to diphtheritic myocarditis, in which cardiographic changes are common and conspicuous. To follow their progress is useful: fortunately a complete recovery is likely.

In acute rheumatic myocarditis the cardiogram may become abnormal, and it is worth taking in a doubtful case. But the clinical evidence of increased heart rate at rest is probably the most sensitive indication of its presence, and a normal cardiogram by no means excludes carditis. Should an abnormal feature be detected repeated curves should be done to check its persistence.

Metabolic Abnormalities.—In metabolic abnormalities such as hypothyroidism (both myxoedema and cretinism) abnormal curves may commonly be met with. What the precise change in the curve is due to is not entirely clear, but it is definite evidence of the involvement of the myocardium and a return to normal should be looked for in controlling treatment. There are many causes for change in the T wave—for example, alterations in the acid-base level and in the potassium level in the blood; such toxic states as uraemia; and deficiency states such as severe anaemia, thiamin deficiency, and possibly also lack of nicotinic acid. These should be borne in mind when curves are being interpreted, and it is useful to remember, too, how in patients suffering from such diseases the myocardium may become diseased. The alterations in the cardiogram due to digitalis are as a rule fairly obvious. However, it is better for a patient not to have had it for 10 to 12 days before the curve is taken; and if it has recently been given the information should always be passed on to the cardiologist.

Pericarditis.—This may cause definite and diagnostic changes in the cardiogram: these are easily recognized, but the clinical diagnosis will in most cases be made on the physical signs. In the constrictive type low-voltage curves are often seen, but the diagnosis depends finally on other clinical findings.

Pulmonary Circulation.—This has troubles of its own. Pathological changes in the pulmonary vessels tend to throw strain on the right ventricle and cause hypertrophy in slow chronic cases and dilatation in acute ones. The effects of pulmonary fibrosis, of whatever type, appear only relatively late; but their detection with the help of the cardiogram assists in grading the severity of the disease. The same applies to emphysema; and also to the rather uncommon disorders which affect the pulmonary vessels, in some of which a raised pressure seems primarily to play a part. Pulmonary infarction may be difficult to diagnose; when the heart is affected by it the result is acute dilatation of the right ventricle. A fairly characteristic cardiogram is seen in about a quarter of all cases, and this may help in the diagnosis when there is doubt. But a normal curve will not exclude pulmonary infarction.

Trauma.—Occasionally a severe blow on the sternum may bruise the heart. This may happen in motor accidents when the driver is thrown against the steering wheel. The cardiogram may give evidence of the damage, and it is important to detect this so that ample time is allowed for recovery. It is well known that patients may suffer from angina of effort after such bruising of the heart.

Congenital Lesions.—As these may cause predominant enlargement of one or other ventricle, the cardiogram may help in making the final accurate diagnosis.

Life Assurance.—In the case of an elderly proposer a cardiogram is useful in helping to exclude early latent disease of the myocardium. As already stated, a normal curve may not exclude it, but, on the other hand, a defect may be detected which has so far caused no symptoms. In such cases a cardiogram is well worth doing.

Prognosis

As already stated, the prognosis in any individual patient should be based on as many points as possible. The evidence of the state of the myocardium as given by the cardiogram is one of them, but is only a relatively small part of the picture. It is probably correct to say that the larger and more extensive the infarct, the more serious is the outlook. A return to normal in a curve showing ischaemic changes is a good point. At one time it was said that bundle-branch block carried a very bad prognosis, but this is by no means always the case, for the lesion causing it may be quite local. On the other hand, it usually means that there is widespread disease too. If, in following a case with serial curves at intervals, progressive deterioration is found, even when there is not much to be noted on clinical grounds, the prognostic significance is obviously bad.

The psychological effect of the cardiogram is not inconsiderable. The general public has begun to learn something about this method of investigation. To a nervous, apprehensive patient who has become heart-conscious and who may be the subject of a cardiac neurosis the demonstration of a normal curve may mean a good deal in restoring his confidence and peace of mind.

To give an account of the many and various types of curve met with nowadays is quite beyond the scope of this survey. My aim has been to give the ordinary medical man some idea of how far and in what type of case the cardiogram is likely to help in diagnosis and prognosis, with some indication of how that help is obtained. The precise details have not been touched on. These are best left to the cardiologist. The pitfalls are many, and "a little learning is a dangerous thing."

The subject at the moment is changing and complex. The interpretation of the curves is a matter of expert experience. But I believe that out of the present complexity a measure of simplicity will emerge far clearer than any that has hitherto existed.

Figs. 2, 3, and 4 were redrawn by Miss Mary Waldron from East and Bain's *Recent Advances in Cardiology* and are published by kind permission of Messrs. J. & A. Churchill, Ltd.

THE ROLE OF THE MEDICAL LIBRARY

During the annual conference of the Library Association held recently in London a meeting of the Medical Section was arranged at the Wellcome Research Institution on September 20 to discuss "The Role of Libraries in the Advance of Medicine." The chair was taken by Mr. W. R. Le Fanu, librarian of the Royal College of Surgeons.

Sir Cecil Wakeley, P.R.C.S., said that the conference celebrated the centenary of the public library movement in Great Britain. But many medical libraries, of course, were much more than a century old. They varied greatly in type and function. Some were the private working-places of the staff of a particular institute, others were freely open to the whole profession, others again provided a reference service for readers living at a distance. Many attempts had been made to co-ordinate their activities. More than 40 years ago, when he first came to Oxford, Sir William Osler founded a Medical Library Association of Great Britain, but it proved to be short-lived. Twenty years later Sir D'Arcy Power promoted a measure of co-operation among the medical libraries of London. The Royal Society of Medicine had organized, with the Rockefeller Foundation, the Central Medical Bureau, to act as a clearing-house for readers' inquiries, to obtain the necessary literature from associated libraries and pass it on to all parts of the world in photographic reproduction.

The Medical Section of the Library Association, founded in 1947, acted as a link between medical librarians and provided a forum for the discussion of common problems. Under its auspices training lectures for medical librarians had been arranged, advice had been prepared for the new hospital medical libraries which were being promoted by the regional hospital boards, and a pool for the distribution of duplicate books and periodicals had been organized.

Service to readers rather than conservation of books was the keynote of library work. The opportunity had therefore been taken of inviting a number of leading representatives of various interests within the profession to give their views on the present state of medical libraries and on the most urgent needs for their improvement.

Library Services for the Research Worker

Dr. C. H. Kellaway, director-in-chief of the Wellcome Research Institution, said that, in general, medical research was a continuous process—an accumulation of facts until the time was ripe for their co-ordination and for the making of some generalization on which further research could be based. It was rare for scientific discoveries to break entirely new ground, and it was part of the library service to make sure of the connecting links. Few scientific workers could have fully at their command all that had been done in their fields in the past, and the average worker, at all events, needed the aid to his memory which was afforded by an efficient library service. But even when such service was at hand it was the duty of the worker himself to make a critical study of the relevant literature. It was quite common to find papers describing observations and results which, unknown to the writer, had been published perhaps some years before. However, there were some advantages in the repetition of earlier work, and scarcely ever was this done by a worker of ability, with new tools at his disposal, without some new angle of truth being brought to view.

Dr. Kellaway touched on the difficulty of an efficient library service when the units of an organization were scattered over a considerable area. It was easy to provide a good service if all the workers were gathered in one building, but when they were geographically scattered and it became necessary to build up a series of libraries, none of them as efficient as the central one, the difficulty of the task became obvious.

The Role of the Librarian

Dr. Hugh Clegg, Editor of the *British Medical Journal*, said that medical librarianship was now a highly skilled profession, for which an exacting training was necessary. A library that was solely a storehouse for books and periodicals had only a limited use for those ultimately responsible for the advance of medicine. The storehouse must be converted into something dynamic, and the instrument for this purpose was the trained librarian. He would have preferred the title of the discussion to be "The Role of the Librarian in the Advance of Medicine," because it was on the ability, the character, and the industry of the librarian that the usefulness of a library depended.

The earliest libraries were in temples, and the first librarians probably priests. Later the monasteries became storehouses of learning—collecting, preserving, and cataloguing volumes. The modern library had "stemmed" from the temple and the monastery, and the idea of a jealously guarded collection had persisted into modern times. The 13th edition of the *Encyclopaedia Britannica* (1926) stated that "libraries are now coming to be regarded more and more as workshops." Just when medical libraries began to be converted from storehouses to workshops he did not know. He suspected that the most potent cause of this change had been the need of the research worker for an efficient collaborator in the library, thus compelling advances in library technique and the emergence of a new type of librarian who was something more than a mere cataloguer. One of the functions of the librarian was to teach the research worker how to make the fullest use of the resources of the medical library. The librarian must have a

wide knowledge of medical literature and a sound judgment of the trustworthiness of sources. Dr. Clegg here mentioned the danger of the overloaded bibliography. He had at one time supposed that the author of a paper had at least dipped into the authorities whose references he cited; but there were cases in which the author had done little more than ask the librarian to compile the list for him. The librarian should have the courage to say to the author, "Is your bibliography necessary?"

As a medical editor he had a strong feeling of kinship with the medical librarian. Neither of them was a research worker, but they did try to keep the party clean. A distinguished journalist had said to him that an editor had one most important duty, that of saying "No." His responsibility for exclusion was as great as, or greater than, for inclusion. The librarian, too, must be prepared to say that he would not have a certain book or periodical in his library. The selection of periodicals was a very onerous task, especially now that textbooks were out of date as soon as they were published and the periodical had become more and more important. The librarian was increasingly making his voice heard in all matters of documentation, and without efficient documentation no scientific advance was possible.

The Library User

Mr. ZACHARY COPE spoke as a library user who had received the most ungrudging help from medical librarians. Libraries could diffuse medical knowledge more quickly than any other means yet devised. Where such diffusion of knowledge was lacking, the result was marked and grievous. He had recently had the duty of reviewing some German textbooks on surgery, and had been surprised at the lack of knowledge concerning some things which were common property in this country—the use of penicillin, for example. Many German libraries had been destroyed during the war and free communication had been interrupted, and although much was now being done to remedy these evils the effect on the literature was still woefully apparent.

Unquestionably the part of the library which was most valuable to the research worker was that concerned with current periodicals. There were 1,500 or more medical journals, and it was impossible for any library to carry more than a small proportion. It saddened him sometimes to find young men depending on the librarian to look up their references for them. To look up one's own references was a valuable means of education.

Professor E. C. DODDS spoke of the library of the Royal College of Physicians, some part of which dated from before the Great Fire, and which had had an uninterrupted existence since 1670. In that library were to be found works on every subject, not only on medicine, but on astrology, theology, and Oriental philosophy. The library was now being carefully surveyed by the college authorities. It was felt that there was no point in making it a modern library; nevertheless, this extraordinary collection of books would be of very great value to research.

Mr. W. A. LEE spoke as the librarian of an old provincial library founded by a few physicians and surgeons in Liverpool about 170 years ago. In these changing days it was difficult to foresee what might happen to these old-established libraries, founded privately and depending for their income on the subscriptions of members. The question was how they could continue to play their part now that new libraries were being set up in teaching and other hospitals by the regional hospital boards. There should be some method whereby these collections made many years ago could be kept up to date and be useful for succeeding generations.

Medicine in the Public Library

Mr. GEOFFREY STEPHENS, librarian of the borough of St. Marylebone, described an important scheme whereby each of the 28 London boroughs had accepted responsibility for specializing in their libraries in one particular branch of literature. St. Marylebone, probably because it included Harley Street and about twice as many hospitals as any other borough, as well as central pharmacies and orthopaedic establishments, had been asked to specialize in medicine. He had been reluctant to undertake this, foreseeing the morbid curiosity of some lay readers. But the nucleus of a medical section had been created in the public library. Two years' experience had shown that the demand was chiefly for preclinical literature and some standard encyclopaedias, and that the requests came mainly from hospital nurses, medical students, and those working in medical auxiliary occupations. Quite 90% of the requests were from people in these categories. Whether the policy was a good one or not, it had been better received than he in his reluctance had thought possible. He did not know of any other municipal public library which specialized in medicine.

The idea of a public library specializing in medical literature was criticized from several quarters, notably by Mr. A. J. FIELDER (Staines) and Mr. W. J. BISHOP (Wellcome Historical Medical Library). It was pointed out that it would be absurd to expect library committees, unless there were medical people on them, to build up a useful section. The expense attending it would be very great, and it was well known that, in any economy "push," public libraries were the Cinderella of local authorities. Stock of this kind which a public library could carry must necessarily be inadequate for any serious purpose. Mr. STEPHENS explained that the Association of Metropolitan Chief Librarians had drawn up a scheme whereby £200 a year would be spent on each of these specialized sections, but this was not sufficient in the case of medicine; he was spending very nearly £300, and if that was not enough he would ask for more. He added that the medical books were not exposed on the public shelves.

The Microfilm Service

Mr. G. R. EDWARDS (secretary, Royal Society of Medicine) said that the establishment of libraries in hospitals, teaching or otherwise, was an excellent idea: the facilities provided all over the country were woefully inadequate. For papers appearing in less easily available sources the microfilm documentation service which the Royal Society of Medicine had sponsored might be recommended. A small non-profit-making fee was charged, and the service extended from Reykjavik to Singapore. Hardly any day of the week passed without a filmstrip being dispatched from London conveying information to medical people in distant parts of the world—information which was unobtainable in their local libraries. Mr. Edwards applauded what had been said about the necessity for special training for medical librarians. Speed in obtaining the desired information was often of great importance.

In conclusion the CHAIRMAN said that all the problems attending this subject, including the possible joining of forces of the libraries of the smaller medical societies and the regionalization of hospital libraries, were receiving the careful consideration of the Section.

CHARING CROSS HOSPITAL MEDICAL SCHOOL

The inaugural address of the winter session at Charing Cross Hospital was delivered on October 5 by Dr. Gordon M. Holmes, consulting physician to the hospital, and Mrs. Holmes presented the prizes and certificates. In the absence of Lord Inman, owing to influenza, the chair was taken by Sir John Stewart-Wallace. The new dean, Dr. E. C. Warner, gave an account of the school year.

Dr. Gordon Holmes's brief address was directed chiefly to those who had not yet been through the "mill," though he hoped seniors might profit from some of the lessons which he himself had not learnt until his later years. Students at Charing Cross were fortunate in having joined one of the smaller schools of the University of London. It was true that Charing Cross was looking forward to a larger hospital, but there were many advantages attaching to the small school.

Clinical Observation

He reminded his audience how relatively little even now was known of the phenomena presented in disease. The student might find by his careful examination of a case symptoms or signs not mentioned in the textbook; but this demanded hard work and a discipline of observation not easily acquired.

He recalled that when he was house-physician to Hughlings Jackson the latter was accustomed to give him notes with a request that he elaborate them a little more. Afterwards he would be told that he had failed to observe one detail or another—a lesson for any of them who thought they had learned all about a case after an examination lasting ten minutes or half an hour. Dr. Holmes also spoke with great appreciation of the prolonged examination which another of his teachers, Henry Head, always made of a case—sometimes more like 20 hours than 20 minutes. Casual observation assisted little. He knew how students to-day were burdened with the prospect of examinations, but he thought that if they took pains to familiarize themselves thoroughly with one definite example of a disease in a particular class they would find less difficulty in understanding the other members of that class. He did not undervalue accessory aids to diagnosis, such as radiological and biochemical methods, but for the student at least these should be supplementary to the clinical study. What was afforded by these methods could only fill in and complete the knowledge already gained at the bedside. The rule in his time was that no *x*-ray or other report should be presented until the case had been fully investigated by clinical methods. Clinical studies were not only essential for the efficient practice of medicine, but, approached in the proper spirit, they afforded an intellectual and human satisfaction and pleasure unrivalled by any other method. He wished the students happiness throughout their career, content in their work, and pleasant fellowship.

A vote of thanks to Dr. Gordon Holmes was proposed by Dr. L. R. Broster and seconded by Professor Jocelyn Patterson.

WESTMINSTER MEDICAL SCHOOL

The inaugural address at Westminster Medical School was given on October 2 by Sir Cecil Wakeley, P.R.C.S., who also presented the scholarships and prizes.

Sir Cecil Wakeley declared that surgery, as present students knew it, might perhaps be deemed a new profession when compared with the profession of medicine. After briefly sketching the history of surgery from mediaeval times, he said that three factors formerly held back its progress: a lack of knowledge of anatomy (for many years any effort to obtain bodies for dissection was frowned upon by the Church), the incidence of sepsis, and the lack of adequate anaesthesia. With the rise of surgery there had been associated a more detailed study of anatomy, physiology, and pathology. The last 30 years had seen the advent of the sulphonamides and antibiotics, great developments in radiology and biochemistry, and a rapid improvement in methods of anaesthesia such that operations which could not have been carried out 20 years ago were now performed as everyday procedures. As a result of these advances, many more old people were undergoing operations and surviving without becoming a burden to the community.

In earlier days the student was apprenticed to a surgeon, and there was a great deal to be said for that form of instruction. It was to be hoped that when the new Medical Act came into force, making a year of postgraduate experience compulsory prior to registration, the qualified student would be able to get some clinical experience with a general practitioner. There was too great a tendency to overlook clinical observation and to rely on radiological, pathological, and biochemical checks in making a diagnosis. He doubted whether for that reason the clinician to-day had the clinical acumen of the great Victorian physicians, who, without such aids, were amazingly accurate. Not that he was decrying these ancillary helps in all branches of medicine and surgery, but surely they should be used to confirm the diagnosis, not to make it.

Whole-time professorial units tended to become too academic and to lose touch with patients. It was part-time professors of surgery, who were also in consulting practice, from whom advances had come. He mentioned Lister, Macewen, Stiles, and Watson Cheyne as examples. Specialization in surgery was good up to a point, but surgeons on the staffs of teaching hospitals should remain general surgeons.

There had always been a relationship between war and surgery. Many of the famous surgeons of former times were military surgeons before they became well known in civil life. The lessons of war were of great value in civil practice. During war surgical knowledge was pooled and made available to vast numbers of surgeons. The value of blood transfusion, the use of penicillin, and early evacuation by air were lessons of the last war not easily to be forgotten. Every branch of surgery made advances during wartime. Perhaps the greatest advance had been in the treatment of nerve injuries and in the surgery of the heart and great blood vessels.

What should the surgeon disclose to the patient? Instruction in the early stages of cancer might be justifiable and important, but it would be a tragedy if they were to be responsible for creating a national cancer-phobia. When the mystery went out of surgery the patient often lost a great deal, and much of his co-operative confidence disappeared. A description of his impending operation might be stimulating to one patient and make a nervous wreck of another. Confidence was the sheet anchor.

Sir Cecil Wakeley ended his address with a tribute to the part which Westminster surgeons had played in the advance of surgery.

Sir Stanford Cade proposed a vote of thanks to the orator, and Mr. Lawrence Abel seconded.

A SECRET REMEDY FOR CANCER

We publish below correspondence which has passed between the Minister of Health and Mr. Rees Evans about the latter's treatment for cancer (see *Journal*, September 16, p. 662). The Minister's proposal is the subject of comment elsewhere (p. 875).

Dear Mr. Rees Evans,

I am writing to confirm the proposal which I placed before you at our meeting to-day.

I consider it essential that your claims to have discovered a treatment for cancer should be fully and fairly investigated. I am therefore asking the following gentlemen to act as an independent committee to consider your claims and to advise whether they warrant further investigation and, if so, the way in which any investigation should proceed. The committee would be:

Sir Robert Robinson, O.M., F.R.S., President of the Royal Society.

Sir Alexander Fleming, F.R.S., M.B., F.R.C.S., F.R.C.P., the discoverer of penicillin.

Sir Ernest Rock Carling, M.B., B.S., F.R.C.S., F.R.C.P., chairman of the Standing Advisory Committee on Cancer and Radiotherapy.

Professor Himsworth, M.D., F.R.C.P., secretary of the Medical Research Council.

I hope that you will be able to accept this offer but, in putting it forward, I must ask that you on your part will agree to abide by any decision which they may reach and, furthermore, that you will be prepared to submit to the committee, should they require it, full details of your materials and methods and will no longer insist that these can be disclosed only during the actual treatment of patients.

Yours sincerely,

September 28, 1950. ANEURIN BEVAN.

Dear Mr. Bevan,

I should like to thank you most sincerely for your letter.

I feel that this important new step towards a full investigation can only have come about as the result of your own personal interest in the matter and your wish to investigate any treatment for which a good case can be made out.

I could not ask for a committee of greater distinction than the one you have chosen, and I have, on my side, only two points which I wish to make.

The first is that I am perfectly willing to submit to the committee the fullest records I can of past cases and whatever they may ask concerning my materials and methods. My own personal feeling, however, is that my work can never be fully and finally tested unless actual treatment of patients forms part of the investigation.

The second point is that I am a simple man with no scientific background. I must ask that in putting my case before these learned men I may be allowed the constant help of Mr. Derek Wragge Morley, who knows more about my treatment and ways of working than anybody else, and who in addition has the capacity for explaining the details of my work in a way which I am unable to do.

I take it, of course, that the committee's full report will be made available to me when it is finally completed.

Yours sincerely,

September 29, 1950. D. REES EVANS.

Nova et Vetera

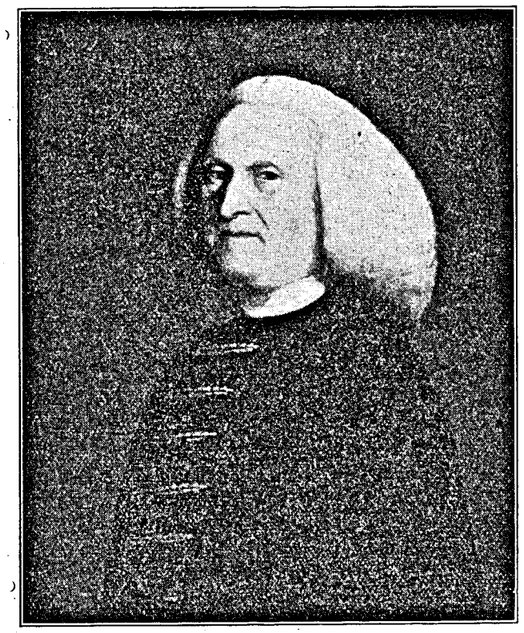

Fig. 1.—Portrait of William Hunter, painted by Sir Joshua Reynolds in 1782.

A NEW PORTRAIT OF WILLIAM HUNTER

When Dr. William Hunter, elder brother of the immortal John Hunter, died in 1783 it was found that his famous museum and library which had previously been offered to and refused by the English Government had been bequeathed, on the advice of Samuel Johnson, to Glasgow University. The university showed its gratitude for the munificent bequest by commissioning Sir Joshua Reynolds to paint the portrait of the donor which now adorns the Hunterian Museum. No other portrait of William Hunter by Sir Joshua was known to exist until a picture, which for over a hundred years had been in the possession of the family of Mr. John Liston Dalrymple, recently came to light and was acquired by the Hunterian Society (see Fig. 1).

Fig. 2.—Part of Zoffany's picture "The Life Class," showing Sir Joshua Reynolds and Dr. William Hunter in the centre.

In the past there have been many surgeons in the Dalrymple family. The daughter of Robert Liston, F.R.S. (1794–1847), married into it. There was John Dalrymple, F.R.S. (1804–52), the ophthalmic surgeon and author of *Diseases of the Eye*; and Archibald Dalrymple (1810–63) and his father William Dalrymple (1772–1847) were both well-known surgeons. It is not therefore surprising that in such a surgical environment a portrait of William Hunter should be found, and that the details of its early history should be faithfully recorded on the canvas back by some careful owner in the distant past.

Fig. 3.—William Hunter, after the portrait by M. Chamberlin (1769).

We learn thus that the portrait was painted by Sir Joshua Reynolds in 1782, a year before Hunter's death, and that it was sold after the artist's decease in 1793 with his collection of pictures. We cannot unfortunately trace it through the sale-room, as the descriptions in the catalogues are insufficient to identify it, but the style of the painting gives every indication that the date stated is correct. In 1782 Reynolds returned to England from his tour in Holland and Flanders. From the time of this visit a change took place in his painting: it acquired a new refinement, and a more direct approach derived from the influence of Rubens and the Dutch school was at once seen to replace the grand classical tradition of Italian baroque which hitherto the artist had followed. The portrait of William Hunter clearly belongs to the period of these new loyalties. There is nothing academic about this unassuming and natural portrait, shrewdly observed and sympathetically portrayed. It may perhaps represent an act of friendship on Reynolds's part rather than an official commission, a view that receives support from the fact that it remained in the studio until after the artist's death. William Hunter, as might be expected from his love of the fine arts, numbered many artists in his circle of friends. Foremost among these was Reynolds, with whom he was closely associated throughout his life.

William Hunter was the professor of anatomy and Reynolds the president of the Royal Academy from its foundation in 1768; and when George III commissioned Johann Zoffany (his favourite painter) in the same year to paint for him his Royal Academicians in full session the artist replied with the spirited "Life Class" (Fig. 2), in which William Hunter and Reynolds are placed side by side in a conspicuous position in the centre of the group. There are many other portraits of William Hunter, but the best likeness is said by Simmons, his contemporary biographer, to be a small oval print (Fig. 3) from M. Chamberlin's portrait (1769), which is now in the Diploma Gallery of the Royal Academy. The resemblance in physiognomy between this print and the newly discovered Reynolds portrait is particularly striking.

Fig. 2 is reproduced by gracious permission of His Majesty the King; Fig. 3 by permission of the Royal Academy of Art.

C. Robert Rudolf, L.D.S. R.C.S.
Honorary Librarian of the Hunterian Society.

Correspondence

Royal Medical Benevolent Fund

Sir,—Again I appeal to members of the medical profession, whether subscribers to the Royal Medical Benevolent Fund or not, to send a donation for Christmas gifts for beneficiaries of the Fund, all of whom are facing a time of special difficulty owing to the present high cost of living. Last year it was decided to send each beneficiary a gift of £10, but the donations to the Christmas Gifts Fund were not enough to meet the cost, and half of this sorely needed help had to be taken from general funds. This cannot be done this year owing to the present heavy calls on the Fund.

I hope that there will be a generous response to this special appeal for Christmas gifts, which are not only desirable but necessary and most deeply appreciated. Let us warm the hearts of the beneficiaries of the Fund by showing them that they are not forgotten by their more fortunate colleagues. Donations and subscriptions, marked "Christmas Gifts," should be sent to the secretary of the Royal Medical Benevolent Fund, 1, Balliol House, Manor Fields, Putney, London, S.W.15, and will be gratefully acknowledged.—I am, etc.,

Webb-Johnson,
President, Royal Medical Benevolent Fund.

London, S.W.15.

Distinction Denied

Sir,—The Ministry of Health Memorandum, B.G. 48 (2) of June, 1948, permits a practitioner to enter into an engagement (with a hospital board of governors) "on an honorary basis provided there is a clear undertaking to perform defined services." It is not widely known that a substantial number of consultants have chosen to take advantage of this provision and have accepted unpaid contracts with the Ministry of Health which allow them to continue to serve their hospitals without payment as they did before the "appointed day."

Many of these consultants have now been selected as suitable recipients for distinction awards and find that they are unable to accept them because a Ministry instruction lays down that no unpaid member of a hospital staff may receive a distinction award unless he holds a paid professorial appointment. In plain words, consultants who have been selected on their professional merits to receive distinction awards are disqualified because they are not in receipt of a salary from public funds.

Consultants who have chosen to forgo their rights to a salary have no legitimate claim to a further *douceur* which is officially described as an item of remuneration, but distinction awards mean rather more than money. In spite of the desire expressed by the Ministry that the names of recipients of distinction awards will be kept secret (apparently in order that the public may not be deluded into thinking that the receipt of such an award implies professional distinction), lists of recipients lie at this moment on the table at every hospital office and cannot fail to be public property in a very short time. In these circumstances few consultants will wish to relinquish the status implied by the distinction award, though many may find the monetary award distasteful.

Surely there should be provision for allowing those on whom a distinction award has been conferred to retain the status which is implied, even though they are debarred from accepting its cash value because they hold an honorary contract with the Ministry.

I am sorry that I must ask you to publish this letter without my name. There are too many issues now which divide the staffs of hospitals, and no one wishes to add to them by bringing to the fore the question of paid or unpaid. Those of us who have chosen to refuse payment have done so for reasons which appear good to us, but we are quite aware that they may not be valid for others. We have given up a good deal, but we should like to retain the right at least to remain on the road to distinction.—I am, etc.,

X.

Distinction Awards

Sir,—Having read Mr. R. L. Newell's letter (September 30, p. 783), I feel that it can safely be left to others to decide whether, as Mr. Newell suggests, I have clouded the issue. The main point raised by my last letter was not whether Lord Moran is right in going around the country addressing meetings of non-teaching consultants, but whether he is right in setting up subcommittees in the way he has done. In that I have been a member of the North-west Metropolitan Regional Consultants Committee since its formation I am, of course, fully aware of the nature of the discussions which have gone on in both the Central and the Regional Consultants Committees. My letter was therefore written with full knowledge of the facts.

I am somewhat surprised by Mr. Newell's letter, because, on December 9, 1948, in Minute 81 of the Central Consultants Committee, of which Mr. Newell was chairman, it was proposed "that in each region there should be established by the National Committee (i.e., the Distinction Awards Committee—my insertion) . . . a committee of distinguished medical practitioners of consultant status who are not interested personally in merit awards (i.e., practitioners already in receipt of the highest award or who are retired from practice) under the chairmanship of a layman to be chosen in agreement with the nominating bodies, and the Central Consultants and Specialists Committee." Although the point about a lay chairman was subsequently dropped (in November, 1949) the original minute has not, so far as I am aware, been rescinded, and I would like to ask Mr. Newell whether the formation of the *ad hoc* committees I have so strongly criticized is not completely contrary to the intentions of his own committee. I cannot, therefore, agree with Mr. Newell when he says "the present method has been accepted by the consultants."

Lord Moran is, of course, an accomplished and highly practised speaker, and it would be surprising if he had not given a lucid account at the meetings attended by Mr. Newell, more particularly as these followed more than a score of similar meetings elsewhere in the country. To pay homage to Lord Moran's eloquence is one thing, but to be mesmerized into accepting an irregular and unsatisfactory procedure is quite another matter.—I am, etc.,

R. S. Murley.

Radlett, Herts.

Women in Medicine

Sir,—Your leading article "Women in Medicine" (*Journal*, October 7, p. 822) contains several statements which may be misconstrued and which call for comment. In 1947 all the medical schools of the University of London became co-educational. Considerable latitude was allowed to the individual medical schools in their interpretation of what was meant by co-education, but a maximum percentage of 15% women was held to be a "reasonable" proportion in several of the schools. There were probably excellent reasons for this cautious start, but there is obviously no particular virtue in a proportion of 15% nor yet in the 20% recommended by the Goodenough Committee. The advantages of co-education are best achieved by parity, with neither sex in an undue minority.

The Royal Free Hospital School of Medicine accepted the principle of co-education, but laid down no maximum or minimum percentage of one sex or another. The founders of our school strove for equality of opportunity and the defeat of prejudice in days when the opportunities for women in medicine were practically non-existent. It was felt that their aims would best be achieved by accepting co-education wholeheartedly and by continuing to select students on ability only, regardless of sex. There were indeed some understandable misgivings expressed by the authorities of the school. Though other medical schools in London had for many years admitted a proportion of women students, in general the postgraduate opportunities offered to them had not been sufficiently good to allow them to obtain consultant appointments in their own training hospitals. The Royal Free Hospital was unique for many years in its appointment of women to its honorary staff, thus enabling them to show that, when opportunity arose, they were able to achieve the highest ranks of the profession. In

spite of these misgivings it was, however, decided that the full policy of co-education with all its implications should be adopted. For several good reasons the change has been a gradual one, but the following figures will show that the Royal Free is fulfilling its promises.

In 1948–9 the ratio of men to women was, as you state, 1:93.
In 1949–50 the ratio of men to women was 1:27.
In 1950–1 the ratio of men to women is 1:16.
In the last year, 1950–1, the actual ratio for entry was 1:6.

We may seem to hasten slowly, but the doors are opening, and the provision of equal opportunities, postgraduate as well as undergraduate, will in all likelihood be found to be in the best interests of the whole profession.—I am, etc.,

KATHARINE LLOYD-WILLIAMS,
Dean.

Royal Free Hospital,
London, W.C.1.

Protection of Laboratory Animals

SIR,—On September 23 you did me the honour of publishing (p. 724) comments by a special correspondent on my draft of a model Act for the above purpose. May I now reply to these? The draft is admittedly tentative and intended as a basis for discussion. The idea is to embody in it as much as possible of the wisdom that has been gained during seventy-five years of relevant experience in this country, and eventually to offer an improved version to overseas humanitarians. Hitherto the latter have depended mainly on the anti-vivisectionists for inspiration.

A number of holders of Home Office licences have been good enough to provide constructive criticisms of my draft, and various amendments appear to be needed. For instance, it was a mistake to try to cover experimentation and manufacture in a single Act. Again, the discretionary power to include specified invertebrates (I had chiefly the higher molluscs in mind) is too far in advance of current opinion to be retainable.

However, your special correspondent feels that the draft is so bad as not even to be "capable of amendment or revision." He would strangle it at birth. That is unfortunate, because it is based on and developed from existing British practice, less the unnecessary red tape. For instance, your correspondent pours withering scorn on my definition of the kind of experiment to which the Act would relate, but in fact the essential part of my definition is taken verbatim from the definition used at the Home Office for the guidance of inspectors. I got the wording some years ago from an authoritative source and published it on page 7 of the *UFAW Handbook* without encountering any objections. I have now proposed extending it so as to include such things as the experimental induction of neuroses, but the added words are capable of amendment or even of omission if analysis should show that they have impracticable implications.

Your special correspondent makes two other specific criticisms as examples of what he objects to. My draft suggests that if the Minister interprets "anaesthesia" as including electric anaesthesia he should specify the requisite conditions. It must be remarked, first, that electric curarization—that is to say, mere paralysis by electric stimulation—may bear a close but misleading clinical resemblance to anaesthesia; secondly, that tests used for chemical anaesthesia are not necessarily valid for electrical anaesthesia; thirdly, that a good deal of important knowledge has been gained by experimental work on this subject; and, fourthly, that further experimental work is now in hand. Your correspondent alleges as an objection to my proposal that the Minister would have to set up an advisory body to carry out the requisite experiments. It is not clear to me why the Minister should have to duplicate the work which has been or is being done, nor why it should be absurd for him to set up an advisory body if he wants to, nor why he ought to permit persons who may be unacquainted with the special risks and difficulties of electrical techniques to make a reckless use of them without knowing whether the supposed anaesthesia is genuine or spurious.

Your correspondent's other specific objection is as follows. My draft suggests in effect (though in wording that is possibly capable of amendment or revision) that experimenters' licences should be granted by a board of control whose members would between them have scientific, veterinary, and humanitarian qualifications. Your correspondent infers that persons ignorant of science might be appointed to the board, but this could happen only if no available scientists had shown themselves to be humanitarians, or, alternatively, if the Ministry which appointed the board was incompetent. Neither of these assumptions is reasonable.

Your correspondent's more general objections are a little intangible, but they seem to boil down to two. He thinks that my draft is so rigid that it could not be adapted to future changes in knowledge and opinion. What I have done is to list the points on which the Minister must make a decision, while allowing him power to revise his decisions from time to time. I cannot think of any other device for combining flexibility with effectiveness in legislation. If my critic can think of a better one I would be glad to know of it.

His second general objection, so far as I can understand it, amounts to this, that the proposed Act could be administered in such a bureaucratic way that "animal experiments would for all practical purposes be brought to an end." Of course it could; but then under the existing British statute the Home Secretary could bring pathological research to an end by cancelling all certificates A. He could bring research in endocrinology to an end by cancelling all certificates B. He could bring all experimentation on animals to an end by cancelling all licences. He could turn the lives of research workers into nightmares of litigation by granting permission, under Section 21 of the statute, for anti-vivisectionists to prosecute anybody who does any animal experiment at all. But since no Home Secretary has hitherto done any of these things—not even Mr. J. R. Clynes, who was himself an anti-vivisectionist—I am entitled to assume that an Act such as the one I propose would be administered with some approach to a semblance of common sense.

The problem of striking a balance between the claims of science and those of laboratory animals is an excessively difficult one, and perfectly decent people disagree on where the line should be drawn. The only means for reaching an ideally just conclusion is free and frank discussion among humane scientists, and it was for the purpose of eliciting such discussion that my draft was issued. There has been a most helpful response, sometimes commendatory and sometimes critical, from a number of humane vivisectors, but unfortunately some persons who are specially qualified to help have shrunk into their shells as bashfully as bachelors in a leap year or periwinkles in a storm.—I am, etc.,

C. W. HUME.

London, N.3.

SIR,—I believe there is a greater concern in the profession than is generally realized about animal experiments. I remember the master of a famous hospital describing at a public lecture an experiment which, to use his own words, was "revolting and served no useful purpose." But doctors do not care to discuss this subject for fear of being called anti-vivisectionists. I believe that anti-vivisectionists have done their cause much harm by their unscientific and emotional approach. I am not an anti-vivisectionist, but like some of my colleagues I am not satisfied that laboratory animals obtain the humane care which public opinion expects. The large majority of doctors never see the inside of a laboratory after qualification: the ordinary layman never.

I welcome Major C. W. Hume's attempt to draw up a draft for a model Act for the protection of laboratory animals (see *Journal*, September 23, p. 724). I am sure he will welcome criticism, but it is not true to say the draft is incapable of amendment or revision, as your special correspondent suggests. Moreover, I believe I am correct in saying that the definition of experiment to which he objects embodies the one at present in use by the Home Office.

I agree most emphatically with Major Hume that it is of the greatest importance to set up a board of control to advise the Minister. The composition of such a board must necessarily include physiologists, but I submit, Sir, should equally include laymen. For otherwise how can the guiding principle, "To relate the maximum amount of pain which it is permissible to inflict on animals for the acquisition of knowledge, to that which public opinion tolerates in other pursuits," be observed?

Finally, I would ask all those interested in animal welfare whether they are happy about the facilities for laboratory inspection, and whether they have never met a physiologist whom they thought would be better employed outside a laboratory.—I am, etc.,

H. ROBINSON.

London, W.2.

Bact. coli and Infantile Gastro-enteritis

SIR,—The letter from Dr. C. Giles (*Journal*, September 2, p. 577) tends to emphasize the role of *Bact. coli* in infantile gastro-enteritis, and at the same time the existing muddle in the classification of *Bact. coli* organisms. At the risk of perhaps increasing the muddle for some, and yet, I trust, of clarifying it for others, may I call attention to a classification put forward by me in 1943 of such organisms as I consider play an important role in this and like conditions (see my *Synoptical Table of Aerobic Excretal Bacteria*[1])? As a matter of passing interest the term "beta" is therein used over and over again to define serological types of *Bact. coli* belonging to differing biochemical subgroups.

That a multiplicity of phage-susceptible coliform organisms appears to be concerned in the gastro-enteritis of infants is borne out by the records of Dr. Bathia Kanievsky, who in an unpublished investigation into the use of tablets of dried phage carried out in 1943 at a child-welfare clinic in Alexandria recorded a curative response in six out of seven cases treated. Her cases ranged in age from 4 months to 2 years. The phage-preparation employed was made at the expense of 80 coliform organisms of my C_1 to C_8 subgroups (see the aforementioned table), 45 dysentery group organisms, 39 salmonella group organisms, 24 meta-dysentery group organisms, and 18 giumaiform group organisms, all phage-susceptible, which had been isolated by me from intestinal upsets ranging from simple diarrhoea to full-blown bacillary dysentery at all ages in the Alexandria area. Dr. Kanievsky's failure case, which was unaffected by sulphaguanidine, responded ultimately to "enterovioform." But as no laboratory work was done on the case it is just possible the infection may have been of a lamblial rather than of a bacterial origin, which, if so, would account for the seeming phage-therapy failure.

With the writer of your annotation (*Journal*, July 22, p. 205) I am afraid I cannot agree, that the close association between infantile diarrhoea and *Bact. coli* was first recognized in this country. If he will consult my writings of 1941–4[2] he will find abundant evidence that in Egypt we were fully aware of such connexion, and took steps to deal with it, as concerns both adults and infants.

Your annotator finishes by challenging the belief that certain *Bact. coli* cause infantile diarrhoea, and states that this "at present rests only on epidemiological evidence." The assumed epidemiological causes operating, and the specific treatment effects realized, in our work with Dr. Kanievsky constitute to my mind quite definite additional evidence of a cause and effect connexion here.—I am, etc.,

ARTHUR COMPTON.

London, W.2.

Cigarettes and Cancer

SIR,—I would like to be allowed to comment briefly on the able and instructive paper by Dr. R. Doll and Professor A. Bradford Hill in your issue of September 30, page 739. The spectacular sudden increase in carcinoma of the lung began about the end of the first decade of the present century. During the greater part of last century, and at least the earlier years of this one, men in debilitating climates chain-smoked strong cheroots, yet carcinoma of the lung was a rarity. During the first five years of this century there was no sign of any increase in that condition, yet I should think that arsenical sprays were by then in use. Apart from this, industrial diseases associated with working with arsenic have never included carcinoma of the lung. The new increase in the disease has not spared non-smokers and children and those who live in countries where non-urban roads are not tarred and where there is no factory contamination of the air. In these circumstances surely none of these factors can be the cause of the suddenly increased incidence. Whether they are capable of aggravating it is doubtless another question.—I am, etc.,

H. GALL,
Colonel, late R.A.M.C.

Stanmore, Middlesex.

SIR,—The article in the *Journal* (September 30, p. 739) shows that pipe smoking is less closely related to cancer of the lung than cigarette smoking. This suggests an interesting possibility—i.e., that it is the saltpetre or other substance used to make the tobacco more easily inflammable that is the carcinogen.

It is well known that manufactured cigarettes contain more of this substance than pipe-smoking tobaccos. If the "roll your own" cigarette smokers were subjected to the very interesting analysis that has been carried out under the headings of cigarette and pipe smokers, the result might well put them in the pipe-smoking liability class. Should saltpetre be definitely incriminated it would be easy to make smoking less lethal. Of course the pipe smoker does not smoke burnt paper.—I am, etc.,

ERIC J. TRIMMER.

Essex.

SIR,—In your leading article (September 30, p. 767) you state, quite correctly, that those who smoke 40 cigarettes a day are occupied with smoking for about 46 hours a week. I should like to point out, however, that the average number of inhalations per standard size cigarette is about 13, each inhalation of approximately eight seconds' duration. The person who smokes 40 cigarettes a day therefore spends most of his smoking time simply burning tobacco. His lungs will be full of smoke for about 69 minutes per day, 104 seconds per cigarette, or just over eight hours per week.—I am, etc.,

A. D. COLLEDGE.

Midlothian.

SIR,—In "A Counterblast to Tobacco" James I seems to have reached much the same conclusion as Dr. Doll and Professor Bradford Hill (*Journal*, September 30, p. 739), although admittedly on less scientific and laborious lines. "A custom loathsome to the eye, hateful to the nose, harmful to the brain, *dangerous to the lungs*, and in the black, stinking fume thereof nearest resembling the horrible Stygian smoke of the pit that is bottomless."—I am, etc.,

A. PINEY.

London, W.1.

Safety in Prams

SIR,—Following the recent letter of Dr. David Thomas (*British Medical Journal*, July 22, p. 219) a good deal of publicity has been given to the subject of accidents to children through prams tipping, but I have yet to read a really authoritative and instructive statement on the matter by anyone competent to make one. I claim to know something of this subject, having dealt with this problem many times during a period of over a quarter of a century in the retail pram trade, and I propose therefore to supply the facts of the case, which I think the public are entitled to know and which the trade will do well to study.

First let me say that in spite of all this publicity the actual number of accidents is extremely small and mothers need not fear that in buying any reputable make of pram they will be taking any undue risk. My recommendation on this point is—go to a firm of repute and on the advice given select a make of repute. No pram by any reputable maker will tip unless misused, which usually happens in one of the following ways:

(*a*) Tipping forwards through overloading at the handle end by excess weight in shopping receptacles.

(*b*) Tipping forwards through the wrong use of a single pram for two children.

(*c*) Tipping backwards through wrong use of the safety-strap.

(*a*) Requires no special explanation, as the remedy is obvious—do not carry excess shopping if it can be helped, and if it must be carried put some of it in the well and as far back in it as space will allow.

(*b*) Results from indiscriminate use for two children of a lightly balanced single pram constructed for one child only. This fault is largely encouraged by the unrestricted sale of "toddlers' seats" which are made to accommodate a second child. The unfortunate mother takes home one of these seats and fits it on her pram, which is probably quite unsuitable for such an accessory, and in spite of the claims of the makers that these seats "fit any pram" she finds that her pram is now very top-heavy. Having bought the thing, however, she tries to make do with it and in an unwary moment she lets go of the handle and down goes the pram. It is asking for trouble to buy these seats from any but firms willing to fit them and competent to "vet" the pram beforehand as to its suitability. Most prams are unsuitable without alteration. In any case, I strongly recommend that when two children are in one single pram, however accommodated, the elder child should be taken out if the pram is to be left unattended, even for a few moments, unless special modifications to the pram have been carried out to make it safe for its double load.

(*c*) Is the result of a bad trade practice, coupled with the ignorance of the average mother of the proper use of the safety-harness.

Many pram manufacturers have for very many years persisted in supplying with each pram a practically useless "safety-belt." This is usually put in merely to satisfy the public demand for completeness of specification. It is almost invariably fitted in a position much too near the hood end of the pram, which not only renders it unusable but potentially dangerous. The correct position is from 9 in. to 11 in. from the interior back of the pram according to its size. This should bring the strap fastening to a position from which a vertical line will come within the wheelbase. This safety belt has two side-pieces which are attached to the pram, and these vary from 4 in. to 7 in. in length and are fitted with a plated loop of metal to take the belt. When the average mother finds this belt is useless she discards it and buys a complete safety-harness. Unfortunately the latter is usually supplied merely as a piece of merchandise with no instructions whatever, and it is left to the mother to fit it in the pram as best she can. She invariably does this by strapping the two side straps of the new harness to the existing wrongly placed side-pieces of the original belt. She has now unwittingly fallen into the trap which the indifferent (or ignorant) manufacturer has set for her. The infant, instead of having a few inches of "play" and being restricted to a proper sitting position, has nearly a foot of play each side and without much strain can turn round and lean right over the folded hood. This is highly dangerous, as the pram is not balanced to take the infant's weight so far back, and it may easily tip over backwards. The results of this may be far more serious than in tipping forwards, as there is no handle to stop it, and the child can easily hit the ground.

The remedy for this danger is first for the makers of prams to cease fitting useless belts at all or at least to put them, or any fittings supplied in lieu, in the right place. Secondly, the mother buying a safety-strap should go to a pram specialist and either insist on it being properly fitted or receiving instructions on how to do the job at home. Thirdly, all retailers of prams should know the correct position and method of fitting the safety-strap and see that customers are not left in ignorance on this point. Under no circumstances should the new safety-harness be fitted to the two side-pieces of the original belt. These should be entirely removed. Makers of safety-straps could help by boxing them with full instructions on each box or otherwise attaching a tag to each strap with a warning on wrong use, and makers of second seats would be well advised to take a similar course.

Retailers handling safety-straps and second-seat fitments and treating them merely as merchandise are very much to blame for the ignorance of the public on these matters, and many of them should never be in the business at all, it being a highly specialized one requiring years of experience.

If these remedies for pram accidents can be publicized and the information given here circulated in clinics and all places where mothers meet I feel sure that pram tipping will rapidly become a thing of the past.—I am, etc.,

Croydon. D. L. Davies,
Chairman,
National Association of Pram Retailers, Ltd.

Medicine by Radio

Sir,—"Older people with shingles should always stay in bed for a while" (or words to that effect), says the doctor on the radio at 8.15 on a Friday morning. And so one has to scuttle off to the elderly osteoarthritic, whom on the previous day one had urged to get up despite his shingles, lest his stiff joints should become even stiffer. One has to explain—and sense his disbelief as one explains—that perhaps the doctor on the radio was not thinking about older people with osteo-arthritis *and* shingles when he issued his dictum.

I do not know how the rest of the profession feels, but I am getting a little tired of these anonymous medical voices which come booming across the breakfast table from nowhere on a Friday morning, as if with the direct authority from the highest source. A snappy five minutes on tuberculosis, or two and a half minutes on the diagnosis and treatment of infantile paralysis, and that will leave the rest of the time free to deal with schizophrenia. Enough damage has been done in the past by books of the home doctor type. I am not sure that the mischief resulting from these informal little chats is not even greater.—I am, etc.,

Perranporth, Cornwall. Douglas Robb.

Medical Items in the Popular Press

Sir,—Readers of the popular press are regularly treated to sensational news items based on gleanings from the *Journal* or one of its contemporaries, often before the publication reaches its medical subscribers. In view of the wide range of subjects covered in this way, we must wonder why the usual publicity has not so far been given to the conclusions of Dr. R. Doll and Professor A. Bradford Hill on "Smoking and Carcinoma of the Lung" (September 30, p. 739)—a topic of much more general interest than the design of perambulators, the dangers of staying in bed, or many others recently in the headlines. Do newspaper editors fear that their public may resent being disillusioned about the "harmlessness" of the tobacco habit, or are they a little unwilling to risk the displeasure of some of their major advertisers?—I am, etc.,

London, S.W.16. D. J. Parr.

Early Rising for Puerperal Women

Sir,—I was interested in Dr. D. Wheatley's reply in the *Journal* of May 13 (p. 1142) to an earlier letter by Dr. A. B. Swarbreck (April 22, p. 936). During the years 1935-42 I had charge of a fairly extensive hospital and domiciliary practice in New Guinea where one of my prime concerns was obstetrics in native women. The universal custom among New Guinea women is to treat labour as an incident in the day's work. They have a rest and sleep after labour and then proceed with their ordinary work. I was brought up to believe, as Dr. Wheatley does, that this would lead to uterine prolapse, but, to my great surprise at first, out of many thousands of women examined I can recall seeing only one case of prolapse, and that in an elderly woman who had obviously had a nearly complete perineal laceration. Seeing that no apparently harmful effects followed early rising I did not forbid it in my native patients and later extended the practice to my European patients. In the case of the latter, psychological and sociological factors among others make post-puerperal rest desirable, but for some 14 years I have encouraged early rising, and have yet to see anything but good result from it. I have recently delivered the third child of one patient all of whose puerperia have been so conducted; in this case as in others there is no suggestion of prolapse.

My practice in normal deliveries is to get the patient out of bed about 12 hours after labour and encourage her to walk about 25 yards, then immediately return to bed. This is repeated twice daily, lengthening the distance each time. From the fourth day onwards a shower is allowed, sitting out of bed from the sixth day, and home to light duties on the tenth. In an experience of many hundreds of confinements treated thus I have yet to see either femoral thrombosis or uterine prolapse, though it is admittedly early to form definite conclusions about the latter. The feeling of well-being and relief from stiffness, and the absence of depression and tiredness on returning to work at home, have been commented on by many mothers who have had previous experience of the orthodox method of rest. Is it not time that rigid post-puerperal rest along with several other obstetric shibboleths be reconsidered in our teaching schools?—I am, etc.,

Victoria, Australia. B. D. Vaughan.

A Foreign Body in the Rectum

Sir,—I was most interested to read in your correspondence (September 16, p. 680) the letter by Mr. J. B. Prendiville, particularly as in the same week I was myself confronted with a similar case. Within the last nine months I have had to deal with two cases of tumbler in the rectum; apart from the age these cases are otherwise similar.

The first one was a married man aged 58 who gave a history of having slipped in the bathroom, "accidentally" sitting on a tumbler and causing the latter to become lodged in the rectum. Removal in this case was easily accomplished without assistance, using the orthodox technique of filling the glass with plaster-of-Paris in which a piece of wood was embedded to provide a hold.

The second case was a married man of 70 years of age with exactly the same history; he had exactly the same type of tumbler in the rectum; but he admitted having had a tumbler in his rectum on a previous occasion, which he had been able to remove himself. The patient was thoughtful enough to produce an identical tumbler for our inspection. The photograph shows the tumbler removed, with a portion of the rim broken off, and a second tumbler for detail.

This second case presented more difficulty on account of the broken rim, which rendered the rectum liable to laceration when the tumbler was pulled upon as it lay *in situ* in its inverted position; plaster-of-Paris failed to fill the gap and the technique employed in the first case failed. A laparotomy through a lower paramedian incision was performed and, with the assistance of a hand in the rectum, version of the tumbler was performed within the rectum and the tumbler delivered base first. No damage was caused to the rectum and the abdomen was closed without colostomy, a rectal tube being inserted for forty-eight hours. Convalescence was uneventful.

I am indebted to Mr. J. Jemson, consulting surgeon, for his help in extracting the foreign body in the second case.—I am, etc.,

London, S.E.13. E. Moragas.

Rectal Thiopentone in Children

Sir,—Dr. Gordon M. Wyant (August 5, p. 368) is worried because Dr. J. Lorber (July 1, p. 21) does not stress the potential hazards of rectal thiopentone in children. The dosage the author recommends—1 g. per 50 lb. (22.5 kg.) body weight—was, I think, first suggested by Weinstein (Weinstein, M. L., *Curr. Res. Anesth.*, 1939, **18**, 221), and I have used it myself as a premedication for children very satisfactorily for 10 years and have never met the "considerable respiratory depression" that Dr. Wyant says may ensue. My experience has been that the children are so lightly asleep that any undue stimulus in transport from the bed to the operating table may wake them up. I believe that theoretically the rectal route is less likely to cause laryngospasm than the intravenous, because the hypnotic concentration in the blood stream is reached much more gradually—and many anaesthetists believe that laryngospasm is more likely to attend rapid induction. As practical evidence of this I offer Dr. Wyant my 10 years' experience without a single case of laryngospasm.

From this distance in space and time I am prepared to accept Dr. Lorber's own diagnosis of "severe spasm of coughing and temporary cyanosis," but even if it had been a mild attack of laryngospasm, as Dr. Wyant prefers to believe, was it so very surprising that it fortunately resolved spontaneously? I am sure that an attempt to relieve a mild attack of laryngospasm with the aid of a laryngoscope and endotracheal tubes would only aggravate the condition—to say nothing of the danger of trauma to teeth, pharynx, and larynx from attempted laryngoscopy with inadequate relaxation of the jaw.

I have no means of knowing the dosage of atropine usually employed by Dr. Wyant, but to judge from most American publications it is the custom in that country to use much smaller doses in children than usually employed in England, and it may be that the threat of laryngospasm is more real in his experience for that reason. Dr. Lorber's case which aspirated vomitus (explained in his article as due to a nursing error in feeding the child immediately before rectal hypnosis) certainly does not bear out the suggestion that there is any increased tendency to laryngospasm with rectal thiopentone. There was not in this case even enough glottic reflex to prevent aspiration.

In parts of Europe it is held that the risk involved in any anaesthetic is too high a price to pay for tonsillectomy, and therefore the routine there is to remove children's tonsils and adenoids without any anaesthetic at all—a procedure given the approval of nursing staff who have not time to spare to nurse unconscious patients. To such lengths can the desire to avoid all risks take normally humane people.—I am, etc.,

Johannesburg, S. Africa. F. W. Roberts.

Haematemesis from Leeches

Sir,—I had an experience similar to Dr. A. Cameron's (September 16, p. 679) when E.N.T. specialist at a stationary hospital at Kantara in 1917.

A private was admitted, and his brief notes were: "R.M.O.: bleeding from naso-pharynx; Field Ambulance: blood clot in naso-pharynx; C.C.S.: blood clot in naso-pharynx."

At that time my facilities for examining patients were still primitive in that I had to use the sun as my source of illumination. I had to be careful not to get the part examined at the focal point of the mirror and cause burning pain. This, however, did happen occasionally, and in this particular patient the "blood clot" wriggled. It was an enormously engorged leech, which I removed with some difficulty.

I learned later from an elderly missionary stationed for many years at Beersheba (or Hebron) that removal was easy if one first touched the region with a little weak cocaine solution.

I agree with Rokitansky's aphorism as quoted by Dr. Cameron, but suggest to him that he need not go so far back as Rhazes. He should investigate Hahnemann and his work, when he will find that he has not grasped the principle of the law of similars, and that, though the results from the application of the law are often surprising, they are not "magic" in the sense in which he uses the word.—I am, etc.,

London, W.1. A. T. Cunningham.

Histamine Desensitization

Sir,—The appearance of a new drug urges us always to revise old treatments. This must be done in a careful manner, not to discard helpful therapeutic aids for the sake of fashionable new drugs. The present status of the treatment of allergic diseases with antihistamine drugs challenges criticism of non-specific desensitization with increasing doses of histamine. Clinical and experimental literature on this matter was reviewed by Feinberg (1946). Since this time new indications have been described for this treatment (e.g., Atkinson, 1946; Paul, 1949).

Fabinyi and Szebehelyi (1949) recommended histamine desensitization and protecting the patient with antihistamines during the treatment. The following advantages may be expected from histamine desensitization over the use of antihistamines: permanent cure, or at least longer lasting effect; no side-effects peculiar to antihistamine drugs; effectiveness in conditions where antihistamines have no

effect. Besides certain diseases where the pathological role of histamine is questionable, antihistamines do not reduce histamine-induced gastric secretion (review: Loew, 1947) and do not prevent blood changes caused by histamine (Winter and Musnet, 1948).

On the other hand, histamine desensitization shows the following disadvantages as compared with antihistamines: it takes a long time to develop resistance to histamine—some authors even question whether this is possible in humans (Feinberg, 1946); side-effects of the treatment.

In recent studies we analysed experimentally the effects of histamine desensitization (Ambrus *et al.*, 1950). Gastric-secretion-inducing effect of histamine was decreased in guinea-pigs desensitized with very high doses of histamine over a long period. Spontaneous occurrence of gastric ulcers following pylorus ligation according to the method of Shay *et al.* (1945) was not significantly decreased in histamine-desensitized animals.

In further (hitherto unpublished) experiments we determined the duration of histamine desensitization in guinea-pigs. To test histamine resistance the animals were exposed in a glass chamber to a fine spray of 10% histamine solution, and the time in which symptoms of asthma developed was recorded. Protection by desensitization was maximal after the last application of histamine. It remained on this level for 24 hours, then started to decrease and disappeared completely within a few days. Protection by 2 mg./kg. "neoantergan" lasted for 2-4 hours and by "phenergan" for 9-12 hours. On the basis of these experimental data there is no reason to prefer histamine desensitization to antihistamine drugs, although the effect of the former may last somewhat longer, but there is no permanent desensitization even toward the effects of histamine itself. On the other hand, it takes a long and difficult treatment to reach resistance. The use of histamine desensitization in the therapy of gastric ulcers must be studied further.

—We are, etc.,

Situs Inversus and Perforated Appendix

SIR,—The only reason for publishing the following case is its rarity. A search of the literature available revealed no similar case.

A schoolboy aged 17 was admitted into hospital with a three-day history of abdominal pains, generalized at first but later localized to the left iliac fossa. They were not severe and passed off with rest in bed. On the third morning of his illness the patient felt quite well and went to school, but the pain restarted two hours later and he cycled back home, a distance of about five miles. He vomited twice in the evening and his bowels opened once. During the night he felt feverish.

On admission there was tenderness over the lower abdomen, but more marked on the left side. Abdominal reflexes were sluggish in three quadrants and absent in the left inferior quadrant. The temperature was 103° F. (39.4° C.) and pulse 140. An enema resulted in the passage of some flatus only, but not faeces. The bases of both lungs were auscultated and found to be clear, but the front of the chest was not examined. The patient had never before been ill, and therefore never seen by a doctor.

If the pain had been on the right side, a diagnosis of acute appendicitis would have been made without hesitation. An inflammatory condition on the left side would have suggested diverticulitis of the sigmoid colon, but in view of the age of the patient this possibility was also ruled out. The possibility of it being a case of malaria was considered because the patient spent a night in a malarious district about one week before. An injection of quinine was consequently given and hot-water bottles were applied to the abdomen.

Next morning the patient felt slightly better, the temperature fell to 98° F. (36.7° C.) and the pulse to 100, but during the day the temperature and the pulse started to rise again. As there was no improvement in the physical signs it was decided to do an exploratory laparotomy. Under spinal analgesia a low median incision was made. On opening the peritoneal cavity some seropurulent fluid was found in the pelvic cavity. The right iliac fossa was searched, but no caecum or appendix was found. A loop of the large intestine when traced downwards was found to end in the rectum. Perforation of a left-sided appendix was immediately thought of, and therefore search was made in the left iliac fossa. There an inflamed appendix was found covered with some fibrin, but completely free without any omentum in the neighbourhood. There was a neat perforation situated about 1 in. (2.54 cm.) from the tip of the organ. The appendix was removed, the stump buried with a purse-string suture, and the pelvic cavity drained. The patient was given 100,000 units of penicillin immediately and then 50,000 three-hourly. He also received 1 g. of soluble sulphamezathine every six hours for one week, during which time the temperature was about 1° F. above normal. After one week the drain was removed. Convalescence was otherwise uneventful, and the patient was discharged twenty days after the operation.

An *x*-ray examination was made before his discharge and it was found that all his organs were normal, but his heart, liver, stomach, and duodenum were completely transposed. The lesson to be learned from the above case is that in any obscure condition a thorough examination of the patient is necessary; had the front of the chest been also examined, the heart would have been found on the right side and immediately the possibility of a left-sided appendix would have been thought of.

My thanks are due to the Director of Medical Services for permission to publish the above case.

—I am, etc.,

Mauritius. M. SHUN SHIN.

Dexedrine Poisoning

SIR,—To add to the previously recorded cases (see for instance *British Medical Journal*, 1949, 2, 1394) of acute "dexedrine" poisoning, the report of a case in a boy aged 2 years may be of interest.

The child was said to have swallowed five 5-mg. tablets from his mother's handbag. He was given a saline emetic ten minutes later, but with no effect. He appeared well 30 minutes later and was given his breakfast. One hour later he became flushed and jumpy. He repeatedly picked up and dropped objects, and then ran to his parents, calling to them as if frightened. A few minutes later twitching movements of his arms were noticed. On admission three hours after taking the tablets he was delirious and threw himself violently around the bed, and, if restrained, repeatedly tossed his head from side to side.

Examination showed his pupils were dilated and only just responded to light; his tendon reflexes were not elicited; his plantar responses were flexor; and his temperature and pulse were slightly raised. Lumbar puncture showed a clear colourless fluid with a pressure of 190 mm. of water, and the cells and chemistry were normal.

His stomach contents were aspirated and consisted of semi-digested food. He was given 2 dr. (7 ml.) of paraldehyde (through a Ryle's tub passed nasally), and this was repeated four hours later. Subsequently, five doses of 1 dr. were given as the degree of narcosis decreased and the state of excitement recurred, but eventually he fell asleep and finally awoke 46 hours after admission, when he appeared tired but otherwise well.

Christchurch, Hants. S. T. LANGHAM.

Pernicious Anaemia and Gastric Carcinoma

SIR,—The article on gastric carcinoma and pernicious anaemia by Drs. J. Mosbech and A. Videbaek, like your editorial on the subject, appearing in the *British Medical Journal* for August 12, pp. 390 and 405, appears to me to fail to take into account one simple and obvious explanation of the fact that gastric carcinoma appears to be commoner among victims of pernicious anaemia than it should be: namely, that pernicious anaemia may be due in some instances to carcinoma of the stomach. To put it differently, not all cases of pernicious anaemia are truly cases of pernicious anaemia; some are cases of carcinoma of the stomach masquerading as instances of pernicious anaemia. If we could separate the "true" or idiopathic or agnotogenic cases of pernicious anaemia at the outset, we might find that they were no more subject to gastric carcinoma than the average person—or perchance even less so.

—I am, etc.,

Honolulu. HARRY L. ARNOLD, JUN.

Delayed Post-natal Separation of the Cord

SIR,—I thought that possibly the following case of delayed separation of the umbilical cord might be of sufficient interest to record. The mother, aged 30, is an exceptionally healthy young woman. Her pregnancy was normal throughout, and I delivered her—a simple low forceps—on July 27, 1950.

The baby, a male, weighed 7 lb. 12 oz. (3.5 kg.) at birth, and appeared healthy in every way. In particular, the cord presented a perfectly normal appearance, neither unduly thick nor thin. The child developed an hordeolum on his left lower eyelid on the sixth day. This cleared up in a few days with saline bathing and ung. hydrarg. nit. dil., but a gland in the left anterior triangle of the neck began to enlarge and subsequently an abscess formed, which I incised on the 21st day.

The cord meanwhile had remained dry throughout, but showed no signs of separating. The home conditions were excellent, and I had a most experienced resident nurse in charge. On the 27th day the cord began to separate, accompanied by a little bleeding. The final separation occurred on the 33rd day, the cord then presenting the appearance normally seen about the 6th or 7th day. The stump gave no trouble; one application of silver nitrate was made as a precautionary measure.

The baby remained healthy all through, and fed and slept well. His temperature never rose above 98.4° F. (37° C.) even while the cervical abscess was developing. He was breast-fed throughout, apart from a supplementary feed of 2 oz. of full-cream dried milk, after the 10 p.m. feed, from the 9th day. He lost 6 oz. in weight the first week, but had regained his birth weight (7 lb. 12 oz.) by the 14th day. From then on he gained steadily, and weighed 9 lb. (4 kg.) on the 31st day (two days before the separation of the cord).

I began to feel a bit perturbed when no signs of separation had shown themselves in a fortnight, and this was intensified at the end of three weeks, especially as none of the colleagues I consulted—either specialist or G.P.—had ever encountered anything comparable. The infant's general condition, however, remained so good that I decided that no active interference was called for, and I should not worry if similar conditions arose in a subsequent case.

The circumstances appear to be distinctly unusual, and it would be interesting to know what is the longest period recorded for separation of the cord.—I am, etc.,

Clitheroe, Lancs. E. R. B. MURRAY.

Gastric Ulcer after Vagotomy

SIR,—The excellent article from the pen of Mr. D. M. Morrissey (September 16, p. 651) is timely in that it calls attention to what may prove quite an important side-effect of vagotomy. Ulceration occurring in a vagotomized stomach may be entirely painless, and therein lies the menace. Not only may haemorrhage supervene, but presumably, what is worse, a developing carcinoma may be even more silent than usual. Further to the cases quoted by Mr. Morrissey, the following have come under our observation:

(1) In our own series of seventeen vagotomies, two cases had developed gastric ulcer nine months and two years after operation, respectively. The first one was in the pyloric antrum and the other high up on the lesser curve.

(2) A third case presented in out-patients recently, having had a gastro-enterostomy for a duodenal ulcer in 1928, followed by transhiatal vagotomy in 1947. This patient has now developed a gastric ulcer high on the lesser curve. He was symptom-free for two years following the vagotomy, but his indigestion returned one year ago.

(3) In Toronto last year Dr. E. B. Tovee told one of us that of 50 vagotomies done at the Toronto General Hospital three had developed gastric ulcer within a year of operation. All had an insulin-fast achlorhydria.

(*a*) Male aged 52. Large duodenal ulcer at operation; developed a gastric ulcer high up on the lesser curve, only diagnosed on barium meal.

(*b*) Male aged 21. Barium meal at one year showed a gastric ulcer on the mid-zone of lesser curve, symptom free.

(*c*) Male aged 25. Barium meal at one year showed gastric ulcer of the mid-zone infiltrating the pancreas.

In assessing these cases the normal coincidence of gastric and duodenal ulcers must, of course, be borne in mind. Drossner and Miller (*Amer. J. med. Sci.*, 1940, **199**, 90) stated that in 15% of patients with a gastric ulcer a second duodenal ulcer or duodenal cap deformity will be found. Furthermore 5% of patients with an active duodenal ulcer also have an active gastric ulcer. These figures will have to be carefully considered in an attempt to assess whether the gastric ulcer is indeed a sequela of vagotomy. It is to be hoped that the large-scale follow-up of vagotomy cases now proceeding in this country and the U.S.A. will include routine barium meals and gastroscopies in order to exclude the presence of a silent gastric ulcer.

Is it possible that the change from the hypertonic steerhorn stomach of the frank duodenal ulcer to the more atonic J-shaped stomach following vagotomy is a factor in the development of ulceration on the lesser curve?—We are, etc.,

Bristol. W. M. CAPPER.
T. J. BUTLER.

The Dangers of Mixing Domestic Cleansers

SIR,—I received an urgent call to a woman who was said to have been "gassed." On arrival I found the patient, a middle-aged woman with a tendency to asthma, in a very distressed state. She was dyspnoeic and a little cyanosed, complaining of sternal pain and an aggravating cough. Her story was this. Her usual method of cleaning the lavatory bowl was by sprinkling it with "harpic." This time she sprinkled the harpic on first, and followed it with half a bottle of "brobat." A cloud of yellow fumes arose, which nearly overcame her before she could get into the fresh air. Test-tube experiment shows harpic + brobat → chlorine gas. This reaction is not to the prejudice of either of these preparations, as they clearly are not intended for the same purpose, but a wider knowledge of the danger is perhaps desirable.—I am, etc.,

Canterbury. E. BELLAMY.

The Sprue Syndrome—A Plea for Help

SIR,—In collaboration with Dr. J. R. Fountain I published in the *Journal* (1950, 7, 1157) an aetiological study of some 2,000 cases of the sprue syndrome (tropical sprue, idiopathic steatorrhoea, and coeliac disease) who received priority rations during the period 1943–8. We produced evidence to suggest that the syndrome might be conditioned by a genetic factor which may be accentuated and brought to light by a variety of environmental agents. The rarity of the syndrome (one case of idiopathic steatorrhoea per 700,000 of a population over 15 years of age, and one case of coeliac disease per 135,000 of the population below 15 years of age) makes it unlikely that any individual will see sufficient cases to throw additional light on the aetiological importance of the genetic factor. I am therefore appealing to medical men in all parts of the world to help in this investigation by forwarding to me any information which they may possess in regard to the occurrence of two or more cases of the sprue syndrome in a single family. I would also be grateful for any information which would help to answer the question, What happens to children with coeliac disease? What percentage die, recover, or appear in adult life as cases of idiopathic steatorrhoea? Any help will be gratefully received.

—I am, etc.,

Department of Medicine, University of Edinburgh. L. S. P. DAVIDSON.

POINTS FROM LETTERS

The True Source of Colchicine

Dr. GEOFFREY E. LOXTON (London, W.1) writes: The writer of the interesting leading article entitled "Colchicine in the Chemotherapy of Cancer" (*Journal*, September 23, p. 718) is mistaken. Colchicine is not extracted from the autumn crocus (*Crocus sativus*) but from *Colchicum autumnale*, the sole official source. . . . Although the flowers of the two bear a superficial resemblance they are pharmacologically and botanically distinct. *Crocus sativus*, although of great historical interest as the source of saffron, is pharmacologically inert. With the related *Crocus vernus*, it belongs to the natural order Iridaceae, the flower having three stamens; *Colchicum autumnale* belongs to the natural order Liliaceae, its flowers having six stamens. Each bulb carries two to six delicate lilac crocus-like flowers in the autumn. The seed pods winter underground and appear in spring, making meadows poisonous to cattle. . . . *Crocus sativus* was extensively cultivated at Saffron Walden, in Essex, in Edward III's reign, and extensively used in cookery until the nineteenth century, the old crocus farmers being known as "crokers," and the name in literature is often used to signify a grumbler. The use of colchicine was introduced into regular practice in this country by Stoerck in 1763.

Obituary

Sir ERNEST GRAHAM-LITTLE, M.D., F.R.C.P.

A long career of distinguished service to his university and his profession is ended with the death, which took place suddenly at his Epsom home on October 6, of Sir Ernest Graham-Little in his eighty-fourth year. He shared his life fairly evenly between medicine, education, politics, and his family.

Ernest Gordon Graham-Little (he took the name Graham as an additional surname in 1931, the year of his knighthood) was born in 1867. His father, Mr. Michael Little, J.P., was in the Indian Civil Service; his mother came from Capetown. He was educated at South African College, Cape University, where he took his B.A. and a gold medal, and then came to London to study medicine at Guy's and St. George's, completing his medical training in Dublin and Paris. He graduated M.B. (London) with honours in 1893, and proceeded M.D. in the following year. In 1895 he became a Member of the Royal College of Physicians, and a Fellow of the College in 1906. In 1902 he succeeded Sir Malcolm Morris as physician in charge of the skin department at St. Mary's and lecturer in dermatology to the medical school, and he remained there until his retirement in 1934, resuming charge of the department in 1940–1 when the hospital staff was depleted by war. In addition to his large private consulting practice in Wimpole Street, he was consulting physician to the East London Hospital for Children, Shadwell—the appointment he most enjoyed—and consulting dermatologist to several charitable and professional organizations. Throughout his dermatological career he maintained a great interest in pathology, and he was the first to describe, in 1901, what was later termed the Waterhouse–Friderichsen's syndrome. During the first world war he was consulting dermatologist to a number of military hospitals. Graham-Little's eminence in his specialty was quickly recognized, and students found him a model teacher. He was one of the early presidents of the Dermatological Section of the Royal Society of Medicine, a corresponding member of the American Dermatological Association, and honorary or corresponding member of similar societies in half a dozen European countries. In 1935 he was elected honorary president of the International Dermatological Congress. He made many contributions to dermatological literature and was editor of the section on skin diseases in the *Medical Annual*.

In his later career his dermatological work was overshadowed by his preoccupation with university and, later still, Parliamentary affairs. His desire was to see every clever boy and girl given the chance of university education. He represented the medical graduates of London University in the Senate from 1906 until the present year. An ardent protagonist in various controversies concerning medical education, he was foremost in resisting an attempt to fasten upon the university an official co-operation in its final M.B., B.S. examinations with the Conjoint Board, a proposal which, in his view, if carried out would have lowered the standard and reputation of the London University degrees in medicine. Some may have judged him a diehard; he was certainly a strong individualist, with a pronounced dislike of Socialism in medicine as in other spheres, attested by his opposition to the National Health Service, which he thought inimical to medical freedom. But in many respects he was progressive. Largely owing to his insistence, increased provision was made for the clinical education of women in London by the recognition of the West London Hospital as an institution for the admission of women as external students of the university. This action helped to undo a serious injustice to women students, who, having completed their preclinical education in London, had found it impossible to take their clinical studies there.

His services to the university make a long catalogue. He was chairman of the Council for External Students and president of the University Graduates Association from 1922. In 1924 he was returned as Member of Parliament for the university after a memorable contest, in which he had against him representatives of the three principal parties of the day. The late Sir John Rose Bradford was the runner-up, and Graham-Little beat him by 400 votes. At the next election his majority was nearly 3,000, and on two subsequent occasions it passed 5,000, but in 1945 he came within a very few votes of being beaten by Dr. Mary Stocks, principal of Westfield College. He sat as an Independent or, during his last ten years in Parliament, as a Nationalist. He devoted himself assiduously to his Parliamentary duties, especially after his retirement from his hospital appointment in 1934. His voice was often heard resisting any insidious proposal for giving countenance to unqualified practice. He fought strenuously for granting to doctors the same privilege of professional secrecy in courts of law as was enjoyed by the legal profession. He opposed the compulsory clauses of a Bill dealing with the notification and treatment of venereal disease, and he was able to influence Government policy with regard to the more scientific use of radium. He employed his medical knowledge effectively in committee work on various measures which had a medical bearing, notably the recent Criminal Justice Act. He was chairman of the Medical Parliamentary Committee in 1943. On his retirement from the Senate of London University last May a resolution was passed placing on record the Senate's high appreciation of his services as one of its members for 44 years and as Member of Parliament for 26 years.

Sir Ernest Graham-Little was frequently in the thick of controversy, in which he did not spare his opponents; but, like many other doughty fighters, when he took off his armour he was the gentlest of men, as those can testify who accompanied him on his walking tours or met him over the chessboard or among the Knights of the Round Table. Among his other interests were his membership of the British Science Guild, the Commons and Footpaths Preservation Society, the Society of Individualists, and the League for European Freedom. He was a prolific writer of letters to the Press, but he also contributed weighty articles on medical education, hospital policy, and like subjects to the monthly and quarterly reviews. Though not a member of the B.M.A. all his professional life—he was first elected a member in 1895, but he twice resigned and was twice re-elected—he served on the Association's Parliamentary Elections Committee and on the Central Medical War Committee. He was a representative at the Annual Meeting on a number of occasions, and chairman of the Marylebone Division in 1935–6. As far back as 1908, at the Annual Meeting at Sheffield, he was president of the Section of Dermatology.

Sir Ernest was keenly interested in the liberal arts, and his house was full of many treasures: unfortunately it was completely destroyed by air attack in the last war. Of all his treasures none were so dear to him as the portraits and busts he had of his wife and children. Throughout his career Lady Graham-Little was a constant counsellor and fought by the side of her husband in all his elections. They shared bravely together the loss by drowning of their only daughter in 1932 and the death on active service in 1942 of their only son.

Dr. C. CHARLES BURLINGAME, psychiatrist-in-chief of the Institute of Living, Hartford, Conn, U.S.A., died in Leicester on July 22. He represented the American Psychiatric Association at the annual meeting of the Royal Medico-Psychological Association, and developed the acute symptoms of his illness when in this country. He was born in Rockford, Illinois, in 1885, and he graduated in medicine from the Illinois Medical College in Chicago in 1908. His early training in psychiatry was obtained in state hospitals in Massachusetts and Minnesota. Subsequently he accepted an appointment as the first full-time psychiatrist in industry, and this interest in the application of psychiatric principles to industry he retained throughout a very active career. In 1921 he was appointed executive officer of the Columbia University–Presbyterian Hospital Medical Centre, and he received credit for much of the success of that colossal structure and organization. Later he returned to private practice in New York, and it was in 1931 that he was appointed psychiatrist-in-chief of the Institute of Living. Under his guidance the activities of the institute expanded in all directions. While he offered facilities for the practice there of all recognized forms of therapy, he was dissatisfied with the adequacy of the Freudian theories to deal with the problems of abnormal behaviour and was not in sympathy with psychoanalytic methods. He was firmly of the belief that aftercare should be extended on the basis of re-education and reconstruction, and he developed an elaborate programme of educational therapy. Research facilities were lavish, and he was a stimulating chief. Research in psychiatry was encouraged in this country by his generous gifts to the Royal Medico-Psychological Association for the Burlingame Prize. At the time of his death he was president, director, and chairman of the board of managers of the institute. Burlingame was editor of the *Digest of Neurology and Psychiatry* and associate editor of the *American Journal of Psychiatry*. Not only did he edit the *Digest* but he distributed this gratis each month to 19,000 professional people and libraries in many countries. Its reception was always eagerly awaited, and it remains a monument to his organizing skill and ability. A man of unbounded energy, with a flair for the dramatic, he was a fluent speaker and always in great demand. He was a regular visitor at the annual meetings of the Royal Medico-Psychological Association, and was made an honorary member of the association the day before his illness developed. He was similarly honoured by other international psychiatric bodies and was the recipient of a number of decorations from foreign Governments. Of these he greatly prized that of Officer of the French Legion of Honour, to which he had been elevated in 1947. He married Ruth Beardsley Parsons in 1912, to whom the sympathy of his many friends in this country is extended.

Dr. ARCHIBALD MACLEAN died suddenly while on holiday on August 3 at the age of 43. He had been in practice in Hamilton since 1934. After graduating M.B., Ch.B.(Glasgow) in 1930, he held resident appointments at the Victoria Infirmary. For two years he worked as an assistant in a practice at Old Cumnock, Ayrshire, and in 1934 he moved to Hamilton as a partner to Dr. Stewart. He became senior partner in the practice in 1945, holding the appointments of factory surgeon, Treasury medical officer, and medical officer to the post office for the Hamilton district. He had a large practice and was exceptionally popular with his colleagues, patients, and friends because of his constant cheerfulness, though he had known for some time of the possibility of a sudden catastrophe. An elder of his church and a good friend to many, he will be sadly missed. He is survived by his widow and two young daughters.—N. D.

Dr. CHARLES JAMES PALMER, J.P., for many years a well-known medical practitioner in Mansfield Woodhouse, Notts, died in Nottingham on September 2. He was born in Ireland in 1871, and studied medicine at Liverpool and Birmingham, qualifying L.S.A. in 1895. After holding posts at the Royal Orthopaedic and Spinal Hospital, Birmingham, and the Doncaster Royal Infirmary, he began general practice in Mansfield Woodhouse in 1896, and he remained there until his retirement in 1947. He was honorary surgeon at the Mansfield General Hospital until 1920, when he resigned as a result of the strain of the very heavy duties he took on during the first world war. Dr. Palmer was an active member of the British Medical Association from 1896, and when the Association met in Nottingham in 1926 he was vice-president of the Section of Medical Sociology. He was a member of the Insurance Acts Committee, 1919–29, and also of its Executive Subcommittee and its General Purposes Committee. Taking a great interest in the affairs of colliery surgeons in Nottinghamshire, he was instrumental in forming the Notts Collieries Medical Service Association and the Mansfield Public Medical Service, being president from 1928 to 1943. In addition to these activities Dr. Palmer devoted much time to local government affairs, and was chairman of the Mansfield Woodhouse Urban District Council from 1907 to 1909. He was elected a county councillor and made a J.P. in 1910, and from 1940 to 1944 was chairman of the Mansfield Petty Sessional Division Bench, from which he retired in 1946. As a Freemason, Dr. Palmer lived up to his principles in every respect. He was immensely popular with his patients, who were impressed with his kind-heartedness and generosity. His widow and daughter will have the sympathy of the many who will feel his loss.—H. D. P.

Dr. THOMAS HANSON CROSSFIELD DERHAM, J.P., who died at Bexhill-on-Sea on September 14, was a native of Preston, Lancashire, and spent the whole of his professional life there. Born in 1874, he was educated at Preston Grammar School and Edinburgh University, graduating M.B., C.M. in 1894. His father, who was in medical practice in Preston, died while he was still a student, but Tom Derham returned to the house in which he had been born and rebuilt the practice in which he laboured so acceptably until his retirement in 1946. For many years he was a member of the visiting staff of the Preston Royal Infirmary and had charge of the physiotherapy department. He was a member of the Preston County Borough Council for 30 years, an alderman from 1926 to 1934, and mayor in 1932–3. In the first world war he served in the R.A.M.C., and was on active service from 1915 to 1918, attaining the rank of major. A lifelong supporter of Preston North End Football Club, he was for many years medical officer to the club and never missed a match. He was a borough magistrate for many years, and was also associated with the St. John Ambulance Brigade and with the Preston Nursing Association. Derham was a member of the Preston Insurance Committee for over 33 years and chairman in 1923–4. For many years a member of the B.M.A., he was chairman of the Preston Division from 1939 to 1944, chairman of the Preston panel committee from 1938 to 1944, and of the Preston local medical war committee from 1939 to 1946. He represented the Preston Division at the Annual Representative Meeting in Aberdeen in 1939. Compact and solid in his build, he looked a model of calm dependability, and this is just what he was, with a saving sense of humour added. He earned the gratitude and affection of his patients and townsmen and the respect and love of his colleagues. During the latter years of the war he became increasingly crippled with rheumatoid arthritis, but he continued to work until his son, who succeeded him, returned from Service. He is survived by his widow, three daughters, and one son. One son was killed in Italy during the last war.—F. M. R.

Dr. ALFRED WILLIAM MOORE, at one time Deputy Director-General of the Ministry of Pensions, died at his home at St. Albans on September 20. He was born in Norwich in 1881, and received his medical training at Emmanuel College, Cambridge, and St. George's Hospital, qualifying in 1905 and graduating M.B., B.Chir. a year later. After holding house appointments, he settled down to general practice in a partnership at Stony Stratford, Bucks. Very soon afterwards the Territorial Army was formed and Moore's senior partner, Dr. Bull, raised a cavalry field ambulance with its headquarters at Stony Stratford. In this Moore took a commission. At the outbreak of war in 1914 he was second in command, and became C.O. the next year, after the evacuation of Gallipoli, where his field ambulance served dismounted with its brigade—the Bucks, Berks, and Dorset Yeomanry. From 1916 to 1918 Moore continued to command his unit in Siniai, Palestine, and Syria in a series of campaigns which are likely to remain historic as the last in which cavalry played a decisive part. It was then that he displayed that talent for organization, the balanced judgment, and the combination of personal charm with sweet reasonableness which were to mark his subsequent career. He was mentioned in dispatches three times, and was awarded the O.B.E., the Territorial Decoration, and the Order of the Nile. After the war he joined the medical staff of the Ministry of Pensions and became a permanent Civil Servant, reaching before retirement in 1946 the position of Deputy Director-General of Medical Services. He was a member of the Central Medical War Committee from 1938 to 1944. Moore was an English gentleman of a type now becoming uncommon. His father was a canon of Norwich Cathedral, but came of an old Norfolk family of yeoman farmers, and his son retained throughout life the tastes and outlook of the countryman. A fine shot and a good oar—he was in the Cambridge trial eights of 1900—he spent nearly all his holidays on the Norfolk Broads sailing his beloved boats. He was a man of quite exceptional charm, and both his manners and his personal appearance had a rare distinction. None who were privileged to observe it will forget the warm happiness of his family life with his wife and five children. To them the sympathy of many friends will go out. —H. F. H.

We record with regret the death of Sir GEORGE ROBERTS, Bt., who was Almoner of St. Thomas's Hospital from 1926 to 1943. He was born in 1859. In 1919 he became a member of the council of the King Edward's Hospital Fund for London. Roberts made a gift of £105.000 to the Fund as a thank-offering for the recovery of King George V from his serious illness in 1929. He was created a baronet in the following year.

B. M. writes: Some there are who so identify themselves with the institution they serve that their passing leaves among colleagues a deep void. Such a man was NORMAN STUART CARRUTHERS. Success came rapidly in his specialty, for his commanding presence radiated confidence, and his surgery was marked by a craftsman's skill. Kindness and generosity were his outstanding qualities, and particularly were these shown to children, of whom he had deep understanding. Confident in his own strong will, he expressed his opinion decisively, leaving those from whom he differed under no misapprehension as to his own views. His judgment and foresight were such as to lead inevitably to involvement in hospital administration and appointment to many committees. His chief interest, however, was in the nursing committee, of which he was chairman and where his death will be most keenly felt. In addition to his professional work Carruthers had many other interests. He was skilled in carpentry and mechanics and later became interested in farming. Life was not too kind to him. Of his two sons, one died in infancy from diphtheria—in his memory was given the Jock Carruthers medal for the outstanding student nurse of her year at the Norfolk and Norwich Hospital. His other boy twelve months after qualification was accidentally killed while serving in the Army in India. To his son's widow and two young children the remainder of his days were devoted. To them, his widow, and other members of his family the sympathy of all his many and grateful friends is extended.

Universities and Colleges

UNIVERSITY OF ABERDEEN

At a graduation ceremony held on September 27 the following medical degrees were conferred:

M.D.—[1]I. A. Anderson, [1]A. D. Macrae, [1]A. Mair, I. C. Cowan, L. G. Tulloch.

M.B., CH.B.—[1 2]C. U. Webster, [1]Rosamond Beattie, [2]Elizabeth A. F. Priest, [2]J. G. Stewart, [2]D. M. McLellan, Elizabeth P. N. Bell, A. M. Blackwell, I. M. Brooker, W. R. Bruce, W. R. Buchan, J. N. Burry, D. D. Carmichael, J. P. Chadwick, S. C. Clifford, A. M. Cook, G. J. Cordice, G. G. Duncan, A. L. S. Duthie, A. T. Edwards, Jean McG. Edwards, A. L. Florence, N. G. Fraser, D. T. Gordon, Dorothy Gray (*née* Armstrong), [4]K. T. Gruer, R. T. S. Henderson, A. F. Henry, R. W. Hilton, N. B. Hopper, W. I. Horne, C. R. Innes, G. Innes, G. S. Joss, Janina E. Koperska, A. W. Laing, R. A. Laing, G. S. Laird, Zofia K. W Laszewski (*née* Kinel), Helen C. Lawson, G. Lorimer, A. D. Lyall, D. S. McConnach, D. J. McCulloch, W. G. MacDonald, Winifred W. McDonald, A. W. McIntosh, W. McIntyre, I. Mackay, J. McKay, M. Mackay, K. J. Maclean, H. N. MacPhail, R. T. Macpherson, N. Marshall, Valerie MacA. Milne, R. A. Mitchell, D. M. Moir, J. S. V. Mouat, R. R. Mowat, Muriel J. Mucha (*née* Mackie), D. R. Murray, N. T. Nicol, T. A. A. Pearce, W. J. W. Rae, Frances S. Ritchie, Margaret Robson, Helen C. de C. Roll (*née* Scott), N. Z. Sacks, H. G. Saunders, A. Sillars, L. C. Skinner, D. M. Slessor, I. W. Strachan, J. Strachan, Dorothy A. Sutherland, K. I. Sutherland, Janina Z. M. Szamocki (*née* Skroczynski), A. J. Taylor, Katharine J. Thicknesse, Isabella E. M. F. Thomas, I. D. H. Todd, Audrey M. G. Towns, E. I. Watty, Dolores F. Webster, R. D. Weir.

[1]With honours. [2]With commendation. [3]Passed Final M.B., Ch.B. degree examination with distinction in surgery, medicine, and midwifery. [4]Passed Final M.B., Ch.B. degree examination with distinction in midwifery.

UNIVERSITY OF LONDON

The Semon Lecture for 1950 entitled "The Development and the Present Use of Bronchospirometry" will be delivered by Dr. Paul Frenckner, lecturer at the Karolinska Institutet and head of the Department of Oto-rhino-larnygology, Southern Hospital, Stockholm, at the Royal Society of Medicine, 1, Wimpole Street, London, W., on Thursday, November 2, at 5 p.m.

A special university lecture on "The Circulation in Pregnancy" will be delivered by Professor R J. Kellar, Professor of Obstetrics and Gynaecology in the University of Edinburgh, at University College Hospital Medical School, University Street, London, W.C., on Friday, November 3, at 5 p.m.

Professor F. A. E. Crew, F.R.S., Bruce and John Usher Professor of Public Health and Social Medicine in the University of Edinburgh, will deliver a course of three special university lectures on "The Biological Aspects of War" at the Senate House, University of London, Bloomsbury, W.C., on Thursdays, November 16, 23, and 30, at 5.30 p.m.

The lectures are addressed to students of the University and to others interested in the subjects. Admission is free, without ticket.

Dr. W. S. Feldberg, F.R.S., will deliver a course of three lectures on "Chemical Transmitters" in the physiology theatre of University College (Gower Street, W.C.) on November 10 and 21 and December 1, at 5.15 p.m.

Professor Hamilton Hartridge, F.R.S., will deliver a course of three lectures on "Some Recent Advances in the Physiology of Vision" in the physiology theatre of University College, Gower Street, W.C., on Tuesdays October 24 and 31 and November 7, at 5.15 p.m.

Four lectures on "Aspects of Protein Structure" will be delivered by Dr. A. Elliott and Dr. W. E. Hanby in the physiology theatre of University College, Gower Street, W.C., on Mondays, November 20 and 27 and December 4 and 11, at 4.45 p.m.

UNIVERSITY OF BIRMINGHAM

Dr. Kurt Aterman has been appointed Lecturer in Biophysics in the Department of Anatomy, from October 1.

The following resignations are announced: Dr. Harold Scarborough (Reader in Medicine) from September 30 on appointment as Professor of Medicine and Director of the Medical Unit at the Welsh National School of Medicine, Cardiff; Dr. C. N. Iland (Lecturer in Bacteriology).

Professor H. F. Humphreys, Vice-Principal and Professor of Dental Surgery in the University, will deliver a lecture entitled "The Horn of the Unicorn" in the Mason Theatre, Edmund Street, Birmingham, on Tuesday, October 17, at 1.45 p.m. He will also discuss "Malthus and Modern Times" in a lecture to be given in the Union Debating Hall, Edgbaston, Birmingham, on Thursday, October 26, at 1.45 p.m.

Professor K. Mather, D.Sc., Professor of Genetics in the University, will deliver a lecture on "Genetics and its Relation to Human Affairs" in the Mason Theatre on Tuesday, November 14, at 1.45 p.m.

A lecture on "Henry VIII: A Medical Study" will be delivered by Professor J. F. D. Shrewsbury, Professor of Bacteriology in the University, in the Mason Theatre on Thursday, November 23, at 1.45 p.m.

On Friday, December 1, at 1.45 p.m., in the Union Debating Hall, Bertrand Russell, O.M., F.R.S., will deliver a lecture on "The Impact of Science on Society."

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

At a recent meeting of the Council of the College the President, Professor Hilda Lloyd, was appointed to represent the College on the General Medical Council.

The Honorary Fellowship of the College was conferred on Dr. George William Kosmak, of New York, editor of the *American Journal of Obstetrics and Gynecology*, in recognition of his services to obstetrics and gynaecology.

Mr. Geoffrey Keynes and Dr. R. J. Minnitt were elected to the Fellowship under the rule permitting the election annually of not more than two practitioners who are not obstetricians or gynaecologists, but who have made valuable contributions to the advancement of obstetrics and gynaecology.

It was announced that Sir Arthur Sims had made a gift of securities to the value of over £25,000 to establish the Nancy Sims and Margaret Black Travelling Professorship Fund, the income from which will enable the College to appoint a senior obstetrician-gynaecologist to visit Australia and New Zealand and the other countries of the Commonwealth in alternate years.

It was also announced that the trustees of the Bernhard Baron Charitable Trust intended to make a gift of £10,000 to found a Travelling Scholarship.

The following were admitted to the Membership of the College: G. T. Altimas, J. D. Andrew, P. R. Blahey, G T. Carson, C. J. Champ, F. L. Clark, T. R. Clarke, W. W. Coppinger, B. M. Corkill, E. D. Crichton, T. Dean, C. N. DeGaris, W. Donovan, H. P. Dunn, Isabel L. Dyke, M. W. Elliott, C. J. Farr, B. Fatima, W. R. Foote, M. B. Fox, H. H. Francis, A. C. G. Frost, W. D. Giffen, C. A. Haxton, H. A. Henderson, H. F. Hills, R. Hodkinson, R. H. Horner, D. R. Hughes, T. G. Ingram, D. J. McI. Irvine, H. A. Kelsey, D. Kutty, J. F. Leaver, J. L. MacArthur, D. C. McEwen, K. T. MacFarlane, Ishbel M. Macrae, C. M. H. Mair, W. D. Marshall, Helen M. Noble, R. H. O'Hanlon, D. G. P. Paranjothy, M. G. Pearson, E. Quehl, P. D. Rajaratnam, I. Ramamurthi, K. E. E. Read, H. A. Rowley, A. M. Rutherford, S. A. Scorer, D. R. Sheumack, E. M. Southern, D. W. Sparling, S. K. S. Roy, S. N. Upadhyay, L. G. R. Van Dongen, D. B. B. Whitehouse, J. Wilbush, E. A. Williams, M. H. V. Young.

The Services

Surgeon Rear-Admiral T. Madill, O.B.E., R.N., has been appointed Honorary Physician to the King in succession to Surgeon Rear-Admiral O. D. Brownfield, C.B., O.B.E., R.N., who has been placed on the Retired List.

A *Supplement* to the *London Gazette* has announced the following awards:

Four Clasps to the Territorial Efficiency Decoration.—Colonels J. L. Hamilton, M.C., T.D., and H. J. D. Smythe, M.C., T.D., R.A.M.C.

Three Clasps to the Territorial Efficiency Decoration.—Colonel J. Gwynne-Morgan, C.B.E., T.D., R.A.M.C.

Two Clasps to the Territorial Efficiency Decoration.—Colonel R. H. Robinson, T.D., Lieutenant-Colonels W. C. Barber, T.D., and F. A. Belam, T.D., and Major (Honorary Colonel) G. M. Frizell, T.D., R.A.M.C.

1st Clasp to the Territorial Efficiency Decoration.—Lieutenant-Colonel W. R. Blunt, T.D., R.A.M.C.

Territorial Efficiency Decoration with 1st Clasp.—Lieutenant-Colonel (Honorary Colonel) F. A. R. Stammers (T.A.R.O.), Lieutenant-Colonel C. W. Arnot, Major (Honorary Colonel) W. Barclay, M.C., and Major R. K. Reeves, R.A.M.C.

Territorial Efficiency Decoration.—Lieutenant-Colonel G. M. Komrower, Major (Honorary Lieutenant-Colonel) H. W. Featherstone, Majors J. P. W. Hughes and D. J. Wigginton, Captains (Honorary Majors) J. Kerr, D. B. Brown, L. T. Clarke, D.S.O., and D. W. Gillies, and Captain A. R. Darlow, R.A.M.C.

No. 38

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended September 23.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Measles is not notifiable in Scotland, and the returns are therefore an approximation only.

† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

‖ Includes puerperal fever for England and Wales and Eire.

¶ Primary pneumonia no longer notifiable in Eire.

EPIDEMIOLOGICAL NOTES

Poliomyelitis

Notifications of poliomyelitis in the week ending September 30 were: paralytic, 222 (268); non-paralytic, 109 (151); total, 331 (419). The figures for the previous week are in parentheses. Total uncorrected notifications for 1950 up to and including the week under review are 6,351. The corresponding figures for 1947, 1948, and 1949 were 6,665, 1,449, and 3,641 respectively. It will be noted that the total figures for 1947 for the corresponding period now exceed those for 1950.

The steady reduction in notifications is maintained in the week under review, and these were less than those for the preceding week by 46 paralytic, 42 non-paralytic—total, 88. The county areas with decreases of more than 5 compared with the preceding week were: London 8, Essex 7, Kent 6, Lancashire 11, Northumberland 10, Southampton 7, Stafford 6, Surrey 7, and Middlesex 15. Any increases which occurred were generally distributed and insignificant in number. Non-paralytic cases in the week under review comprised 32.9% of the total.

Quarterly Returns for Scotland

(Second Quarter, 1950)

The birth rate during the second quarter of this year was 19.1 per 1,000, being 0.6 below the average of the June quarters for the five preceding years. The infant mortality was 34 per 1,000 registered live births and was the lowest ever recorded in Scotland for any quarter, being 2 below the rate for the corresponding quarter of 1949 and 13 below the average of the five preceding second quarters. The stillbirth rate was 26 per 1,000 total births. The general death rate was 11.6; this rate was 0.2 less than the rate in the second quarter of 1949 and 0.3 below average of the five preceding June quarters. The death rate from all forms of tuberculosis was 56 per 100,000 and 47 from respiratory tuberculosis; both these rates were 13 below the rate for the corresponding quarter of 1949 and they were respectively 24 and 17 below the five-years' average. The marriage rate was 6.7 per 1,000 of the population, and was the lowest for any quarter since the first quarter of 1939 and lower than the pre-war average.

Discussion of Table

In *England and Wales* increases in the number of notifications were reported for measles 179 and scarlet fever 21, while decreases were recorded for whooping-cough 151, acute poliomyelitis 59, and dysentery 45.

A small rise in the incidence of measles occurred in most areas of the country; the largest increases were Lancashire 75, London 55, and Cheshire 52. The outstanding exception to the general rise was a decrease of 215 in Lincolnshire. Very small changes occurred in the local trends of scarlet fever. A rise of 3 in Glamorganshire and a fall of 3 in Lancashire were the chief features of the returns for diphtheria. The largest declines in the number of notifications of whooping-cough were Middlesex 34 and London 33.

The chief centres of dysentery were: Yorkshire West Riding 35 (Shipley U.D. 10); Wiltshire 25 (Calne and Chippenham R.D. 25); Leicestershire 19 (Leicester C.B. 19); Lancashire 19; London 14; Durham 9.

The largest returns of acute poliomyelitis were: Lancashire 41 (Liverpool C.B. 14, Manchester C.B. 12); Middlesex 25 (Harrow U.D. 5, Hayes and Harlington U.D. 5, Ealing M.B. 4); London 24 (Hackney 5, Wandsworth 4); Yorkshire West Riding 24 (Sheffield C.B. 7); Kent 23 (Chislehurst and Sidcup U.D. 4, Orpington U.D. 4); Gloucestershire 18 (Bristol C.B. 15); Staffordshire 17 (Wolverhampton C.B. 6); Durham 17; Northumberland 16 (Newcastle-upon-Tyne C.B. 5); Warwickshire 15 (Birmingham C.B. 6); Surrey 15; Devonshire 15 (Newton Abbot R.D. 4); Southampton 13; Somerset 13 (Long Ashton R.D. 4); Essex 13; Cheshire 10 (Nantwich R.D. 4).

In *Scotland* an increase was recorded in the number of notifications of dysentery 30, measles 17, whooping-cough 14, and a decrease was reported for acute poliomyelitis 26 and scarlet fever 14. The chief centres of dysentery were Glasgow 49, Edinburgh 20, Dumfries 14, Dumfries county 12, Stirling county 9. The largest returns for acute poliomyelitis were from Dundee 8, Glasgow 6, Lanark county 5, Moray and Nairn county 5, Edinburgh 3.

In *Eire* the incidence of infectious diseases was unchanged from the preceding week's level. The largest variation in the local trends was a decrease of 8 in the number of notifications of measles in Dublin C.B.

In *Northern Ireland* the chief feature of the returns was a decrease of 15 in the notifications of acute poliomyelitis. The largest returns of acute poliomyelitis were Antrim county 3 and Down county 3.

Week Ending September 30

The notifications of infectious diseases in England and Wales during the week included scarlet fever 937, whooping-cough 2,616, diphtheria 50, measles 2,963, acute pneumonia 281, acute poliomyelitis 331, dysentery 187, paratyphoid fever 11, typhoid fever 7.

Medical News

Hunterian Society

For many years the Hunterian Society has had no permanent home for its many mementoes of John and William Hunter and their friends. Now the whole collection is effectively displayed in one of the rooms of the Ciba Foundation at 41, Portland Place. On Thursday last the annual party of the Hunterian Society was held there, and Lord Horder, who was introduced by Sir Arthur Porritt, the president of the society, formally opened the museum and library. There are many interesting items in the museum. There is the gold watch which the staff of St. George's Hospital presented to John Hunter and which he bequeathed to Charles James Fox, M.P. There is a copy of the songs which Haydn dedicated to Mrs. John Hunter and for which she wrote the words. The best known of them is probably "My Mother Bids me Bind my Hair." There are many manuscript letters and lecture notes, and even snuff-boxes and spectacles find a place in the glass show-cases. Quite the most interesting exhibit, however, is a new and fine portrait of William Hunter which was painted by his friend Sir Joshua Reynolds (see p. 886).

Heberden Society Dinner

The council of the Heberden Society on October 5 gave a dinner in honour of Dr. and Mrs. Philip Hench. The other guests present were Sir William Douglas and the Editor of the *British Medical Journal*. The president of the society, Dr. W. S. C. Copeman, was in the chair, and Lord Horder, on behalf of the Society, gave a short speech of welcome to which Dr. and Mrs. Hench replied. Dr. Hench is at present in this country giving lectures on the work originated by himself and his colleagues at the Mayo Clinic on the treatment of rheumatic and other conditions with cortisone and A.C.T.H.

Rockefeller Grants

The Rockefeller Foundation has made grants totalling nearly £20,000 to assist in studies on heredity, anthropology, and anatomy in London, Cambridge, and Bristol. A grant of £10,000 to the Galton Laboratory, University of London, for work on human heredity is to be used in part to employ social workers to collect data on individuals and families. The Royal Statistical Society will receive £7,142 to develop library facilities in its new centre in London. The department of anthropology at Cambridge University will receive £1,000 to defray the cost of a field study in India. A grant of £1,250 to the anatomy department at Bristol University is to facilitate research work under the direction of Professor J. M. Yoffey.

Mass Radiography at Oxford

Freshmen arriving at Oxford University this term are being offered *x*-ray examination of the chest. The facilities are being provided by the Oxford Regional Hospitals Board.

Advancement of Radiology

The Detroit Roentgen Ray and Radium Society has elected Dr. J. F. Brailsford an honorary member in recognition of his "outstanding contribution to medicine and the advancement of the science of radiology."

Health Education

A conference on "Health Education" was held at the Institute of Education, University of London, from September 27–30. The conference was primarily for training college lecturers on hygiene, and the subjects dealt with included: health education in schools, nutrition, school meals, infection in schools, rheumatic disease in school-children, tuberculosis, and various psychological problems.

British Rheumatic Association

Lord Nuffield has accepted the presidency, to which he was unanimously elected at the annual general meeting of the association held at Friends House, London, on Thursday, September 28.

Association of Scientific Workers

Lord Haden-Guest has accepted the invitation of the executive committee of the Association of Scientific Workers to become president of the association. Lord Boyd-Orr, who was president until recently, has resigned because of increased commitments.

Manchester Medical Society

All the medical and dental societies of Manchester have amalgamated to form one society—the Manchester Medical Society. Mr. Wilson Hey has been elected first president. At the first ordinary meeting of the society on October 4, which was attended by the Vice-chancellor of the University and the Presidents of the Royal Colleges and the Royal Society of Medicine, Mr. Wilson Hey delivered his presidential address on "The Story of the Manchester Medical Societies."

British Epilepsy Association

A British Epilepsy Association has been formed with the principal object of carrying out an educational and propaganda campaign to create a proper understanding of the epileptic. Lady Cynthia Colville is chairman of the provisional council, and Miss Irene Gairdner, honorary secretary. The headquarters of the association are at 39, Queen Anne Street, W.1. The council includes five medical members—namely, Sir Charles Symonds, Dr. Russell Brain, Dr. Macdonald Critchley, Dr. Letitia Fairfield, and Dr. Denis Williams—and about 20 lay members. One of the activities of the new organization will be the establishment of an information bureau and advisory service. The association will assist in the provision of hostels and convalescent homes and will publish literature designed to promote the interests of epileptics.

Moyne Institute of Preventive Medicine

The foundation-stone of the Moyne Institute of Preventive Medicine, Trinity College, Dublin, was laid by the Honourable Grania Guinness on September 30. The Institute is the gift of Miss Guinness in memory of her father, the first Baron Moyne. Lord Moyne, who had a distinguished record of public service, was assassinated in Cairo in 1944 while acting as British Minister Resident in the Middle East. The Moyne Institute will house the departments of bacteriology and of social medicine, and will also contain a theatre to accommodate 100 students, a lecture room, a departmental library, and laboratories for large and small classes and for individual research workers. Space will be provided for diagnostic laboratories, inoculation rooms, sterile rooms, incubator rooms, a media kitchen, and rooms for washing and sterilizing, etc. One floor of one wing will be devoted to a department of social medicine, which the College authorities intend to establish when the Institute is completed, probably by the autumn of 1952. Much thought and care have gone to the planning of this new building. By the generosity of the Rockefeller Foundation and of Trinity College Professor J. W. Bigger and the architect were enabled to visit laboratories in England, Scandinavia, and the United States. The growth in size and importance of the department of bacteriology has been due in no small measure to the personality of Professor Bigger, and it is much to be regretted that ill-health has recently forced him to retire.

COMING EVENTS

Neurological Demonstrations

A series of clinical neurological demonstrations will be given at the Maida Vale Hospital Medical School, London, W., on Fridays, at 5 p.m., from October 13 to December 15. Details will be published in the "Societies and Lectures" column of the *Journal* week by week.

Annual Harveian Commemoration

Sir Leonard Parsons, F.R.S., will deliver the Harveian Oration on "The Influence of Harvey and His Contemporaries on Paediatrics" before the Royal College of Physicians of London (Pall Mall East, S.W.) on Wednesday, October 18, at 3 p.m. A dinner will be held at the College on the same day at 7.45 for 8 p.m.

Society of Medical Officers of Health

A meeting of the Society of Medical Officers of Health will be held in the Hastings Hall, B.M.A. House, Tavistock Square, London, W.C., on Thursday, October 19, at 5.30 p.m., when Dr. J. M. Gibson will be installed as president of the Society for 1950–1 and will deliver his presidential address entitled "Give Us the Tools."

Biological Hazards of Atomic Energy

The Institute of Biology and the Atomic Scientists' Association, with the support of the British Association, will hold a conference on the biological hazards of atomic energy. The conference will take place at the Royal Institution, Albemarle Street, London, W.1, on Friday and Saturday, October 20–21, and will be divided into the following sessions: I. Biological and Medical Effects of Radiation (chairman: Sir Henry Dale, O.M., F.R.S.). II. Tolerance Levels and Measures of Protection (chairman: Sir John D. Cockcroft, F.R.S.). III. Biological Implications (chairman: Sir Ernest Rock Carling). IV. Atomic Energy and the Future (chairman: Lord Boyd-Orr, F.R.S.). Discussion will follow the various papers; there will be an exhibition in connexion with the conference. Admission is by ticket, and further information can be obtained from the secretary, British Association, Burlington House, W.1.

St. George's Hospital Medical School

A series of lecture-demonstrations on neurology and psychiatry will be given in the large lecture theatre of St. George's Hospital Medical School, Hyde Park Corner, London, S.W., on Thursdays, at 4.30 p.m., from October 19 to December 21. The lecture-demonstrations are open, without fee, to all medical practitioners and senior medical students. Details will be published in the "Societies and Lectures" column of the *Journal* week by week.

Wessex Rahere Club

The autumn dinner of the Wessex Rahere Club will be held at the Spa Hotel, Clifton, Bristol, on Saturday, October 21, when Mr. John Hosford will be the guest of honour. Membership of the club is open, without subscription, to all St. Bartholomew's Hospital men resident in the West Country. All interested are invited to communicate with the honorary secretary, Mr. A. Daunt Bateman, F.R.C.S., 3, The Circus, Bath.

Nurses' and Midwives' Conference

The thirty-fifth annual Professional Nurses and Midwives Conference and Exhibition, held under the auspices of the *Nursing Mirror*, is to take place at Seymour Hall, Seymour Street, London, W.1, from October 23–27. The opening

ceremony will be performed by Countess Mountbatten of Burma. A number of conference lectures will be given by distinguished medical men and women, and in addition a full film programme has been arranged.

Public Health Administration

A Chadwick Public Lecture on "Public Health Administration in Western Union Countries: A Comparative Synthesis" will be delivered by Dr. Neville M. Goodman (Ministry of Health) in the Sir Edward Meyerstein Lecture Theatre, Westminster Medical School, 17, Horseferry Road, Westminster, London, S.W., on Tuesday, October 24, at 4.30 p.m. Admission to the lecture is free and no tickets are required.

Honyman Gillespie Lectures

A series of Honyman Gillespie Lectures has been arranged, in association with Edinburgh postgraduate courses, to take place during the autumn term in the anatomy theatre, University New Buildings, Teviot Place, Edinburgh, on Thursdays at 5 p.m., from October 26 to December 14, both dates inclusive. The lectures are open to all graduates and senior students, and details will be published in the "Societies and Lectures" column of the *Journal* week by week.

Prize Offered by American Chest Physicians

The Board of Regents of the American College of Chest Physicians offers a cash prize award of $250 to be given annually for the best original contribution, preferably by a young investigator, on any aspect of medicine relating to chest disease. The prize is open to contestants of other countries as well as those residing in the United States. The winning contribution will be selected by a board of impartial judges, and the award, together with a certificate of merit, will be made at the forthcoming annual meeting of the College to be held in Atlantic City, New Jersey, on June 7–10, 1951. The College reserves the right to invite the winner to present his contribution at the annual meeting and to publish the essay in its official publication, *Diseases of the Chest*. Contestants are advised to study the format of *Diseases of the Chest* as to the length, form, and arrangement of illustrations to guide them in the preparation of the manuscript. The following conditions must be observed:

1. Five copies of the manuscript, typewritten in English, should be submitted to the executive office of the College, 500, North Dearborn Street, Chicago 10, Illinois, not later than April 1, 1951.

2. The only means of identification of the author or authors shall be a motto or other device on the title page and a sealed envelope, bearing the same motto or device on the outside, enclosing the name of the author or authors.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Friday

MAIDA VALE HOSPITAL MEDICAL SCHOOL, London W.—October 13, 5 p.m., clinical neurological demonstration by Dr. Samuel Nevin.

Monday

●INSTITUTE OF NEUROLOGY, National Hospital, Queen Square, London, W.C.—October 16, 5 p.m., "*Electroencephalography in Children*," by Dr. Denis Hill.

INSTITUTE OF OPHTHALMOLOGY (UNIVERSITY OF LONDON), Judd Street, London, W.C.—October 16, 5.30 p.m., "*The Optic Nerve and Chronic Simple Glaucoma*," by Mr. A. G. Cross.

●ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW, 242, St. Vincent Street, Glasgow.—October 16, 4 p.m., "*The Effect of Cortisone and A.C.T.H. on Rheumatic Diseases*," Inaugural Walker Trust Lecture by Dr. Philip S. Hench (Rochester, U.S.A.).

Tuesday

BRISTOL UNIVERSITY.—October 17, 8.15 p.m., "*Some Food Infection Problems*." Long Fox Memorial Lecture by Sir William Savage.

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C., October 17, 5.30 p.m., "*The Assessment of Nutritional Status in Population Groups*," by Dr. D. A. Smith.

EUGENICS SOCIETY.—At Royal Society, Burlington House, Piccadilly, London, W., October 17, 5.30 p.m., "*Colonial Medical Policy in Relation to Population Growth*," by Professor T. H. Davey.

●INSTITUTE OF DERMATOLOGY, Lisle Street, Leicester Square, London, W.C.—October 17, 5 p.m., "*Pathology*," by Dr. J. O. Oliver.

INSTITUTE OF NEUROLOGY, National Hospital, Queen Square, London, W.C.—October 17, 5 p.m., "*The Physiology of Neuromuscular Transmission and Neuromuscular Block*," by Dr. W. Feldberg.

LONDON UNIVERSITY.—At St. Mary's Hospital Medical School (Wright-Fleming Institute Lecture Theatre), Paddington, London, W., October 17, 5 p.m., "*Hormones of the Sympathetic Nervous System and the Adrenal Medulla*," by Professor U. S. von Euler (Stockholm).

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—October 17, 4 p.m., "*Contact Lenses*," by Dr. C. G. Kay Sharp; 5 p.m., "*Genetics in Ophthalmology*," by Professor A. Sorsby.

SOCIETY FOR THE STUDY OF ADDICTION.—At Medical Society of London, 11, Chandos Street, Cavendish Square, London, W., October 17, 4 p.m., "*Alcohol and the Motorist, with special reference to the Proceedings of the First International Conference on Alcohol and Traffic*," by Dr. W. R. Bett. A discussion will follow.

UNIVERSITY COLLEGE, Gower Street, London, W.C.—October 17, 1.15 p.m., "*Unresting Cells*," by Mr. M. Abercrombie.

Wednesday

GLASGOW UNIVERSITY.—In Department of Ophthalmology, October 18, 8 p.m., "*Extra-foveal Perception of Form*," by Dr. Stewart Renfrew.

HARVEIAN SOCIETY OF LONDON.—At 26, Portland Place, London, W., October 18, 8.15 p.m., "*Byssinosis*." by Dr. R. E. Lane.

●INSTITUTE OF DERMATOLOGY, Lisle Street, Leicester Square, London, W.C.—October 18, 5 p.m., "*Medical Mycology*," lecture-demonstration by Dr. R. W. Riddell.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.—At Royal Free Hospital School of Medicine, 8, Hunter Street, London, W.C., October 18, 8.30 p.m., annual general meeting.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East, S.W.—October 18, 3 p.m., "*The Influence of Harvey and his Contemporaries on Paediatrics*," Harveian Oration by Sir Leonard Parsons, F.R.S.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE, 28, Portland Place, London, W.—October 18, 3.30 p.m., "*Housing and Health—Problems in Great Britain and France*," by Mr. B. S. Townroe, M.A., D.L.

Thursday

BRITISH INSTITUTE OF RADIOLOGY, 32, Welbeck Street, London, W.—October 19, 8.15 p.m., "*Opportunity Knocks at the Door*," presidential address by Dr. R. Fawcitt.

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C., October 19, 5.30 p.m., "*Nutritional Factors in Liver Disease*," by Dr. H. P. Himsworth.

EDINBURGH CLINICAL CLUB.—At B.M.A. Scottish House, 7, Drumsheugh Gardens, Edinburgh, October 19, 8 p.m., "*The Future Status of the General Practitioner*," by Dr. W. D. D. Small.

LONDON HOSPITAL MEDICAL COLLEGE, Turner Street, E.—October 19, 4.15 p.m., "*Clinical Medicine*," Schorstein Memorial Lecture by Dr. F. M. R. Walshe, F.R.S.

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—October 19, 5.30 p.m., "*Visual Fields: Normal and Pathological*," by Mr. C. Taylor.

ROYAL SANITARY INSTITUTE.—At Oldway Mansion, Paignton, October 19, 10 a.m., papers: "*Detection of Enteric Carriers in Towns by Means of Sewage Examination*," by Dr. B. Moore; "*A Food Hygiene Scheme in a Health Resort*," by Mr. G. J. Loveless, M.S.I.A. Afternoon: visits will be made.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—At 26, Portland Place, London, W., October 19, 7.30 p.m., "*Tropical Pulmonary Eosinophilia*," by Dr. Donald Ball. A discussion will follow.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, Hyde Park Corner, London, S.W.—October 19, 4.30 p.m., lecture-demonstration on neurology by Dr. D. J. Williams.

Friday

BIOCHEMICAL SOCIETY.—At National Institute for Medical Research, The Ridgeway, Mill Hill, London, N.W., October 20, 11 a.m., 290th meeting. Papers will be read.

BRITISH INSTITUTE OF RADIOLOGY, 32, Welbeck Street, London, W.—October 20, 5 p.m., meeting of medical members; 6.30 p.m., "*The Use of Scintillating Crystals and Solutions in the Measurement of Radiation*," by Mr. E. H. Belcher, M.A.

FACULTY OF RADIOLOGISTS.—At Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C., October 20, 2.15 p.m., diagnosis section meeting. "*The Value of Straight X-ray Examinations of the Skull in the Diagnosis of Lesions of the Central Nervous System*," by Dr. J. W. D. Bull.

INSTITUTE OF OPHTHALMOLOGY (UNIVERSITY OF LONDON), Judd Street, London, W.C.—October 20, 5.30 p.m., "*Orbital Inflammation and the Ear, Nose, and Throat*," by Mr. J. Marshall.

MAIDA VALE HOSPITAL MEDICAL SCHOOL, London, W.—October 20, 5 p.m., clinical neurological demonstration by Dr. P. H. Sandifer.

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—October 20, 4.30 p.m., "*Medical Ophthalmology*," by Mr. A. J. Cameron.

ROYAL MEDICAL SOCIETY, 7, Melbourne Place, Edinburgh.—October 20, 8 p.m., "*The Mechanism of Sleep*," dissertation by Mr. A. E. Meek.

Sunday

LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—At Rose Hertz Hall, Woburn House, Upper Woburn Place, London, W.C., October 22, 3 p.m., "*Common Errors in Cardiovascular Practice*," presidential address by Dr. Geoffrey Konstam.

APPOINTMENTS

Harold Balme, O.B.E., M.D., F.R.C.S., has been appointed technical consultant on rehabilitation to the U.N. Department of Social Affairs and the World Health Organization.

CULBERT, T. D., M.B., D.A., Senior Consultant Anaesthetist, Manchester Babies' and Children's Hospital Group, with duties in Manchester Northern Hospital Group.

DONE, JANET M., M.D., D.P.H., D.R.C.O.G., Senior Assistant Medical Officer of Health for Maternity and Child Welfare, Coventry.

LOWE, MURIEL J., M.B., B.S., D.P.H., D.C.H., Assistant County Medical Officer, Goole Area Division No. 10, West Riding of Yorkshire.

PATTERSON, JOHN, M.B., B.Ch., B.A.O., D.P.H., Assistant Divisional Medical Officer, No. 1 Division (Ulverston), County of Lancashire.

ROSS, ALASTAIR IAN, M.D., D.P.H., Deputy Medical Officer of Health, City of Leicester.

SOUTH-WESTERN REGIONAL HOSPITAL BOARD.—*Consulting Dermatologist in North Gloucestershire Clinical Area*, R. E. Bowers, M.D., M.R.C.P.; *Physicians in Psychiatry at Bristol Mental Hospital*, G. M. Gibb, M.B., Ch.B., D.P.M., and J. B. Phillips, M.D., D.P.M.

VICKERY, K. O. A., M.D., D.P.H., Deputy Medical Officer of Health, County Borough of Bournemouth.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Burkitt.—On October 1, 1950, at 133, Gresham Road, Staines, Middx., to Violet, wife of R. T. Burkitt, M.D., F.R.C.S.I., a daughter.

Hill.—On October 7, 1950, at Robinson Hospital, Ballymoney, to Nancy, wife of Dr. William J. C. Hill, Portrush, a daughter.

Hotchkis.—On September 29, 1950, to Jean M. Hotchkis (formerly Smout), M.B., Ch.B., wife of Mr. Alistair Hotchkis, Balgowan, Pitlochry, Perthshire, a son.

Illingworth.—On October 1, 1950, to Dr. Cynthia Illingworth, M.R.C.P. (formerly Redhead), wife of Professor R. S. Illingworth, M.D., F.R.C.P., a son.

Imray.—On September 1, 1950, to Peggy, wife of Dr. M. A. Imray, Bowden House, Market Harborough, Leics., a sister for Elizabeth and Robin—Gillian Mary.

Lawrence.—On October 8, 1950, at Redruth, to Jane (formerly Thom), wife of Dr. D. B. Lawrence, a son.

Matthews.—On September 12, 1950, at St. Luke's Hospital, Guildford, to Diana (formerly Tenby-Smith), wife of Dr. Harold W. Matthews, a daughter—Roha Elizabeth Hayden.

Merry.—On July 8, 1950, at the Point Fortin Hospital, Trinidad, to Kathleen, wife of Dr. C. H. Merry, a daughter.

Scurr.—On September 23, 1950, at Westminster Hospital, to Jean (formerly Spiller), wife of Dr. Cyril Scurr, a son.

Spicer.—On October 4, 1950, to Faith (formerly James), wife of Dr. C. C. Spicer, of 65, Beaufort Mansions, London, S.W., a son.

DEATHS

Avery.—On September 30, 1950, at 928, London Road, Leigh-on-Sea, Essex, John Avery, M.R.C.S., L.R.C.P.

Charsley.—On September 29, 1950, Gilbert William Charsley, M.R.C.S., L.R.C.P. of 6, Regina Court, 42, Fitzjohn's Avenue, Hampstead, London, N.W., formerly of Sydenham.

Fawssett.—On September 29, 1950, Francis William Fawssett, M.B., M.R.C.S., of 31, Chantry Lane, Grimsby, Lincs.

Fraser.—On September 29, 1950, at a nursing-home, Edinburgh, Robert Murray Fraser, L.R.C.P.&S.Ed., H.D.D., L.D.S.Ed., of 28, Morningside Place, Edinburgh.

Graham-Little.—On October 6, 1950, at his Epsom home, Wimpole Lodge, Sir Ernest Gordon Graham-Little, M.D., F.R.C.P.

Lowson.—On September 27, 1950, at New House, Moat Drive, Tamworth, Staffs, William Lowson, M.B., Ch.B., aged 79.

Maclean.—On August 3, 1950, Archibald Maclean, M.B., Ch.B., of Auchencairn, Union Street, Hamilton, Lanarkshire, aged 43.

McCutcheon.—On October 1, 1950, at Warren House, Mayfield, Sussex, Oliver Edward McCutcheon, M.B., B.Ch., aged 80.

McQuade.—On September 18, 1950, at Ilorin, Nigeria, Henry Gray McQuade, M.B., B.Chir., of Wyndfell, Steyning, Sussex.

Miskin.—On September 25, 1950, at the Kent and Canterbury Hospital, Canterbury, Leonard John Miskin, M.B., F.R.C.S., of Perry Farm, Wingham, near Canterbury, Kent.

Moran.—On September 25, 1950, at 1a, Winster Avenue, West Didsbury, Manchester, Peter Moran, M.D.

O'Gorman.—On September 22, 1950, at the London Hospital, Patrick Wilkins O'Gorman, C.M.G., M.D., M.R.C.P., D.P.H., Lieutenant-Colonel, I.M.S., retired, of 3, St. John's Road, Harrow-on-the-Hill, aged 92.

Plummer.—On October 6, 1950, Francis Christopher Plummer, M.D., of Hillmorton, Dunsan's Lane, Burton-in-Wirral, and Rodney Street, Liverpool, aged 62.

Purdy.—On September 20, 1950, after a long and painful illness, Margaret Mary, beloved wife of Gordon Purdy, M.B., F.R.C.S.Ed., of Ashby House, Oakham, Rutland.

Raeburn.—On September 28, 1950, at Dumfries, James Alexander Raeburn, M.D., D.P.H.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Dispensing of P.A.S.

Q.—*Is it essential for P.A.S. powder to be dissolved freshly each day, or is it possible to make up a supply to last, say, for three days or longer?*

A.—It is unnecessary for P.A.S. to be dissolved freshly each day in water, and it is quite in order to make up a supply to last for three days, but preferably not for longer. Many patients complain of the unpleasant taste and nauseating effect of such solutions. On the other hand, if P.A.S. is dispensed in tablets of 0.5 g., it may be necessary for the patient to swallow as many as 30 a day. Some patients prefer therefore to take the drug in cachets, each containing 1.5 g. This method of prescribing P.A.S. was mentioned by Dr. Hayman Jones in the *Journal* of June 10 (p. 1375), and such cachets are now on the market. Two cachets dipped in water and taken with a draught of water are not usually found very difficult to swallow, and there is no unpleasant taste. This dose should be taken at three-hourly intervals between 9 a.m. and 9 p.m. Some patients are nauseated by the drug when therapy is first begun, so it is wise to start with a daily dose of 5 g., gradually increasing to the full quantity of 15 g.

"Infective Gingivitis"

Q.—*What is the aetiology and treatment of infective gingivitis?*

A.—The aetiology of the condition is unknown, and, although it has been suggested that the virus of herpes simplex plays some part, there is no clear evidence that the lesions are infective. In women the ulcers may arise just prior to the onset of menstruation. The tip of the tongue, the gum some little distance from the teeth, and the inner aspect of the lips are the most common sites of ulceration. More rarely the palate may be involved. There is no infallible method of treatment, but the condition often responds to administration of one or more components of the vitamin-B$_2$ complex—e.g., 2 mg. riboflavin and 100 mg. nicotinamide daily—together with local applications of 1% gentian violet. Recurrences are relatively common.

Thrombophlebitis Migrans

Q.—*A male clerk, aged 30, first came to me four months ago with a thrombophlebitis of the external saphenous vein about 4 in. (10 cm.) above the knee-joint. Despite penicillin and anticoagulants in the usual dosage, the process has since been progressive—wandering about the leg in a most haphazard fashion. Not a week has passed but a fresh patch develops, and both patient and doctor have wearied of its persistence. No septic focus has been found. (1) Can we institute any treatment now? (2) Should we have ligated long ago? (3) What is the likelihood of Buerger's disease developing here?*

A.—The case is probably one of thrombophlebitis migrans. Each outburst should be treated with "elastoplast" support and enough dicoumarol to obtain a prothrombin time increased by 120%; this increase should be maintained for about a month. Penicillin seems to be of no value in this condition, and neither is internal saphenous ligation unless the veins are grossly varicose. The possibility of Buerger's disease developing can be put at 20%. The disease eventually burns itself out, but may last as long as two years. It is usual for these cases to continue normally at work provided there is no pyrexia. If this is present, there is lassitude and malaise which prevents work for short periods.

High Morning Blood Pressure

Q.—*I am treating a woman of 49 who suffers from hypertension. She has occasional headaches and a faint albuminuria, but otherwise appears well. The curious feature of her case is that the blood pressure on awakening in the morning is about 220/130, but it steadily diminishes during the day to about 170/110 when she retires. What is the significance of this?*

A.—It is certainly unusual for the blood pressure to be higher after a night's rest than later in the day. It suggests the influence of some substance causing vasodilatation, such as alcohol; it is presumed this is not the case. Other such agents include heat and gentle exercise. It is also assumed that all pressures are taken with the patient in the horizontal position, for a drop in blood pressure on standing up is not incompatible with hypertension. This is seen typically after a Smithwick operation.

Pregnenolone

Q.—*I hear that a substance called "pregnenolone," which is said to be non-toxic and cheap to produce, has been used in America for the treatment of rheumatoid arthritis with a success approaching that of "cortisone." Can you tell me if pregnenolone has been used in this country and, if so, with what results?*

A.—Pregnenolone has been advocated for the treatment of rheumatoid arthritis in several recent papers published in America. This substance has been tested in this country under controlled conditions in at least two centres, but the English workers have been unable to reproduce these beneficial results. In one series only did improvement occur, in one patient, for a time; but a further course of this treatment failed to reproduce the benefit. It is difficult to know why the American results should differ so markedly from those of English observers; it should be noted, however, that very recently reports have been received from American physicians who have also been unable to produce permanent clinical improvement in their patients treated with pregnenolone. The report of a trial in this country of pregnenolone and other steroid compounds is given in the opening pages of this week's *Journal*.

Bogomoletz Serum

Q.—*Will you please give me some information on the treatment of degenerative diseases with Bogomoletz serum?*

A.—Bogomoletz's antireticular cytotoxic serum (A.C.S.), although originally prepared in 1924, was the subject of a note in this country first in 1943 (*British Medical Journal*, 1943, **2**, 203). It was pointed out that the resistance of the organism to bacterial infection and to neoplasm, the healing of wounds and ulcers, and the normal union of fractured bones depended on the activity of "connective tissue"; "connective tissue" in this context being probably more accurately represented by the wider term "mesenchyme." Bogomoletz devised his serum with the object of stimulating the physiological activity of the mesenchyme. It was prepared by the repeated injection into horses of the cellular elements of human spleen and bone-marrow; in large doses the resulting serum was claimed to depress, and in small doses to stimulate, mesenchymal activity.

At a conference in Ufa, Russian clinicians reported the results in 2,500 cases treated with A.C.S. It was said to promote union in fractures which were uniting slowly, to hasten wound healing, to improve suppurative states, frost-bite, and burns; it was claimed to have a beneficial effect on cerebrospinal fever, pelvic sepsis, rheumatism, pneumonia, lung abscess, tonsillitis, neuritis, meningo-encephalitis, disseminated sclerosis, and certain psychoses; some cases of peptic ulcer and of eczema were stated to have been favourably influenced. Organisms resistant to sulphonamides were said to be rendered sensitive after injection of A.C.S. (Kavetsky, 1946). The serum has been the subject of several studies in the United States. Straus and his collaborators (1946) investigated methods of producing A.C.S. and were able to show that a large dose delayed healing of fractures in rabbits, although there was no evidence that small "stimulating" doses increased the rate of union above normal. Maltz, Spain, and Molomut (1948) with a similar antisplenic-tissue serum obtained accelerated healing of non-infected wounds in mice. Controlled experiments of the therapeutic effect of A.C.S. in man have been largely negative, although Ilfeld (1948) claimed that fractured femora united more rapidly when a patient was given A.C.S. The only "degenerative" diseases in which the serum has been widely used outside Russia are various rheumatic disorders. There is general agreement that the effects in rheumatoid arthritis are slight and transient (Rogoff *et al.*, 1947; Solomon and Stecher, 1948; and Kling, 1948). The same authors have noted even less benefit in osteoarthritis and fibrositis. Abernethy *et al.* (1948) found A.C.S. without effect in Hodgkin's disease. Thus, although great benefit is claimed in Russia from the use of A.C.S. in many and varied diseases, it has been employed little elsewhere, and insufficient data are available for a critical appraisal of its value. The technique of the preparation and administration of A.C.S. is described by Marchuk (1943).

Resistance to Streptomycin

Q.—(*a*) *What is the mechanism of development of resistance to streptomycin by the tubercle bacillus?* (*b*) *Is the change reversible?* (*c*) *In the case of bone or joint infection is the response to conservative treatment less favourable when the organism is "streptomycin-resistant"?*

A.—(*a*) The mode of action of streptomycin is not known with certainty: hence we are similarly ignorant of how bacteria escape from it. The action must consist of checking some metabolic process, and this is made all the more likely by the fact that resistance may be accompanied by "dependence"—i.e., the drug may become an essential nutrient without which the organism will not grow. It has been fully recognized for several years that other species of bacteria undergo this change, and recent evidence suggests that the same may be true of tubercle bacilli.

(*b*) In general, acquired resistance to streptomycin is permanent. In a few patients, sensitive tubercle bacilli have been recovered from sputum when a previous culture had shown resistant bacilli. This is not as encouraging as it may seem, because the bacterial population in a case under treatment is known to be highly heterogeneous, including bacilli of very varying degrees of resistance along with some which are still sensitive (and possibly some which are dependent): hence chance colony-selection may yield an anomalous result although the general trend of the change taking place is towards an increasing degree of resistance.

(*c*) So far as is known, the reaction of tubercle bacilli to streptomycin has no influence on any treatment other than the use of the drug itself.

LONDON SATURDAY OCTOBER 21 1950

VALUE OF GENETICS IN MEDICINE*

BY

L. S. PENROSE, M.D.

Galton Professor of Eugenics, University College, London

A routine procedure which is accepted as part of the correct technique in clinical medicine is the inquiry into family history. The student is instructed to ascertain the state of health or cause of death of the parents, brothers, sisters, and children of the patient. The facts elicited may tell him, it is alleged, whether the patient is disposed by heredity to any particular disease (Hutchison and Hunter, 1949). In spite of these injunctions, the use which is to be made of the family history remains wrapt in obscurity. From the patient's point of view, perhaps this is advantageous.

In the past there has been a tendency to look upon the family history as though it were a kind of Wassermann test, usually negative but occasionally positive and sometimes strongly positive. When the family history reaction turned out to be positive the disease was regarded as hereditary and the patient's condition would be apt to be judged incurable or even unmodifiable. In these circumstances the first thing to be done after taking a family history would be to forget all about it and to treat the case on its own merits. Indeed, the positive or negative family history is a very poor index of heritability. The recurrence of disease of a particular kind in more than one member of a family is no certain index of genetical causation. Serious mistakes were made in the past, rickets, syphilis, leprosy, and tuberculosis being classified as hereditary conditions because they were familial. Conversely, a rare recessive trait or a fresh mutant often appears without any trace of familial incidence.

It is now clear to most physicians that the interaction between hereditary constitution and environment is exceedingly subtle and complex. The course of every ailment known to medicine is influenced to a greater or lesser degree by the genetical structure of the individual patient. We are accustomed to the necessity of making exhaustive researches into environment, both physical and psychological, in order to understand the causes of disease. Infection, diet, occupation, and climate are searched for causal factors.

Similarly, it is logical to investigate the details of genetical constitution as profoundly as possible. We must, however, avoid imagining that genetical inquiry will lead us towards *the* cause of the condition except in the rarest cases. The correct interpretation of pedigree material is usually a matter of the greatest difficulty, partly because of the limited state of our knowledge of human genetics at the present time and partly on account of the inadequacy of the inquiries made at routine examinations—for example, the omission of inquiries about parental consanguinity. My first point is, then, that if family histories are to be taken as part of routine clinical procedure it is surely worth while to teach medical men and women enough of the principles of human genetics to enable them to know what use, if any, is to be made of them.

The central question for discussion is, however, the actual value of genetics in clinical medicine at the present time. It must be freely admitted that this value is very limited, and nothing would be more injurious to the proper development of human genetics than to give the impression that it will prove to be any kind of a panacea.

*Read in opening a discussion in the Section of Medical Genetics at the Annual Meeting of the British Medical Association, Liverpool, 1950.

Use in Serology and Pathological Biochemistry

There are two strictly clinical fields in which genetics has a very definite place. One of these is the study of serology. Incompatibility of donor's corpuscles with recipient's serum has been recognized as an avoidable danger in transfusion if cross-matching of bloods is carried out. Genetical knowledge is helpful here but not absolutely essential. Incompatibility of a foetus with its mother can, however, be predicted on genetical grounds and appropriate treatment planned before examination of the foetal blood is possible. The association of foetal disease with rhesus incompatibility, first recognized by Levine, Katzin, and Burnham (1941), is the most dramatic and convincing demonstration of the use of genetics in clinical medicine.

There is another field in which the value of genetics is becoming increasingly obvious—namely, the study of inborn biochemical specificities. The groundwork of the subject was well prepared by Garrod (1902), who showed that genic differences between individuals, responsible for clinical peculiarities, could be detected biochemically. The first disturbance to be fully described was alkaptonuria, which only very rarely produces any disability. This condition contrasts with phenylketonuria, first described by Fölling (1934), which is invariably associated with a subnormal level of mental functioning. There are conditions of intermediate medical significance, like hyperuricaemia, which are usually innocuous but sometimes cause severe symptoms, like gout.

The successful treatment of some cases of inborn methaemoglobinaemia with ascorbic acid or with methylene blue, and the treatment of cases of the syndrome of de Toni and Fanconi with vitamin D and alkali, have shown that knowledge of pathological biochemistry in these hereditary diseases can lead to striking practical results. The genetical part of the work enables such treatments to be accurately aimed because we know that gene differences produce sharp distinctions. If a precisely defined biochemical diathesis is

detected in a healthy relative of a known case of illness caused by the same genetical peculiarity, prophylactic measures can be confidently recommended. Bacterial genetics have latterly demonstrated that genic differences are often manifested in the loss of particular enzymes. Sometimes, however, genic effects are shown in specific peculiarities of membrane permeability or, as in some anaemias, peculiarities in the structure of the haemoglobin molecule. These discoveries, together with the advances of human biochemical genetics, have enabled the study of diathesis to be placed on a sound and logical basis, and great progress in this field may now be expected.

Eugenics in Prevention of Hereditary Disease

I now come to the negative side of the question—namely, the prevention of hereditary disease by eugenic recommendations. A view sometimes expressed is that it should be part of any efficient scheme of public health to attempt to cleanse the population of injurious genes. Such an aim, directed not towards improving the health of the existing population but that of future generations, is hardly consistent with the fundamental medical tradition of treating every individual case on its own merits. In the present state of genetical knowledge, moreover, the prospects of making any appreciable change in the genetical composition of the population by preventive eugenics are remote. Evidence is accumulating which suggests that natural selection has produced balanced genetical systems that are resistant to change, and I have attempted to apply the idea to the genetics of intelligence (Penrose, 1950).

Benefits for individual parents or prospective parents can be derived from genetical studies on rare familial diseases. If unaffected carriers of injurious genes could be diagnosed much comfort could be given to inquiring patients. Little practical help can be expected from genetical prognoses in relation to common diseases—for example, those with a frequency of the order of 1 in 100 or commoner. The belief was held by earlier workers, and is still accepted in some quarters, that many common traits, such as mental defect (Goddard, 1914), diabetes (Pincus and White, 1933), and schizophrenia (Kallmann, 1938) are inherited in simple ways, perhaps caused by common recessive genes. A careful study of the natural histories of these conditions, as exemplified in variability of clinical type, onset age, and sex incidence, at once rules out all simple genetical explanations. Furthermore, the elements in the causation due to environment can be changed but constitution cannot, so that medicine must concentrate on environment.

Besides strictly genetical problems arising in medicine, there are many of a semi-genetical kind concerned with the maternal influences on foetal development. These influences may be closely associated with maternal age, parity, health, nutrition, and so on. Advice is often requested by prospective parents on all these matters, and it might be advantageous if full use could be made in health services of the rather limited knowledge at present available.

Need for Accurate Information

Though human geneticists hope ultimately to be of practical use, at present they are contributing to the general body of scientific knowledge rather than to therapeutic medicine directly. While genetics has some contribution to make to medicine, this is far outweighed by the service which has been and will continue to be rendered by medicine to genetics. One may ask, then, what is particularly required from medical science at the present time? The question is easy to answer. Accurate information is needed about the incidence of disease in the general population. The ascertainment of really useful data on these matters is difficult. The geneticist requires to know not only the crude incidence of a condition like, say, diabetes mellitus, but the incidence in different age groups as well, classified also by sex. Moreover, degrees of severity have to be taken into account. The classification into two categories of presence and absence of disease is insufficient, because there are usually many degrees of severity.

The importance of such data in medical genetics is clearly seen in the model investigation of Doll and Buch (1950) on the familial incidence of gastric and duodenal ulcer. A population survey previously carried out gave much greater stability to their results than could have been provided even by careful analysis of a control series of families. Precise knowledge of population data is also necessary for the estimation of gene frequencies, of mutation rates, and of fertility or biological fitness of particular genotypes. Beyond this, it is essential in the study of sex influence, begun by Sedgwick (1861), and of genetical and environmental modifying agencies. Without such data the meaning of consanguinity cannot be assessed (Harris, 1949). From the point of view of future work on the genetics of relatively common conditions like cancer, diabetes, cardiovascular disease, schizophrenia, rheumatism, and so on, the ascertainment of the incidence among the population should, in my view, take precedence. Such a task might naturally be included in a programme of social medicine.

With relatively rare abnormalities the measurement of incidence is equally important. Nothing is so misleading to the geneticist as the exclusive recording in medical literature of noteworthy familial cases, neglecting sporadic or "non-familial" examples, which are usually more characteristic of the conditions concerned. Let me give an example. From time to time cases of mongolism in two sibs—two cousins or other close relatives—are reported in the literature. How do we know whether these instances imply real familial concentration? If cases were distributed at random sooner or later two would occur in the same family. Moreover, since maternal age affects the incidence of mongolism, in that young mothers are much less prone to have such offspring than older mothers, two related cases with maternal ages between, say, 20 and 30 years are much more remarkable (about twenty-five-fold) than two cases with maternal ages over 40 years.

Similar problems arise with most familial studies because in so many diseases the ages of onset are subject to wide variation. Such an example is mammary cancer. Familial cases in females aged 60 or over will often occur even if there is no hereditary influence. The population incidence, ascertainable in mortality statistics at all ages, however, enables a base-line to be drawn for examining the strength of any familial tendency there may be in this condition. It is clear from the case material collected by the Galton Laboratory staff, as well as from that collected at the Royal Cancer Hospital, that relatives of sufferers from mammary cancer are significantly more prone to the same disease than are random members of the general population; such relatives are, however, not more than normally predisposed to develop cancer at other sites (Penrose, MacKenzie, and Karn, 1948).

Summary

To summarize, then, the family history is accepted as an integral part of clinical examination. It should be properly taken and its uses and limitations appreciated. Genetical knowledge has helped treatment directly in the fields of serology and pathological chemistry. It is not likely that harmful genes will be eliminated or even appreciably reduced by eugenical measures, but some guidance can be given to parents in special cases.

Closer contact between geneticists and medical students is desirable if full advantage is to be taken of existing knowledge. Even more important is the assistance that properly directed researches in social and clinical medicine could give to the future development of human genetics. At the present time the most pressing need is the ascertainment of population frequencies of any diseases determined, to a significant degree, by genetical factors. Such ascertainment would enable the analysis of pedigree studies to be put upon a firm basis.

ABSORPTION OF VITAMIN B_{12} IN PERNICIOUS ANAEMIA

I. ORAL ADMINISTRATION WITHOUT A SOURCE OF INTRINSIC FACTOR

BY

C. C. UNGLEY, M.D., F.R.C.P.

Physician, Royal Victoria Infirmary, Newcastle-upon-Tyne

There are many who find difficulty in orientating recent work on vitamin B_{12} with teaching based on Castle's original hypothesis. Following experiments in which beef and gastric juice were fed separately and together to patients with pernicious anaemia, it was suggested that an intrinsic (gastric) factor interacted with an extrinsic (food) factor to produce the anti-pernicious-anaemia factor stored in liver. Efforts to obtain from mixtures of beef and gastric juice a product as heat-stable as the liver active principle were, however, unsuccessful. Moreover, the hypothesis failed to explain why the dosage required for orally administered liver extract so vastly exceeded the amount needed for injection. Even when it was shown that the simultaneous administration of a source of intrinsic factor allowed a greatly reduced oral dose of liver (Reimann and Fritsch, 1934) or liver extract (Fouts, Helmer, and Zerfas, 1935) most of us misinterpreted this to mean that liver contained extrinsic factor in addition to liver active principle.

The problem has been clarified by the behaviour of vitamin B_{12}. This heat-stable substance isolated from liver is effective both in pernicious anaemia (West, 1948) and in subacute combined degeneration of the cord (Berk, Denny-Brown, Finland, and Castle, 1948; Ungley, 1949b). It thus fulfils all the criteria of a true "liver active principle."

When administered orally, however, vitamin B_{12} behaves like Castle's extrinsic factor in that small amounts are effective only if accompanied by a source of intrinsic factor (Berk, Castle, Welch, Heinle, Anker, and Epstein, 1948). In this case at least "extrinsic factor" appears to be identical with "liver active principle," interaction with intrinsic factor being necessary only if the material is given by mouth.

The present work is an attempt (*a*) to determine how effectively vitamin B_{12} is absorbed when given alone or with gastric juice, and (*b*) to answer the question: Does Castle's intrinsic factor directly facilitate the absorption of B_{12} or merely protect it from destruction in the gastro-intestinal tract?

The results are described in consecutive papers, with the following subtitles: I. Oral administration without a source of intrinsic factor. II. Oral administration with normal gastric juice. III. Failure of fresh milk or whey concentrate to function as Castle's intrinsic factor or to potentiate the action of orally administered vitamin B_{12} (with Mr. G. A. Childs). IV. Administration into the buccal cavity, into a washed segment of intestine, or after partial sterilization of the bowel. No. V, on the influence of gastric and intestinal juice on the availability of vitamin B_{12} determined microbiologically (with Dr. W. F. J. Cuthbertson), will be published later.

To facilitate cross-reference, the cases are numbered from 101 in Paper I, 201 in Paper II, and so on.

Methods

Haematological methods, dietary control, and selection of cases have been described (Ungley, 1949a). All patients had pernicious anaemia with megaloblastic marrow and complete achlorhydria even after histamine and alcohol. All showed at least one characteristic reticulocyte response to potent material and ultimately attained complete remission, usually after further treatment with vitamin B_{12} or liver extract. Only relevant parts of the case histories are included.

Dietary histories are summarized because of the possibility—still being explored—that even in pernicious anaemia the chance of a patient responding to orally administered vitamin B_{12} may be greater if low intake as well as deficient absorption had contributed to the development of deficiency; and because deficiency of other dietary factors such as folic acid could interfere with the response to vitamin B_{12} even if the latter were injected parenterally.

Pure vitamin B_{12} was used except in the first period of Case 101, in which vitamin B_{12o} was given, and in five cases receiving 3,000 μg. as concentrate, to be reported fully later.

The time of administration was considered in relation to the phases of digestion and the nature of foods ingested within six hours which might affect the availability of vitamin B_{12} to bacteria or to the host. The large doses of vitamin B_{12} concentrate ($\equiv$3,000 μg.) were given fasting, and no food was ingested until six hours afterwards.

Responses were assessed on the increase of red blood cells in 15 days rather than on the reticulocytosis, although the latter sometimes afforded valuable confirmation. Haemoglobin and packed-cell volume were recorded as a further check. The double reticulocyte response method of Minot and Castle (1935) was used in some cases.

To facilitate comparison and to avoid the need for ambiguous terms such as "good," "maximal," or "optimal" response, the increase of red blood cells in 15 days was expressed as equivalent to the reponse expected from a single injection of so many micrograms of vitamin B_{12} (Ungley, 1949a, Tables II and V). Oral preparations were sometimes given daily, whereas standards for parenteral therapy are based on the response to a single dose. Nevertheless the total amount could be compared with the parenteral dose which would be expected to give the same response (see Table). When subsequent tests showed that the patient's actual responsiveness to injected material was below expectation the oral-dose/injection-dose ratio was corrected accordingly.

Even the "corrected" ratios are very approximate. The expected rise of red blood cells in 15 days from a given dose (between 5 and 80 μg.) of injected material has a standard

deviation of 300,000 per c.mm. The sources of deviation are partly technical and partly individual variations in response. Similar deviations in the observed response to oral therapy—and they might be greater—could produce wide and not necessarily linear variations in the parenteral dose which would be expected to produce an equivalent response. This means that the results of any single experiment can give only a rough indication of the oral-dose/parenteral-dose ratio.

Results

Daily doses of 5 μg. were ineffective in Case 201 (see Paper II).

Daily doses of 80 μg.* had a slight effect in the following case.

Case 101

A woman aged 59 had pernicious anaemia without neurological involvement. The dietary history was satisfactory except that she took no cheese and little milk. After a satisfactory control period of 13 days red blood cells numbered 1,700,000 per c.mm., haemoglobin 6.2 g. per 100 ml., reticulocytes 1%, M.C.V. 128 μ^3, M.C.H. 36.7 $\mu\mu$g., M.C.H.C. 30.3%, white blood cells 2,400 per c.mm. The marrow was megaloblastic.

First and Second Periods.—The daily oral administration of 80 μg. of vitamin B_{12o} (Lester Smith, 1950; Ungley, 1950) led to a reticulocytosis, beginning on the third day and reaching 8.8% on the ninth day, and to a small rise of red blood cells. Substituting pure vitamin B_{12} for vitamin B_{12o} led to a secondary reticulocytosis of 7.2% on the seventh day but no further increase of red blood cells.

	First Period			Second Period			Third Period	
Days:	0	5	10	14	19	24	29	34
R.B.C. (mills./c.mm.)	1·70	1·80	1·92	2·21	1·98	2·14	2·45	3·07
Hb (g./100 ml.) ..	6·2	6·8	7·1	8·0	7·6	8·3	8·9	10·5
P.C.V. %	21·0	—	22·0	23·0	22·5	25·0	28·0	—

In the *third period* 1 μg. of vitamin B_{12} was injected daily. Reticulocytes did not exceed 3%, but red blood cells increased rapidly.

Comment.—The reticulocyte responses in the first and second periods point to some therapeutic effect from orally administered material, although equally definite responses have been observed after single injections of only 2.5 μg. Moreover, the increase in red blood cells in 24 days after a total quantity of 1,920 μg. (Fig. 1) was not significantly greater than would have been expected in 15 days from a single injection of 2.5 μg. (Ungley, 1949a, Table V). In other words, the apparent oral-dose/injection-dose ratio was several hundreds to one. The increase of red blood

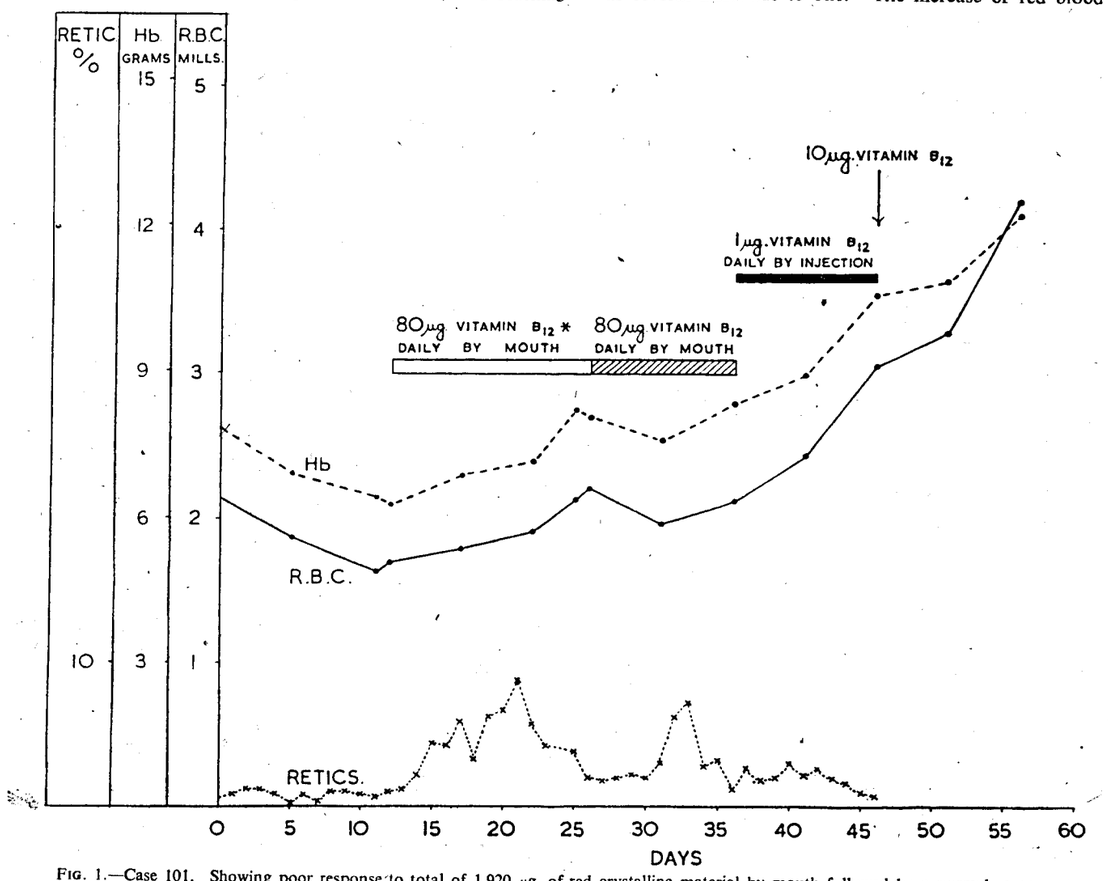

FIG. 1.—Case 101. Showing poor response to total of 1,920 μg. of red crystalline material by mouth followed by a normal response to daily injections of 1 μg.
*The variety of vitamin B_{12} used in the first period was vitamin B_{12o}.

E_0 = Initial erythrocyte count. I_{10} = Increase of erythrocytes in 10 days. I_{15} = Increase of erythrocytes in 15 days.

‖ From chart. † Calculated from I_{10}. ‡ Some of the response may have been due to previous therapy. § These are the calculated equivalents, but the dose-response curve for injected B_{12} has not yet been carried beyond 160 μg. and must flatten out sooner or later. It follows that the amounts of B_{12} actually absorbed may have been greater than those indicated in the table. * Ratios and absorption figures thus marked are uncorrected because the actual response to parenteral therapy was not observed. "Nil" = Response not measurable, but some vitamin B_{12} may have been absorbed.

cells after 10 daily injections of 1 μg. was equivalent to the rise expected from a single dose of 10 μg. Some of this increase may have been due to therapy in the preceding period, but at least there is no suggestion of "resistance" to vitamin B_{12}, and the question of correcting the ratio does not arise.

Five Other Cases

Five patients (Cases 102–106) have recently been given orally a single dose of 3,000 μg. as a concentrate. The cases are the first of a new series, and a full report will be published later. The reticulocyte response was maximal in all, and the increase of red blood cells in 15 days was equivalent to that which would have been expected from single injections of 80 μg., 80 μg., nearly 160 μg., 160 μg., and much over 160 (? 320) μg. The apparent oral-dose/parenteral-dose ratio was between 10 and 40 : 1. The red cell levels reached were so high that comparative tests with parenterally administered vitamin B_{12} were impracticable, but these large responses are perhaps enough to indicate that the patients were not resistant to vitamin B_{12} (see Table).

Indeed, these responses are as great as any observed with injected vitamin B_{12}, which has not been tested in doses over 160 μg. Up to this level there was still a straight-line relationship between mean response and logarithm of dose. Sooner or later the dose-response curve presumably flattens out—i.e., there comes a point beyond which any further increase in dose makes no difference to the rise of red blood cells in 15 days. If 160 μg. is this upper

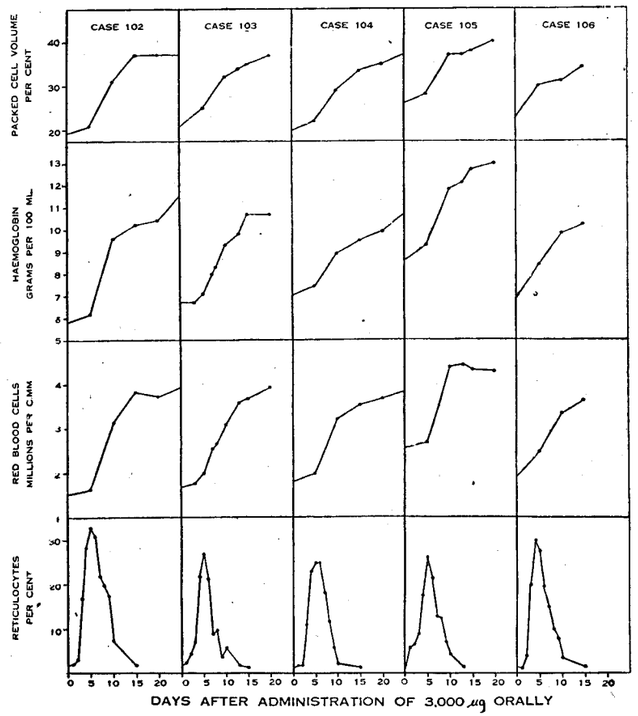

FIG. 2.—Effect in five cases of a single dose of 3,000 μg. of vitamin B_{12} as a concentrate.

limit—and it may vary from case to case—then the figures marked (§) in the Table may be too low.

Discussion

The Table includes results obtained by other workers, whose names will not necessarily be repeated in the text. Daily doses of 5 μg. produced either no response or a small reticulocytosis without rise of red blood cells. In addition to the cases in the Table, Castle (private communication, 1950) has observed 10 others, in six of which there were detectable reticulocyte responses as follows:

Initial R.B.C. in mills./c.mm.	2·25	1·25	1·65	1·60	1·58	1·55
Reticulocytes %	4·3	3·1	14·1	4·0	2·7	11·3

Although not included in the Table, some cases from other sections are worth mentioning here. Negative or trivial responses were observed in two patients receiving daily doses of 10 μg. vitamin B_{12} with fresh milk and in three others given a single or split dose of 50 μg. with whey concentrate (Paper III). A single dose of 80 μg. was ineffective in Case 404 (Paper IV).

In reported cases single doses of 25, 30, 50, 100, 400, and 1,000 μg. gave either negative or trivial results.

In one patient 75 μg. gave a "suboptimal response" and another showed a "maximal reticulocyte response" to 600 μg., but the authors do not give details.

A response to two doses of 800 μg. as concentrate was about equal to the response expected from 20 μg. by injection. The patient, however, was relatively unresponsive to injected vitamin B_{12}—25 μg. gave slightly less than the response expected from 5 μg. Thus the true oral-dose/injection-dose ratio may have been 16 : 1 rather than 80 : 1.

Ten daily doses of 450 μg. were followed by an increase of red blood cells equivalent to that expected from 10 μg. by injection.

An injection of 75 μg. in this patient is said to have given a "similar" response, which if literally true would suggest a response equivalent to 10 μg. Such a degree of unresponsiveness or "resistance" (7.5:1) would reduce the oral-dose/injection-dose ratio from an apparent 450:1 to a possible 60:1, but of course a valid correction cannot be made without fuller information.

In Case 101, given 80 μg. daily, the corrected oral-dose/parenteral-dose ratio was several hundreds to one.

Up to this point one had supposed that the occasional and usually rather poor responses were due to interaction between orally administered vitamin B_{12} and intrinsic factor, traces of which may persist in the gastric juice even in pernicious anaemia (Goldhamer, 1936).

The remarkable responses to a single dose of 3,000 μg. in five recent cases cannot easily be explained on this basis. The patients appear to have effectively absorbed amounts ranging from 80 to 160 μg. or possibly more. From results reported in Paper II it seems that at least 500 ml. of *normal* gastric juice is needed to ensure an adequate haemopoietic response from even 50 to 80 μg. of orally administered vitamin B_{12}. The equivalent volume in terms of pernicious anaemia gastric juice, even supposing traces of intrinsic factor to persist, would be enormous and far beyond the secretory capacity of the atrophic stomach. It would be surprising indeed if a patient with pernicious anaemia secreted enough intrinsic factor to combine with more than one or two micrograms, however large the dose.

These findings suggest that some vitamin B_{12} *can* be absorbed—not efficiently perhaps, but in quite considerable amounts if the dose is large enough—without first combining with the intrinsic factor.

Further speculation seems unjustified, since we do not yet know whether Castle's intrinsic factor combines stochiometrically with vitamin B_{12} or whether it acts as a catalyst. It will be interesting to determine whether a single large dose of vitamin B_{12} administered orally is more or less effective than the same amount of material given in divided doses.

Summary and Conclusions

The absorption of vitamin B_{12} was studied by comparing the effective oral dose with the parenteral dose expected to produce a similar increase of red blood cells in 15 days. The apparent oral-dose/parenteral-dose ratio was corrected if the observed response to injected material was below expectation, indicating a relative resistance to vitamin B_{12}.

In one case daily doses of 5 μg. gave no response. In another, even 80 μg. a day for 24 days produced an increase in red blood cells no greater than would have been expected in 15 days from the injection of 2.5 μg. The response to injected material was normal, so that the corrected oral-dose/parenteral-dose ratio was several hundreds to one. By contrast the oral-dose/parenteral-dose ratio in five cases given a single dose of 3,000 μg. was from 20 to 40 : 1, the increase of red blood cells in 15 days being so great as to suggest the absorption of 80 to 160 μg. or even more. Presumably very little of the vitamin absorbed can have interacted with Castle's intrinsic factor, considering the low quality and quantity of the secretion of the stomach in pernicious anaemia.

Further tests are necessary to determine whether in fact more vitamin B_{12} is absorbed after a single large dose than after the same quantity of material given in divided doses daily.

II. ORAL ADMINISTRATION WITH NORMAL GASTRIC JUICE

BY

C. C. UNGLEY, M.D., F.R.C.P.

Physician, Royal Victoria Infirmary, Newcastle-upon-Tyne

In the preceding paper it was shown that vitamin B_{12} administered orally without a source of intrinsic factor was not efficiently absorbed, although remarkable effects could be obtained with an enormous single dose. The present study attempts to answer two questions: How effectively is vitamin B_{12} absorbed when given with gastric juice? How much gastric juice is needed per microgram of vitamin B_{12}?

Methods

A general account of methods is given in Paper I. Normal human gastric juice was obtained almost entirely from students in response to two injections of 0.5 mg. of histamine at intervals of 30 minutes. Specimens without free HCl and those containing more than a trace of bile were discarded. After filtering through nainsook to remove mucus and debris, the juice was pooled and kept at approximately 5° C. The period of storage did not exceed three days, except in Case 404 (Paper IV), in which the juice had been stored 14 days.

The highly acid juice (*p*H 1 approx.) was neutralized to *p*H 7 with a predetermined quantity of N/1 NaOH. Vitamin B_{12} was then added. In Cases 201, 202, 401, and 402 the mixture was given within two hours, while in Cases 303, 304, 305, and 404 the interval was prolonged to six hours. The mixture was incubated for one hour in Case 304, but not in others. Food was withheld for four hours before and after the mixture. In Cases 303, 304, and 305 the intervals were prolonged to eight hours.

The gastric juice used for the second period of Case 201 was passed through a Seitz filter while still acid. As the Seitz-filtered juice was inactive this procedure was not used again.

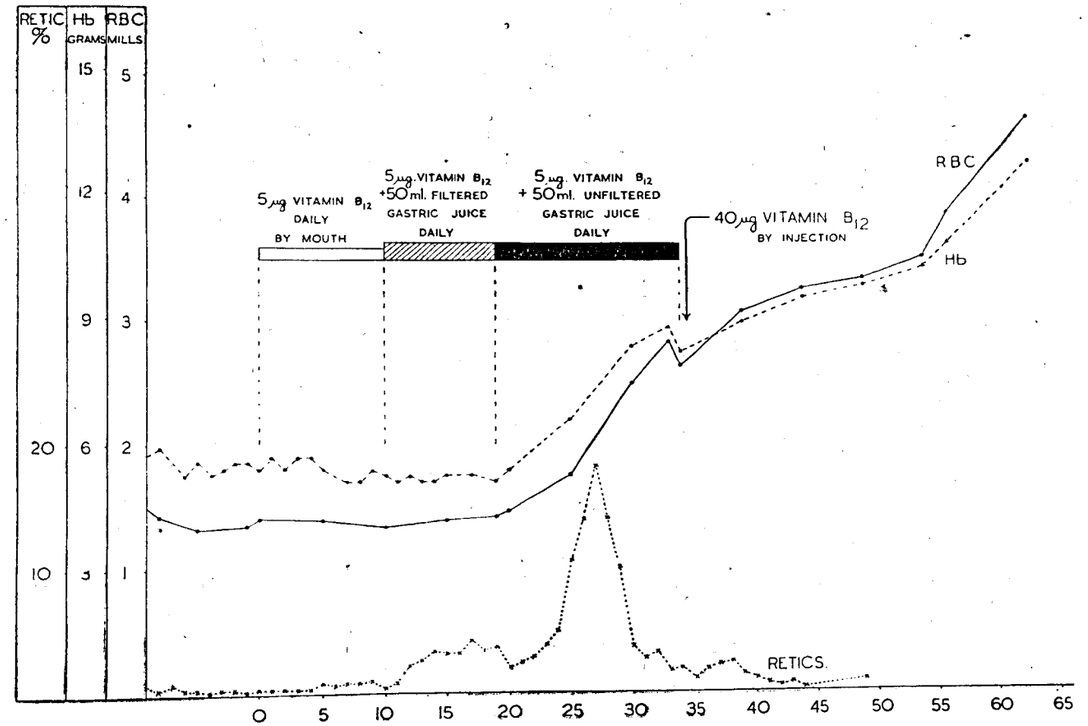

FIG. 1.—Case 201. Showing that 5 μg. of vitamin B_{12} was ineffective when given alone or with gastric juice which had been Seitz-filtered, but produced a good response when given with unfiltered gastric juice.

Results

Eight patients were treated with vitamin B_{12} and normal human gastric juice.

Case 201

A miner aged 58 had pernicious anaemia without neurological involvement. Having recently lost his teeth, he ate little meat, but otherwise his diet was satisfactory.

After 10 days' control period, during which reticulocytes remained less than 1%, the red blood cells numbered 1,400,000 per c.mm., with haemoglobin 5.3 g. per 100 ml., reticulocytes 0.4%, M.C.V. 130.6 μ^3, M.C.H. 38.2 $\mu\mu$g., M.C.H.C. 31.3%, white blood cells 1,700 per c.mm. The marrow was megaloblastic.

In the first period 5 μg. of vitamin B_{12} was given daily by mouth. There was neither reticulocytosis nor increase of red blood cells (Fig. 1).

	First Period			Second Period	
Days:	0	5	10	15	19
R.B.C. (mills./c.mm.)	1·40	1·38	1·33	1·39	1·41
Hb (g./100 ml.)	5·3	5·3	5·2	5·2	5·0
P.C.V. (%)	17·5	18·6	17·0	—	—

In the second period the same amount of vitamin B_{12} was mixed with 50 ml. of normal gastric juice neutralized just before administration. Before neutralization the gastric juice had been passed through a Seitz filter. Reticulocytes rose to only 4.2% on the seventh day and red cells did not increase.

In the third period the same amounts of vitamin B_{12} and gastric juice were administered, but this time the gastric juice was *not* Seitz-filtered. Reticulocytes rose on the fourth day and reached 18.2% on the eighth day. There was subjective improvement and red cells increased.

	Third Period			Fourth Period			
Days:	0	6	11	15	20	25	30
R.B.C. (mills./c.mm.)	1·41	1·75	2·48	2·63	3·09	3·28	3·36
Hb (g./100 ml.)	5·0	6·5	8·3	8·1	8·9	9·5	9·8
P.C.V. (%)	—	21·0	27·0	28·0	33·0	33·0	35·0

In the fourth period an injection of 40 μg. of vitamin B_{12} led to a negligible reticulocytosis of 2.4% on the fourth day. Red blood cells continued to increase.

Comment.—The daily oral administration of 5 μg. of vitamin B_{12} alone or with Seitz-filtered gastric juice was ineffective. The same quantity with unfiltered gastric juice was effective. The increase of erythrocytes in 15 days after giving a total of 75 μg. with unfiltered gastric juice was equivalent to the response expected from an injection of 10 μg. In fact, however, the patient was relatively "resistant" to injected material in that the increase of red blood cells after 40 μg. was slightly less than that expected from 5 μg. Even then some of the increase may have been due to previous therapy. Correction for this resistance reduces the oral-dose/parenteral-dose ratio from an apparent 7.5 : 1 to the region of unity.

Case 202.—Administration of 50 μg. Vitamin B_{12} with 500 ml. of Gastric Juice by Stomach Tube

A woman aged 63 had pernicious anaemia with sore smooth tongue and minor neurological involvement. The dietary history was normal.

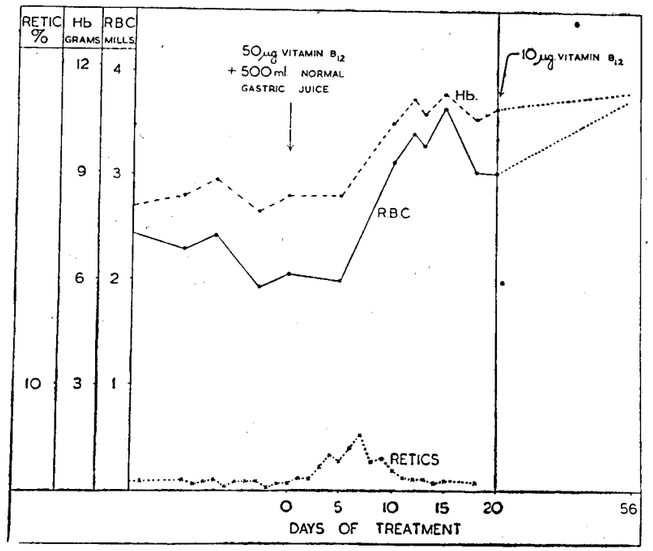

FIG. 2.—Case 202. Response to single dose of 50 μg. of vitamin B_{12} with 500 ml. of normal gastric juice given by stomach tube.

After a satisfactory control period of several weeks the red blood cells numbered 2,050,000 per c.mm., with haemoglobin 8.3 g. per 100 ml., M.C.H., 40.4 $\mu\mu$g., M.C.V. 127 μ^3, M.C.H.C. 31.9%, reticulocytes 0.6%, and white blood cells 4,400 per c.mm.

A single dose of 500 ml. of pooled normal gastric juice was neutralized and mixed with 50 μg. of vitamin B_{12} just before administration by stomach tube. Reticulocytes began to rise on the fourth day, reaching 5.2% on the seventh day (Fig. 2).

Red blood cells increased rapidly, sore tongue was relieved, appetite and well-being were restored. These effects lasted fully 15 days, but by the twentieth day the tongue was again sore and the counts were beginning to fall. Injections of vitamin B_{12} subsequently brought about complete remission.

Days:	0	5	10	15	20
R.B.C. (mills./c.mm.)	2·05	1·99	3·13	3·66	3·02
Hb (g./100 ml.)	8·3	8·3	10·4	11·3	10·8
P.C.V. (%)	26·0	27·0	35·0	37·0	31·5

Comment.—The increase of red blood cells in 15 days slightly exceeded the response expected from an injection of 40 μg. Because of this excellent result there can be no doubt about the patient's responsiveness to vitamin B_{12}, even though the actual effect of injection was not measured. Thus the apparent oral-dose/parenteral-dose ratio of near unity needs no correction for "resistance" to vitamin B_{12}.

Remaining Six Cases

These six cases are described in Papers III and IV. Case 401 was given 5 μg. daily with 50 ml. of gastric juice. Case 402 received 40 μg. with 150 ml. of gastric juice. Case 404 received 80 μg. with 500 ml. Cases 303, 304, and 305 received 50 μg. and 500 ml. of gastric juice after a preliminary trial of milk or whey as a source of intrinsic factor.

The findings in the eight patients are summarized in the accompanying Table along with other published cases.

Discussion

Differences in dietary control and in the source, filtration, storage, and time of administration of the gastric juice may account for some of the variation in the results observed (see Hall, Morgan, and Campbell, 1949).

In the first period of treatment in three of the cases described by Berk, Castle, Welch, Heinle, Anker, and Epstein (1948), vitamin B_{12} and gastric juice were given twelve hours apart and there was no haemopoietic effect.

Vitamin B_{12} given two hours before the gastric juice was effective in one case (Hall, Morgan, and Campbell, 1949). In all other cases cited in the Table the gastric juice and vitamin B_{12} were given simultaneously.

In the cases of Berk *et al.* and in mine, the diet was restricted and no food was given four hours before or after the administration of gastric juice mixtures. In the cases of Hall *et al.* the mixtures were given only one hour before the morning meal and the patients were allowed meat and eggs later in the day. Thus the effects attributed to gastric juice and vitamin B_{12} may have been partly due to the interaction of gastric juice with other extrinsic factor(s) in food.

* From graph. † Ratios and absorption figures marked † are uncorrected, because the actual response to parenteral therapy was not observed.

Except in one patient (Case 404) who received juice stored for 14 days, the juice was either fresh or not more than three days old. Other workers have used pooled gastric juice which may have been stored. Campbell, Hall, and Morgan (1949) state that the intrinsic factor in gastric juice is not destroyed by storage at 5° C. for three months, but did not indicate whether there is a lessening of activity.

Hall *et al.* (1949) found that Berkefeld-filtered gastric juice was active in a proportion of 150 ml. per 5 μg. of vitamin B_{12}, but comparisons with unfiltered gastric juice are not mentioned. In our Case 201 Seitz filtration of gastric juice apparently led to loss of all or most of its intrinsic factor activity.

How Efficiently is Vitamin B_{12} Absorbed When Given Orally With Gastric Juice?

It is obvious from the Table that the results are very variable. In four out of eight of my patients the effect of vitamin B_{12} given orally with gastric juice was about as effective as if the same dose of vitamin had been injected into these patients. In two others the corrected oral-dose/parenteral-dose ratio was about 10 : 1. In one case oral therapy failed completely, and in another the amount of gastric juice was too small.

Calculations similar to those used for my cases can be applied to the first three cases reported by Berk *et al.* (1948). These patients received 5 μg. of vitamin B_{12} with 150 ml. of normal gastric juice daily for 10 days. The increase in red blood cells in 10 days was approximately equivalent to that which would have been expected from single injections of 10, 5, and 5 μg. In other words, the amounts of vitamin B_{12} given orally with gastric juice were approximately 5, 10, and 10 times as great as would probably have been needed to produce a similar response with injected material. This is assuming that the patients of Berk *et al.* would have been normally responsive to injected vitamin B_{12}. Their fourth case is excluded from discussion because of the poor response not only to orally but to parenterally administered material.

In one of Hall, Morgan, and Campbell's cases the increase of red blood cells in 15 days after a total of 75 μg. with gastric juice was less than would be expected from 5 μg. by injection. In another case the response to a total of 75 μg. with gastric juice was slightly less than would have been expected from 20 μg. by injection. The apparent oral-dose/injection-dose ratios were approximately 15 and 3.75, but the actual responsiveness of these patients to injected material was not determined.

Some of the factors which may have contributed to the difference in the results obtained by the three observers have already been discussed.

How Much Juice is Needed?

This can roughly be estimated from (*a*) the total amount of gastric juice given, and (*b*) the amount of vitamin B_{12} absorbed (judging this by the haemopoietic response and correcting for "resistance," if any).

In the cases of Berk *et al.* (1948) and Hall *et al.* (1949) a correction for responsiveness to injected vitamin B_{12} was possible in only one instance. So far as one can judge from the uncorrected oral-dose/parenteral-dose ratio each 100 ml. of gastric juice seems to have been enough for the absorption of only 1 μg. or less. In all their patients and in the first two of mine the material was given daily and not as a single dose.

In Case 401 a total of 50 μg. was adequately absorbed when administered with a total of 500 ml. of gastric juice. In other words, each 100 ml. was enough for the absorption of 10 μg. Similar calculations for all my cases in the Table suggest that 100 ml. of gastric juice was enough for the absorption of the following amounts of vitamin B_{12} (μg.): 10, 10, 10, *nil*, 5 or 10, 1, less than 2, less than 1.

It is interesting to compare these figures with those of Ternberg and Eakin (1949) for the vitamin B_{12}-binding power of samples of normal gastric juice, which were: 2, 6 (pooled sample from at least three subjects), 6, and 1.5 μg. per 100 ml. of gastric juice.

It will be even more interesting, in the future, to measure microbiologically in this way the activity of samples of gastric juice which are to be clinically tested for their power to promote absorption of vitamin B_{12} in pernicious anaemia.

Summary and Conclusions

The effect of vitamin B_{12} given with normal gastric juice was observed in eight patients with pernicious anaemia. The total amounts were usually 50 μg. + 500 ml. given as a single dose or in divided doses.

One patient failed to respond to oral therapy. In one who received 40 μg. with only 150 ml. of gastric juice the response was very poor. In two the oral-dose/parenteral-dose ratio was about 10:1, suggesting that about 10% of the vitamin had been absorbed. In the remaining four the response was about as good as would have been expected if the same dose of vitamin B_{12} had been injected. Thus small doses of vitamin B_{12} given with normal gastric juice are *sometimes* efficiently absorbed.

In these eight experiments each 100 ml. of gastric juice seemed to be enough for the absorption of 0, less than 1, 1, less than 2, 5 or 10, 10, 10, and 10 μg. of vitamin B_{12}. Thus the amount of gastric juice necessary to promote the absorption of a given amount of B_{12} varied considerably. These variations are perhaps only partly due to differences in the amount of intrinsic factor in the samples of gastric juice; differences in the recipients may have been equally important.

III. FAILURE OF FRESH MILK OR CONCENTRATED WHEY TO FUNCTION AS CASTLE'S INTRINSIC FACTOR OR TO POTENTIATE THE ACTION OF ORALLY ADMINISTERED VITAMIN B_{12}

BY

C. C. UNGLEY, M.D., F.R.C.P.

Physician, Royal Victoria Infirmary, Newcastle-upon-Tyne

With the assistance of

G. A. CHILDS

Chemist, Research Division, Glaxo Laboratories, Greenford, Middlesex

In another paper we have confirmed the findings of Ternberg and Eakin (1949) that normal gastric juice combines with vitamin B_{12} and renders it unavailable to certain bacteria (Ungley and Cuthbertson, 1950: Paper V of this series, to be published).

The possibility that milk might have similar properties has been investigated. For this purpose microbiological tests proved useless, milk being an unsatisfactory material for the microbiological assay of vitamin B_{12}. Nevertheless, exploratory clinical tests have been made to determine whether milk would be effective as a source of Castle's intrinsic factor.

Methods

A general account of methods is given in Paper I.

For the first two tests fresh cow's milk was cooled quickly immediately after milking and kept in a vacuum flask for not more than four hours before administration.

For the first whey concentrate 7.5 litres of skimmed milk was treated at 37° C. with 455 ml. of diluted acetic acid to *p*H 4.5. The casein was filtered off to yield 6,800 ml. of crude whey. The whey was concentrated at *p*H 6.5 to 790 ml. and dialysed against distilled water overnight at 4° C. to eliminate salts and some of the lactose. During dialysis a precipitate composed mainly of lactose and lactoglobulin came down. This precipitate was combined with the concentrated supernatant fluid to make a total volume of approximately 650 ml., representing 7 litres of milk.

The second whey concentrate was prepared from 22 litres of milk. The casein was removed and the whey evaporated to small bulk at low temperature. This concentrated whey was then dialysed to remove most of the lactose.

Results

Two patients received fresh milk and three cases were given whey concentrates, in each case with added vitamin B_{12}.

Case 301

A woman aged 58 had pernicious anaemia with minor neurological involvement. The dietary history was normal. In a control period of 14 days, during which reticulocytes did not exceed 3.4%, the red blood cells fell from 1,610,000 to 1,070,000 per c.mm. After transfusion the count rose to 2,300,000 per c.mm. (Fig. 1). After a further control period of 13 days during which reticulocytes did not exceed 1.6%, the red blood cells numbered 1,480,000 per c.mm., haemoglobin 5.6 g. per 100 ml., reticulocytes 1%, M.C.V. 131.7 μ^3, M.C.H. 37.9 $\mu\mu$g., M.C.H.C. 28.2%, white blood cells 2,800 per c.mm. The marrow was megaloblastic.

In the first period she was given daily 500 ml. of preserved fresh milk to which 10 μg. of vitamin B_{12} was added before administration. There was a slight reticulocytosis, reaching 3% on the eighth and ninth days with little change in the anaemia.

In the second period she received daily 500 ml. of preserved fresh milk to which 100 μg. of folic acid was added before administration. There was no second reticulocyte response, but the anaemia improved.

Days :	First Period 0	5	10	Second Period 15	20	35
R.B.C. (mills./c.mm.)	1·48	1·54	1·62	2·39	3·03	3·23
Hb (g./100 ml.) ..	5·6	6·2	6·7	8·4	9·3	9·9
P.C.V. (%)	19·5	21·0	22·5	31·0	35·0	34·5

In the third period treatment reverted to the daily administration of 500 ml. of preserved fresh milk plus 10 μg. of vitamin B_{12}. The anaemia continued to improve.

Days :	Third Period 0	5	10	15
R.B.C. (mills./c.mm.)	3·16	4·00	4·24	4·26
Hb (g./100 ml.) ..	9·8	11·1	11·8	11·8
P.C.V. (%)	34·5	36·0	40·0	40·0

Comment.—The slight reticulocytosis in the first period might equally well have occurred from the daily oral administration of 10 μg. of vitamin B_{12} alone, without the milk. In the absence of any further reticulocyte response the improvement in the second and third periods cannot safely be attributed to treatment. Spontaneous remission is a distinct probability.

Case 302

A retired labourer aged 65 had pernicious anaemia without neurological involvement. The dietary history was normal.

After a control period of five days, during which the reticulocytes did not exceed 1%, the red blood cells numbered 2,010,000 per c.mm., haemoglobin 7.8 g. per 100 ml., reticulocytes 0.6%, M.C.V. 111.9 μ^3, M.C.H. 39.1 $\mu\mu$g., M.C.H.C. 34.7%, white blood cells 5,100 per c.mm. The marrow was megaloblastic.

In the first period he was given daily for 15 days 500 ml. of preserved fresh milk to which 10 μg. of vitamin B_{12} was added before administration. There was a slight reticulocytosis reaching 4.6% on the seventh day, but no increase of red blood cells (Fig. 2).

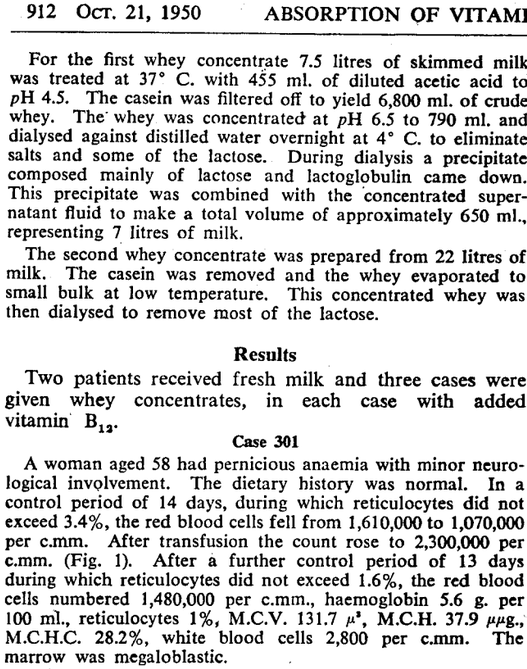

FIG. 1.—Case 301. Showing a fairly continuous increase in red blood cells during treatment, with only a slight reticulocytosis. This may have been a spontaneous remission.

Days :	First Period 0	5	10	15
R.B.C. (mills./c.mm.)	2·01	1·86	1·78	1·93
Hb (g./100 ml.) ..	7·8	7·0	6·5	7·0
P.C.V. (%)	22·5	22·0	22·5	22·5

In the second period 1 μg. of vitamin B_{12} daily was given parenterally for 15 days. There was a second reticulocytosis of 4.6% on the eighth day, followed by subjective improvement and some increase in red blood cells.

Days :	Second Period 0	5	10	15	Third Period 20	25	30
R.B.C. (mills./c.mm.)	1·93	2·18	2·31	2·33	2·87	3·28	3·36
Hb (g./100 ml.) ..	7·0	8·0	8·9	9·3	10·7	11·3	11·7
P.C.V. (%)	22·5	24·0	28·0	29·0	33·0	34·0	36·0

In the third period 0.8 μg. of vitamin B_{12} plus 100 μg. of folic acid daily was given for 15 days. There was no reticulocytosis. The red blood cells continued to increase.

Comment.—In this case fresh milk was clearly not a satisfactory source of Castle's intrinsic factor. The reticulocyte response of 4.6% was no greater than might have been expected from the vitamin B_{12} alone, and there was no increase of red blood cells in 15 days.

The remaining cases were given whey concentrate instead of fresh milk.

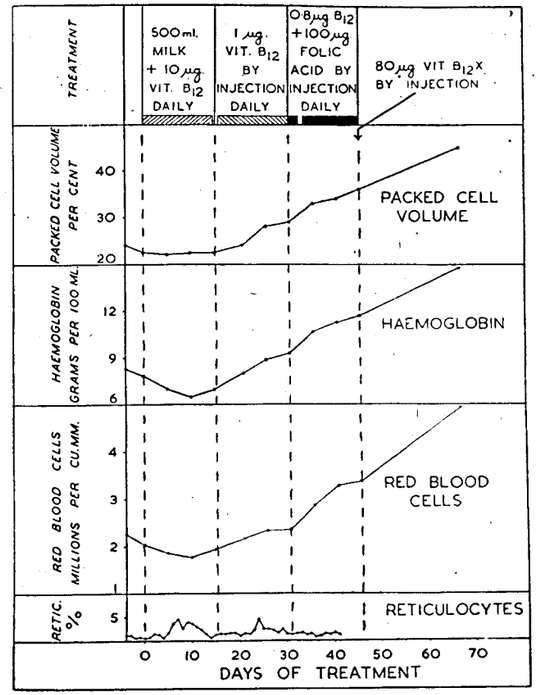

FIG. 2.—Case 302. The administration of milk and vitamin B_{12} produced only a small reticulocytosis without rise of red blood cells. Following the daily injection of 1 μg. vitamin B_{12} there was a secondary reticulocytosis, but the increase of red blood cells was below expectation. There was no further reticulocytosis when part of the vitamin B_{12} was replaced by folic acid.

Case 303

A housewife aged 73 had pernicious anaemia without neurological involvement. She ate little meat or cheese, and no eggs or tomatoes.

After a control period of 12 days, during which the reticulocytes did not exceed 3.8%, the red blood cells numbered 2,270,000 per c.mm., haemoglobin 8.6 g. per 100 ml., reticulocytes 1%, M.C.V., 121.1 μ^3, M.C.H. 37.9 $\mu\mu$g., M.C.H.C. 31.2%, white blood cells 5,100 per c.mm. The marrow was megaloblastic.

In the first period she received a whey concentrate derived from 7 litres of milk to which was added 50 μg. of vitamin B_{12}. The mixture stood at room temperature for seven hours and was then given by stomach tube approximately eight hours after the last meal and eight hours before breakfast. There was a slight variable reticulocytosis of 2.6% on the seventh day and some improvement in the anaemia (Fig. 3). The marrow remained megaloblastic.

Days :	First Period 0	5	10	15	Second Period 16	21	26	31
R.B.C. (mills./c.mm.)	2·27	2·36	2·92	2·51	2·55	2·45	2·61	2·44
Hb (g./100 ml.)	8·6	9·3	10·8	10·5	10·8	10·4	10·4	10·4
P.C.V. (%)	27·5	28·0	36·0	34·5	35·0	35·0	36·0	35·0

In the second period she received 500 ml. of normal gastric juice with 50 μg. of vitamin B_{12}; the mixture was left at room temperature for seven and a half hours and given by stomach tube in the same manner as before. There was no reticulocytosis and no rise of red blood cells in 15 days; after 12 days

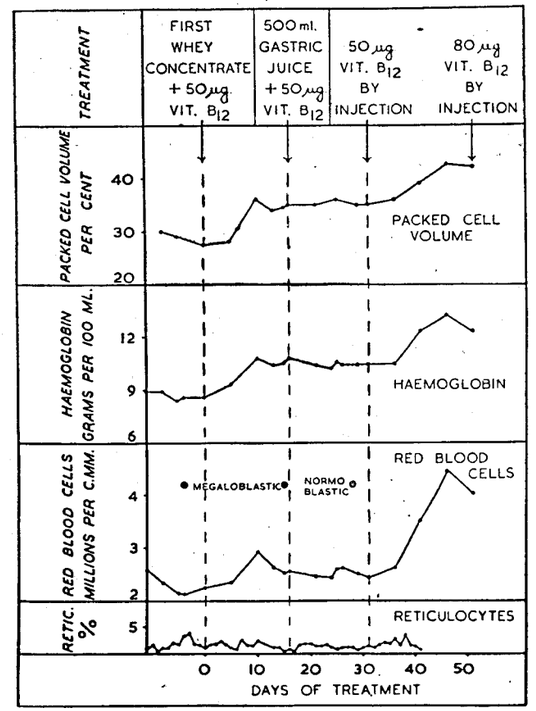

FIG. 3.—Case 303. In the control period there was a small spontaneous reticulocytosis without a rise of red blood cells. Following the administration of the whey concentrate with vitamin B_{12} there was a transient increase of red blood cells but no reticulocytosis, and the marrow remained megaloblastic. Vitamin B_{12} with gastric juice had no effect on reticulocytes or red blood cells, but the marrow became normoblastic. The response to an injection of 50 μg. of vitamin B_{12} was better than expectation.

the marrow picture was predominantly normoblastic and macronormoblastic.

In the third period 50 μg. of vitamin B_{12} was given parenterally. A slight reticulocytosis of 3.4% on the seventh day was followed by a good increase in red blood cells.

Days :	Third Period 0	5	10	15
R.B.C. (mills./c.mm.)	2·44	2·61	3·50	4·41
Hb (g./100 ml.) ..	10·4	10·4	12·3	13·2
P.C.V. (%)	35·0	36·0	39·0	42·5

Comment.—The result in the first period, when whey concentrate was given as a possible source of Castle's intrinsic factor, was probably negative, the response being no greater than might be expected from the vitamin B_{12} alone, but for some reason the patient did not respond to B_{12} and gastric juice. She was not "resistant" to vitamin B_{12}, for the increase in red blood cells after an injection of 50 μg. was greater than would be expected from an injection of 80 μg.

Case 304

A housewife aged 67 had pernicious anaemia with minor neurological involvement. She ate very little meat or vegetables.

After a control period of 11 days, during which the reticulocytes did not exceed 1.2%, the red blood cells numbered 2,460,000 per c.mm., haemoglobin 8.9 g. per 100 ml., reticulocytes 1%, M.C.V. 118 μ^3, M.C.H. 36.1 $\mu\mu$g., M.C.H.C. 30.6%,

white blood cells 3,700 per c.mm. Sternal marrow showed megaloblastic erythropoiesis.

In the first period she received the second whey concentrate derived from 3 litres of milk which was incubated for one hour with 50 μg. of vitamin B_{12} and given by stomach tube approximately eight hours after the last meal and eight hours before breakfast. In 10 days there was neither reticulocytosis nor rise of red blood cells (Fig. 4).

	First Period		
Days :	0	5	10
R.B.C. (mil'ns./c.mm.)	2·46	2·34	2·21
Hb (g./100 ml.)	8·9	9·3	8·9
P.C.V. (%)	29·0	28·0	27·0

In the second period she was given 500 ml. of normal gastric juice which was neutralized, incubated for one hour with 50 μg. of vitamin B_{12}, kept at 5° C. for seven and a half hours, and given by stomach tube in the same manner as before. Reticulocytes rose to 7.8% on the sixth day and the red blood cells increased.

	Second Period				Third Period		
Days :	0	5	10	15	20	25	30
R.B.C. (mills./c.mm.)	2·25	2·34	2·73	2·84	3·05	3·79	3·47
Hb (g./100 ml.) ..	8·7	8·9	10·4	9·9	10·8	12·1	11·1
P.C.V. (%)	27·0	27·0	33·0	29·0	32·0	36·0	36·0

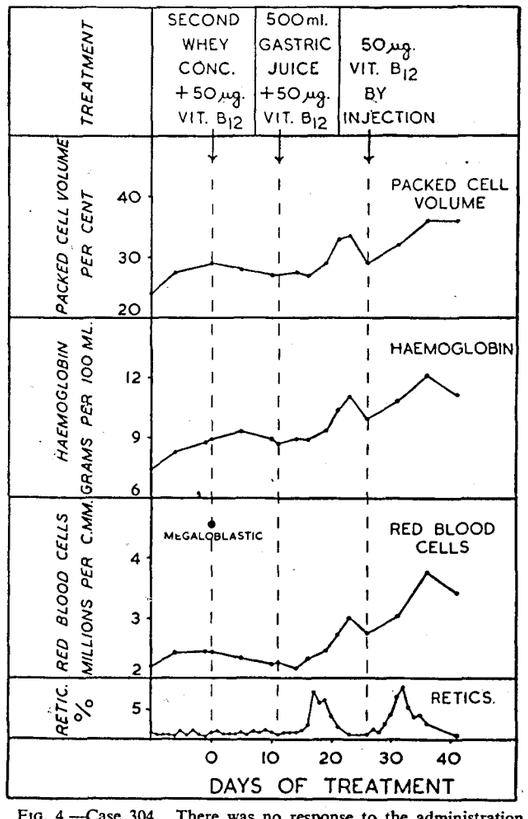

FIG. 4.—Case 304. There was no response to the administration of a whey concentrate and vitamin B_{12}. The response to 50 μg. of vitamin B_{12} with gastric juice was less than that which would be expected from an injection of 5 μg. The response to 50 μg. of vitamin B_{12} by injection was below expectation.

In the third period 50 μg. of vitamin B_{12} was administered parenterally. There was a second reticulocytosis of 8.6% on the sixth day and the red blood cells increased.

Comment.—The result in the first period when whey concentrate was given was completely negative. The rise of red blood cells after giving 50 μg. of vitamin B_{12} and 500 ml. of gastric juice was less than that expected from an injection of 5 μg. The response from the injected dose of 50 μg. was also slightly less than that expected from an injection of 5 μg. Thus the oral-dose/parenteral-dose ratio was probably 1 or 2 : 1.

Case 305

A woman aged 60 had pernicious anaemia with minor neurological involvement. She ate little meat, eggs, fish, cheese, or fruit, but plenty of milk, cereals, and vegetables.

After a control period of nine days, during which the reticulocytes did not exceed 1.6%, the red blood cells numbered 1,810,000 per c.mm., haemoglobin 6.5 g. per 100 ml., reticulocytes 0.6%, M.C.V. 116 μ^3, M.C.H. 32.8 $\mu\mu$g., M.C.H.C. 31%, white blood cells 4,000 per c.mm. The marrow was megaloblastic.

In the first period she was given on two successive nights 575 ml. of the second whey concentrate derived from 3 litres of milk which was incubated for one hour with 25 μg. of vitamin B_{12} and given by stomach tube approximately eight hours after the last meal and eight hours before breakfast. There was a slight reticulocytosis of 4.6% on the sixth day (Fig. 5). The red blood cells had increased at the tenth day.

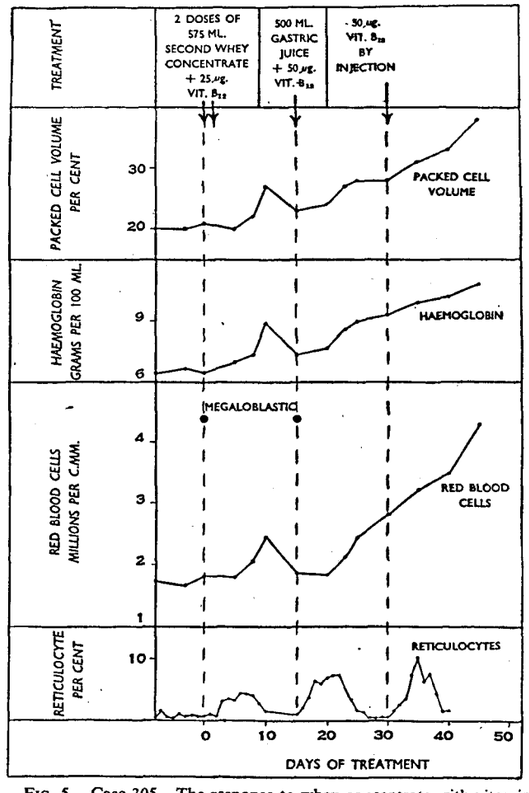

FIG. 5.—Case 305. The response to whey concentrate with vitamin B_{12} was poor and no greater than might have been obtained by giving the vitamin B_{12} by mouth alone. The response to 50 μg. of vitamin B_{12} given with gastric juice was equivalent to that which would have been expected from an injection of 5 μg. The response to an injection of 50 μg. of vitamin B_{12} was up to expectation.

but by the fifteenth were back to their former level. The marrow was still megaloblastic.

	First Period			
Days :	0	5	10	15
R.B.C. (mills./c.mm.) ..	1·81	1·80	2·46	1·88
Hb (g./100 ml.) ..	6·5	7·0	8·9	7·4
P.C.V. (%)	21·0	20·0	27·0	23·0

In the second period she received a single dose of 500 ml. of normal gastric juice which was neutralized, incubated for one hour with 50 μg. of vitamin B_{12}, kept at 5° C. for seven hours, and given by stomach tube eight hours after the last meal and eight hours before breakfast. Reticulocytes rose to a second peak of 7.4% on the sixth and seventh days, and this time the improvement in the anaemia was sustained.

	Second Period				Third Period		
Days :	0	5	10	15	20	25	30
R.B.C. (mills./c.mm.)	1·88	1·86	2·46	2·83	3·21	3·50	4·32
Hb (g./100 ml.) ..	7·4	7·7	9·0	9·3	9·9	10·2	10·8
P.C.V. (%)	23·0	24·0	28·0	28·0	31·0	33·0	38·0

In the third period 50 μg. of vitamin B_{12} was given parenterally. Reticulocytes rose to 10.2% on the fifth day. Improvement in the anaemia was accelerated.

Comment.—The result with the whey concentrate plus vitamin B_{12} was regarded as negative as there was only a slight reticulocytosis of 4.6% with no rise of red blood cells in 15 days—that is, a very slight response which might well have occurred from the oral administration of similar doses of vitamin B_{12} without the whey concentrate. In the second period the rise in red blood cells after giving 50 μg. of vitamin B_{12} plus 500 ml. of gastric juice was equivalent to that expected from an injection of 5 μg. In the third period the response to the injected dose of 50 μg. was greater than expected. The patient therefore was not "resistant," and the oral-dose/parenteral-dose ratio was probably about 10 : 1.

Conclusions

Neither fresh milk nor a whey concentrate in the doses given was an adequate substitute for normal human gastric juice as a source of Castle's intrinsic factor.

IV. ADMINISTRATION INTO BUCCAL CAVITY, INTO WASHED SEGMENT OF INTESTINE, OR AFTER PARTIAL STERILIZATION OF BOWEL

BY

C. C. UNGLEY, M.D., F.R.C.P.

Physician, Royal Victoria Infirmary, Newcastle-upon-Tyne

The object of these experiments was to determine whether vitamin B_{12} even without intrinsic factor would be efficiently absorbed if destruction by intestinal contents could be avoided or reduced. This was attempted in three ways: (1) by the application of vitamin B_{12} to the buccal mucosa; (2) by instillation into a washed segment of the intestine; and (3) by the oral administration of vitamin B_{12} after preliminary partial sterilization of the gut.

Methods

A general account of methods is given in Paper I.

For *buccal administration*, vitamin B_{12} was applied daily to the floor of the mouth in the sulcus between the alveolar margin and the cheek. Over a period of 30 minutes a solution containing 5.5 μg. was added gradually by syringe to a pledget of cotton-wool lying on the mucous membrane which formed the base of an artificial cavity created by a dental appliance, designed to prevent leakage from the sulcus. For the next 30 minutes water alone was added. Afterwards the cotton-wool pledgets were stored for microbiological assay by Dr. W. F. J. Cuthbertson, 10 pledgets yielding 8 μg. of vitamin B_{12}.

There were four experiments in which B_{12} with or without gastric juice was *instilled into a washed segment of intestine*. In Case 402 a Miller–Abbott tube with two balloons was passed until *x*-ray examination confirmed that the end was in the small intestine. The balloons were inflated, and the intervening section of intestine was washed out with normal saline until the washings were clear. Then a solution of 40 μg. of vitamin B_{12} in 10 ml. of water was instilled, followed by water to wash through the tube. After one hour the remaining material was aspirated and the segment washed out again. A sample of the aspirate contained 0.5 μg. of vitamin B_{12} per ml.

In the second period the Miller–Abbott tube was again passed into the small intestine and the balloons were inflated as before. After washing out, the segment between the balloons was filled with 150 ml. of Seitz-filtered normal gastric juice mixed with 40 μg. of vitamin B_{12}.

In Case 403 in the first period a Miller–Abbott tube with two balloons attached 15 cm. apart was passed as in Case 402 until the end was well down the small intestine. The balloons were inflated and the intervening section of intestine was washed out with 200 ml. of normal saline until the washings were almost clear. Then 80 μg. of vitamin B_{12} in 10 ml. of normal saline was instilled, followed by 30 ml. of saline to wash through the tube (approximately 10 ml. would remain in the tube). After two hours the material remaining in the segment of intestine was aspirated, and the segment was washed again. The aspirate contained 0.45 μg. of vitamin B_{12} per ml.

In the second period a Miller–Abbott tube was passed as before but with the balloons 30 cm. apart. Intestinal juice collected on the way down contained 0.01 μg. of vitamin B_{12} per ml. The balloons were inflated and the segment was washed out with 500 ml. of distilled water, of which 300 ml. was recovered and found to contain 0.018 μg. of vitamin B_{12} per ml. Then 40 μg. of vitamin B_{12} in 250 ml. of normal gastric juice adjusted to *p*H 7 was instilled very slowly into the segment and left in place for one hour. Aspiration after one hour yielded 14 ml. of clear yellow fluid containing 0.05 μg. of vitamin B_{12} per ml. Washings yielded 35 ml. of clear pale yellow fluid containing no vitamin B_{12}. A further 40 μg. of vitamin B_{12} with 250 ml. of normal gastric juice was instilled. This caused colic, and the patient vomited 150 ml. of dark-brown fluid containing approximately 0.001 μg. or less of vitamin B_{12} per ml. Aspiration after one hour yielded 20 ml. of dark-brown fluid containing 0.025 μg. of vitamin B_{12} per ml. The segment was again washed out with 500 ml. of water, 118 ml. of which, containing 0.02 μg. of vitamin B_{12} per ml., was recovered.

An attempt to *sterilize the small intestine* is described in Case 404.

Application of Vitamin B_{12} to Buccal Mucosa

Case 401

A farm labourer aged 50 had pernicious anaemia with sore tongue but no neurological involvement. The dietary history was normal.

After a satisfactory control period of 11 days the red blood cells numbered 1,620,000 per c.mm., haemoglobin 5.9 g. per 100 ml., M.C.H. 36 $\mu\mu$g., M.C.V., 111 μ^3, M.C.H.C. 32.9%, reticulocytes 0.4%, and white blood cells 1,800 per c.mm. The marrow was megaloblastic.

After the daily instillation of approximately 5 μg. of vitamin B_{12} into the buccal cavity there was a negligible reticulocytosis of 2.8% on the tenth day and the red blood cells fell to 1,270,000 per c.mm. (Fig. 1).

In the second period the patient received 5 μg. of vitamin B_{12} daily mixed with 50 ml. of unfiltered gastric juice, neutralized

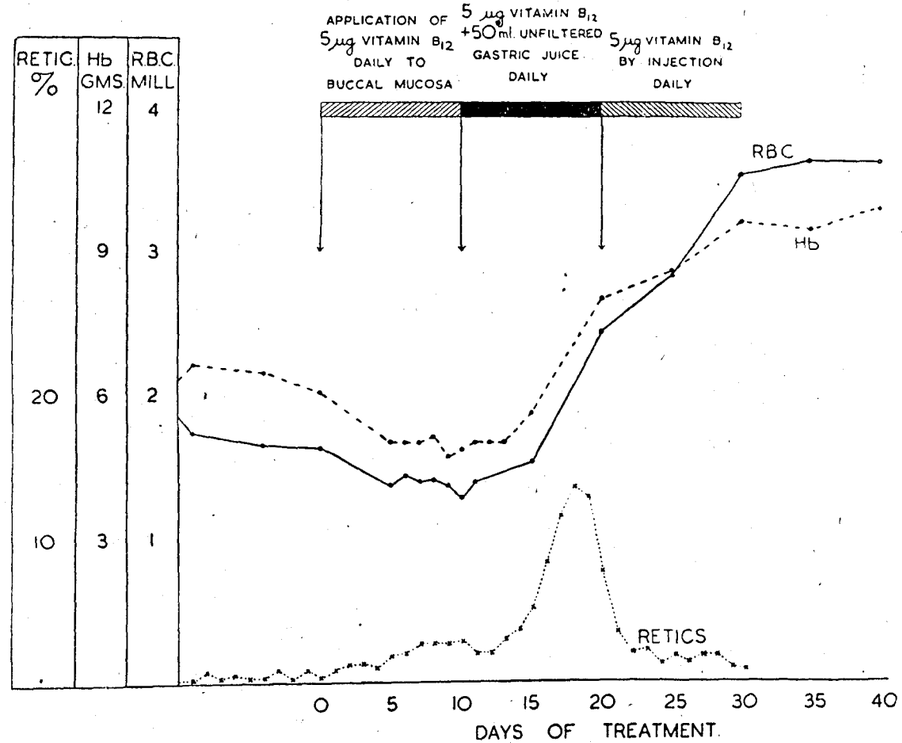

FIG. 1.—Case 401. Failure of vitamin B_{12} administered via the buccal mucosa. Good response to same dose of vitamin B_{12} given with gastric juice.

just before administration. The reticulocytes began to rise on the fourth day, reaching a peak of 13.4% on the eighth day. There was subjective improvement and the red blood cells increased.

	←Second Period→		←Third Period→		←Nil→		
Days:	0	5	10	15	20	25	30
R.B.C. (mills./c.mm.)	1·27	1·52	2·43	2·83	3·54	3·64	3·63
Hb (g./100 ml.) ..	4·7	5·5	7·8	8·4	9·5	9·3	9·8
P.C.V. (%)	14·0	—	25·0	29·1	31·0	32·5	35·0

In the third period he was given injections of 5 μg. of vitamin B_{12} daily for 10 days. There was no secondary reticulocytosis. The red blood cells continued to increase. Subsequent treatment with vitamin B_{12} brought the counts to normal.

Comment.—The absence of haemopoietic response in the first period suggested that little, if any, vitamin B_{12} was absorbed from the mouth. Disappearance of liquid from the chamber was not regarded as proof of absorption of vitamin B_{12}. The increase of red blood cells in 10 days after a total of 50 μg. of vitamin B_{12} given orally with gastric juice was equivalent to the response expected from a single injection of 20 μg. The adequacy of the response is further suggested by the absence of any secondary reticulocytosis in the third period when the same daily dose of vitamin B_{12} was given by injection. Incidentally the increase in red blood cells after a total of 50 μg. (plus any effect left over from the previous therapy) was equivalent only to the increase expected from 20 μg. Thus the true oral-dose/injection-dose ratio may have been close to unity; 50 μg. given orally with gastric juice and 50 μg given by injection both produced a response equivalent to that normally expected from a single injection of 20 μg.

Instillation of Vitamin B_{12} into an Isolated Washed Segment of Intestine

This was performed twice in each of two patients.

Case 402

A man aged 54 had pernicious anaemia with minor neurological involvement. He disliked meat except bacon, but ate plenty of eggs, milk, cheese, fruit, and vegetables.

During the control period of nine days the reticulocytes were less than 1% and red blood cells fell from 2,650,000 to 2,090,000 per c.mm., with haemoglobin 7.4 g. per 100 ml., M.C.H. 35.5 $\mu\mu$g., M.C.V. 109 μ^3, M.C.H.C. 32.6%, and white blood cells 1,800 per c.mm.

After instillation of 40 μg. of vitamin B_{12} into a washed segment of intestine there was neither reticulocytosis nor increase of red cells (Fig. 2).

In the second period 40 μg. of vitamin B_{12} was instilled with 150 ml. of normal gastric juice. Unfortunately the gastric juice had been passed through a Seitz filter, which, as we learned subsequently, may have removed most of the intrinsic factor activity (Case 201). There was no reticulocytosis or increase of red blood cells.

In the third period the patient was given by mouth 150 ml. of unfiltered normal gastric juice neutralized just before administration and mixed with 40 μg. of vitamin B_{12}. The reticulocytes began to increase on the fourth day, reaching 7% on the sixth day. There was no increase of red blood cells, and clinical improvement was transient.

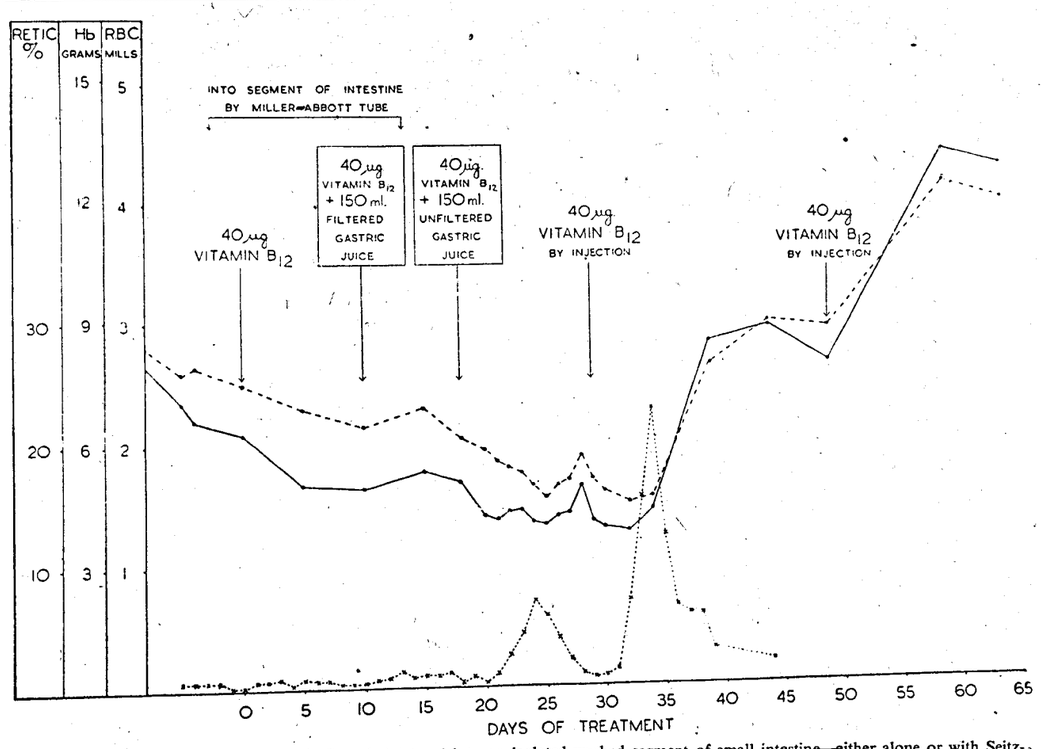

FIG. 2.—Case 402. Failure of vitamin B_{12} administered into an isolated washed segment of small intestine—either alone or with Seitz-filtered (and thus probably inactivated) gastric juice. Poor response to same dose of vitamin B_{12} given orally with 150 ml. of unfiltered gastric juice. (150 ml. is probably not enough for the absorption of 40 μg.) Normal response to injection of 40 μg.

	←Third Period→			←Fourth Period→		
Days:	0	5	11	16	21	26
R.B.C. (mills./c.mm.)	1·68	1·45	1·35	1·44	2·83	2·96
Hb (g./100 ml.) ..	6·1	5·2	5·0	4·6	7·8	8·9
P.C.V. (%)	19·0	16·5	—	18·0	30·0	31·0

In the fourth period a single injection of 40 μg. of vitamin B_{12} led to a reticulocytosis of 22.8% on the fifth day and the red blood cells increased rapidly. Further injections of vitamin B_{12} brought the counts to normal.

Comment.—Vitamin B_{12} in a dose of 40 μg. administered into a washed segment of intestine twice failed to produce a haemopoietic effect. This suggests that little or no vitamin B_{12} was absorbed. The high concentration of vitamin B_{12} in the aspirate even after one hour (see Methods) is perhaps further evidence that absorption was absent or incomplete, but one cannot be certain how efficiently the tube had been washed clear of vitamin B_{12} before the final aspiration. The poor response in the third period suggests that 150 ml. of the gastric juice used was enough for the absorption of only a small fraction of the dose of 40 μg. of vitamin B_{12}. A similar reticulocytosis without rise of red blood cells has been produced by doses as low as 1.25 or 2.5 μg. by injection. In the fourth period the increase of red blood cells in 15 days after 40 μg. by injection (plus any effect left over from previous therapy) was close to the expected increase. This suggests that there was no "resistance" to vitamin B_{12}.

Case 403

A crane-driver aged 56 had pernicious anaemia without neurological involvement. The dietary history was normal.

On admission red blood cells numbered 1,670,000 per c.mm., haemoglobin 5.9 g. per 100 ml., reticulocytes 0.4 %, P.C.V. 18%, M.C.V. 108 μ^3, M.C.H. 35.5 $\mu\mu$g., M.C.H.C. 33%, white blood cells 5,300 per c.mm. During a control period of 11 days the reticulocytes did not exceed 1.6% and the red cells did not increase. The marrow was megaloblastic.

After the instillation of 80 μg. of vitamin B_{12} into a washed segment of intestine reticulocytes rose slightly to 4.2% on the fifth day, but there was no increase of red cells (Fig. 3).

	←First Period→			←Second Period→		
Days:	0	5	10	14	19	25
R.B.C. (mills./c.mm.)	1·58	1·56	1·53	1·45	1·33	1·38
Hb (g./100 ml.) ..	6·2	6·4	5·9	5·6	5·3	5·9
P.C.V. (%)	19·0	19·0	18·0	18·0	17·0	17·0

In the second period the distance between the balloons was doubled and 80 μg. of vitamin B_{12} with 500 ml. of normal gastric juice was instilled in two lots for an hour each. Reticulocytes rose to a peak of 5.4% on the sixth day and after 11 days the red cell count was essentially unchanged. A further marrow puncture showed that, although there was some maturation compared with the control period, erythropoiesis was still predominantly megaloblastic.

In the third period the patient was given an intramuscular injection of 80 μg. of vitamin B_{12}. The reticulocytes rose on the third day and reached a peak of 27.8% on the sixth day. The red blood cells increased rapidly.

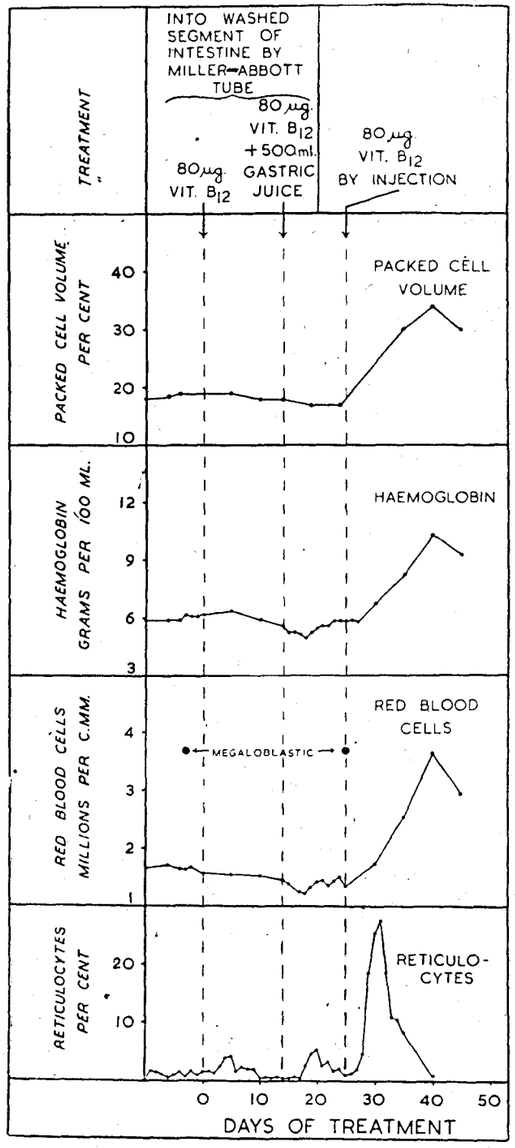

FIG. 3.—Case 403. Showing that the instillation of 80 µg. of vitamin B_{12} with or without gastric juice into a washed segment of intestine failed to produce anything more than a slight reticulocytosis. There was afterwards a good response to 80 µg. of vitamin B_{12} by injection.

Days:	Third Period				
	0	5	10	15	20
R.B.C. (mills./c.mm.)	1·38	1·76	2·58	3·69	2·95
Hb (g./100 ml.)	5·9	6·8	8·3	10·4	9·3
P.C.V. (%)	17·0	19·0	30·0	34·0	30·0

The patient ate well and had no soreness of the tongue during any of the experimental periods, but notable improvement in strength and colour was observed in the third period.

Comment.—Vitamin B_{12} instilled into a washed segment of intestine, either with or without gastric juice, was not effectively absorbed. The small reticulocytosis observed in the first and second periods was no greater than might have been observed from the oral administration of 80 µg of vitamin B_{12}. The response to injected vitamin B_{12} was better than expectation.

Not much reliance can be put on the negative results of these intubation experiments. The segment of intestine may have been too small or sited in an area unsuitable for absorption of vitamin B_{12}. Moreover, the protection against contact with intestinal contents was anything but complete.

Oral Administration of Vitamin B_{12} after Partial Sterilization of the Intestine

The object of this experiment was to determine whether vitamin B_{12} would be effectively absorbed if intestinal bacteria which might take up the vitamin were destroyed.

Case 404

A coal-screener aged 56 had pernicious anaemia without neurological involvement. His diet had been satisfactory. During a control period of 12 days the reticulocytes did not exceed 1% and the red cells fell from 1,700,000 to 1,260,000 per c.mm. He was transfused with blood of a different but compatible group so that his own cells could be enumerated. The next day the total count was 1,730,000.

In the first period intestinal antiseptics were given as follows:

1st day: Phthalylsulphathiazole 4 g., six times.
2nd day: Phthalylsulphathiazole 2 g., six times; also "aureomycin" 0.75 g., four times.
3rd day: Same as second, with dihydrostreptomycin 1 g., four times.
4th, 5th, and 6th days: All three drugs as on third day.

Bacteriological examination (Dr. C. A. Green) showed that *Bact. coli* had disappeared from the stools by the third day and cocci by the fifth day. Yeasts persisted even up to the last examination on the seventh day. On the evening of the fifth day the patient received orally 80 µg. of vitamin B_{12}. There was neither reticulocytosis nor increase of red blood cells (Fig. 4).

In the second period 80 µg. of vitamin B_{12} with 500 ml. of gastric juice was given at 7.30 p.m. No food was given for four hours before or after the mixture. The reticulocytes rose to 15.8% on the sixth day. Changes in blood counts were as follows:

Day:	Second Period			
	0	5	10	15
R.B.C. (mills./c.mm.)	1·34	1·51	2·13	2·16
Hb (g./100 ml.)	5·3	5·9	7·4	7·7
P.C.V. (%)	16·0	20·0	24·0	23·0

In the third period 80 µg. of vitamin B_{12} was injected. There was another reticulocytosis, reaching 17.2% on the fifth day. Changes in counts were as follows:

Day:	Third Period			
	0	5	10	15
R.B.C. (mills./c.mm.)	2·16	2·24	3·21	3·70
Hb (g./100 ml.)	7·7	8·0	9·3	10·8
P.C.V. (%)	23·0	24·0	33·0	37·0

Comment.—Preliminary partial sterilization of the intestine did not permit absorption of vitamin B_{12} given orally. The rise of red blood cells in 15 days after giving 80 µg. with 500 ml. of gastric juice was rather less than that expected from the injection of 5 µg. The response to the injected dose of 80 µg. was almost equal to that expected from 40 µg. Thus the oral-dose/injection-dose ratio was probably more than 8 : 1.

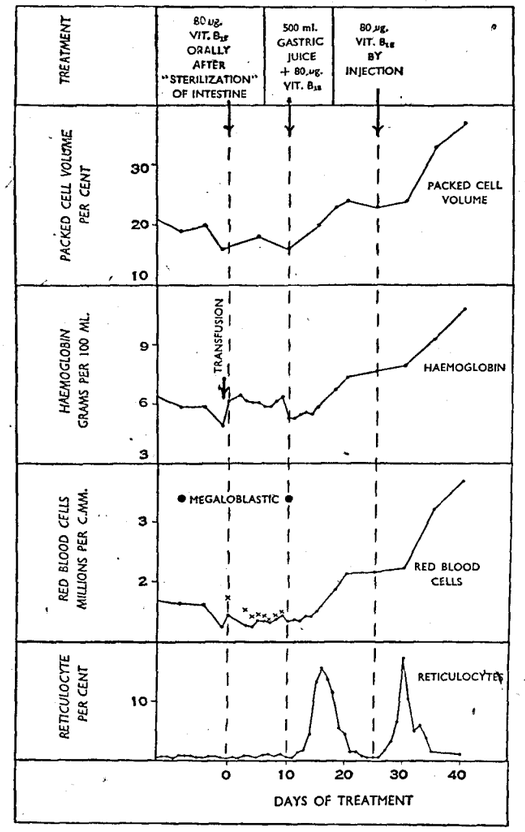

FIG. 4.—Case 404. Showing that 80 µg. of vitamin B_{12} administered orally after partial sterilization of the intestine did not lead to any reticulocytosis or increase of red blood cells. Thereafter the same dose of vitamin B_{12} given with gastric juice produced a response rather less than that expected from an injection of 5 µg. The injection of 80 µg. of vitamin B_{12} was followed by a response almost equal to that expected from 40 µg. (In the section for red blood cells the crosses represent the total count including transfused cells, whereas the continuous line represents the patient's own cells, the donor's cells have been separated by differential agglutination.)

Discussion

Results in Case 401 suggest that there was little, if any, absorption of vitamin B_{12} from the buccal mucosa. Negative results are also reported by Erf and Wimer (1949).

These negative findings and our failure on four occasions to procure effective absorption from a washed isolated segment of intestine lend no support to the idea that vitamin B_{12} given via the alimentary tract might prove effective if contact with intestinal juice were prevented.

The intubation experiments were, however, not altogether satisfactory (see Cases 402 and 403). In another type of experiment an attempt was made to destroy intestinal bacteria which might otherwise take up orally administered vitamin B_{12} and render it unavailable to the host. Using phthalylsulphathiazole, aureomycin, and dihydrostreptomycin, we succeeded in sterilizing the stools except for yeasts. The small intestine was presumably equally sterile. Even so, the administration of 80 µg of vitamin B_{12} orally was without effect.

Moreover, in microbiological tests we showed that "pernicious anaemia" intestinal juice did not destroy added vitamin B_{12}, in the presence either of "pernicious anaemia" or normal gastric juice (Ungley and Cuthbertson, 1950—Paper V of this series, to be published).

The results reported here are negative but not conclusive. They do not support, but neither do they entirely rule out, the hypothesis that Castle's intrinsic factor acts by protecting vitamin B_{12} from destruction in the alimentary tract. Further work is in progress.

Summary and Conclusions

Efforts were made to determine whether vitamin B_{12} would be effectively absorbed if the possibly destructive action of intestinal juice could be reduced or avoided.

Application of 5 µg. daily to the buccal mucosa gave a negative response in a patient who subsequently responded to the same quantity of vitamin B_{12} given with gastric juice.

In four experiments in two patients the instillation of vitamin B_{12} with or without gastric juice into a washed segment of intestine isolated between the two balloons of a Miller–Abbott tube led to negative or trivial responses. In each case the subsequent administration of vitamin B_{12} by injection or orally with gastric juice was effective.

Even after preliminary partial sterilization of the intestine with aureomycin and other drugs the oral administration of 80 µg. of vitamin B_{12} was ineffective. The patient subsequently responded to the same dose of vitamin B_{12} given with gastric juice.

These negative findings are against, but do not entirely exclude, the possibility that Castle's intrinsic factor acts by protecting vitamin B_{12} from destruction in the gastro-intestinal tract.

ADDENDUM.—Since these papers were submitted additional evidence on the effect of orally administered vitamin B_{12} and the role of Castle's intrinsic factor has been reviewed by Dr. Byron E. Hall (*British Medical Journal*, September 9, 1950, p. 585).

I am grateful to the medical, nursing, and lay staff of the hospital and medical school and to many general practitioners for their co-operation. I have to thank Dr. L. W. Carstairs for intubating the small intestine and Dr. R. B. Thompson for marrow biopsies. Special thanks are due to students and others who donated gastric juice. The dental appliance used in Case 401 was constructed with the kind co-operation of Professor John Boyes and Mr. H. G. Hanley, L.D.S., of the Dental School, King's College, University of Durham. Dr. E. Lester Smith, of the Research Division of Glaxo Laboratories, Ltd., Greenford, supplied the crystalline vitamins B_{12} and B_{12c} and also the vitamin B_{12} concentrate used in these investigations. Dr. W. F. J. Cuthbertson, also of Glaxo Laboratories, was responsible for all the microbiological assays.

ACUTE INTUSSUSCEPTION IN CHILDHOOD

BY

Sir JAMES SPENCE, M.D., F.R.C.P.

AND

DONALD COURT, M.D., M.R.C.P.

(From the Children's Department, Royal Victoria Infirmary, Newcastle-upon-Tyne)

This is a sequel to the account of 100 cases of acute intussusception in children given by Morrison and Court (1948). That study revealed the relationship between the delay in reaching a diagnosis and the outcome of the disease, and the parts played by the parents and the family doctor in the process. Although the risk of death increased sharply when intussusception had been present for more than two days, a considerable number of affected children failed to reach hospital within this favourable period. Yet almost every child had been seen by the family doctor before the second day was over. These facts together suggest that the illness was in most cases intense enough to alarm the parents but that in many it failed at this stage to provide the doctor with sufficient evidence for diagnosis. Knowing the difficulties of diagnosis, Morrison and Court paid special attention to the clinical events on the first and second days of the illness. They described these in detail and time-sequence, and asked practitioners to send suspected children to hospital as soon as their suspicions were aroused.

In the three years following the initial study we have seen another 139 children with acute intussusception. With this further experience we return again to the significance of early diagnosis, and comment briefly on the improvement that has occurred and the reasons for it. We attempt also to set this problem in its right perspective. During the six years of this survey the average number of children with intussusception seen by any practitioner in that period was only one, and, although a small number saw more than one in six years, many doctors saw none at all. How, then, shall a family doctor maintain his diagnostic skill with this infrequent contact? The facts and suggestions given below may help to answer these questions.

TABLE I.—*A Comparison of Mortality in 177 Infants with Intussusception Admitted Before and 62 Admitted After the 48th Hour of the Disease*

Year	All Cases			Under 48 Hours			Over 48 Hours		
	No.	Deaths	Death Rate %	No.	Deaths	Death Rate %	No.	Deaths	Death Rate %
1944 ..	29	4	14	14	1		15	3	20
1945 ..	25	2	8	18	—		7	2	28
1946 ..	46	4	9	32	2		14	2	14
1947 ..	49	2	4	38	1		11	1	9
1948 ..	40	3	7	31	—		9	3	20
1949 ..	50	2	4	44	2		6	—	
All years	239	17	7	177	6	3·4	62	11	17·8

Table I shows the mortality in the entire group of 239 children admitted to one hospital from a wide area. It reveals a number of interesting differences between those admitted before and those after 48 hours. First, a fall in the death rate from 14% in 1944 to 4% in 1949. Yet over the six years, the death rate for children admitted within 48 hours has not deviated significantly from 3–4%, and of those admitted after 48 hours from 18%. It is still, therefore, of first importance that children with this disease should be in hospital well within 48 hours of the onset of symptoms. A larger number of children were treated in the 1947–9 period, and there has been a gratifying increase in the percentage reaching hospital in the first two days of the illness. This percentage rose from 48 in 1944 to 88 in 1949—an increase which is statistically significant (Table II).

TABLE II.—*The Proportion of 239 Cases of Acute Intussusception Admitted to Hospital Within 48 Hours of Onset*

	1944	1945	1946	1947	1948	1949
% Admitted within 48 hours	48	72	70	77	78	88
	64			81		

Differences in the anatomical types of intussusception have been difficult to measure consistently owing to a lack in some cases of a precise indication of the starting-point. If there has been any change in the first three years it has been a slight increase in the small-bowel invaginations of the ileo-ileocolic variety, while the incidence of pure ileo-ileal intussusception has remained the same throughout. The general paediatric care and surgical technique, too, were unaltered in the second period. A group of surgeons have shared the work, and there has been no attempt to limit this experience to one or two people. Pre-operative resuscitation with plasma has been the rule in almost every child.

In view of these facts the fall in mortality can be primarily attributed to the increasing number reaching hospital within 48 hours, and therefore to the skill of the family doctors concerned.

We have wondered how this earlier recognition of the disease has come about, as intussusception is not common, and most doctors' memories will not be refreshed by frequent contact with the disease.

Interest in the exact incidence of the disease within a community, and in the chance of a doctor's seeing it, led us to trace every child with acute intussusception resident within the City of Newcastle-upon-Tyne during the six years covered by our review. There were 127 such children admitted for treatment to a hospital or nursing-home within the city. The average annual number of births over the period was 5,600, so the incidence of intussusception was 3.8 per 1,000 births, or about 1 in 250 births. The yearly variation was considerable and is set out in Table III.

TABLE III.—*Annual Incidence of Acute Intussusception in Newcastle-upon-Tyne, 1944 to 1949*

	1944	1945	1946	1947	1948	1949	All Years
No. ..	13	13	14	30	20	37	127

During this period the number of doctors resident and practising in Newcastle-upon-Tyne did not vary significantly from 120 in each year. The way in which the 127 children with acute intussusception were distributed among these doctors is shown in Table IV. This gives an average of one case to a single practitioner every six years. Yet during this period 42% of the practitioners did not see the disease at all and a further 36% saw it only once; at the other end of the scale a small group of 27 doctors, 22% of the total, saw 83 cases between them, or 65% of all the affected children in the city. There is therefore no constant pattern in the distribution of this disease within the experience of the urban family doctor, though the majority are not likely to see more than one affected child every six years—that is, 6 or 7 in a professional lifetime.

How, then, has this earlier recognition come about? The article by Morrison and Court may have been noticed

TABLE IV.—*Distribution of 127 Children with Acute Intussusception Among 121 Family Doctors in Newcastle-upon-Tyne, From 1944 to 1949*

Cases per Doctor	No. of Doctors	Total Cases
0	50*	0
1	44	44
2	12	24
3	8	24
4	4	16
5	1	5
6	1	6
7	0	0
8	1	8
Total ..	121	127

* Estimated from the average number of doctors practising in Newcastle-upon-Tyne during the survey period.

by some practitioners. The main facts were also presented to a well-attended local meeting of the Newcastle and Northern Counties Medical Society. But a new influence has been used in the letters to doctors when the children were discharged from hospital. These have been worded in the last few years with the need for early admission in mind. When the doctor's suspicions of the disease had been quickly aroused and the child reached hospital in good time, confirmation alone was required to complete the happy story. When, however, diagnostic hesitation lasted beyond the second day, the writers of the discharge letters have ventured to discuss those points in the history which might have suggested earlier diagnosis and have led to earlier admission if their significance had been recognized.

As a result of conferences with practitioners we feel that the discharge letter, or a telephone conversation, should usefully go beyond the mere statement of what has been done in hospital, since it is concerned with the fate of a particular person for whom the doctor is responsible. The letter (or the conversation) is an instrument of postgraduate education and commands more interest and attention among practitioners than comprehensive reviews of the subject in journals. Moreover, this exchange is a two-way process of education: it helps the hospital doctor to appreciate the difficulties of practice, from which he may learn what sort of letters to write.

Whatever the full explanation may be, we suspect that these letters, the contents of which would be extended to partners and colleagues by the inevitable discussion among doctors of the unusual or exciting case, may have assisted general practitioners in the North-east to make a notable contribution to the better management of acute intussusception. In any case we are grateful for the facts and offer our thanks to all doctors concerned, both in the home and in the hospital.

Our thanks are due to Mr. H. Campbell, of the Nuffield Department of Industrial Health, for his expert comments on the figures presented in this paper.

A report entitled "Towards the Better Care of the Elderly" has been issued by the Public Health Department, Salford. The report, which has an introductory note by Lord Amulree commending the care of the elderly in their own homes, is an account of two informal conferences, sponsored by the local health department, which were held at Salford this year on May 4 and 5. The first conference dealt with the medical aspects of the care of the aged, and the second with the co-operation of home and hospital in this task. A limited number of copies of the report may be obtained, free of charge, on application to the Medical Officer of Health, Health Department, 143, Regent Street, Salford, 5.

ACTIVITY IN ADVANCING YEARS*

BY

MARJORY W. WARREN, M.R.C.S., L.R.C.P.

Consulting Physician to the Geriatric Unit, and Deputy Medical Director, West Middlesex Hospital, Isleworth, Middlesex

Full health, and with it usefulness and happiness, depends upon activity of mind and body. This applies equally to all age groups, though the amount of mental and physical work which can be undertaken at different ages and by different persons must vary widely, even among healthy individuals. The elderly are no exception to this rule, and the subject of activity is closely associated with modern ideas of their treatment, which embrace psychological and physical methods. In order to strengthen my arguments for retaining or obtaining the maximum activity amongst them it may perhaps be profitable to consider briefly first the results of inactivity both to the individual and to the community, and then to discuss therapeutic measures (medical and social) against such a background.

Anatomically and physiologically, man has been designed for an active existence in the upright or vertical position, and any grave departure from such, for any appreciable length of time, inevitably brings troubles, both mental and physical. Anyone who has inherited patients who have been bedridden for a long time will readily appreciate the picture here described.

Effects of Inactivity on the Individual

Confined to bed, most patients develop rarefaction of bone, stiffness of soft tissues, and contractures. Muscles atrophy, tendons shorten, and limbs assume malpositions, varying with circumstances. The type and degree of contracture will depend upon the position in bed. When propped up for long periods of time flexion of hips and knees is almost inevitable. Feet assume a varus, valgus, or equino-varus position, according to the physical disability, the mental state, and the condition of the bedclothes. The elderly when nursed sitting in bed show a great tendency to keep the upper limbs adducted to the trunk in a position of flexion. This results in stiffness and contractures of shoulders and elbows, and is always more marked in the left upper limb with right-handed persons. Also there is a tendency towards some degree of fixed flexion of the head on the chest—often in minor degrees only and therefore not easily noticed when the person is propped up. Such contractures and stiffness lead to difficulties in changing patients' positions in bed and hence lead to the development of pressure sores.

With lowered metabolism, reduced body needs, and the absence of all exercise and voluntary movement, obesity often follows. Such obesity, which is a well-recognized feature in these conditions, is frequently aggravated by the patient's inclination to eat between meals (often of carbohydrate foods), and shows earliest in the anterior abdominal wall. This additional deposit of fat adds another factor to the difficulty of movement in bed, and indeed often prevents a patient from sitting up. It also affects the heart, as such general increases tend to infiltrate the myocardium and so reduce normal cardiac efficiency. Overweight and immobile, such patients show a reduced respiratory excursion and develop signs of

*Read in opening a discussion in the Section of Geriatrics at the Annual Meeting of the British Medical Association, Liverpool, 1950.

basal congestion which are potential sources of active pulmonary infection.

Lack of exercise produces a sluggish bowel action, with resulting constipation. In passing, I would draw attention to the fact that much of the so-called incontinence of faeces is in reality retention of faeces with overflow—a condition not sufficiently recognized. On the nervous and psychological side, such conditions soon produce a degree of mental apathy, especially among those who are less erudite or who, by reason of poor sight and/or poor hearing, are somewhat isolated from their fellows.

Such apathy produces two main results: (1) irregular sleep, with a tendency to sleep between meals by day, and a failure to sleep well at night; and (2) laziness, resulting in incontinence of urine, which further adds to the difficulty of preventing pressure sores. Occasionally, instead of incontinence of urine, retention occurs. This is usually found in men—often in those who have a mild degree of prostatic enlargement. I have, however, met a few such cases in women.

The last case was in an old woman aged 90 who developed retention of urine when put to bed at home following a fractured right humerus. On admission she was in great discomfort with a grossly distended bladder. In spite of all encouragement she could pass only a few ounces of urine normally. Catheterization undertaken slowly over a period of several hours resulted in withdrawal of 5½ pints (3.1 litres) of urine which showed no abnormal constituents and was sterile on culture. She had a small sessile urethral caruncle, which I do not think was in any way responsible. She was allowed up in a chair daily and at the end of a week normal micturition was re-established.

Effects of Inactivity on the Community

Failure to retain or obtain the fullest possible activity, independence, and useful work amongst the elderly will inevitably lower the general standard of health. With increasing numbers of elderly persons in our population it is obvious that as many as possible must be helped to remain as active members. The more invalids or bed-fast patients there are the greater the burden will be on personnel of all kinds engaged in looking after them and the greater will be the financial strain on the country.

It is obvious, then, that all must play their part in helping the elderly to remain active and retain their full independence—by providing domiciliary service as soon as it is needed, along with recreational interests—and it is certain that the first call should be to the relatives and friends.

There must, I feel, be general agreement on the advisability of maintaining or restoring activity even if there is divergence of opinion on methods, and I therefore propose to discuss the subject from three angles: (1) Conditions relating to a maintenance of personal independence, with or without useful work. (2) Therapeutic methods necessary to bring about a return of useful function and a measure of personal independence where this has been lost. (3) Conditions required for creating and maintaining optimum morale.

Maintenance of personal independence with or without useful work depends upon the attitude of mind of both the individual and those around him, and the patient's medical and social condition.

If the mental attitude of those around an elderly person favours inactivity, or they are quite unaware of the methods by which activity and interest can be maintained, then, indeed, unless help is given, he will become inactive and an unnecessary burden to himself and the community. Overindulgent relatives often persuade an elderly person to take more and more rest and to do less and less; at the other extreme we have the inattentive people who offer nothing to the aged, who in turn rebel and demand everything.

Patients who develop increasing arthritis, considerable cardiac failure, pernicious anaemia, or a mild cerebrovascular catastrophe all need treatment; but these conditions are not infrequently overlooked in the early stages and consequently result in long periods of inactivity.

Finally, an elderly person whose living conditions include an outside toilet, accommodation on the third or fourth floor, or no domestic help may well give up the unequal struggle and demand full service.

It is obvious that such psychological, medical, and social conditions call for full preventive measures. These measures include, in addition to education of the public when needed, full medical treatment when required and use of all domiciliary services which are available, and an increase where these are insufficient.

Treatment

To provide a well-run medical service for the elderly the importance of activity must be well understood, and methods must be fully implemented to ensure it.

Without due care inactivity is apt to follow any illness (medical or surgical) which necessitates a period of time in bed. It therefore behoves all those concerned to regard such a period of rest in bed as a "danger period." With considerable years of personal experience, and after reading widely on the subject, I know of no reasons *on age alone* for recommending a long stay in bed. Indeed, I would suggest that, in treating the elderly, rather than deciding how soon they may safely get up, one should consider very carefully whether it is really necessary and wise to put them to bed.

Although any elderly patient may become inactive after a long time in bed, there are certain conditions which particularly predispose to this state: painful feet from any cause; cerebro-arteriosclerosis with some added minor medical or social problem; cerebrovascular accidents; cardiac disease, in failure; arthritis; progressive nervous disease—for example, Parkinsonism; and post-traumatic and post-operative conditions.

Full activity, which must be aimed at in all cases, depends upon psychological and physical fitness, and these are closely interrelated. Without a degree of mental activity physical progress is very slow, and in the absence of physical progress mental activity wanes appreciably. It must therefore be the aim of the physician to get and to maintain a good balance.

In order to ensure the fullest activity and the most complete rehabilitation the following general methods should be adopted: (1) a detailed history of the patient's illness and earliest symptoms and signs must be obtained from him or his relatives or friends; (2) a full clinical examination, including a rectal examination and blood-pressure reading, must be made before starting treatment. Only with these prerequisites can a sound plan be made and detailed treatment arranged. Many diagnoses are missed in the elderly owing to failure to undertake such preliminaries. With as full knowledge of the patient as possible, treatment must be undertaken by a team, and the members of this team must work in complete harmony if full success is to be obtained.

Such a team will usually include:—In the home: a general practitioner; domiciliary services; relatives and friends. In the hospital: the physician and his medical staff; nursing staff; physiotherapists; occupational therapists; almoner; dietitian, etc. To complete the picture it is necessary that general practitioners and physicians should work together concerning the patient's future.

When treating sick elderly patients the following principles should be adhered to.

1. A patient must be encouraged to retain full independence for his personal needs whenever possible while under treatment—for example, he should wash and feed himself, brush his teeth, comb his hair, and assist in dressing himself. Nothing that a patient can do for himself should be done for him.

2. If his medical condition has diminished his independence or rendered him immobile, then full treatment by means of physiotherapy, occupational therapy, or speech therapy must be arranged to overcome his disabilities.

3. At all times a patient must be encouraged to persevere with treatment, to keep active in every possible way, and to interest himself in his own full recovery and in his surroundings.

4. Exercise should be frequent and for short periods of time, as the elderly tire easily and yet need repetitive treatment.

5. The time allowed up or for exercise should be laid down in detail, as only with such precision can a true assessment of progress or fatigue be measured.

6. Great care should be taken to ensure that conditions are good as regards flooring, sanitation, temperature, light, etc.; that clothes, especially shoes, are comfortable, well-fitting, and warm enough but not too heavy; and that appliances, including prostheses, are correct in every detail. Crutches and sticks particularly should be the right length or walking may be difficult, or even dangerous.

7. Equipment should be provided with a view to giving the maximum help to patients under treatment, and this includes rails overhead and bed-end pulleys, armchairs, wheel-chairs, self-propelling chairs, etc.

8. All medical conditions must be treated in order to avoid general deterioration from one disability hindering progress of another.

Exercise

In most cases well-planned treatment giving successful results does not depend on elaborate apparatus, but on the knowledge of the therapeutic principles involved. In general, massage is to be avoided, as it is time-consuming and of less value than exercise. Exercises should be undertaken by the patient after careful education, and these will give him an interest in his progress. The physiotherapist, where available, should give regular attention to such patients, partly individually and partly as group therapy. Ideally, treatments should be frequent and short—not more than 15 minutes. Where, however, physiotherapists are not able to give all the treatment necessary some members of the nursing staff—and especially, in my experience, the State-enrolled assistant nurses—can be taught to undertake valuable work in this connexion; but, whatever help is available, the overall supervision must remain with the physician and should never be handed over entirely to ancillary staff.

Exercise may be passive or active, and in many instances a combination of the two methods will prove best. All joints need exercise through a full range of movements daily.

Arthritis

In the case of arthritics, where flexion deformities are commonest, an increased range of movement must be aimed at. This can best be undertaken by a series of graded exercises against springs of varying tension with the limbs suspended in slings—Guthrie Smith frame or an improvised modification. I have found that where pain interferes with exercise it is sometimes profitable to give radiant heat immediately before treatment. This can be provided equally well by any of the recognized radiant-heat machines or by an electric heat cradle placed over the affected part. Active movements against resistance improve muscle tone. Movements between fixed points give some measure of range of movement, and should be encouraged for the sake of accuracy.

Much valuable work can be undertaken on these lines either with the patient lying on the bed with all bedclothes removed, or with him sitting on the edge of the bed swinging his legs and thus overcoming flexion deformities of the knees.

When planning suitable exercises it should be remembered that the aim of treatment is to restore full function so that the patient may be independent regarding his personal needs. It is therefore necessary that all exercises should serve this purpose.

Many patients can be more safely nursed sitting in an armchair by day than reclining in bed, where they tend to become less active. Before a patient can walk he can sometimes get about in a self-propelling wheel-chair, which greatly improves his morale.

When a number of patients can be grouped together for such exercise the natural element of competition is often most stimulating. Encouraging a patient to get into his own clothing (and this is much easier for a woman than for a man, because the clothing of the former is much looser) is in itself very good physiotherapy.

Other exercises which are useful include sitting up from a lying-down position, by any means in the first instance and later with the arms folded, contraction and relaxation of abdominal muscles while lying flat on the bed, and regular quadriceps drill. Arthritics should be told that small degrees of flexion deformity of hips and knees are in themselves no absolute bar to walking.

From bed exercises arthritics should proceed to exercises in standing and walking—in the early stages holding on to a rail, and with the help of sticks, crutches, or poles. Sticks should always be provided with a rubber ferrule, and may be ordinary one-legged sticks, or have three or four legs; the latter I have found of great use in my department when a patient feels insecure with an ordinary stick. Crutches are useful where the upper limbs are able to support them, and are sometimes preferred to sticks. When arthritis is mainly confined to the lower limbs, and is especially marked in the lumbo-sacral spine, I have found duralumin poles provided with rubber ferrules at both ends particularly helpful. Poles have a limited use, but when acceptable they are very good, as they overcome the tendency to stoop.

It is important that patients should never be allowed to try to walk until they are able to rise from a sitting position holding on to a rail, but otherwise unaided, and to maintain the erect position correctly balanced.

Hemiplegics

Patients with hemiplegia resulting from a cerebrovascular accident are from a medical point of view one of the most interesting groups to re-educate and guide—and at the same time one of the most neglected. They range from those who are very easy to those who call for the greatest experience, patience, and detailed work.

From the very moment of catastrophe these patients, if they are to do really well, need detailed care and treatment. On the one hand, it is essential to prevent development of stiffness and contractures, particularly of the affected shoulder-joint, and on the other it is necessary to give re-education as early as possible. As soon as

the patient is conscious he must be taught to play an active part in his own re-education, and his activities must be carefully supervised.

Bed exercises in the early stages are followed by exercises while learning to stand, and, later, by practice in walking with a stick and a little assistance, and, finally, by walking with a stick unaided on the flat and then on the stairs.

During the treatment of all these conditions suitable occupational therapy should be provided, and general interest be stimulated by encouraging visiting, reading, conversation with other patients, and by wireless programmes (via headphones and *not* loudspeakers, unless a room can be set aside for such purpose).

If these principles are adhered to then success in treatment will depend upon early and full treatment, attention to detail in an atmosphere of optimism, strength of the team-work, confidence of the patient in the team, and the experience and activity of the physician.

Summary

The results of inactivity both to the individual and to the community are outlined, and an argument is put forward for the maintenance of full activity and independence among the elderly and for their rehabilitation.

Inactivity may be brought about by psychological, physical, or social conditions; preventive measures against these are described.

Medical conditions which particularly predispose to inactivity are enumerated, and principles underlying their management and treatment are discussed. Warning is given that long periods of rest necessitated by illness must be regarded as "danger periods."

Points stressed are: that good results depend on a high standard of medicine, on really good team-work, and on an atmosphere of optimism and activity, combined with the patient's confidence and co-operation in his treatment.

Some suggestions are made with regard to the treatment of arthritics and hemiplegics.

USE OF INTRAVENOUS AMPHETAMINE SULPHATE IN ACUTE BARBITURATE POISONING

BY

J. D. N. NABARRO, M.D., M.R.C.P.

First Assistant, Medical Unit, University College Hospital

The possible use of intravenous amphetamine sulphate in conjunction with other remedies in cases of acute barbiturate poisoning is seldom considered in this country. When Alles (1933) was investigating the pharmacological properties of this drug in dogs under barbiturate anaesthesia he found that the animals often awoke after its injection. Myerson (1940), in a review of the rationale of amphetamine sulphate treatment, mentioned its possible value in counteracting the effects of barbiturate poisoning. Freireich and Landsberg (1946) reported 14 cases of this condition in which the drug was used; but few of these were severe, and the maximum dose employed was 400 mg. Newman and Feldman (1948) have reported a series of cases of poisoning in which massive doses of picrotoxin were used, supplemented in four by amphetamine sulphate. In the treatment of one of their patients who was 135 hours in coma, 14,190 mg. of picrotoxin and 1,950 mg. of amphetamine sulphate were given.

Pharmacological Aspects

Barbiturate poisoning may cause the death of the patient either by depression of the respiratory centre or through the development of bronchopneumonia. The former is more likely to occur with very large doses and with the short-acting derivatives, whereas the latter is associated with prolonged coma. Specific treatment is therefore directed at stimulation of the respiratory centre and hastening the recovery of consciousness. Picrotoxin has an established place in the management of these cases, principally as a stimulant of the respiratory centre. It has much less action on the cerebral cortex, but on account of its convulsant properties must be used with care.

Amphetamine is widely known as a cerebral stimulant, and its power of awakening both men and animals under the influence of various narcotics has often been reported (Reifenstein and Davidoff, 1938; Myerson *et al.*, 1939), although it has been found to increase the death rate in mice after LD50 doses of barbiturate (Chakravarti, 1939). The action of amphetamine on the respiratory centre has been the subject of conflicting reports, and no consistent stimulant action can be demonstrated. In addition to its effect on the central nervous system amphetamine is a powerful sympathomimetic agent. It produces a rise of blood pressure and should therefore be used with care in older patients and hypertensive subjects. Disturbances of cardiac rhythm following its administration have also been reported (Anderson and Scott, 1936; Waud, 1938).

The very large amounts of amphetamine used in Newman and Feldman's case and in that reported below raise the question of the fate of the drug in the body. When given by mouth in normal doses, part is excreted in the urine, in which it may be detected for some days (Beyer and Skinner, 1940; Monroe and Drell, 1947), and the remainder is probably metabolized (Beyer, 1942). There are a few reports in the literature of the results of large doses being taken by patients not under the influence of narcotics. Transient hypertension, excitement, or confusional states have followed the ingestion of amounts up to 450 mg. (Ehrich *et al.*, 1939; Monroe and Drell, 1947). A few deaths have been attributed to the drug, usually after much smaller quantities, and presumably due either to idiosyncrasy (Smith, 1939) or, as in one case, to subarachnoid haemorrhage (Gericke, 1945). The administration of large doses to monkeys has been found to produce toxic degeneration of the nerve cells and perivenous haemorrhages in the meninges (Ehrich *et al.*, 1939).

Case Reports

Over a period of 18 months intravenous amphetamine sulphate has been used, usually in conjunction with other remedies, in the treatment of seven cases of acute barbiturate poisoning. Four were mild cases with coma lasting a few hours, and in three of these picrotoxin seemed more effective in awakening the patient, although the amount of amphetamine used was probably inadequate in the light of subsequent experience. In the fourth, recovery was little accelerated by either drug. The other three cases had points of particular interest and are recorded in more detail.

Case 1

A woman aged 29 was admitted two and a half hours after taking 80 gr. (5.3 g.) of sodium amytal. The stomach was washed out and picrotoxin (100.5 mg. intramuscularly and 115.5 mg. intravenously) was administered over the next 17 hours. In spite of this the patient remained comatose, and tendon reflexes were obtainable for only a few minutes after each injection. During the next 75 minutes 70 mg. of amphetamine sulphate was given intravenously, and after this the patient woke up and spoke. After an hour without treatment she relapsed into coma and 6 mg. of picrotoxin failed to rouse her. Thirty minutes later a further intravenous injection of 10 mg. of amphetamine again woke the patient, and when this was repeated one hour later she became fully conscious and required no more treatment. (This patient was treated in collaboration with Dr. A. G. Spencer.)

This case demonstrates the superiority of amphetamine over picrotoxin as an awakening agent in the later stages of the treatment of a case of severe barbiturate poisoning. Its action in shortening the period of unconsciousness should reduce the risk of bronchopneumonia.

Case 2

An asthmatic patient, aged 54, 24 hours before admission took 2 gr. (0.13 g.) of phenobarbitone and 1½ gr. (0.1 g.) of pentobarbitone sodium, followed while in a drowsy state by a further 9 gr. (0.58 g.) of pentobarbitone sodium. He was unconscious and cyanosed on arrival at hospital, with widespread rhonchi all over his chest and a respiration rate of 25. He was given 20 mg. of amphetamine intravenously, after which he opened his eyes, and a further 10 mg. 45 minutes later restored him to full consciousness.

This was a mild case of barbiturate intoxication, but in view of the patient's pulmonary condition it was essential to terminate the coma as quickly as possible. Amphetamine sulphate in quite small doses proved effective.

Case 3

A man aged 38 took 96 gr. (6.3 g.) of phenobarbitone and was admitted to hospital 31 hours later deeply comatose, with stertorous respirations at a rate of 16 a minute and a blood pressure of 100/68. The pupils were small with poor reaction to light; the corneal and tendon reflexes were sluggish and plantar responses flexor. The stomach was washed out, but only traces of barbiturate were present in the fluid. In the first three hours 180 mg. of amphetamine was given intravenously; the pupils became dilated and fixed, and the coma and blood pressure were unchanged. During the next three hours 69 mg. of picrotoxin was given intravenously and the blood pressure rose to 120/80. For the next 32 hours picrotoxin, 12 mg., and amphetamine, 20 mg., were given every half-hour, the injections being made into a glucose-saline drip every 15 minutes. Muscular twitching appeared and the dose of picrotoxin was reduced to 6 mg.; after a further 13 hours the twitching became more marked and picrotoxin was discontinued.

Over the next five hours amphetamine only was given; the patient's condition deteriorated, his coma became more profound, and respiration was shallower. Picrotoxin was then restarted, and eight hours later the condition had improved and the amphetamine was discontinued to see if this led to any change in the patient's condition; there was no deterioration of either blood pressure or respiration. However, after another four hours vigorous muscle-twitching occurred and the picrotoxin was permanently stopped and amphetamine in 20-mg. doses recommenced. Seventeen hours later, when 116 hours had elapsed since the drug had been taken, the urine for the first time was free from barbiturates. The patient, however, remained deeply comatose; lumbar puncture was performed and a normal cerebrospinal fluid was obtained which did not contain any barbiturate. Twelve hours later the coma lightened, and after another eight hours the patient regained consciousness—137 hours after taking the tablets. Amphetamine was continued in decreasing amount and at lengthening intervals for a further 15 hours.

Over a period of 121 hours the patient received 4,230 mg. of amphetamine sulphate, 1,086 mg. of picrotoxin, and by intravenous drip 8 pints (4.5 litres) of 5% glucose in normal saline, 12 pints (6.8 litres) of 5% glucose in half-normal saline, 14 pints (8 litres) of 5% glucose, and 1 pint (570 ml.) of plasma. He was also given penicillin, vitamins of the B complex, two-hourly inhalations of 5% CO_2 in oxygen, and was frequently turned from side to side. During this prolonged coma the lungs remained completely clear, and great credit must go to the house-physician (Dr. D. A. Hodgson) and the nursing staff for their conscientious care of the patient. He was subsequently transferred to a mental hospital in which he had previously received treatment. His physician noted no change in his mental condition; the only sequelae to the poisoning and its treatment were thromboses in the leg veins into which the drip had been given. Lamson *et al.* (1949) have shown that in some animals the intravenous infusion of glucose potentiates the action of barbiturates; however, no such effect has been reported in humans, though the relationship has not apparently been specifically investigated.

Comment on the Cases

Many of the properties of amphetamine already referred to make it questionable whether the use of this drug in barbiturate poisoning is ever justified. In mice it increases the death rate from large doses of barbiturate. In man it raises the blood pressure and may produce cardiac arrhythmias; some patients show idiosyncrasy to the drug, which may be fatal. It disappears from the body very slowly, partly by an uncertain metabolic process and partly in the urine; hence with these large doses the amount accumulated must be considerable. In monkeys it produces histological changes in the brain cells.

Kempf (1946) has discussed its possible value, and points out that in mild cases there is little to be gained in the ordinary way by awakening the patient rather than letting him "sleep it off." Case 2 represents an exception to this: the patient was an asthmatic, and if his coma had persisted much longer he would probably have developed bronchopneumonia. Amphetamine in quite small doses proved effective, and there is little reason to suppose that such an amount would be dangerous. The use of larger doses in the severer cases requires more justification.

The outcome in Case 3 is unusual. The patient had taken a fatal dose of phenobarbitone, nearly all of which was probably absorbed, and he did not come under treatment until 31 hours after the drug had been ingested. He received large doses of picrotoxin and amphetamine in the course of treatment, and it is important to try to assess what part, if any, they played in his recovery. During the first three hours, when amphetamine was being administered, his condition remained poor, whereas picrotoxin at once stimulated the medullary centres and removed much of the immediate anxiety. Forty-eight hours later, when muscular twitching necessitated a break in picrotoxin therapy, there was definite deterioration despite the continued administration of amphetamine. Newman and Feldman (1948) recommend that picrotoxin should be used until preconvulsive muscular twitchings appear and amphetamine treatment then be started. It seems, however, that picrotoxin may have to be recommenced if the patient's condition is not maintained. In the early stages of this patient's treatment amphetamine had no demonstrable beneficial effect, but it is possible that subsequently it accelerated the recovery of consciousness. The progress of the first case showed this very clearly. No undesirable results seem to have followed the very large amounts of amphetamine administered.

Management of Cases of Acute Barbiturate Poisoning

These cases are not very common, and frequently first come under treatment during the night. The remedies used are often employed in a half-hearted and haphazard fashion. The following programme is outlined for the management of severe cases in deep coma.

1. If there is marked respiratory depression restorative measures should be applied at once. Intravenous picrotoxin, 6 mg., should be given, and if there is no response 12 mg. every 30 minutes. Oxygen administration may be useful, and in extreme cases the use of a mechanical respirator should be considered.

2. When respiration is restored, or in less severe cases immediately on admission, the stomach should be washed out with 16 pints (9 litres) of saline. (The stomach contents should be retained for examination.) Twenty grammes of magnesium sulphate should be left in the stomach.

3. The intravenous administration of picrotoxin, 12 mg. every 30 minutes, should be continued. A careful watch must be kept for twitching of the facial muscles; picrotoxin must be stopped if this occurs, and amphetamine, 20 mg. at similar intervals, should be given. If the coma then deepens, picrotoxin, 6 mg., every 30 minutes should be restarted; otherwise amphetamine should be continued until the patient regains consciousness and for some hours after, in decreasing doses and at lengthening intervals.

4. If the patient shows no response after the first few hours it is desirable to cut down on a leg vein and set up a drip infusion. A plaster cast should be applied to the leg, otherwise as the patient becomes restless serious damage may occur. The analeptic drugs are given into the tubing of the drip. The fluid given should be glucose (5%) in varying concentrations of saline according to the urinary chloride content. The rate of flow must be regulated to maintain a good urinary output without causing any pulmonary oedema.

5. Rectal wash-outs should be done daily in order to remove any barbiturate in the lower bowel.

6. Milk by gastric tube should be given, and probably vitamin-B complex by intramuscular injection as long as a glucose drip is running.

7. To prevent pulmonary infection prophylactic penicillin should be given, also CO_2 and oxygen inhalations every two hours, and the patient should be nursed on his side and turned frequently.

In mild cases in which the patient exhibits spontaneous movements, a stomach wash-out is in many cases all that is needed; but if for any reason rapid awakening is desirable, one or two intravenous injections of 20 mg. of amphetamine at 30-minute intervals may be given. Some patients admitted shortly after the ingestion of the drug may present a deceptive appearance and should be watched carefully, since they may sink deeper into coma.

Summary

Intravenous amphetamine sulphate is a useful ancillary drug in the treatment of acute barbiturate poisoning. In mild cases in which rapid awakening is desirable it is effective and safe. In severe cases it is of little value in the early stages, but it may shorten the duration of coma if given later, particularly when picrotoxin is producing preconvulsive muscular twitchings.

A case is described in which the patient took 96 gr. (6.3 g.) of phenobarbitone 31 hours before admission to hospital. He recovered after 137 hours in coma. Treatment included 4,230 mg. of amphetamine sulphate and 1,086 mg. of picrotoxin.

A programme for the management of cases of acute barbiturate poisoning is outlined.

I have to thank Professor H. P. Himsworth, Dr. E. E. Pochin, Dr. A. Morland, and Dr. J. F. Stokes for permission to report cases under their care, and Professor C. Rimington for examination of specimens for barbiturates.

PREGNANCY IN A RUDIMENTARY HORN OF A BICORNUATE UTERUS

BY

DOUGLAS LATTO, M.B., Ch.B., M.R.C.O.G.

AND

RICHARD NORMAN, M.R.C.S., L.R.C.P.
D.Obst.R.C.O.G.

(From the Nuffield Department of Obstetrics and Gynaecology, Radcliffe Infirmary, Oxford)

This case of pregnancy in a rudimentary horn is discussed at some length because of the great danger there may be to the patient. Unlike tubal gestation, in which less than 50% rupture and present the classical picture, 90% of the cases of pregnancy in a rudimentary horn rupture, and as this occurs about the sixteenth week the bleeding is profuse. Very little has been written on this subject recently, and the relatively high incidence of the condition is not generally realized.

Pregnancy in a rudimentary horn was first described by Mauriceau and Vassal in 1669. Kehrer in 1900 collected 84 cases from the literature, and Beckmann in 1911 found 146 cases. DeLee and Greenhill (1947) state: "Perhaps 100 cases have been described. Mulsow found reports of only nine cases since 1911." Mulsow (1945) himself, however, said: "With the aid of the librarian of the Iowa State Medical Library at Des Moines, I have been able to review the records of nine cases which have been reported since Beckmann's review in 1911." In the *Index Medicus* for the past 25 years we have found over 40 reported cases: in all probability, therefore, well over 200 cases have now been described.

Case Report

The patient was admitted to the Radcliffe Infirmary on January 15, 1950, complaining of severe abdominal pain of four hours' duration. She had had vague pain in the right iliac fossa for the past week, and had felt sick but had not vomited. Menstruation had been regular until September 16, 1949, since when there had been amenorrhoea. There was very little else of significance in her history except that she had a normal full-term pregnancy in 1946, a spontaneous breech delivery; also she had rather severe hyperemesis in the first three months of this pregnancy.

The patient looked distressed and was obviously very ill, with restlessness and air-hunger. The skin was cold and clammy, and she had the typical pale waxy appearance indicative of sudden profuse loss of blood. The pulse was rapid and thready, and the blood pressure 70/30. The abdomen was slightly distended and there was extreme tenderness all over it. A soft mass was palpated in the pouch of Douglas. Bimanual examination was unsatisfactory because of the abdominal rigidity and distension. A provisional diagnosis of pregnancy in a ruptured rudimentary horn was made. Other conditions considered in the differential diagnosis were ruptured ectopic gestation and rupture of and haemorrhage from an ovarian cyst. Operation was decided upon soon after the patient had begun to respond to the initial shock therapy—warmth, ½ gr. (11 mg.) of morphine, and blood transfusion (Group A, Rh-negative).

Under general gas, oxygen, and ether anaesthesia the abdomen was opened through a paramedian subumbilical incision. The abdominal cavity contained about four pints (2.27 litres) of blood. The foetus could be seen inside the intact amnion and was attached to the rudimentary horn. The normal horn was about the size of a 10-weeks pregnancy. The foetus and rudimentary horn and tube were removed leaving the ovary. The round ligament and ovary were then stitched to the normal horn for support and to cover the raw area. The remainder of the blood was removed from the peritoneal cavity and one pint (570 ml.) of saline inserted. The abdomen was closed in layers. The patient's condition was satisfactory at the end of the operation and the blood pressure was 100/60. She made an uninterrupted recovery (a pyelogram showed the renal tract to be normal).

On February 27 a blood transfusion follow-up showed: Group A, Rh-negative; complete anti-D antibodies, titre 1:2; incomplete anti-D antibodies, titre 1:2; haemoglobin, 92% (13.5 g.).

Discussion

It is said that the part of the rudimentary horn attached to the normal horn usually has no canal. Piquand (1910) states that there is a canal in only 15% of cases, but this is observed only when the uterus approaches the bicornis-unicollis type.

One may read in any textbook that the spermatozoon ascends the normal horn and Fallopian tube and crosses the peritoneal cavity to fertilize the ovum. The fertilized ovum then gets into the rudimentary horn. This explanation seems untenable, and we are of the opinion that the rudimentary horn is not occluded until after pregnancy in most cases, for the following reasons:

1. It is improbable that one spermatozoon can fertilize an ovum, and it is very unlikely that a sufficient number of spermatozoa can find their way across the peritoneal cavity. A large number of spermatozoa are required to fertilize an ovum because of the hyaluronidase content required to "dissolve" off the corona radiata surrounding the ovum. A man with 10 million spermatozoa per ml. is virtually incapable of becoming a father because somewhere in the region of 50–100 million spermatozoa per ml. is thought necessary.

2. The corpus luteum is usually found on the same side as the rudimentary horn. On rare occasions it has been reported that the corpus luteum was found on the opposite side, the fertilized ovum then crossing the peritoneal cavity (internal migration of the ovum cannot always be excluded in these cases). With prolapse of the ovaries the tubes may be almost lying side by side, which may account for a few of these anomalies. It is well known that an ovum may cross the peritoneal cavity as in the cases of pregnancy reported after previous contralateral removal of tube and ovary.

3. Many cases show a canalization of the distal end of the rudimentary horn, and this canal leads into the cavity of the normal horn, as illustrated by Munro Kerr and Chassar Moir (1949). The canal was easily demonstrated in the case described.

4. The microscopical examination of the canal is almost invariably made after a pregnancy has occurred. The canal could easily have been occluded by the tissues reacting to the advancing syncytium and by the fibrin laid down in the small haemorrhages. To a less degree a similar occlusion can be found in the Fallopian tube in ectopic gestation.

5. The cervix uteri in comparison is occasionally completely occluded during pregnancy in conglutination of the cervix, which may happen after trauma and mild infection at a previous pregnancy. The canal may be so obliterated that no evidence of it can be found, but, as in the case of the rudimentary horn, the spermatozoa must have got in before the canal was occluded.

6. A case described by Banister (1937) lends further support to our contention. In this case an ovarian cyst was thought to be complicating pregnancy. At laparotomy a four-months foetus was found in a normal horn and a three-months foetus in a rudimentary horn. If this is a case of superfoetation or superfecundation it is possible that the pregnancy in the normal horn occurred first. Before the uterine cavity was completely filled the other conception took place. The rudimentary horn was attached near the cervix of the normal horn. (It is possible that the foetus in the rudimentary horn was growing more slowly because of the poor "soil.") The pregnancy in the rudimentary horn was removed and the other pregnancy went to term and resulted in a spontaneous delivery of a normal child.

7. Pregnancy in a rudimentary horn has been shown not to be extremely rare, and if the horn were not canalized one would expect to see more cases of haematometra. Of course it must be admitted that they occasionally do occur, and, furthermore, it has been said that the endometrium in the rudimentary horn is infantile and refractory to hormonal stimulation.

Summary and Conclusions

A case of pregnancy in a rudimentary horn is described and its aetiology discussed.

Pregnancy in a rudimentary horn is more frequently encountered than one is led to believe by many textbooks. We are of the opinion that the theory of transabdominal migration of a spermatozoon is untenable, and that if a patient gets a pregnancy in a rudimentary horn the canal of that horn is patent before pregnancy in almost every case.

The Society for the Rehabilitation of Disabled and Crippled Children (of India) has issued its first annual report, covering the period March, 1947, to December, 1948, with a postscript on 1949. It is the first time in India that something is being done to provide organized physiotherapy and orthopaedic treatment for children after poliomyelitis, or with spastic paralysis. The Society's out-patient clinic in Bombay is housed in a military hut loaned by the Government of Bombay and equipped by private donors; it is staffed by a number of ex-Army physiotherapeutic technicians and voluntary social workers. Up to the end of September, 1949, about a thousand patients had registered for treatment, over 800 of them poliomyelitis cases.

Medical Memoranda

Larval Conjunctivitis

Although larval conjunctivitis is well recognized in hot climates, it is rarely encountered among white patients. It is of interest, therefore, to describe three cases which occurred among British Service men in Egypt.

Case Reports

Case 1.—An aircraftman was referred to the ophthalmic department with a history that while cleaning a 20-mm. cannon three days previously he felt something enter his left eye. Immediate examination by his colleagues revealed no foreign body. The eye became red and irritable, and watered. On examination the conjunctiva was seen to be inflamed and oedematous. With a loupe several tiny larvae were seen moving in the upper and lower conjunctival fornices and wriggling across the cornea. The larvae were less than 1 mm. long and owing to their small size and transparency were almost invisible to the naked eye. After cocainization seven larvae were removed with pointed conjunctival forceps. The larvae were identified as those of *Oestrus ovis.* Two days later, following irrigations with bland lotions, the patient was symptom-free and the eye normal.

Case 2.—A healthy young soldier was referred to the ophthalmic department complaining of a sudden stabbing pain in the right eye, as if there was a foreign body in it. He had been cleaning an air cleaner from a tank with a mixture of petrol and oil, and he thought that some had entered his eye. On examination conjunctival injection was present and several larvae were seen crawling across the tarsal conjunctiva and moving further into the fornices. The cornea was criss-crossed with multiple superficial abrasions, a result of the larvae being rubbed across the corneal epithelium. Eleven larvae of *Oestrus ovis* were removed. The conjunctival irritation settled down the following day, and the patient was returned to his unit free from symptoms.

Case 3.—An aircraftman felt something fly into and out of his right eye while he was removing an aircraft propeller. The eye became painful and was irrigated several times. He was seen eight hours later, when the upper lid was oedematous, the conjunctiva injected, and the cornea showed superficial abrasions. Several worms were seen moving across the cornea, and thirteen were removed from the conjunctival sac. They were identified as larvae of *Oestrus ovis.* Three days later the conjunctiva was white and the abrasions healed.

Comment

In these cases it may be assumed that the fly deposited its young directly on the conjunctival surface, though *Oestrus ovis* is said to lay its eggs at times while flying, without alighting (Strong, 1942).

Oestrus (bot-fly) is one of the genera of the Oestridae. It is parasitic normally in the nasal passages and sinuses of sheep, and also infects man. Oestridae possess penetrating organs known as ovipositors and can lay their eggs beneath the conjunctiva (Duke-Elder, 1938). Most of the recorded cases have been infections by *Hypoderma bovis,* the larvae of which may penetrate the globe.

Robinson (1949) reported a case of larval conjunctivitis in a naval officer at Malta in whom three larvae of *Oestrus ovis* were found. The greatest number recorded is 77.

Prompt treatment of the condition is advised in order to prevent the serious complications of corneal ulceration and intraocular invasion.

I wish to express my thanks to the Director-General of Medical Services, Royal Air Force, for permission to publish this paper.

Arteriovenous Fistula Complicating an Amputation Stump

The occurrence of an arteriovenous fistula is an unusual complication of an amputation, and was thought to be a sufficient rarity to warrant publication.

Case Report

On December 9, 1948, a man was referred to the Bradford Royal Infirmary complaining of pain in an amputation stump. The following history was obtained.

In 1936, when aged 17, he was involved in a road accident, a heavy vehicle passing over his left leg. An above-knee amputation was performed on the same day. He was subsequently fitted with an artificial limb, which he stated was never very comfortable but did not cause any pain. The stump was quite satisfactory until about a year ago, when he experienced pain accompanied by a throbbing sensation. The pain had increased during the past three months to such a degree that he had to discard his prosthesis for long periods, with resultant loss of earnings. He stated that he had no dyspnoea or palpitation.

On examination the amputation stump was satisfactory in shape and length. Posterior to the scar one could feel a distinct thrill over a pulsatile ill-defined mass coinciding with the heart beat. A loud bruit with systolic accentuation could be heard on auscultation over the mass. The B.P. was 140/98 mm. Hg. The pulse rate was 82, this slowing to 68 on pressure over the femoral artery in the groin. Release of the compression caused the pulse rate to rise to 80. A skiagram of the chest showed the transverse diameter of the heart to be increased, with prominence of the right ventricle. An arteriovenous fistula between the femoral vessels was diagnosed. An arteriogram was attempted with a view to revealing the type of connexion between the affected vessels. This was of little value, but it revealed a tortuous dilated vein in the stump.

He was admitted to the Infirmary on December 30. An incision was made along the medial aspect of the lower end of the stump, curving posteriorly to end below the mass. An irregular saccular pulsatile mass was exposed, the femoral artery entering this proximally. The femoral vein was grossly dilated and was seen to emerge from the mass, while numerous small vessels entered it. The main trunks and smaller vessels were ligated, the fistula excised, and the wound closed with drainage. Recovery was uneventful.

Attempts to demonstrate the vascular communication in the excised mass by radiology failed, but on dissection a well-marked arteriovenous fistula was demonstrated 2½ cm. from the cut ends of the vessels.

Comment

The fistula probably either originated as the result of a mass ligation of the damaged femoral vein and artery or developed from damage to the arterial and venous walls at the time of the original injury. The latter is the probable explanation, in view of the late onset of symptoms.

A. Naylor, Ch.M., M.Sc., F.R.C.S.,
Consultant in Orthopaedic Surgery to the Bradford Royal Infirmary.

In *British Health Resorts,* the official handbook of the British Health Resorts Association, information is given on the climate and special features of health resorts in Britain and the British Commonwealth. The particular conditions for which patients may be sent to a resort are listed under each one, and full meteorological data are included. The eighth edition of the handbook is obtainable for 4s. 6d. from the association at Bourdon Street, Berkeley Square, London, W.1.

Reviews

HAEMATOLOGY EXPANDS

Disorders of the Blood. Diagnosis: Pathology: Treatment: Technique. By Sir Lionel E. H. Whitby, C.V.O., *M.C.,* M.A., M.D.(Cantab), F.R.C.P., D.P.H., and C. J. C. Britton, M.D.(N.Z.), D.P.H. Sixth edition. (Pp. 759; 12 colour plates and 94 text-figures. £2 2s.) London: J. and A. Churchill. 1950.

Practical Haematology. By J. V. Dacie, M.B., B.S.(Lond.), M.R.C.P.(Lond.). (Pp. 172; 13 illustrations. 10s. 6d.) London: J. and A. Churchill. 1950.

The sixth edition of Whitby and Britton's *Disorders of the Blood* will be sure of a welcome, and haematologists in this country in particular will be grateful to the authors for coping successfully with the Sisyphean task of keeping the book and its readers up to date and maintaining the high reputation of this standard British text. In the present edition the literature is surveyed to the end of 1949. Vitamin B_{12} is adequately treated, but A.C.T.H. is a cloud no bigger than a man's hand, and the names of Hench, Kendall, and Selye are not mentioned. The main changes have been in the fields of coagulation, blood grouping, and haemolytic anaemia, where considerable progress, not to say complication, has occurred. The book now has 759 pages, of which the index occupies over 40. The production is excellent. Some coloured photomicrographs have been added; these are commonly regarded as being more objective than paintings, but they are not so illustrative, and owing to difficulties in focusing rarely reveal all that the observer can see in the cell.

Some five hundred people from all over the world attended the recent international congress on haematology at Cambridge. Although the famous names were a big draw, different topics attracted rather different audiences, and it seems that the subject of blood coagulation and also that of blood grouping, with which is associated the serological study of the haemolytic diseases, have already developed into separate entities. The importance of the former depends on the frequency of thrombosis and embolism, that of the latter on the world-wide development of blood-transfusion services, and neither of them is the exclusive concern of haematologists in the narrow sense. Leukaemia and allied conditions have an enormous literature which merges with that of cancer as a whole. One cannot help wondering how long it is going to be possible to write textbooks of haematology which deal in detail with all these subjects, and whether they will not have to give place to the primer, the separate monograph, and the encyclopaedia. Meantime we are grateful to Whitby and Britton for having made so much learning so easily available to us.

Dr. Dacie's little book is sure of a welcome by haematologists and directors of laboratories. It is based on lectures to students taking the course for the London University Diploma in Clinical Pathology, and it contains descriptions of the routine haematological techniques—including some for the haemolytic and haemorrhagic diseases and for blood grouping, which are relatively new, but which are being increasingly demanded. Methods of staining films are given, but there are no pictures of blood cells. The book should therefore be used in conjunction with a textbook or an atlas. This is an advantage, as it means that the book has been produced at a low price and no one need be afraid of using it on the working bench. A great virtue is that it emphasizes the errors made and the time lost in certain classical haematological procedures. Another writer (Jennings, D., *Lancet,* 1950, **2**, 234) has recently asked:

> "Does any haematologist who knows the clinical history, the haemoglobin and the haematocrit reading, and who has a stained blood film in front of him, get any further aid in diagnosis from a red-blood-cell count which is likely to be more than 10% out in a third of cases and more than 20% out in one of twenty cases? Have our patients derived any benefits from these counts, or have millions of hours during the last 30 years been squandered?"

The classification of anaemias by the diameter, volume, and shape of the red cells has made the profession too red-cell conscious, and it is not sufficiently realized that a Price-Jones curve is a research procedure and that an accurate red-cell count is difficult to obtain. Estimation of the haemoglobin and a glance at the film, supplemented if necessary by the haematocrit and E.S.R., are quick and accurate guides which tell us all we need to know about most cases of anaemia. Elaborate procedures such as counting red cells, platelets, and differential white cells should probably be centralized in laboratories where special apparatus and mechanical aids can be installed. There will always be individual preferences over technique, but it is surprising that Dr. Dacie devotes so much space to the estimation of haemoglobin by the methods of Haldane, Sahli, alkaline haematin, and cyanhaematin. Most haematologists now prefer to estimate haemoglobin as oxyhaemoglobin in a grey-wedge visual photometer or a photo-electric colorimeter. Measurement of clot retraction is of no value in diagnosis and should be replaced by measurement of platelets and fibrinogen. Dr. Dacie does not mention the help obtained from a simple hand tally in most forms of counting.

L. J. Witts.

DIAGNOSTIC RADIOLOGY

Lehrbuch der Röntgendiagnostik. By H. R. Schinz, W. E. Baensch, E. Friedl, and E. Lehlinger. Vol. 1, Skelett. Fifth edition. (Pp. 426; 507 illustrations. M. 66.) Stuttgart: Georg Thieme. 1950.

To many diagnostic radiologists Schinz's textbook is a bible, and it is therefore a great pleasure to see this new edition appear after a lapse of twelve years since the last one. It is almost inevitable that some of the contributors should have died during this period. Lysholm, Holz, and Ulrich have gone, and the rest of the old team has been strengthened by the addition of ten new contributors. Nearly all, both old and new, are Swiss and Swedes, mostly from Zurich and Stockholm.

This first part, entitled "Skelett," deals only with some aspects of the skeleton. None the less one gains a fair impression of what is yet to come. The most striking change from the last edition is the greatly increased size of the work. The new edition promises to be over twice as large and will probably be completed in about ten parts. The basic structure of the book remains unchanged; some illustrations have been removed and many new pictures, diagrams, and tables added.

The first 100 pages are on the physical properties of *x* rays as applied to diagnostic radiology, and a new chapter by Brandenberger on structure analysis has been added. The chapter on bone growth and epiphysial development is excellent; it has been much enlarged and new work on this subject has been incorporated. No fewer than 155 well-chosen references are appended to this chapter alone. Although the bibliography has a Continental bias, the main British and American papers are quoted.

The last chapter—on fractures—has been increased from 40 to 200 pages and many good line diagrams have been added. The remaining parts are expected to be published at intervals of roughly six months.

Until now the reader who has no German (or Spanish, for the last edition was translated into that language) has been denied access to this bible of much of the European continent. It is indeed good news to learn that a New York publisher has undertaken the translation into English and that the volume under review will appear in English before the end of the year.

J. W. D. BULL.

ACTINOMYCETES

The Actinomycetes. Their Nature, Occurrence, Activities, and Importance. By Selman A. Waksman, Ph.D. (Pp. 230; 39 figures. $5.) Waltham, Mass.: Chronica Botanica Company. London: Wm. Dawson and Sons. 1950.

Waksman, the discoverer of streptomycin, is a soil microbiologist, and he cultivated *Streptomyces griseus*, the source of this antibiotic, from a sample of soil so long ago as 1916. In a sense we owe to him not only this discovery but that of the newer antibiotics, since they too are derived from organisms of the same genus, and it was he who opened the gate to this fruitful field of exploration. A delightful and apposite quotation from Walt Whitman which prefaces this volume reminds us of the author's primary interest, and of the fact that the soil is the main habitat of the actinomycetes. Indeed, they may form as much as 40% of its total microbial population and play a large part in the breakdown of plant and animal residues. To this beneficent activity may be added on their credit side the formation of antibiotics and at least one useful vitamin (B_{12}) and enzyme (superbiolase). On the other hand, two genera (not, it is now believed, soil inhabitants) are pathogenic to man and animals, and one to plants.

The only chapter in this book having direct application to medicine is that on actinomycosis and related diseases, and this is of interest rather as a historical account and as a guide to classification of pathogenic species than from any clinical point of view. To the microbiologist, on the other hand, the whole book will be of great value as a systematic and authoritative account of these organisms, for the author describes in detail their classification, distribution, morphology, metabolism, and functions. It is well illustrated, largely by photographs, and thoroughly documented.

L. P. GARROD.

MEDICAL PHOTOGRAPHY

An Introduction to Medical Photography. By Josephine Hunt, S.R.N., S.R.C.N., F.I.B.P., F.R.P.S. With a foreword by Sir Cecil Wakeley, K.B.E., C.B., D.Sc., F.R.C.S., F.R.S.Ed., F.R.P.S. (Pp. 243; 87 illustrations, 4 in colour. £1 10s.) London: Staples Press. 1950.

Advanced manuals of photography on the one hand and elementary handbooks on the other are freely—the latter perhaps too freely—available. In her book Miss Hunt has set out to bridge the intervening gap for the student medical photographer, who, it is assumed, will already have a basic knowledge of photography but will know nothing of hospitals.

The author has thirty years of practical experience: the book is a rather conversational distillate of that experience, and it will be of great value to the neophyte. It is not a textbook of medical photography, nor is it intended to be. But it does contain a wealth of good advice on the relations of the photographer (and for that matter any medical auxiliary) with the medical and administrative staff. The chapter on "The Patient" reveals a humanity which is refreshing in these days of centralization.

The book ends with a chapter on cardiography, on which the author is an authority, with many years' experience at King's College Hospital. In the present context it is misplaced; the medical photographer is rarely associated with the subject, and his field to-day is wide enough without it.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY OCTOBER 21 1950

EUGENICS AND HEREDITY

The first two occupants of the Galton Chair of Eugenics at University College, London, Karl Pearson and R. A. Fisher, started their careers as mathematicians. The present professor, L. S. Penrose, is the first to be medically qualified; and it is inevitable that his outlook should differ from that of his predecessors. A mathematician will tend to concentrate on the problem of how the numbers of congenitally handicapped members of a population can be diminished in future generations and the numbers of congenitally superior members increased. A physician, while not neglecting this problem, is likely to be at least equally interested in the therapeutics of inborn diseases and abnormalities; and in the paper which Professor Penrose read at the Annual Meeting of the B.M.A. in Liverpool last July, and which is reproduced in the opening pages of this issue, he emphasized this point.

Many readers will think that he has underestimated the possibilities of preventive eugenics—that is to say, the elimination of injurious genes. But a careful perusal of his article will show that his statement is correct. There are abnormalities in which about half the children of affected persons resemble their parents. But, on the one hand, such clear-cut dominance is quite rare, and, on the other, such injurious genes are constantly reappearing by mutation. For example, in Sjögren's recent study of blindness due to congenital microphthalmia in Sweden, only 12 of the 65 children investigated had one parent similarly affected. Had these parents been prevented from breeding, these 12 children, and 18 normal ones, would not have been born. While preventive eugenics could prevent the birth of a few thousand abnormals in each generation, the conditions to which it could be effectively applied are all rare; and such measures, even if rigorously carried out, would not succeed, in Professor Penrose's words, in "making any appreciable change in the genetical composition of the population." There is certainly, as he points out, a genetical element in the causation of such common diseases as diabetes and mammary cancer; and unfortunately the number of patients with either of these two diseases is much larger than the number suffering from all the comparatively rare complaints with straightforward dominant inheritance. This does not mean that preventive eugenics are worthless. It does mean that, with our present knowledge, they cannot achieve very much.

On the other hand, Professor Penrose was, if anything, over-cautious in his claims for the therapeutic importance of human genetics. In very many cases, including diabetes and gout, there is good evidence that what is genetically determined is not the disease but the diathesis. The rapid progress of biochemical genetics makes it entirely possible that such inborn diatheses may be detectable long before the appearance of overt symptoms, and that dietary moderation, and perhaps therapeutic measures as yet unexplored, may postpone, or even completely prevent, the onset of manifest disease. We all have our weak points: it may be that the main function of medical genetics will be to reveal them before they have betrayed us. But Professor Penrose has done a service in emphasizing that because a disease is congenital or hereditary it is not incurable. In some cases, as with neonatal jaundice, the cure may be permanent. In others, such as methaemoglobinaemia and the de Toni-Fanconi syndrome, treatment may have to be continued indefinitely. Those who regard the treatment of such conditions as weakening the human stock should logically deprive congenital myopics of their spectacles and trust to their selective elimination by motor traffic.

It is, however, conceivable that one of the main contributions of human genetics to medical progress will be its influence on the development of physiology and biochemistry. It is not perhaps always remembered that cystine was first produced by a congenital cystinuric, and that this unfortunate victim of stone in the bladder played a substantial if indirect part in saving the lives of sufferers from arsenic poisoning treated with British anti-lewisite a century after his death. At the present time a study of what can fairly be called the congenital diseases of the mould *Neurospora* is elucidating the intermediary metabolism of the amino-acids. It is almost certain that when we understand why phenylketonuria—which is due to a block in phenyl-alanine metabolism affecting the whole body—profoundly disturbs brain function without affecting that of other organs, we shall have enough clues to the peculiarities of brain metabolism to open a new chapter in pharmacology. When we understand just what has gone wrong with bone metabolism in the osteopsathyrosis associated with blue sclerotics, we may be able to speed up the healing of fractures. A genetically determined disease, like any other, may be regarded as an experiment performed by nature on a patient. But it differs from most infectious diseases in being a far more precise experiment. Whereas tuberculosis can kill by damaging almost any organ in the body, a disease of the type studied by geneticists is due to an abnormality of one

or two genes in each cell nucleus, the genes playing the same sort of parts in the physiology of the cell as organs do in that of the body as a whole. Each such disease is a disturbance of a particular function, and may be compared with a malady such as Graves's or Addison's disease which has not only demonstrated the function of a particular organ but led to the discoveries of substances as valuable as thyroxine and "cortisone."

The close connexion between genetics and obstetrics was mentioned by Professor Penrose. Strictly speaking, the influence of the mother on the foetus during pregnancy should be regarded as environmental rather than hereditary. Nevertheless, the geneticist must study it very carefully, and can give invaluable aid to the human embryologist in distinguishing between congenital effects which can properly be ascribed to heredity and those which are more correctly regarded as due to prenatal environment and therefore likely to be more easily preventable. Professor Penrose finished his address with a plea on behalf of geneticists for more medical information, and particularly for accurate data on the frequency of congenital abnormalities in the population. Without such data pedigree studies may often be meaningless, since until we know the frequency of a condition we do not know whether its occasional presence in two relatives means anything: this will come about only with the diffusion of genetical notions in the medical profession. But had Professor Penrose been speaking to a different audience he might equally well have stressed the need for a clinical point of view among geneticists, including animal and plant geneticists. For medicine is not merely a useful art: it is a science which can and should influence all other branches of biology, including genetics.

VITAMIN-A DEPRIVATION IN MAN

Some anxiety about the adequacy of the wartime diet to maintain the health of the population was inevitable, and as a means of increasing the consumption of vitamin A in the form of carotene the Ministry of Food made strenuous efforts in advertising campaigns to popularize carrots. An insurance against severe deficiency was also provided by the compulsory addition to margarine of vitamin-A concentrates, which were mostly obtained from whale livers. Doubts still remained, however, about the exact amount of vitamin A required by human beings, and in 1942 the Medical Research Council was requested to undertake experiments to obtain definite information on this point. The report of the investigation, which was organized by the Vitamin-A Subcommittee of the Accessory Food Factors Committee, was given the title "Vitamin-A Requirements of Human Adults—A Study of Vitamin-A Deprivation in Man."[1]

The volunteers who acted as experimental subjects for these prolonged experiments were 20 young male conscientious objectors and three women. They were housed at the Sorby Research Institute, Sheffield, a large villa with some rooms converted for use as laboratories. At first the organization of the investigation was in the hands of Dr. Kenneth Mellanby, and subsequently of Professor H. A. Krebs. Most of the volunteers had already proved their reliability and patience in experiments on the transmission of scabies, and they tolerated without protest a monotonous diet made deficient in vitamin A and carotene by exclusion of foods such as butter, whole milk and its products, liver and other animal organs, fat fish, and all green and yellow vegetables and fruits. With the co-operation of laboratories at Cambridge, Liverpool, Oxford, and Reading numerous routine tests for vitamin A and carotene were carried out, both on the blood and faeces of the volunteers and on the foodstuffs which they were allowed to consume. Measurements of the capacity for dark-adaptation were made at the institute mainly by means of an apparatus designed by Mr. W. Bartley, one of the volunteers, or by rod scotometry. The scope of the investigation can be judged from the fact that the research team consisted of about 25 doctors, scientists, and senior technicians. Many commercial firms assisted by providing specially prepared foodstuffs or in other ways. The heavy task of co-ordinating the efforts of the various groups of workers was undertaken by Miss E. M. Hume.

In 16 of the volunteers who subsisted on the diet without supplements and in two who were dosed with preformed vitamin A, carotenoid pigments disappeared almost completely from the blood plasma during the first few weeks of the experiment. The decline in the plasma vitamin A, which at first ranged from 65 to about 120 i.u. per 100 ml., was less rapid, and in one subject the original level was maintained for no less than 22 months. The mean figure of 88 i.u. obtained from tests made shortly after the experiment had started fell only to 74 i.u. in nine months, and in seven subjects who remained in the experiment for 14 months the mean was still as high as 61 i.u. The decline in both plasma carotenoids and vitamin A was prevented or reduced in control subjects by daily doses of 2,500–6,700 i.u. of carotene in various forms, while the fall in the plasma vitamin A, but not in carotenoids, was prevented by doses of 2,500 i.u. of a distilled concentrate of vitamin-A esters. In the parallel dark-adaptation tests some evidence of a seasonal variation was found in all subjects, the final-rod-threshold values reflecting the variations in the monthly averages of

[1] *Spec. Rep. Ser. med. Res. Coun., Lond.*, No. 264, 1949, London: H.M.S.O.
[2] *Biochem J.*, 1937, **31**, 155.

daily minimum temperatures. Considerable deterioration in capacity for dark-adaptation not related to the season of the year was observed in only three of the volunteers who received no supplements; all three had plasma-vitamin-A values of 40 i.u. or less. Only in these cases was it possible to carry out satisfactory therapeutic tests. Preformed vitamin A, in a daily dose of 1,300 i.u. given over a prolonged period, was found both to improve the dark-adaptation and to restore the plasma vitamin A to about its original level. With a daily dose of 1,250 i.u. of carotene in oily solution the amounts of vitamin A and carotenoids in the plasma were slightly increased, but dark-adaptation was improved only when the dose was raised to 2,500 i.u. Studies of the efficiency of absorption of carotene from carrots and green vegetables were made by finding the difference between the amounts eaten and those excreted in the faeces. With allowances for a safety margin and for wastage during absorption the daily requirement of an adult male may be assessed as 2,500 i.u. of preformed vitamin A, 4,000 i.u. of carotene in oil, 7,500 i.u. of carotene in green vegetables, or 12,000 i.u. of boiled sliced carrots. With ordinary diets, of course, the daily requirement will not be derived from a single item but will be contributed by foods containing both preformed vitamin A and carotene. Larger amounts may be needed by pregnant or lactating women and by children.

Apart from the changes mentioned the volunteers had no symptoms which could be ascribed to deficiency of vitamin A, though two of them were found during the course of the experiment to be suffering from tuberculosis. While it may seem surprising that a diet containing only traces of the vitamin should have caused no symptoms of deficiency in most of the subjects, it has long been known that the human liver normally contains large reserves of vitamin A. In this country before the war Moore[2] found that the reserves present in the liver of persons who died as a result of accidents usually appeared to be sufficient to meet the body's requirements for several months, and there is nothing in the M.R.C. report to indicate that wartime dietary changes have had the effect of decreasing reserves. Nevertheless it is surprising that some of the volunteers were able to subsist on this restricted diet for 1½–2 years, and the conclusion must be that the reserves in the liver are mobilized and expended with great economy. The clear evidence of incipient vitamin-A deficiency found in three out of 16 subjects was perhaps as much as could be expected from an experiment which could not be prolonged indefinitely. Both the research team and the volunteers must be commended for their patience and perseverance in completing one of the longest and most laborious nutritional experiments yet to be undertaken in this country.

ABSORPTION OF VITAMIN B_{12}

A few weeks ago in this *Journal* Dr. Byron E. Hall[1] reviewed recent work on the intrinsic factor of Castle and described some of his own experiments which shed light on the interaction between the intrinsic factor and vitamin B_{12}. In a series of papers in this issue Dr. C. C. Ungley reports the results of carefully devised therapeutic experiments to test the absorption of vitamin B_{12} administered orally to patients with pernicious anaemia. Briefly, the investigation was concerned with the effect of normal gastric juice in promoting absorption of the vitamin, with absorption of massive doses of vitamin B_{12} alone, and with the demonstration that milk or concentrated whey does not serve as an alternative source of intrinsic factor or of protein capable of affecting vitamin B_{12} in such a way as to lead to its absorption. In addition Ungley tested the absorbability of vitamin B_{12} alone from the buccal cavity and from the intestine, absorption from the latter site being considered in relation to such possible destructive agents as the intestinal juice and bacteria.

Some investigators, using small doses or even fairly large single doses of up to 1,000 μg. of orally administered vitamin B_{12}, have obtained either no response or variable and inadequate responses in patients with pernicious anaemia,[1] though Spies and his colleagues[2] found that about 50 times the smallest parenteral dose was slowly effective when given by mouth. Goldhamer[3] has shown that the quantitatively reduced gastric juice in patients with pernicious anaemia may contain a very small amount of intrinsic factor, so that some slight absorption might be expected. Ungley has now obtained evidence that the absorption of vitamin B_{12} when administered orally in small daily doses is very poor: no response was observed in a patient given 5 μg. daily for 10 days, and in another patient receiving 80 μg. daily for 24 days a rise in erythrocytes occurred which was no greater than would be expected after a single injection of only 2.5 μg. When filtered and neutralized normal gastric juice was given with vitamin B_{12} to eight patients with pernicious anaemia the responses were variable, but indicated that each 100 ml. of juice may potentiate the absorption of from 1 to 10 μg. of the vitamin. One of these patients failed completely to respond, and another, receiving only 150 ml. of juice with 40 μg. of vitamin, responded unsatisfactorily. A remarkable result, however, was obtained in five patients receiving a single massive dose of vitamin B_{12}

concentrate by mouth—3,000 μg. without added gastric juice. All responded, and, by computation from the expected response to parenteral treatment, it was considered that in no case was less than one-fortieth of the dose absorbed. Such a large dose of vitamin B_{12} is of course greatly in excess of what would normally be ingested in the diet, and it appears very unlikely that the gastric juice in these achlorhydric patients can have contained enough intrinsic factor to potentiate absorption of the vitamin in the amounts necessary to bring about such a result. The probability is, therefore, that the vitamin was directly absorbed.

Ungley's experiments on absorption of vitamin B_{12} from the intestine are of great interest, though the unavoidable difficulties render interpretation less easy. In two patients a segment of the small intestine was isolated after the passage of a Miller–Abbott tube with two balloons: the balloons were inflated and the intervening section of intestine was washed out with normal saline. Vitamin B_{12} was then instilled into the isolated segments and its absorption studied. No response occurred in either case, and microbiological tests showed that wash-fluids recovered from the segments contained the vitamin.

In both cases intubation was performed again, and this time vitamin B_{12} was instilled together with normal gastric juice. Again there was practically no response. In one case, however, the juice had been Seitz-filtered—a process which was afterwards shown to remove much intrinsic-factor activity. In the other case 500 ml. of gastric juice was given with 80 μg. of vitamin B_{12}, and the small reticulocyte response indicated only very slight absorption. This patient later responded well to parenteral therapy. There is thus no evidence for the absorption of free vitamin B_{12} from a segment of intestine protected from contact with general intestinal contents. Positive evidence for absorption of vitamin B_{12} from this site (the exact position of which is not known) in the presence of intrinsic factor is also lacking.

Perhaps a more informative experiment was that in which the bowel of a patient with pernicious anaemia was partially sterilized by oral doses of chemotherapeutic agents before he was given 80 μg. of vitamin B_{12}. No response occurred, though later, when the vitamin was given with normal gastric juice, the reticulocytes rose to 15.8% on the sixth day. Later still the injection of 80 μg. further greatly increased the rise in erythrocytes. This would seem to indicate that failure of absorption of vitamin B_{12} when unprotected by the intrinsic factor is not due to avidity of coliform organisms for it, though Hall[1] quotes an experiment by Lichtman and his colleagues with the opposite result. This problem requires further exploration, for Ternberg and Eakin[4] have observed that union of vitamin B_{12} with intrinsic factor renders it unavailable microbiologically, and Ungley and Cuthbertson have confirmed this. It is important to note, however, that, although vitamin B_{12} appears to unite with several proteins and lose microbiological activity,[5,6] Hall found the vitamin in the lysozyme complex was not absorbed when given by mouth, whereas absorption occurred when it combined with intrinsic factor in human gastric juice or swine gastric and duodenal mucosae.

The evidence to date perhaps favours the view that failure of absorption occurs in pernicious anaemia, rather than destruction of vitamin B_{12} in the intestine or its deviation to micro-organisms. In any case, union with the intrinsic factor appears to be of prime importance when vitamin B_{12} is ingested in physiological amounts, though it is of great interest that ingestion of huge amounts of the vitamin may lead—perhaps by a mass action—to by-passing of this normally essential mechanism and to direct absorption. Growing knowledge of the chemical and physical nature of the B_{12} molecule may allow the problem of its absorption to be studied in model systems. It is not yet known whether the interaction with the intrinsic factor is of the nature of an enzyme reaction, with the properties and limitations of such a system, or whether the intrinsic factor is a highly specific protein, union with which is normally necessary for active transfer of vitamin B_{12} across the barrier of the intestinal epithelium—as opposed to passive transfer of the vitamin by diffusion through what is sometimes likened to a sieve-like membrane. If the protein takes part in the absorption, it may well be a very exceptional case. But from the picture which is emerging of the vitamin B_{12} molecule, which is perhaps built up somewhat on the porphyrin model and which must be absorbed intact, its steric and other characteristics may well render its absorption a special biological problem. Also, in view of recent evidence for the fairly ready interconvertibility between vitamin B_{12} and the more chemically reactive vitamin B_{12b},[7-9] the results of complex therapeutic experiments must be interpreted with caution.

TREATMENT OF NEUROSYPHILIS

In the pre-penicillin era the treatment of neurosyphilis presented many difficult problems. Meningeal and meningovascular forms reacted reasonably well to arsenicals and bismuth, but parenchymatous forms were more resistant; and general paralysis of the insane was nearly always fatal until malaria treatment was introduced by Wagner-Jauregg. Penicillin, however, completely altered the picture, and most forms of neurosyphilis have been found to react remarkably well to it, though it is clear that even penicillin cannot restore dead nerve cells and nerve fibres. There has been some discussion recently about whether penicillin alone can accomplish as much as penicillin combined with malaria. At a meeting of the Society for Investigative Dermatology in the U.S.A. Spiller and his colleagues[1] reported on 170 cases of neurosyphilis, 105 of which were treated with penicillin alone and 65 with penicillin combined with malaria. These patients were observed for from six months to four years or more, and the authors found that so far as the cerebrospinal fluid was concerned response was about equal with the two methods of treatment, but that clinical results were slightly better with combined treatment. Most of those who spoke at the discussion which followed this paper were in favour of using penicillin alone, and other American opinion seems to be swinging in the same direction[2,3] (as it is in other forms of syphilis). A number of workers, however, still think that fever therapy aids the action of penicillin.[4-7] In Great Britain the tendency is to assume that it is useful to have two strings to one's bow. Thus Nicol,[8] who probably has more experience of neurosyphilis, and particularly G.P.I., than anyone in this country, found that malaria plus tryparsamide gave better results than malaria alone in G.P.I., and that the best results are now obtained with penicillin and malaria. Admittedly malaria and other forms of pyrexial treatment carry a certain risk to life, but a careful technique and suitable selection of patients will reduce this to very small proportions. No doubt it is this risk, due largely to lack of experience and adequate facilities, which has led so many to give up or omit a form of treatment which has accomplished much in the past. It seems to be fairly generally agreed that in optic atrophy and perhaps active tabes dorsalis results are better with combined treatment than with penicillin alone.[9-11]

It certainly seems logical that when two forms of treatment, each of which has been shown to be effective, are available both should be employed unless there are definite contraindications. However, it may be advisable to try penicillin alone at first and if that is not successful to resort to pyrexial treatment as well. In this connexion several authors have stated that increasing the amount of penicillin beyond a certain point—4 mega units, according to Callaway and his colleagues[12]—did not improve results. The effectiveness of the treatment of neurosyphilis is judged by examination of the cerebrospinal fluid and by clinical progress, though the two do not necessarily go hand-in-hand. Admittedly it is often difficult to measure clinical improvement, but this is what the patient looks for, and the wise syphilologist will adopt that form of treatment which in his experience is most likely to restore the patient to normal or render him a useful member of the community.

R.S.M. SECTION OF GENERAL PRACTICE

In response to a petition promoted by two general practitioners, Drs. G. M. Kerr and G. O. Barber, the Royal Society of Medicine has formed a Section of General Practice, and its inaugural meeting will be held on November 22 at 8.15 p.m. Future meetings will be held on the third Wednesday in each month during the winter. The petition was signed by 74 specialists (Fellows of the Society) and 78 general practitioners (13 of them Fellows). This promises to be an excellent departure from tradition, and will no doubt be welcome to the many general practitioners who will be able to take advantage of it.

The objects of the Section are "to narrow the widening gap between specialists and general practitioners, to provide for the general practitioner an active link with currently accepted ideas, and to keep alive the academic or scientific attitude to medicine and its allied branches, which is so readily lost in general practice." These thoroughly desirable aims have been expressed in various ways recently, and with increasing urgency, as medicine has followed the pure sciences in developing highly specialized techniques for attacking its problems. The difficulty of keeping up to date, and of understanding the relevance to everyday clinical work of much of the research carried out in hospitals and laboratories, are sources of anxiety to general practitioners that barely afflicted their forebears fifty years ago. At the R.S.M. general practitioners will be able to hear the latest views on subjects related to their daily work expressed by the leading specialists in those subjects, and the Society provides that encouraging atmosphere where discussion can range freely over the science and practice of medicine.

There is great need for closer collaboration between these two branches of the profession than circumstances make possible at present. The sponsors of this venture and the R.S.M. are to be congratulated on starting what should be a most interesting and educative Section. It is to be hoped that similar enterprise will be shown by those medical schools and universities where the problems of general practice still receive too little attention in the curricula.

ANTI-CALCIFYING ACTION OF PHYTATE

Some thirty years ago Mellanby recognized that rickets in dogs was caused not only by the absence of a fat-soluble vitamin from their diets but also by the presence of harmful factors, which he first termed "antivitamins" and later "toxamins." A clue to the nature of these substances was subsequently given by Bruce and Callow,[1] who found that the absorption of calcium from the intestines was inhibited by phytic acid, a phosphorylated form of inositol which is present in cereals in substantial quantities. Harrison and Mellanby[2] established that phytic acid could in fact account for the rachitogenic properties of cereals when fed to dogs. Since adequate dosing with vitamin D prevented rickets even when the food contained phytate it

1 *Biochem. J.*, 1934, **28**, 517.
2 Ibid., 1939, **33**, 1660.
3 *J. Physiol.*, 1949, **109**, 488.
4 *Brit. J. Nutrit.* 1948, **2**, 373.
5 *J. Physiol.*, 1926, **61**, P xxiv.

seemed logical to assume that the vitamin counteracted the action of the phytate in preventing the absorption of calcium.

Further painstaking experiments by Mellanby,[3] carried out over many years, have now shown that the problem is less simple than it had seemed. Comparisons of the rachitogenic actions of phytate with those of corresponding amounts of inorganic phosphorus have given divergent results in different experiments, and the cause of the variation has been traced to irregularities in the vitamin-D reserves of the animals at the commencement of the experiment. When reserves of vitamin could be called on it was invariably found that phosphorus in the form of phytate caused more severe rickets than the same amount as inorganic phosphate, but in the absence of reserves the difference was largely obscured. Moreover, even with high doses of vitamin D phytate still reduced the amount of calcium absorbed from the intestines, with the result that bones were less well calcified and more osteoporotic than when it was absent from the diet or was replaced by inorganic phosphate. A diet high in phytate must therefore be supplemented with both calcium and vitamin D if bone formation is to be perfect. Some evidence was obtained that vitamin D may destroy phytate, and, conversely, phytate appeared to increase the rate of expenditure of the vitamin-D reserves. The main anti-calcifying action of phytate, however, presumably depends on its competition in the intestines with its structural analogue, inorganic phosphorus, for combination with calcium. According to the definition adopted by Kodicek,[4] the term antivitamin may conveniently be reserved for substances capable of interfering with the action of a vitamin by reason of their chemical resemblance to it, which allows them to compete with it in its essential reactions. Clearly the action of phytate is not covered by this definition, and its description by Mellanby[5] as a "toxamin" is therefore perhaps more appropriate.

INHALATION DURING DENTAL EXTRACTION

In a study of 316 non-malignant lung abscesses Brock[1] found that 7% occurred after the removal of teeth. He suggested four main causes for this sequel: multiple extractions under deep anaesthesia; the extraction of septic teeth with tartar masses; the upright position of the patient in a dental chair; and inexpert anaesthesia. Fry and Earl[2] have now published a preliminary report of their attempts to assess the importance of each of these factors in encouraging the inhalation of blood and other debris during dental extraction. They investigated two small series of patients by injecting 2–3 ml. of radio-opaque oil into the buccal sulcus before or during the extractions and radiographing the chest within 30 minutes of the patients' return to consciousness. In their first series of 24 unselected patients undergoing extractions under nitrous-oxide anaesthesia none inhaled a demonstrable quantity of oil. The second group was of 14 patients subjected to multiple extractions, two of whom were anaesthetized with trichlorethylene and the remainder with nitrous oxide. The oil was injected midway through the operation, when the throat-pack was soaked in blood. Only one patient—a man who had seven teeth extracted—was found to have inhaled the oil, which was seen in the right lower-lobe bronchus. The number of patients studied by Fry and Earl is too small to allow firm conclusions to be drawn. The radio-opaque oil used was not miscible with blood and was usually about one-tenth of the volume of blood in the mouth. That no oil was inhaled is therefore no indication that blood was not. This work has, however, demonstrated that inhalation can occur during dental extraction without the knowledge of the operator, and it justifies similar investigations on a larger number of patients, preferably with a radio-opaque substance that mixes freely with blood.

CARDIAC DISEASE AND PREGNANCY

Two recent papers have added to the voluminous literature about cardiac disease and pregnancy. Vander Veer and Kuo[1] studied the records of 409 pregnant women with heart disease—324 with rheumatic, 51 with hypertensive, 18 with congenital heart disease, and 16 with miscellaneous cardiac abnormalities. The mortality was 3.4%, and death was due to congestive failure, apart from one case of ruptured aorta (coarctation), two of bacterial endocarditis, and one of acute exacerbation of rheumatic endocarditis, though this presumably also caused death through cardiac failure. According to some British cardiologists acute rheumatic carditis is an important cause of breakdown in pregnancy, and it may be that this infection is more frequently responsible for failure than is suspected. Pneumonia occurred in four of the patients, though it might be questioned whether this was the cause or the result of the failure. In seven of the ten fatal cases in which congestive failure occurred death took place between the seventh and eighth months of pregnancy. The other three patients died from pulmonary oedema within two days of delivery. The authors state that the reason for this post-partum failure is obscure; certainly their suggestion that it may be caused by blood loss is not acceptable, since venesection gives relief in acute pulmonary oedema. They do not advise abdominal delivery, except perhaps for patients with hypertensive disease. Their recommendations for preventing heart failure are based on well-known principles, according to the severity of the case: first, pregnancy may have to be avoided; secondly, it may have to be terminated in the early months; and, thirdly, close watch must be kept for the earliest signs of failure or other complications. That several pregnancies in women with rheumatic heart disease are quite compatible with the attainment of middle age has been shown by Correll and Rosenbaum,[2] who looked into the records of 53 women who each had from four to sixteen pregnancies. Fifty-two had rheumatic and one congenital heart disease. Out of this total 34 patients had died, the average age at death being 49.5 years. It is quite possible that a number of pregnancies may not occasion any symptoms in a woman with heart disease, and in fact the disease may not be discovered until her children are grown up. It is very different, however, where symptoms have already made their appearance, and in such cases it must be remembered that pregnancy, labour, and, not least, the upbringing of children are additional burdens.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

THE TREATMENT OF ULCERATIVE COLITIS

BY

G. E. BEAUMONT, D.M., F.R.C.P.
Physician, Middlesex Hospital

One of the most eminent teachers of clinical medicine at the Middlesex Hospital is reputed to have said to his students, "The most important thing you have to learn while in the wards is to diagnose the nature of a patient's illness. Once the diagnosis is made the treatment can be looked up in a book."

Like so many epigrammatic statements this is only a half-truth. One of the differences between a newly qualified practitioner and an experienced doctor is that the latter has himself tried various treatments for various diseases, and has found out which are the most successful. There is no doubt that the best way of learning therapeutics is by treating a series of cases oneself; the second best way, perhaps, is by reading detailed accounts of cases treated by others. And so readers of the Refresher Course who still continue to treat at home, or in nursing-homes, the patients who are seriously ill, and do not send them all into hospital, may be interested to read about one or two patients suffering from ulcerative colitis whom I have treated, and to see how they have fared.

One afternoon, when I was teaching on such a case in my ward, I asked a postgraduate student what treatment he would advise. He replied, "Forty treatments have been recommended, but none of them are any good." When I suggested that he might unmuzzle his wisdom he reeled off the following list: vaccines, sera, special diets, sulphonamides, penicillin, bacteriophage, pneumoperitoneum, psychotherapy, vitamins, blood transfusion, oxygen per rectum, astringents and antiseptics per rectum, and various operations such as ileostomy and high colostomy, appendicostomy and caecostomy, and colectomy or hemicolectomy.

Recognizing that he had read a recent article on ulcerative colitis in a medical journal, and not wishing to be outdone, I added to the list ileal extracts taken by mouth, protein hydrolysates, ionization, artificial-fever therapy, and vagotomy.

If we are to adopt this nihilistic view about the treatment of ulcerative colitis I may as well close my article now; but I am not so pessimistic, though I know that in this disease relapses are apt to occur after apparent cure. I propose to give some details about two cases that I treated.

Illustrative Case 1

A married woman aged 31 was admitted to hospital on July 29, 1946. She looked very ill, was pale and thin, and had lost over 2 st. (12.7 kg.) in weight during the last 15 months, weighing now only just over 6 st. (38.1 kg.). She lived in a damp cottage in the country with a concrete floor; there were four children at home under the age of 9 years; and her husband, who worked as a nursery gardener, had a partially paralysed left arm resulting from war wounds. The house-physician described her as being "of a worrying type and rather introverted." In addition to household cares the patient was concerned about the reduction of her husband's war pension. It was difficult to get an accurate history of the illness, but it appeared that blood was first noticed in the stools in August, 1944, during pregnancy. The bleeding was attributed to piles, though at this time the patient also suffered from abdominal pain and diarrhoea. After parturition the diarrhoea stopped. In September, 1945, there was a recurrence of diarrhoea with blood in the motions, and severe griping abdominal pains, which the patient described as "worse than having a baby." This continued until admission to hospital.

Further examination showed that the mucous membranes were very pale, the teeth carious, and the blood pressure low—100/70 mm. Hg. Her temperature was raised to about 102° F. (38.9° C.) in the evening, falling to 99 or 100° F. (37.2 or 37.8° C.) in the morning. The abdomen was distended owing to flatulence; the transverse and descending colon was palpable and very tender. The urine was normal. The bowels were opened on an average six times by day and six times by night.

The first steps in the treatment of such a case were to exclude other causes of diarrhoea, to determine the degree of anaemia, and to establish the diagnosis of ulcerative colitis. The agglutination tests on the blood serum were negative for the typhoid and paratyphoid, and the dysentery and para-dysentery groups of organisms. The stools showed no amoebae or cysts, no ova, and no pathogenic organisms. There were numerous degenerate pus cells, red corpuscles, and macrophages. On culture only *Bact. coli* types of organisms were grown. The blood count indicated a severe hypochromic anaemia, with haemoglobin 55%, red corpuscles 2,000,000 per c.mm., colour index 0.65, white cells 6,600 per c.mm. (polymorphs 53%, lymphyocytes 43%, monocytes 4%). The corrected sedimentation rate of the red cells was 13 mm. % plasma at one hour. Sigmoidoscopic examination showed numerous bleeding ulcers about 5 in. (12.7 cm.) from the anus, with mucosal polypus formation.

Looking back on the cases of ulcerative colitis which I have treated during the last 30 years, I think that the greatest advance has been in the use of blood transfusions in severely anaemic patients. It is impossible to raise the blood count to normal by giving iron by mouth when the blood is steadily dripping away below. Further, the blood transfusions help to restore the plasma albumin, which is always likely to be low, and also aid in effecting an adequate mineral concentration in the blood.

In this case we found the plasma albumin to be 2.3 g. % instead of the normal 4.5 to 5.2 g.%. The figures for the plasma globulin and fibrinogen were normal. The patient was first given ½ gr. (32 mg.) of phenobarbitone three times a day to calm her generally, and 1/200 gr. (0.32 mg.) of atropine sulphate in water by mouth three times a day to cut down vagal and sacro-pelvic parasympathetic nervous impulses to the colon. Bismuth and kaolin preparations must not be given, as they may cause caking of the intestinal contents and pressure necrosis of the intestine. When the abdominal pain was very severe in the early stages, relief was obtained from 15 min. (0.9 ml.) of tincture of opium in water. The patient's blood was found to belong to Group O, and 3 pints (1.7 litres) of compatible blood was given by drip transfusion intravenously.

Ten days or so later, on August 23, the patient said that she was feeling much better; the diarrhoea had almost ceased, the bowels now being opened on an average three

times in the 24 hours. The temperature, however, was still raised to 100 or 101° F. (37.8 or 38.3° C.) in the evenings. In addition to this treatment, a high-protein, high-calorie, and low-residue diet was ordered, the septic teeth were removed under a penicillin "screen," and sulphaguanidine, 1 g. every six hours, was given by mouth for two weeks. Vitamin B complex was administered, two capsules daily, and 4 ml. of "hepastab" was injected intramuscularly every four days. The diet was of necessity subject to wartime restrictions, but a more varied one, which can be obtained now, is given below.

The haemoglobin rose to 66% on August 26 and remained at this level for another four weeks. By the end of September there was no diarrhoea, no blood in the motions, no abdominal pain, but also no gain in weight.

Relapses

During October there was a relapse. The temperature, which had been normal for a week, rose again, with recurrence of diarrhoea, the bowels being opened five times in the 24 hours and the motions containing blood. On October 18 a further blood transfusion was given of 2 pints (1.1 litres), with good results. The temperature fell to normal, the diarrhoea ceased, and the haemoglobin rose to 77%. In a week or so the patient was able to walk around the ward, and she returned home at the end of November. She was now feeling well, had a good appetite, was satisfied with her treatment, and was gaining weight at the rate of 3½ lb. (1.6 kg.) a week.

But this happy state of affairs did not, unfortunately, last long. Two weeks after returning home she relapsed, and her doctor wrote, "The circumstances of her home are absolutely shocking and her idea of diet hopeless." I recommended her to come into hospital again, but she was unwilling to do so, saying that she must look after her home. She remained partly in bed at home, and by the end of March, 1947, was much better. She was very fit during the summer, being able to walk four to five miles (6.4 to 8 km.) a day, and her weight increased to 10 st. 9 lb. (4.8 kg.). One day in September, while carrying a pail of water from the well in her garden to her house, the diarrhoea recurred, with the passage of blood in the motions. The patient, however, kept on with her household work until December 24, 1947, when suddenly there occurred a shivering attack, high temperature, severe abdominal pain aggravated by any movement, diarrhoea, and at times incontinence of faeces. Various opium preparations were administered, but she continued to lose weight, and finally was again admitted under my care in hospital on March 9, 1948.

When I saw the patient I could tell at once that, although very pale, she was not nearly so ill as on the first admission. Her temperature was normal; her weight, however, was very low—6 st. 8 lb. (2.9 kg.). She said she could feel "hard lumps" running across the abdomen from right to left, which resolved themselves into the passage of mucus and wind. The motions were loose, containing mucus but no blood, and the bowels were opened about once by day and six times by night.

This preponderance of night motions is interesting, and is probably due to an exaggeration of the normal predominant activity of the parasympathetic over the sympathetic during sleep. The haemoglobin was lower than it had been before, 32%, and the red cells numbered 3,200,000 per c.mm. A drip transfusion of 3 pints (1.7 litres) of blood was given on March 14, the haemoglobin rising to 60% and the red cells to 3,900,000 by March 18. During the next two weeks the diarrhoea ceased and there was a gain of 8 lb. (3.6 kg.) in weight. In addition to the transfusion, phthalylsulphathiazole was given by mouth in doses of 1 g. three times a day for two weeks, and "trasentin" tablets, 75 mg., one or two a day, as required for abdominal pain. A mixture containing 30 gr. (2 g.) of ferric ammonium citrate was taken three times a day, and 200 mg. of ascorbic acid daily.

On April 3 the patient returned home again, feeling and looking very much better. I had not heard any more about her, and so, before completing this article, I wrote to her doctor, and he replied, "She does not suffer from diarrhoea so much, but has tenesmus and is continually passing some mucus and blood. She says she is too ill to go outside. The anaemia is not so obvious, but the tongue is very pale. Though the legs are not swollen the abdomen has enlarged considerably. I cannot feel anything. Her periods occur every three weeks." I suggested the advisability of another blood transfusion and protein hydrolysate, two teaspoonfuls three times a day with meals.

Diet

The following diet contains approximately 385 g. of carbohydrate, 145 g. of protein, 115 g. of fat: 3,155 calories.

Breakfast.—Milk 8 oz. (230 ml.), porridge (strained) 1 oz. (28 ml.), crustless bread 3 oz. (90 g.), sugar ¼ oz. (8 g.), 1 egg, and bacon 1 oz. (30 g.), or fish 4 oz. (120 g.), butter ¼ oz., pipless jam or honey or syrup ¼ oz.

Lunch.—Cream soup (canned) 10 oz. (280 ml.), meat (minced) 2 oz. (60 g.) or fish 4 oz. or cheese 2 oz., mashed potatoes 6 oz. (180 g.), purée of vegetables 4 oz. (120 g.), pudding made from milk 8 oz., semolina or other cereal ½ oz., fruit purée as desired, sugar ¼ oz.

Tea.—Milk 2 oz., crustless bread 2 oz., butter ¼ oz., sponge cake or plain cake without fruit 2 oz., pipless jam or honey or syrup ¼ oz.

Supper.—As for lunch.

On Waking, at 11 a.m., and Last Thing at Night.—Milk 2 oz., cocoa ½ oz.

The cream soups may be thickened with dry potato powder. Syrup may be used as desired in sweets. The sweet ration should be taken as chocolate. Yoghurt and fruit juices, such as blackcurrant juice and rosehip syrup, make a useful change from the usual pudding. Very ripe bananas, if available, may be taken, as may be sweetbreads, brains, or kidneys.

Some doctors prefer that their patients should not be ordered a low-residue diet, and consider that a certain amount of roughage is beneficial. I do not agree with this. I think it is of importance to avoid raw fruit. I have known an orange, or one or two grapes, brought in by visitors, cause a relapse in a patient who was doing well.

Illustrative Case 2

In December, 1947, I was asked to see a married man aged 45, suffering from the same complaint, in whom the nervous or psychological symptoms were more in evidence. The doctor told me that the patient had suffered from digestive trouble all his married life, chiefly nervous symptoms, nausea, fainting, and appendix pains. He belonged to a more educated class than the first patient, being employed in one of the Ministries, and he was afraid that he would not "make the grade" for establishment. In addition to the anxiety thus produced, he was worried about financial commitments on a house into which he had just moved.

We are all familiar with the literature during recent years dealing with the psychiatric aspects of ulcerative colitis, and

the emphasis placed by some writers on what is termed the "grief response." Stress has also been laid on the dependent personality of many victims of this disease and the close physician–patient relationship which develops during treatment. The cause of ulcerative colitis is not known. It is described as a psychosomatic illness, which means, I believe, that a disorder of the mind produces a disease of the body, and as Sir Toby Belch said, "I am sure care's an enemy to life." The treatment recommended by some seems rather unfair—to cut out the innermost portion of the body which is the victim of the disorder of the mind, rather than to cure the diseased mind by psychological treatment. The latter, however, is found to be of little value. I have not been able to discover convincing evidence in my cases to support the view that a disturbed mind produces a diseased colon, rather than vice versa, and one of my patients told me recently that the diarrhoea resulted in "frayed nerves."

The patient said that he considered another factor in the production of his illness was overwork, both during and after the war. During 1944 he suffered from mild diarrhoea for four weeks, followed by an attack lasting for six weeks in 1945. In 1946 there was a severe attack of lichen planus, perhaps due to nervous disturbances.

When I was consulted on December 7, 1947, the diarrhoea had already lasted for five weeks, accompanied by the passage of blood and mucus. The patient suffered from colicky abdominal pain, intermittent fever, loss of weight, and was confined to bed. His own doctor had prescribed a course of sulphaguanidine followed by phthalylsulphathiazole, without beneficial results, and ten days before my visit had called in a surgeon, who advised a permanent transverse colostomy, saying that medical treatment would be of no avail. A barium enema examination had shown absence of the normal haustrations in the transverse and descending colon. The haemoglobin had fallen to 77% on November 27; the faeces contained much pus and yielded a growth of Morgan No. 1 bacillus.

Question of Operative Treatment

I was asked my opinion: should the patient submit to this operation with its unpleasant aftermath, or could I suggest an alternative form of treatment?

I should like to say a few words here about the operative treatment of ulcerative colitis. We are all agreed that if an operation is to be performed it should not be delayed until the patient is so debilitated that the chance of recovery is slight. The object of any operation is to give complete rest to the affected colon, and this can be most efficiently done by ileostomy, unless a colostomy can be performed in a healthy area of the colon. The ileostomy will have to be permanent in most cases, but a special bag can be worn—the Koenig–Rutzen bag—which is illustrated in the paper by Hardy and his colleagues (1949). McKittrick and Moore (1949), in America, record their experience of 149 cases of ileostomy, with a mortality rate of 22% and about 70% of the patients expressed themselves subsequently as well satisfied with the operation. In others the operation was a failure; one patient committed suicide; another wrote, "the whole thing is a mess, whatever I do." Is a permanent ileostomy too high a price to pay for health?—that is the question.

My answer in this case can be guessed with little difficulty. The patient came into hospital on December 13. The bowels were now opened three to four times during the day and four times during the night. The motions contained mucus and blood, but no abnormal organisms were found on culture. There was a moderate degree of anaemia, the blood count showing: haemoglobin, 79%; red cells, 4,300,000 per c.mm.; C.I., 0.9; white cells, 12,900 per c.mm., with a normal differential count. The corrected sedimentation rate of the red cells was 18 mm. % plasma at one hour. The temperature was normal. This did not appear to be a very severe case of ulcerative colitis, and the psychological factor was a much more prominent feature than in the case previously described. The patient was given a course of phthalylsulphathiazole, 1 g. three times a day for 14 days together with a high-calorie, high-protein diet, 200 mg. of ascorbic acid daily, and 6 gr. (0.4 g.) tab. ferrous sulphate thrice daily.

By December 26 the motions were reduced to four in the twenty-four hours, and they were more formed. Three days later no blood was seen in the motions. On January 1, 1948, the bowels were opened once by day and once by night and the motions were formed. A week later the patient said he felt very well and was pleased with his progress and hopeful of recovery. On January 15 the bowels were opened only once in the twenty-four hours, and sigmoidoscopy showed a healing mucosa, with some residual infection. There was excess of mucus in the bowel lumen, but no blood. The patient soon returned home, having gained 2 lb. (0.9 kg.) in weight.

On March 1, 1948, a further examination was made at hospital. There had been a gain of 18 lb. (8.2 kg.) in weight in the past six weeks and the patient had been working for two weeks. He was completely free from intestinal symptoms, but was still anxious about his work, though every effort had been made to encourage self-confidence.

In this case the degree of anaemia and the condition of the patient did not indicate the necessity for a blood transfusion.

In 1950 I wrote to the patient's doctor inquiring about further progress, but he told me that the patient had now left him. I then wrote to the patient, and he replied that he was very well.

Conclusion

The cause of ulcerative colitis being unknown, treatment must be symptomatic, and repeated blood transfusions are of the greatest value. The ultimate results, however, are very unsatisfactory. In the series of Hardy *et al.* (1949) ileostomy was performed on 21 patients, with six deaths, but half of these deaths were said to be avoidable. Of the last nine patients operated on, however, only one died.

Comanduras, in America, wrote that the word "cure" must not be used; "arrested stage" is preferable, and two-thirds of those who have been operated on will be dead after a few years. Rice-Oxley and Truelove (1950) investigated the records of 72 new cases treated at the Radcliffe Infirmary, Oxford, from 1938 to 1948; of these, 22 died within a year of onset, and one-third of the remainder had succumbed at the end of five years. Recurrences were frequent, and emergency ileostomies did not seem to be justified.

A special advisory committee has been formed by the American Heart Association in order to develop public-health work in the field of cardiovascular diseases. The committee will provide detailed practical plans which can be carried out by local heart associations for the benefit of cardiac patients in their areas. The chairman of the committee is Dr. William A. Brumfield, jun., deputy commissioner of the New York State Department of Health.

Tropical Diseases

Shortt (London) reviewed recent knowledge of malarial parasites with special reference to the exo-erythrocytic cycle. The treatment of amoebiasis with "chloroquine" and with aureomycin was discussed by Conan (Beirut) and Bossa (Naples) respectively.

Haematology

In this section Hall (U.S.A.) reported his work on the intrinsic factor of Castle (see *British Medical Journal*, September 9, p. 585). Bornsdorff (Helsinki) had found that pernicious-anaemia patients fell into two groups, those that reacted to oral B_{12} without the addition of gastric juice and those that did not react even with gastric juice. Kristensen (Stockholm), by attaching a pendulum to clotting blood, could more readily measure the rate of coagulation. Gullberg (Stockholm) recommended urethane as an adjunct rather than a substitute for *x*-ray therapy in leukaemia. Urethane may produce a longer remission in myeloma. Bernard (Paris) had treated acute leukaemias with aminopterin, but had found that the results were better if this was combined with replacement transfusions. Hetenyi (Hungary) showed that in animals injections of venous blood or cyanide into the nutrient artery of a bone stimulated erythropoiesis. Christiaens and Goudemand (Lille) believed that neonatal jaundice may be influenced by maternal antibodies transmitted by the mother's milk. Bacq and Deronaux (Liége) described the pharmacology of a drug, adrenochrome semicarbazone, which has a lasting effect on the bleeding-time and is neither toxic nor sympathomimetic.

Rheumatic Diseases

This section was opened by Nanna Svartz (Stockholm), who had found that, when all agglutinins against normal sheep-cells are absorbed from rheumatoid arthritis serum, there remains in 90% of such sera an agglutinin to sensitized sheep-cells which is not present in normal serum. This agglutinin is also found in rheumatic joint exudates. She believed a special polysaccharide is involved which is abundant in rheumatic nodules. Layani and his colleagues (Paris) had studied the plasma proteins in Paget's disease without finding any constant abnormality. Layani also discussed sarcomatous degeneration in Paget's disease. Séze, Ordonneau, and Robin (Paris) reviewed the limitations of cortisone in treating rheumatic cases.

Miscellaneous Subjects

The Infectious Diseases Section reviewed ornithosis (Lepine, Paris), typhoid carriers (Knittelfeld, Austria), brucellosis (Maldonado-Allende, Argentina), and gonorrhoea (Durel, Paris). The papers on gastroenterology tended to be more general and historical, but Wiebenga, Jansen, and Verdonck (Leiden) described their gastric biopsy results, and Albot and Bernard-Bruker (Paris) reported their belief that treatment with an emulsion of *B. subtilis* had value in some types of diarrhoea. Neurologists were presented with an exhaustive study of the nervous manifestations of porphyria by Garcin and Lapresle (Paris), with a review of the value and limitations of phenylacetylurea in epilepsy by Euziere and his colleagues (Montpellier), a study of muscular cramps by Roger and Schachter (Marseilles), and with other subjects.

In the Nutrition Section, Markees (Basle) claimed value for the use of cocarboxylase in diabetic coma and other conditions in which blood pyruvic acid is raised; this was doubted by Gilliland (London). Salmon-Malebranche (Paris) stressed again the psychological factor in the aetiology of obesity.

Films

Several good films were shown during the Congress, and among these "The Radiography of the Spine" (Séze, Paris), "The Surgical Treatment of Portal High Blood Pressure" (Santy, Lyons), and "Thrombosis and Embolism" (Waterville, Geneva, and Jurgens, Basle) were notable. These were in a sense documentaries, but the film by Mote (Chicago) broke new ground, showing the great value of A.C.T.H. in controlling recovery from severe burns. Pain, infection, and electrolyte disturbance are all minimized and healing and epithelization hastened.

PRESENT STATUS OF CORTISONE AND A.C.T.H.

DR. PHILIP HENCH IN LONDON

Dr. Philip S. Hench, of the Mayo Clinic, has recently delivered two lectures in London. The first, entitled "Cortisone and A.C.T.H. in Rheumatic Diseases," he gave on October 5 to the Department of Rheumatic Diseases of the West London Hospital. Dr. W. S. C. Copeman was in the chair and members of the Heberden Society attended. Dr. Hench also showed a film illustrating the effects of those hormones on patients with rheumatoid arthritis treated at the Mayo Clinic.

Dr. Hench's second lecture was given at the Royal Society of Medicine, where the attendance was so great—the Barnes Hall being packed and the proceedings relayed to another hall—that the chairman, Professor R. A. McCance, decided that to have a discussion after the lecture was impracticable.

In describing the action of cortisone as used by himself and his colleagues—Drs. E. C. Kendall, C. H. Slocumb, and Howard F. Polley—Dr. Hench said that the hormone did not kill any micro-organism or remove any unknown irritant; what it did was to provide susceptible tissues with a shield-like buffer. It did not, so to speak, put out the fire nor even repair the fire damage, but it did provide a kind of asbestos suit by which the patient was protected. When the suit was removed prematurely the tissues were again subjected to the flame. But once the inflammation was suppressed it could remain suppressed by simple maintenance doses.

Individual tolerance to cortisone and A.C.T.H., said Dr. Hench, varied greatly. Males tolerated the hormone better than females, especially adolescent and menopausal females. Such effects as acneiform eruptions or "round face" might be endured temporarily in view of the need of the patient. Fairly common side-effects were minor alterations of psyche, restlessness, and insomnia. Occasional ones were retention of fluid, hypertrichosis, folliculitis, and transient amenorrhoea. More rare were hypoglycaemic alkalosis, altered libido, retrocervical fat ("buffalo hump"), and increased blood pressure. Spontaneous fractures were rare. There were now more than 3,000 rheumatoid patients in the United States who had received cortisone, and he knew of only four cases of spontaneous fracture in elderly osteoporotic persons. To prevent adverse effects, if prolonged administration was necessary after initial suppressive doses, only the smallest effective maintenance dose should be used. The administrator should be content to suppress symptoms and not necessarily to reduce sedimentation rates.

Some 50 steroids, said Dr. Hench, had been studied with a view to finding substitutes for cortisone. These were all more or less related to cortisone, but apart from "compound F" (which had not yet been synthesized, so far as he knew, though it probably would be in the near future) none of them produced significant effects. Dr. Hench added that cortisone was now priced at 50 dollars a gramme. Supplies were now sufficient to make cortisone available in limited amounts to all approved American hospitals, with growing supplies for foreign medical centres. He had recently seen the first specimen of A.C.T.H. from the pituitary of the Norwegian whale.

In May, 1949, a special preparation—a mixture of compound E and compound F—was given to a severely rheumatoid patient by mouth, and the patient became symptom-free. From this and certain animal experiments it was concluded that cortisone was effective when given by mouth. Cortisone tablets had since been given by Dr. Richard Freyberg, of New York, and by Dr. Hench and his associates in 25 rheumatoid cases, with satisfactory results. To their pleasant surprise they found that no larger quantity was needed than when given by intramuscular injection.

After describing the effects of cortisone on rheumatoid arthritis, Dr. Hench turned to some other conditions. Renal lesions were usually not affected, though temporary remission might be afforded. A few cases of chronic ulcerative colitis had been treated; in one of them—arthritis also being present—cortisone was given for 35 days: it brought about complete articular remission, with symptomatic remission of the colitis, which remission had continued for seven months or more after the end of the treatment. Cases of pulmonary tuberculosis had been treated, with subjective improvement, reduction of sedimentation rates, and improvement of *x*-ray picture of the lungs in some but not in other cases. In cases of tubercular arthritis the sedimentation rates had decreased and the articular symptoms cleared up. But because of the possible inhibiting effect of cortisone and A.C.T.H. on fibroblasts these hormones should be used only as an investigative procedure in the presence of tuberculosis.

A few patients with osteoarthritis had been treated (cortisone was so precious that it was not considered advisable to use it on a relatively benign disease), and considerable relief had been obtained in about half. Cases of acute gouty arthritis had been relieved, sometimes after a single large dose. Remissions in cases of asthma had lasted from one week to five months after discontinuance of the hormone. One important use was in inflammatory diseases of the eye—subacute uveitis, iridocyclitis, and other conditions.

Dr. Hench ended his lecture by saying that, although some of the clinical effects recorded were non-specific, the ability of the hormone to influence markedly a disease process, or even to reverse it, appeared to be group-specific. These hormones had furnished a powerful weapon with which to investigate many problems relating to the aetiology and treatment of a wide variety of diseases. Research workers were at the beginning rather than the end of the road.

Correspondence

Psychology and Science

Sir,—I imagine few scientists, and hardly any psychologists, would accept the definition of science which Dr. Clifford Allen has proposed in his recent letter (*Journal*, September 30, p. 783). "Science," he says, "is only a collection of facts and an attempt to explain them so that we can predict what will occur in certain circumstances." This leaves out what is most distinctive of all science—namely, proof. The attempt to predict what may occur in certain circumstances is more characteristic of the practical applications of science (as in medicine or navigation) than of pure science as such. Certainly, if by adopting a given explanatory theory we succeed in increasing the accuracy of our predictions, that may serve as an additional confirmation of the theory; but not every form of proof, nor even every inductive proof, rests on the verification of predictions. In Kepler's demonstration of the laws of planetary motion and in Harvey's demonstration of the circulation of the blood there is no reference (except as an incidental corollary) to any practical prediction.

It ought perhaps to be added that by proof I mean, not the demonstration of a certainty, but the estimation and comparison of probabilities. Dr. Allen contends that "the theories of Freud are no more fantastic than the theories of Hughlings Jackson" or those of the mathematical physicists. But whether a theory seems fantastic or not has little to do with its final validity. Certainly the more fantastic a theory appears—that is, the more the *a priori* probabilities are against it, and the less readily it can be integrated with conclusions already established—the stronger is the need for high *a posteriori* probabilities in its favour: that at least would be my own view. But many scientists have contended that the role of *a priori* probabilities in empirical proof is so small and dubious that it is safer to neglect them.

An almost perfect model of scientific method (as the psychologist would understand it) is contained in the article by Professor Bradford Hill and Dr. Doll in the same issue of your *Journal* (September 30, p. 739). The psychologist's objection to psychiatric theories, like those cited by Dr. Allen, arises mainly from the fact that, so far, little or no attempt has been made to test them by any rigorous experimental or statistical procedure, such as that which Professor Hill adopts. Of course, many psychiatrists would argue, with Dr. F. Cort (p. 785), that it is better to trust to clinical experience or personal impression than to "cold mathematics." Dr. Allen thinks that we should all be content to regard ourselves as "ignoramuses trying to help our sick fellows." But when an ignoramus tries to help them, he is very apt, like the psychiatrists of an earlier generation, to diagnose mental deficiency by stigmata and head measurements, and to recommend craniotomy for its relief, or, like psychiatrists of the present day, to diagnose neuroticism by paper-and-pencil tests and propose leucotomy or convulsion therapy for a type of patient who, for all the existing evidence has shown, is quite as likely to be injured as alleviated. After all, it was "cold mathematics" that demonstrated the failure of craniotomy and the value and limitations of psychological tests.

But, when all is said, clinical experience and statistical comparisons are by no means incompatible; so why not combine them?—I am, etc.,

London, W.C.1. Cyril Burt.

Sir,—Dr. F. M. R. Walshe in his distinguished Linacre lecture (*Journal*, August 12, p. 379) has raised criticisms of a fundamental nature for psychology which cannot simply be ignored but call for a reasoned rebuttal if a convincing case is to be made for psychological medicine to take its place as a branch of science. I put it down to the fact that the lecture appeared during the holiday season that his challenge has not been taken up more seriously.

Dr. Walshe has set forth, eloquently and persuasively, two main theses: that psychology is not, and cannot be, a part of "natural science"; and, secondly, that it properly comes under the discipline of historical science as propounded by R. G. Collingwood—and I would like to emphasize the use of the term "science" in this connexion. He makes a distinction between the data of natural science and those of history. The prime method, he says, of natural science is the observation of events, including controlled experiment. History, on the other hand, is concerned with human actions that lie in the past, which have not the quality of sense-data as these are understood in natural science.

If one of Dr. Walshe's patients has an epileptic fit in his consulting-room he has all the sense-data present for an observation according to natural science. Must we assume that a week later, or, for that matter, half an hour later, when the event has passed into history, it has completely changed its character? In considering the occurrence after a lapse of time he will be concerned with "human actions that lie in the past . . . which have not the quality of sense-data as these are understood in natural science." If the answer is that the event, being observed by himself, remains for him a part of natural science, suppose then he is describing the incident to a colleague, is the latter precluded from accepting it as properly scientific but must perforce consider it merely as historical? One can visualize the colleague, weeping, perhaps, like the Walrus and regretting that, while he believed every word Dr. Walshe said, he could not accept his story as scientific but only as history.

The thesis clearly introduces a number of complications, and I would like to ask at this stage if Dr. Walshe considers that psychological events and processes are less "factual" than the events and processes of the external world which make up the data of natural science. He will, I know, be aware that the "facts" or sense-data of the physical world have been subjected to such a nihilistic analysis of late years by philosophers that they could hardly be made more tenuous and abstract. Bertrand Russell, for example, is compelled to go so far as to maintain that when he sees his friend Jones he knows he is only looking at a bundle of "light quanta."[1] On the other hand, to make the distinction less distinct it almost seems as if certain philosophers tend to endow the sense-data of physical science with psychological attributes. It is not so long ago that Eddington, a "natural" scientist, puzzled at the capricious behaviour of the electrons, decided that they must be endowed with free will—a very mysterious mystery indeed, as Damon Runyon would say.

Collingwood's theory of historical method displays, it seems to me, mainly his naivety and bias against psychology, the

latter manifesting itself quite strongly in his autobiography.[2] As Dr. Walshe mentions, Collingwood teaches that "the historian investigating any event in the past makes a distinction between what may be called the outside and the inside of an event. By the outside of the event I mean everything belonging to it which can be described in terms of bodies and their movements. . . . By the inside of an event I mean that in it which can only be described in terms of thought."[3] What does this mean if not that every historical event has a psychological aspect? But Collingwood evidently did not appreciate this even when he emphasized that the cause of an event to a historian means the thought in the mind of the person by whose agency the event came about. He did not proceed beyond "thought" and, in fact, made the incredible affirmation that those actions which are determined by what may be called a man's animal nature, his impulses and appetites, are not properly the subject-matter for history.[4]

It is clear, in fact, that Collingwood's method is not so much a historical science in which psychology should be included but is a psychological method in which history should be comprehended. To consider, for instance, the example quoted by Dr. Walshe from Collingwood: Why did Brutus stab Caesar? Was it from the highest patriotic motives (the "noblest Roman of them all"), was it from mean personal envy, or was it, perhaps, from a combination of both? Who is the right person to answer these questions? Is it the archaeologist or the decipherer of ancient documents? Or is it the trained psychologist experienced in assessing motives from the available evidence?

Dr. Walshe criticizes Bernard Hart's lucid and convincing exposition of psychological medicine as part of natural science on the ground that "the essential data in psychology, as we find it in medicine, are the mental processes behind the façade of the so-called 'observed facts.' It is surely a *non sequitur* to invoke the canons of natural science in this situation." In the name of all the atoms and celestial bodies, why? Is it unscientific of the astronomer to try to get behind the façade of the stars in the heavens or of the physicist to try to penetrate into the processes behind the particles of material things? It is a matter of inference in each case, and accurate inference is an essential element in the scientific method.

When Dr. Walshe declares that it is impossible to generalize about psychology to-day because it has no unity of method or of concept he is stating something that is, unhappily, true. Psychology has not even yet shaken itself free from superstition, theology, and personal predilection, and neither, I regret to say, have many medical psychologists. To maintain, however, that the data of psychology—the events and processes of the mind—are not facts equally with the admitted facts of the natural sciences seems to me to be merely mysticism. If they are admitted to be facts they will be capable of being collated and manipulated according to the true scientific method.

With great respect I suggest that Dr. Walshe has been led off the straight, narrow, and slippery path of valid scientific thinking largely by falling a victim to Collingwood's fallacious teaching on historical "science," based as it is upon a naive and uninformed attitude to psychology. I must add, again with great respect, that I consider it is a fantasy to think that there can be different kinds of sciences, "natural," "historical," and possibly others. There is only one method of science, and accuracy is its watchword.—I am, etc.,

Distinction Awards

SIR,—Surely Mr. R. L. Newell has misinterpreted (September 30, p. 783) the main gravamen of Mr. R. S. Murley's letter of September 23, p. 726. I was myself chairman of a meeting of specialists addressed by Lord Moran. The letter convening the meeting gave its object as an opportunity for informal discussion. Only a small minority of consultants attended. Lord Moran after a review of the steps taken regarding distinction awards asked for the immediate formation of a small committee to put forward names for these awards. He indicated that delay in appointing such a committee might be prejudicial to potential recipients. The meeting then proceeded to appoint a committee.

I have since been taken to task by certain of my fellow consultants for my acceptance of this procedure. They say that, while there are many consultants who would not feel justified in giving up time for informal discussion of a subject which has already been very fully discussed formally and informally since the report of the Spens Committee was made public, there is not one who would not wish to be present to register a vote in the appointment of this very important selection committee.

Assuming that the conveners of the meeting knew that this important step was to be taken, they ask why there was no mention of it on the agenda of business.

There has been no question of "whether Lord Moran is right in going round the country addressing meetings of non-teaching consultants," but only whether it is right to press for the immediate appointment of a committee to forward names for awards at badly attended meetings, called ostensibly for the purpose of informal discussion.—I am, etc.,

Sudbury, Suffolk. H. BATHURST NORMAN.

Distinction Declined

SIR,—I find myself unmoved by the pathetic appeal by X in your issue of October 4 (p. 887), and I suggest that he is the victim of confused thinking. As one who declined to complete the questionary submitted to consultants by the Distinction Awards Committee, and who said explicitly that he did not wish to be graded for an award, I received a reply from the secretary to the committee informing me that the committee's terms of reference required it to grade me whether I wished it or not. In due course I was notified that I had been graded for an "A" class distinction award, and thereupon replied that I declined to accept it. It would seem, therefore, that I am still on what X calls "the road to distinction."

My own view has always been that this is no road to distinction, but only the road to a very different thing—namely, the road to a "distinction award." No committee can confer distinction on me, except in the neutral sense that it can "distinguish" me from my brethren by placing me in a salary category. Further, if X has declined to accept the basic sessional payment for which he is eligible, how can he reasonably ask to be allowed to accept what is only a pensionable increment to the basic salary? Can there be an increment to nothing?

I agree with X, however, in thinking that the secrecy which purports to surround the award is a pious figment. Already a patient has asked me whether I know Mr. Y, the brother of the general practitioner who referred him to me, adding that Dr. Y has told him that his surgical brother has just received "the very highest distinction award."—I am, etc.,

Z.

St. Luke's Day

SIR,—On October 18 members of the Christian Church remember with gratitude the work of the most famous member of the medical profession. At this season it is fitting to call attention to the remedies prescribed by Luke for the soul of a sick world. Many of us to-day are willing to admit that the world is sick. There is a growing consensus of opinion that the disease is selfishness complicated by materialism. But proceeding to therapeutics we find wide divergence of views.

All down the centuries of our Christian era men and women have been proving the value of the prescriptions left us by Luke and Paul. To-day thousands are learning that by accepting Christ's standards of truth and love human nature can be changed. Is there any other remedy for the world's sickness?

To-day we may share the optimism of Luke and Paul. Never perfect, but always aiming at Christ's standards, we can be confident of final victory.—I am, etc.,

Banstead. HERBERT CAIGER.

Child Health and the Future

SIR,—As one of those who have been interested in child health for over 40 years—I inaugurated a clinic at the Liverpool Maternity Hospital in December, 1907, after reading Budin's book *Le Nourrisson*—I welcome the interest that paediatrics is now taking in preventive work. Professor Alan Moncrieff in his review (*Journal*, October 7, p. 795) is critical of the present and briefly alludes to the past. In 1904 there occurred in Liverpool in a single week of the year many more deaths, twice as many, from gastro-enteritis as now occur in a whole year. The infantile mortality rate has been reduced to one-fifth; it was, as Professor Moncrieff states, to combat this frightful mortality that the first health visitors were appointed by the local authority, and then infant-welfare clinics were set up. Professor Moncrieff criticizes, and rightly, our present efforts against tuberculosis in childhood. It may, however, be pointed out that in this city deaths from tuberculous meningitis under 15 years of age have fallen from 126 in 1915 to 19 in 1949. Most of this reduction occurred before the introduction of streptomycin. Child mortality—i.e., at ages between 1 and 5 years of age—has been reduced to one-tenth of the 1920 figure.

The improvements in child health, as apart from mortality, have been no less striking. At the beginning of the century the out-patient departments swarmed with cases of rickets, tubercular glands in the neck, congenital syphilis, blepharitis, etc., which are now but rarely seen. As recently as 1941 there were in city hospitals as many as 800 cases of diphtheria; now there are but a dozen or less. Deaths classified as from "external causes" are but one-twelfth of what they were in 1900.

These results constitute an outstanding achievement. Compared with them any defects in present-day practice, such as the doubts expressed, *vide* Professor Moncrieff, by one unnamed M.O.H. concerning the value of breast-feeding, are relatively trivial. That there is still room for improvement is true. Leaders in public health are well aware of that.

Nevertheless the resistant hard core of infant mortality, namely prematurity, has been attacked by local authorities even in the midst of wartime difficulties. The death rate under the heading "congenital defects, prematurity, etc.," of which prematurity is the possibly preventable fraction, is but two-fifths of the 1900 figure. The still-birth rate has also fallen, an occurrence associated with better antenatal care and feeding. A year or so ago on visiting a famous maternity hospital I enquired of the paediatrician what arrangements were made for continuity of care of premature babies after discharge from hospital, and was astonished to find not only that there were none, but that they did not appear even to have been considered. At that time in all the four Liverpool municipal hospitals with maternity units there were prematurity sections; these notified the health visitor in whose area the baby's home lay and she, in return, furnished a report on the home conditions *before* the baby's discharge home. Certainly there may be room for more co-operation of this sort between the hospitals on the one hand and the infant-welfare departments and general practitioners on the other.

As regards breast-feeding, I am unaware of any health visitors who discourage or are lukewarm about it; it would be contrary to all their training. The harm is often done before she calls. Such discouragement may indirectly take place in hospitals; the over-segregation of the mother and infant may have psychological consequences, one of which is the—often voluntary—failure of breast-milk. The ready availability of dried milk may make it easy for the mother, either because she wishes to, or more often because she considers her breast milk is inadequate, in quality or quantity, for her child. In this matter popular views have often to be opposed. I hope that those who teach will continue to emphasize the great advantages of breast-feeding.

The achievements related above were not accidental; they were a well-planned co-ordinated effort. Immunization against diphtheria resulted from the combined work of health visitors, infant-welfare departments and clinics, and school doctors and teachers, under unified direction and greatly helped by Sir Wilson Jameson's broadcasts. We have recently seen the unhappy results of disorganization of the tuberculosis services. The pre-eminence of tuberculosis over other infective conditions as a cause of child deaths is largely due to our national failure to use B.C.G.—only this year available and in limited amount. I welcome the aid of all in combating tuberculosis. Many paediatricians, I know, are keenly interested in its use. If we all pull together we may see results comparable to those achieved in relation to diphtheria. I hope nothing further will be done to disintegrate the preventive services. They are at the moment gravely hampered by inadequate salary scales and a great shortage of health visitors. I welcome Professor Moncrieff's observations on family life as all-important in the life and health of the nation. For a number of years I have lectured to health visitors, D.P.H. students, and others on the possibility of improving the basis of mother–child and family relationships by antenatal and post-natal instruction in the clinics. The basis of knowledge of mental health,[1] which I discussed in 1948, should be laid down in the senior medical student years. This is not adequately done now.

One of the causes of neurosis and delinquency in childhood is parental marital disharmony, and this is what those of us who are engaged in marriage guidance are endeavouring not only to heal but also to prevent. We believe that much of the present breakdown of marriages is preventable. A good family life is the main basis of mental health, and the moments when the woman is most open to advice are before marriage and before the birth of the first, and perhaps second, child. There is as wide a field of useful endeavour in the preservation of mental health opening before us as was given to us at the beginning of this century in relation to physical health. If the health services are to be disintegrated into separate over-specialized services I fear that prevention will gravely suffer.

Professor Moncrieff touches also on problem families. These social problems have been illuminated by the researches of M.O.H.s and their staffs—e.g., Savage, Wofinden, Tomlinson, and others—and the Blacker Committee will shortly produce a report. In about one-third of these families the mother is mentally defective and with them infant mortalities of treble that prevalent in the area often occur. I personally have tried the method of case conferences with the other family social workers, statutory and voluntary, involved. I do not think there is any easy answer to this problem in infant mortality and child ill-health. Does anyone know the answer to this?—I am, etc.,

Liverpool. C. O. STALLYBRASS.

SIR,—I had the great pleasure of hearing Professor Alan Moncrieff deliver his Dawson Williams Prize lecture (*Journal*, October 7, p. 795). His delivery was superb, and the text as published in your issue shows him to be a true master of the English language. As a general practitioner I would like to comment upon what he terms a paradox. He says that it is hard to explain a decline in breast-feeding which has been accompanied by a sensational drop in infant mortality figures. He goes on to say that it is acute respiratory disorders which now present the major difficulties after the newborn period.

Even in 1935 Grulee, Sanford, and Schwartz[1] in a study of morbidity and mortality in 20,000 breast and artificially fed infants found that it was the respiratory disorders which were the most prevalent. Both breast and artificially fed infants became susceptible at 5 months, but the artificially fed infants remained highly susceptible up to 9 months, giving a morbidity rate at that age of twice as much as in the breast-fed, and a mortality rate six times as high. This survey was based on the incidence of such infections as elicited by case histories taken in a welfare centre and refer only to the attack and not to its severity or length.

I have been studying this problem also and find that not only is the incidence of respiratory infections higher in the artificially fed, but that they recover more slowly. For all infections during the first year of life I found that the artificially fed infants required five times as many visits from the family doctor.[2] This surely has great significance and is a reason why we should all pay much *more* than lip-service to breast-

feeding. The common cold, with its dangerous sequelae, spreads, as Professor Moncrieff points out, by contact with the family group. Unfortunately, however, the common cold carries no immunity. On the contrary the immunity seems to work in reverse, and the more times a child catches a cold the more likely he is to catch another soon. If the baby is also slow to recover, then the second infection may come along before the first has entirely cleared up. I can see in this a very strong argument for the encouragement of breast-feeding.

One other comment. It has been stated that dried milks are not *displayed* to the public, but only distributed on the orders of the doctors at the clinics. Recently, when on holiday, I had occasion to call at a food office. As I waited for my emergency card I was forced to look upon a veritable pyramid of dried-milk tins displayed along with orange juice and cod-liver oil in bottles. I am sure that this type of display has the same effect upon the mother as the advertisement upon the hoardings has on the public.—I am, etc.,

York. F. Charlotte Naish.

Sir,—The description of the school health service as given in Professor Moncrieff's paper (*Journal*, October 7, p. 795) is far different from that known to myself. I have been some eighteen years in this service with three different authorities, and also have a more or less intimate knowledge of the systems of many other authorities. The conception that a school medical officer need spend most of his time carrying out routine medical inspections is entirely erroneous. In Liverpool only about 25% of the total of the school medical officers' services is occupied with this work. I quite agree that time would be wasted by such inspections. All that is required is a rapid screening, and then provision made for selected cases to be seen at special clinic sessions. The importance of health education is rightly stressed, and there is surely no better means than the giving of advice to individual parents during the course of these routine examinations.

In consideration of the above, together with actual experience of such a system, I would not endorse the carrying out of these inspections by health visitors. This is not work for which health visitors are qualified, and in consequence their selecting of cases is either on such a wide basis that there is no saving in the time of medical officers or else cases of importance are missed. The field of interest in the school health service is much wider than that of clinical paediatrics, and morbidity and mortality statistics are not adequate yardsticks with which to measure the results. I would recommend to those interested in the work of the school health service the Annual Reports of the Chief Medical Officer of the Ministry of Health: "The Health of the School Child." A study of these reports will reveal that the school health service has steadily progressed and is indeed very different from what it was in 1907-8.—I am, etc.,

Liverpool. G. Stuart Robertson.

Sir,—I very much admire the courage of Professor Alan Moncrieff, and I found his Dawson Williams Prize lecture (*Journal*, October 7, p. 795) most stimulating, as many others must have done. I do feel, however, that I would like to defend the principle of routine examinations, as this seems to be coming in for very heavy criticism at this time. Three years ago I started routine annual examinations of my child patients in order to investigate the value of such a procedure. At the beginning I accepted the conventional theory that the main purpose was to bring to light occult and minor ailments the treatment of which would prevent major disease in the future. If this were the only reason for carrying out physical examinations I would be very inclined to agree with Professor Moncrieff that, although some defects are undoubtedly discovered in this way, and quite a lot of good is done, the immense amount of labour produces only a small harvest. There are, however, other reasons for seeing the growing child at fixed intervals. A routine examination can be regarded as the taking of a cross-section of the child's development, a milestone which in practice gives one a very valuable standard of comparison. In other words, the routine examination can be used not only to discover ailments in the past, but as an instrument to discover ailments in the future.

For example, if a mother brings a child and says that he is not getting on well, is off his food and losing weight, reference to the records of the last routine examination will provide a standard by which to judge the child in his alleged illness. If this same child should provide a positive tuberculin reaction, reference to the records will again show whether there has been fairly recent Mantoux-conversion or whether he has been tuberculin-positive for years. It is to be noted that, if routine examinations are carried out for their possible value in the future, then even the obviously healthy children must be included in the scheme.

The value of the routine examination in providing a standard by which to judge the child in the future does not seem to have received much comment, and I would suggest that the reason for this is because the person who normally carries out routine examinations in our child-health services to-day is a different doctor from the one who is consulted when the child is ill. Having had some experience in the school medical service, I have no hesitation in asserting that the value of a routine examination both to the child, his parents, and the doctor himself is very much greater when that doctor is clinically responsible for the child in health and sickness. The natural corollary of this, of course, is that if routine examinations are to remain, some means must be found whereby they can be performed by the child's own doctor.

There is yet another reason why routine examinations are useful, particularly at the present time when normal practice is carried on at rather a fast tempo. Provided that adequate time is allowed, a routine examination is a very convenient time for discussion with the parent on the child's physical and mental development and any other problems that may occur to the mother. It would be difficult to summon a child and parent to an interview for the purpose of health education, but the routine examination provides a very valuable opportunity for such instruction and advice.

I rather wonder if the present reaction against medical examinations for routine purposes is not largely due to the unsatisfactory way in which school medical examinations are normally carried out. The hopelessly inadequate amount of time available for each child, the frequent lack of privacy, and the fact that the doctor is there to "do" so many units, most of whom he will never see again, are all factors tending towards superficiality and the avoidance of long discussion with the parent. Many parents, aware of these deficiencies, are afraid of holding up the moving belt and so keep valuable information about the child to themselves.

There is one further argument in favour of routine examinations that may be valid in the future, if not to-day. Whilst routine examinations may demonstrate very little disease in children, they also show that only a minority have really perfect physique. It must be admitted that for the most part we are ignorant of the factors preventing perfect health. There are a few obvious cases where an underweight, flabby child is obviously mismanaged at home, but we are all too familiar with the substandard child from the perfect home and the perfect child from a poor home to pretend that we know very much about the neglected study of the *health* of the child. Perhaps in the future it will be possible to measure the degree by which a child falls short of perfection and to prescribe appropriate remedies, in which case routine examinations will be of importance again.—I am, etc.,

Bristol. Norman J. Cook.

"Dramamine" and Sea-sickness

Sir,—In view of Professor J. H. Burn's comments on the use of antihistamine compounds in sea-sickness (*Journal*, September 23, p. 692), some observations of mine on their use in a fleet destroyer may be of interest. About a year ago I became aware of the inadequacy of hyoscine in this condition. Its usefulness appears to be confined to the mild cases, and then only if taken before rough weather is encountered. As a sailor usually believes he will be all right next time, he seldom asks for his pills until he is feeling really ill, by which time they are of little help to him. The result is they fall into disrepute and few bother to take them. There being no "dramamine" available, I tried the effect of "benadryl." Its superiority over hyoscine was at once apparent and it became very popular, though again no one applied for it until feeling really ill. Many who were completely incapacitated were able to carry on their work as usual, though some complained of drowsiness.

Recently a small supply of dramamine came into my hands, and I was able to compare its effects with benadryl. Here, again, the pills were not taken until the patient was actually feeling ill.

The results were as follows:

Antihistaminic	No. of Cases	Complete Relief	Partial Relief	No Effect
Dramamine	30	10	9	11
Benadryl	30	19	6	5
Total ..	60	29	15	16

Of 17 cases who have tried both compounds at different times, five preferred dramamine, nine benadryl, and three found them equally effective. Drowsiness was complained of by two with dramamine and five with benadryl. No toxic effects were noticed, but it has never been necessary to continue treatment for longer than three days at six-hourly intervals, owing to improvement in the weather.

This is admittedly a small series of cases, but it would appear that benadryl is at least as effective as dramamine, if not more so, which is interesting in view of the ready availability of the former and scarcity of the latter.—I am, etc.,

J. M. Palmer,
Surgeon Lieutenant, R.N.V.R.

Sir,—I have been a very poor sailor all my life, during which time circumstances have taken me across the North Sea twenty times or more. I was invariably sea-sick unless the sea was dead calm. About fifteen years ago I tried hyoscine hydrobromide to help the sea-sickness. It certainly improved matters, as on comparable seas without it I would have been actually sick. As it was, provided I lay still and quite flat the journeys were endurable on a slight sea. If really rough, it appeared to make no difference, and the nausea continued on land up to 48 hours afterwards.

This summer I started the sea journey on hyoscine and went up to breakfast, where I toyed queasily with a grape-fruit; later I was sick. The stewardess provided me with "dramamine," which sent me to sleep for four hours. Then, although the sea was rougher, I got up perfectly well, and enjoyed a dinner of roast duck, ice with whipped cream, and blue cheese. After the holiday the sea was worse on the return journey, but, thanks to dramamine, I was up and present at all meals the entire journey, and next day on shore I was perfectly well.

Personally, I cannot praise dramamine too highly as a sea-sick cure.—I am, etc.,

Birmingham. Enid Houghton.

Sir,—As an inveterate sufferer from sea-sickness, and, like my friend Dr. M. F. Bethell (October 7, p. 836), a recent ship doctor, I would disagree with his conviction that "dramamine" is superior to the hyoscine preparations.

I was asked by the medical superintendent of a shipping line to carry out a trial of this drug, at that time in short supply. In cases of severe sea-sickness I could not repeat the spectacular results claimed by the Americans despite the usual methods to make the sufferers retain the drug. I often found it ineffective or definitely inferior to hyoscine in warding off impending attacks.

In my own case the recommended dose of dramamine was very alarming; a sense of impending doom convinced me that the proof of this pudding lay in the individual. I would agree with Dr. C. Grantham-Hill that there are many individual types of sea-sickness.—I am, etc.,

Chertsey, Surrey. John C. L. Adams.

Objective Assessment of Symptoms in Rheumatoid Arthritis

Sir,—Progress in rheumatoid arthritis is difficult to assess, and it is not surprising that clinicians relatively inexperienced in the rheumatic diseases have reported results of treatment with such agents as desoxycorticosterone acetate (D.C.A.) and ascorbic acid that conflict with the findings of specialized rheumatism units.

Steinbrocker's system of defining the stage of disease, the functional class of the patient, and his method of assessing the progress made, have been used with success in following a group of patients at the rheumatism clinics of the Leeds General Infirmary and the Royal Bath Hospital at Harrogate. This system is of use only in assessing clinical change over a period of months, and it is quite unsuitable for assessing such rapid change as may follow the administration of such therapeutic agents as cortisone and A.C.T.H.

Any objective test which will measure clinical change or improvement is of importance. C. E. Quin, R. M. Mason, and J. Knowelden (*Journal*, October 7, p. 810) describe four so-called objective tests. A series of cases of rheumatoid arthritis treated with D.C.A. and ascorbic acid, in which similar tests were performed, was reported last year with negative results.[1] I feel that it is necessary to point out that none of the tests performed are entirely objective, and all with the exception of the "walking test" are difficult to measure accurately. Considering these tests in turn, it will be seen that none are entirely objective.

Joint Tenderness.—This is, of course, a subjective test. Even with the use of the analgesiometer (Kellgren), variable results can be obtained. In performing such a test it is essential that preliminary examination of the patient should show that the tenderness is not varying from day to day or at different times of the day.

Grip Test.—I have used this test on more than a hundred patients, and, if the method of gripping the bag is always the same, consistent results can be obtained in the normal and rheumatoid subject. However, a slight variation in the method of holding the bag produces a considerable alteration in the level of mercury. This can be demonstrated easily by anyone wishing to try it. Again, too, the co-operation of the patient is necessary. It is important that such measurements are taken at the same time of the day and at approximately the same room temperature.

Range of Joint Movement.—I have measured the range of movement of joints in rheumatoid patients who are not receiving active therapy, and a variation of ten degrees was often found from day to day. The range through which a patient will move a joint within the limits of fixed deformity will depend upon muscle spasm and local pain—again, subjective. Temperature has a great influence on muscle spasm, and I have on several occasions seen a joint which was clinically fixed move through forty-five degrees following local heating.

The shoulder-joint is one of the most unsatisfactory joints in the body for accurate measurement. From the article it appears that the angle was measured by one observer before the injection and by a different observer after the injection. Even using skin markings and instrumental aids, the readings of different observers measuring the same joint will show a considerable variation.

Using joint movement as a help in assessing clinical change in rheumatoid arthritis, it is essential to use a joint with a simple movement—e.g., the knee or elbow. Preliminary skin marking and the use of a long-armed goniometer are essential. Comparisons should be made between the range of movement measured, and not the actual limit figures. I cannot see how differences of five or six degrees in the range of shoulder movement can be measured without instrumental aid.

Walking Test.—The key sentence here is, "Walk as quickly as possible," and this functional test must have a subjective element. In discussing this and other similar tests at the spring meeting of the Heberden Society, at Manchester, 1950, I mentioned that the walking test was the one I had found most valuable in practice.

There are certain objective tests available, and I am surprised that Quin and his colleagues have been unable to establish a satisfactory method of measuring joint swelling. The method I employed (again limited to accessible joints like the knee and wrist) was to mark out with silver nitrate the maximal circumference of the joint. This line must completely encircle the limb. Parallel to this line, and at a distance governed by the size of the limb and joint—e.g., 2 in. (5 cm.) for the knee-joint—are drawn two other circumferences, one distal and one proximal. The use of these three measurements gives a satisfactory estimation of joint swelling.

As Lewin and Wassén[2] described joint redness and heat accompanying clinical improvement with D.C.A. and ascorbic acid, skin thermometry was performed on a series of cases,[1] with entirely negative results. This is certainly an objective measurement. Kellgren and Janus, at the Heberden Society meeting, 1950, showed a method of measuring joint blood flow, and this is also completely objective.

I am making no attempt to discuss the pathological findings, such as eosinophil counts, which are valuable in such investigations. No criticism is offered of the experimental method used, nor of the actual results obtained.—I am, etc.,

London, W.C.1. R. HARRIS.

Osteoarthritis and Occupation

SIR,—I would like to support Dr. C. W. Buckley's contention (September 23, p. 728) that trauma, especially minor trauma, is an important cause of osteoarthritis. An analysis of the relative occupational incidence, and its effects on knee- and hip-joints in clinics which I attend, tends to confirm this view. In the Sunderland clinic we have a large proportion of miners who work in fairly low coal seams, mostly on their knees or "hunkers," while at the Darlington clinic a considerable number of agricultural workers attend who, as one farmer put it, are "clod-hopping all day." Among the miners osteoarthritis of the knee as against the same condition in the hip occurred in the proportion of twelve to one, while among the agricultural workers the ratio was reversed and there were 14 hip-joint cases as against one knee case. Other trades showed the following figures:

	Hip Cases	*Knee Cases*
Pneumatic tool workers (other than miners) ..	6	4
Policemen, postmen, gamekeepers	7	3
Tram, bus, and lorry drivers	2	8

This investigation was made in 209 cases. I believe a much wider survey would be of considerable use, especially if shoulder- and elbow-joint cases were included. Most orthopaedic surgeons are impressed by a steady increase of arthritis of these joints following the widespread use of pneumatic tool machinery.—I am, etc.,

Sunderland. W. GRANT WAUGH.

SIR,—It seems to me that Dr. C. W. Buckley (September 23, p. 728) and Mr. Franklyn Stonham (September 9, p. 629) are at cross purposes. In his paper Dr. Buckley states quite clearly that major trauma is less often a cause of osteoarthritis than microtrauma, which is often of occupational origin. This is perfectly true, but Dr. Buckley's natural habit of understatement has not, on this occasion, had the desired effect and has led Mr. Stonham into battle. The fact of the matter is, in my opinion, that there are two types of osteoarthritis, one of which might be called simply "osteoarthritis" and the other termed "traumatic osteoarthritis."

Simple osteoarthritis is, as Dr. Buckley says, a matter principally of age and stress. It is sometimes found initially in one joint, and is fully described in textbooks (Fletcher, 1947). It gradually spreads to involve other joints, or it may initially appear in several joints at the same time in the same way as it does in osteoarthritis of the spine, which, although it bears the same name, is not the same disease.

Traumatic or monarticular osteoarthritis is a different condition. It is uncommon, and in 500 cases of osteoarthritis was found only 60 times. So far as I know, it is confined to one joint for all time. I have a case of traumatic osteoarthritis of the left knee (due to a motor accident) which I first saw over nineteen years ago in 1931, and the condition is still confined to that one joint; the *x*-ray changes have gradually advanced over the years. Those unusual cases of traumatic osteoarthritis due to meniscectomy have this same characteristic, and may occur in patients of any age. The youngest case in my experience was operated on for a cartilage in 1943 and was then 23 years of age. I lost sight of the patient in 1946, but the condition was unaltered then, so far as clinical and radiological examination could tell.

Mr. Stonham's view that muscle spasm should call for a revision of the diagnosis is not, to me, understandable and is probably brought about by the fact that prostigmin sometimes relieves the muscle spasm in rheumatoid arthritis.

I think it should be mentioned here that the causation of simple osteoarthritis, although unknown, is closely linked with the incidence of obesity and hypertension. Obesity occurs eight times as commonly and hypertension four times as commonly in connexion with osteoarthritis as in an average cross-section of the sick population. It seems that obesity can only really have an effect through increased stress and strain, which amount to the infliction of multiple microtraumata; hypertension is nearly always associated with arteriosclerosis, and the joints are affected in this way. I certainly agree with Mr. Stonham that patients are justified in objecting to wearing callipers and Marsh knee cages.—I am, etc.,

London, W.1. ERNEST FLETCHER.

Medical Students in Prague

SIR,—As one of the participants in the second congress of the I.U.S. I feel that Mr. Diggory (*Journal*, September 30, p. 780) has been somewhat ungracious in his attitude to our Czech hosts. It is unjust to compare the *Hitlerjugend* with the Czech Youth, who suffered horribly under Nazi oppression for six years. These Czech youths extended to us, and to all other students regardless of nationality, creed, or race, a hospitality unrivalled in its warmth. Whatever may be the political inclinations of the student, it is always in the true spirit of British tolerance to listen and discuss with those who hold opposing views. From these discussions we all learned much, and made many friends among the students of 75 nations. For this reason alone the congress has been worth while.

Mr. Diggory has stressed the earnest desire of Czech students for peace. Would it not be a good thing that we British should show them that we are just as anxious in this pursuit, and may not this common desire for peace become a bond of friendship uniting us ?—I am, etc.,

London, W.C.1. A. HERDAN.

SIR,—As a participant at the I.U.S. Congress in August I was interested in the account of it by Mr. P. L. C. Diggory (*Journal*, September 30, p. 780). There are some factual inaccuracies in his article on which I wish to comment.

The health services in Czechoslovakia differ in several respects from those in this country, but not in the ways Mr. Diggory suggests. Thus the cost of the scheme is borne almost entirely by contributions, assessed in proportion to income from those within the scheme. It is unfortunate that Mr. Diggory did not quote his sources of information. The Czechoslovak National Insurance Act is available in an English translation (Orbis, Prague); it was submitted for consideration at the International Labour Organization (U.N.O.) conference at San Francisco (June, 1948), and the 1949 yearbook of I.L.O. compares the wider benefits of the scheme favourably with our own. Although self-employed persons are still excluded from the sickness insurance part of the scheme, and do not get entirely free treatment, their financial state does not influence the nature of treatment available.

It is hardly surprising that politics should enter into a discussion of the health service, especially if one considers the realms in which conspicuous progress can be readily observed in Czechoslovakia. What we in this country tend to regard as chronic problems in social medicine (notably tuberculosis) are being rapidly solved, new hospitals and health centres are being built, and group practices are encouraged. Compare this with Britain, where not one new sanatorium or health centre will be built in the coming year. I agree with most of Mr. Diggory's actual observations, none of which contradict this assertion, though I saw nothing to suggest that politics enters into medical treatment in the way he implied. I happened, uninvited, to visit two British students being treated as in-patients for a few days

in the Bulovka hospital; the medical and nursing treatment seemed fully comparable with that in this country; in none of the wards did I see any portraits of Stalin (though there was one of Masaryk).

I disagree with Mr. Diggory's allegation that the high living standards and increased educational amenities he describes were achieved at the expense of political discrimination. We saw that the proposals on such things as grants and fees, student sanatoria, wider university entrance and curriculum reform—which our own student organizations N.U.S. and B.M.S.A. have fruitlessly demanded for a number of years—have been achieved in Czechoslovakia, and I think the heavy Marxist trend we observed among students is a result of, rather than a pretext for, the achievements we saw.

The fact that Mr. Diggory omits from his article all reference to the medical faculty conference, which he attended as B.M.S.A. representative, and to the actual policy put forward by the leaders of our own N.U.S. (far less the very objective replies it provoked) leads me to conclude that he is making a purely emotional appeal instead of presenting the facts on the Congress discussions and work of the I.U.S. Throughout his article there is a constant misrepresentation of the feelings and behaviour of the majority of British students present. Thus the gift of £50 worth of medical supplies to the Korean students is referred to as penicillin from the Communist students present; but in fact nearly every British student contributed towards this gift as a token of genuine indignation over the needless destruction of schools and hospitals, of defenceless women and children, from the mass bombing of towns in both North and South Korea. There is little doubt of how the people of Asia regard this feature of the conflict; as a medical student I extend compassion to all who are needlessly giving their lives and blood in Korea.—I am, etc.,

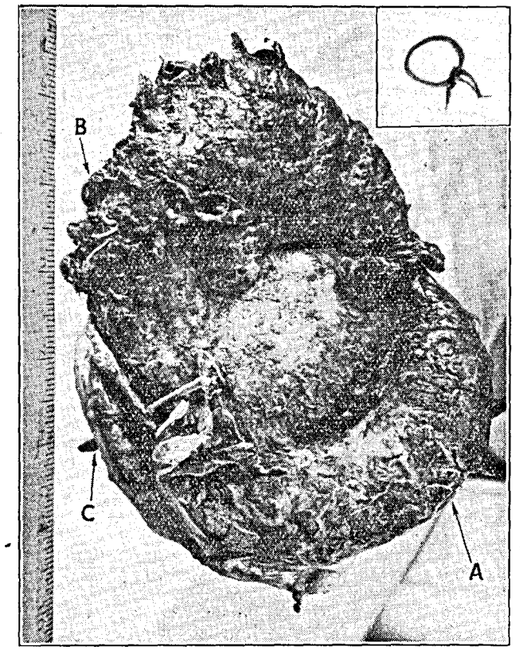
London, W.C.1. S. A. HALL.

Jaundice and Para-aminosalicylic Acid

SIR,—In your issue of September 23 (p. 729) Dr. G. Hurrell reports the occurrence of jaundice in a young woman under treatment with P.A.S., and concludes that it was probably a toxic effect due to the drug. He presumably excluded infective hepatitis as a possible cause because the usual incubation period of that disease was exceeded by the duration of his patient's isolation in hospital—i.e., 35 days before the symptoms of jaundice first appeared.

In this connexion, however, I think it is relevant to refer to an epidemic of 50 cases of infective hepatitis (to be fully reported in due course) that occurred recently in an Oxford college. Here it was fortunately possible to ascertain the two consecutive days on which all the victims almost certainly became infected; and their incubation periods, determined in this way, varied between 24 and 43 days. It seems possible, therefore, that Dr. Hurrell's case was really one of infective hepatitis with a comparatively long incubation period, and that P.A.S. may be exonerated from being the cause of his patient's unpleasant intercurrent illness.

Incidentally, several of my cases also had albuminuria, which was usually slight; and one case during the pre-icteric stage produced an urticarial rash similar to, though not so severe as, the one Dr. Hurrell describes.—I am, etc.,



Oxford. G. A. BALLANCE.

Unabsorbable Sutures

SIR,—Mr. John Howkins (*Journal*, September 16, p. 659) reports a case of uterine sepsis from unabsorbable ligatures used during caesarean section. The following report of the persistence of suture material in the uterus for eight years may be of interest.

A woman, aged 39, was admitted on August 30, 1950, in the 36th week of her third pregnancy. Classical caesarean section was performed for ante-partum haemorrhage in July, 1942, and a lower-segment caesarean section (before the onset of labour) in February, 1945.

She was not in labour on admission, but was complaining of continuous abdominal pain. Foetal parts were easily palpable. A diagnosis of rupture of the uterus was made, and a laparotomy was performed. Both the foetus, in the intact bag of membranes, and the placenta were lying in the peritoneal cavity in front of the uterus, which had ruptured. The rupture had taken place along the whole length of the anterior wall down to the lower segment, and, after the escape of its contents, the uterus contracted, causing wide separation of the torn edges, as can be seen in the illustration. The foetus, which was stillborn, was removed and subtotal hysterectomy performed.

The uterus as it appeared immediately after removal, showing the marked separation of the torn edges. Strands of suture material are seen at A and B. The probe C is lying in the cervical canal. *Inset.*—A loop of the suture material removed from the uterine wall.

Inspection of the uterus showed several strands of suture material along the whole length of both the torn edges. An interesting feature is that the loops were intact, demonstrating that they had cut through the uterine tissues. It has not been possible to confirm the nature of this material, but it looks, however, like silkworm gut or nylon.

—I am, etc.,

Salford, Lancs. E. E. RAWLINGS.

Indications for Globin Insulin

SIR,—The interesting article by Dr. D. W. Pugh (*Journal*, September 16, p. 657) confirms the opinion that globin insulin is successful in mild cases and in older patients. Since the majority of diabetics are over 40 years of age (over 75%) and since about 65% of ambulant patients need 40 units of insulin or less, it is useful in a wide field where its main advantage over other insulins is its simplicity. Dr. Pugh, however, appears to imply that it is not suitable for patients who need more than 40 units of insulin. A high insulin dosage which is more common in, though not confined to, younger patients is, in my experience, not a contraindication to its use, and over 25% of those using G.I. under my supervision do take more than 40 units with success; some indeed have taken quite large doses (80–120 units) for many years.

The "failed globin syndrome" is that of a maladjusted balance between the carbohydrate intake and the absorption of insulin, which causes hypoglycaemia during one part of the 24 hours with diabetic symptoms at another; it is not confined to globin insulin and is typical of P.Z.I. when given alone in ordinary cases. Here there is "diabetes" after breakfast, which may last till mid-afternoon, while insulin reactions occur at night. In the case of globin it is due, I believe, to an idiosyncrasy of certain patients who absorb insulin unusually rapidly so that the insulin acts strongly in the morning and afternoon and has shot its bolt by the evening. Many of these quick absorbers do well on P.Z.I. alone, which brings the blood sugar to normal limits before the midday meal and maintains a steady balance for the rest of the 24 hours. It is always worth trying before reverting to the more complicated method of using a mixture or combination of P.Z.I. and S.I.

One more point: Dr. Pugh gives a dose of G.I. only two-thirds that of the former total dosage of other insulins; in my experience this is not enough, and may account for the greater incidence of the "failed globin syndrome" in his cases.—I am, etc.,

Hove, Sussex. G. M. Wauchope.

Gastric Ulcer and Vagotomy

Sir,—Mr. D. M. Morrissey's finding of two cases of gastric ulceration six months after vagotomy (*Journal*, September 16, p. 651) is interesting and important. However, there is no doubt that palpation of the stomach at the time of the vagotomy, particularly through a transthoracic transphrenic wound, is not a reliable means of excluding gastric ulceration. I see that these two occurred out of seventy-nine cases of vagotomy. Out of seventy-nine cases of partial gastrectomy for duodenal ulcer I would expect to find on carefully examining the specimens one or two stomachs with small gastric ulcers or scars. I believe, therefore, that these two ulcers may have been present as small quiescent impalpable ulcers at the time of vagotomy.

It is important to avoid vagotomy for gastric ulcer. A careful pre-operative gastroscopy is the best safeguard in suitable cases. At operation careful and close inspection of both anterior and posterior surfaces of the lesser curve of the whole stomach is an even better guide to the presence of a small ulcer or scar than palpation.

Despite the possibility that these ulcers may not have developed since the vagotomy, I would still strongly support Mr. Morrissey's contention that vagal section provides no protection against gastric ulceration developing.—I am, etc.,

London, S.W.12. Norman C. Tanner.

Foreign Body in the Rectum

Sir,—A male, aged 50, a sexual pervert, was admitted to hospital with a round-ended bottle, 2¼ in. (6.3 cm.) diameter, presenting above the deep anal sphincter. As in the case recorded in the *Journal* (September 16, p. 680), the bottle was impacted between the bones of the lower pelvis, and could not be moved in any direction.

A vertical incision was made through the sphincters, and extraction was effected without difficulty by short midwifery forceps. The sphincter was then repaired, and convalescence was uneventful.—I am, etc.,

Downpatrick, N. Ireland. J. C. Robb.

Sir,—The recent correspondence (*Journal*, September 30, p. 785) on this matter reminds me of an interesting case when I was a young house-surgeon in the out-patient department at the Royal Infirmary, Edinburgh.

A patient came to the department and on being asked his requirements announced that he had "glass in his bottom." A careful survey of that part of his anatomy revealed no wounds, cuts, or abrasions, and on being pressed for further information he announced that it was "inside." I made a rectal examination and found in the rectum a tumbler, inverted and apparently immovable. How to deal with this situation was outside the scope of my knowledge, and I called in my chief, the late Mr. J. W. Dowden, who under a general anaesthetic endeavoured to remove the tumbler by means of various types of forceps, the tips being protected by rubber tubing. He failed completely to move it. Eventually he had to excise the coccyx, and, having done this, was able with great difficulty to remove the tumbler. I remember that after the whole affair was over the patient was asked to explain how this somewhat unusual occurrence had come about. His reply, for what it was worth, was that he had "sat on it in mistake." The tumbler, I recollect, was one about 3 in. (7.6 cm.) in depth by 2½ in. (6.3 cm.) in diameter, and was a medium for advertising a popular brand of table waters.

I remember feeling some gratitude to the unfortunate patient because this occurrence, and one or two other similar cases very much "off the pattern," enabled me to collect a small surgical prize which my surgical knowledge in no way merited.—I am, etc.,

Carlisle. Kenneth Fraser.

Chlorinated Swimming-baths

Sir,—I agree with Dr. A. D. Symons (*Journal*, September 23, p. 728). In my area I instituted a hypochlorite plant and supplied the public baths and the schools with the hypochlorite fluid, and in addition it was available to the public as a disinfectant. During my period as M.O.H. and school medical officer no school was closed on account of epidemics of infectious diseases. I would point out that the dangers of public swimming-baths are more likely to arise from human pollution from all the orifices and spray infection.—I am, etc.,

Southport. S. T. Beggs.

Sir,—Unfortunately views are usually more colourful than facts and consequently get more publicity than they merit. Mr. R. Ogier Ward (*Journal*, September 9, p. 625; see also September 23, p. 728) thinks it is fair to say that to wash out the nose with water of a chlorinated swimming-pool is to invite disaster simply, it seems, because on the three or four occasions he has been swimming in chlorinated water it has given him nasal irritation. Since then, he says, "I have always believed that this is probably one important factor which encourages the spread of poliomyelitis." Of course anyone can believe the earth is flat or anything else, but contributors to scientific journals whose opinions are apt to be mistaken for truths by the lay press and public should surely give more substantial evidence in support of their beliefs than Mr. Ward has done.

In Gosport (population 59,380), where we have had a chlorinated swimming-pool for the past fifteen years, we have only had 18 cases of poliomyelitis during the same period. Perhaps this is just luck, but certainly lends no support to Mr. Ward's belief. It would be interesting and useful if the Ministry of Health would collect and collate the experience of other towns and cities in this respect and publish their findings. It is unwise to let unsubstantiated opinions go unchallenged, particularly when they tend to discredit what we believe are valuable public health precautions.—I am, etc.,

Gosport. G. W. Fleming, Medical Officer of Health.

Poliomyelitis: Age Incidence

Sir,—One of the most outstanding and puzzling features of the epidemiology of poliomyelitis is the gradual change in age incidence during the last twenty-five years from the first half-decade of life to school age and later. So striking and consistent has this age precession been in all countries that one can confidently predict that nearly half the cases of poliomyelitis in the present epidemic will be in adults. Dr. Simpson Smith's series (September 30, p. 786) showing 60% of cases in children under 6 would seem to be an exception.

There are, however, two factors which tend to lower the age distribution of poliomyelitis in local outbreaks, both of which are probably applicable to this series:

It has been observed many times during outbreaks of poliomyelitis that the age incidence varies with the concentration of populations. This is, of course, true of many other infective diseases, particularly measles, scarlet fever, and whooping-cough, cases being more concentrated in the younger ages in proportion as aggregation of population increases. It is probable that most of Dr. Simpson Smith's cases are drawn from industrial and overcrowded areas.

A change in the age distribution of cases has been noted during the course of practically all epidemics that have been sufficiently well investigated, the younger ages showing a relatively greater proportion of cases early in the epidemic, the older groups later. This series of cases all occurred before September 1, at which date notifications were probably at their peak.

The high proportion of cases in infants (6½%) in this series is most unusual, particularly as the majority of these cases appear to have had severe attacks.—I am, etc.,

Manchester. W. P. Sweetnam.

Chloralose as Antihistamine

Sir,—I have read with interest Professor J. H. Burn's article (September 23, p. 691). Professor Burn and his co-workers have proved experimentally that a number of drugs—e.g., local anaesthetics, analgesics, and spasmolytics—can exert an antihistamine action. These findings are analogous to my own experimental observations dating back to 1927–8. The aim of these investigations was to study the effect of chloralose on the histamine action on gastric secretion in dogs and on the isolated gut of guinea-pigs. Chloralose is a compound of chloral and glucose and has been widely used as a general anaesthetic in animal experiments and is also known to have a local anaesthetic action. In these experiments it was shown that the spasmodic effect of histamine on the excised gut of guinea-pigs in Ringer's solution could be suppressed by adding chloralose (1:1,000). These experiments were extended to investigate the influence of chloralose on the anaphylactic reaction of the isolated gut of guinea-pigs previously sensitized to horse serum. No anaphylactic response of the excised gut could be obtained in chloralose Ringer's solution. However, after repeated rinsing in Ringer's solution the same piece of gut reacted strongly to renewed addition of 0.5 ml. of horse serum. The antagonistic action of chloralose was confined to histamine and to the anaphylactic reaction. The spasmodic effect of pituitrin and acetylcholine on the isolated gut could not be appreciably suppressed by chloralose.

Since so far none of the known antihistamines is capable of counteracting the gastric secretagogue action of histamine, my above-mentioned experiments on dogs may be of interest. In two dogs with gastric pouch (Pavlov) and in one dog with a permanent gastric fistula, 1.5 g. chloralose in 60 ml. of water was given by stomach tube. Thirty-five minutes later 1 mg. histamine was injected subcutaneously. The experiments revealed the uniform result that histamine gastric secretion can be almost completely suppressed by chloralose. When chloralose was administered by rectum, only the volume of histamine gastric secretion was reduced, but free acid concentration and total acidity were not appreciably influenced. Again the antagonistic action of chloralose was confined to histamine, for neither gastric secretion produced by 200 ml. of 5% alcohol nor the action of pilocarpine on the salivary glands was influenced by chloralose.

From these experiments I concluded that chloralose is a potent antagonist to histamine and is therefore, so far as could be ascertained, the first "antihistamine" described in the literature.—I am, etc.,

Radiology and the Diagnosis of Miliary Tuberculosis

Sir,—I am concerned about the informative article (September 23, p. 702) by Drs. J. L. Emery and J. Lorber. I was amazed to note that out of the 52 cases of miliary tuberculosis, with the diagnosis established at necropsy, only 18 of these showed any radiological evidence. The editorial comment, "It is clear that *x*-ray examination cannot be relied upon for the early diagnosis of miliary tuberculosis," is very disturbing to those of us who in the past have implicitly relied on the radiological diagnosis of this disease.

Frequently, and I feel other observers will agree, these closely packed pin-point foci do not show on the radiograph on account of certain technical *x*-ray factors which are difficult to control. It requires only the very minimum of respiratory movement on the part of the child to blot out the foci completely and show clear and normal lung fields. On many occasions I have found a normal chest in these cases, where an immediate repeat of one or more radiographs with attention to minimal respiratory or other movements have shown the foci clearly. This is a snag which should be brought to the notice of all workers in this field. It is of equal importance that the radiograph should be of the best technical quality, preferably taken with a fine focus, rotating anode tube, and the appropriate kilovoltage and distance. We must be prepared to accept these percentage figures and the skilled interpretation of the radiographs by Dr. Grout, but I should feel more at ease if evidence was forthcoming that such precautions were taken before this method of diagnosis tends to fall into disrepute.—I am, etc.,

Hull. J. E. Bannen.

Protection of Laboratory Animals

Sir,—I have read with great interest the article by your special correspondent (September 23, p. 724) on Major C. W. Hume's document. Surely the Minister would have power to choose for his board of control persons who would represent with equal fairness the claims of science and the humane treatment of animals.

Is not a more comprehensive Act called for after a lapse of so many years? The numbers of medical students have increased greatly, and is it not advisable to remind all members of the medical profession that there are ethics to be observed towards animals as well as towards each other?—I am, etc.,

Low Fell, Co. Durham. May Raw.

Hydrops Foetalis and Rhesus Incompatibility

Sir,—The interesting letter of Dr. R. T. D. Franklin and his colleagues (September 16, p. 680) describes a case of foetal hydrops due to erythroblastosis foetalis which had been produced by incompatibility of the ABO blood groups. Certain features of this case deserve comment since they are at variance with those usually encountered in haemolytic disease due to the rhesus factor.

In the first place the patient was a primigravida, and gave no history of previous transfusion or injection of blood. Secondly, the autopsy report made no mention of splenic abnormality or enlargement; in fact, apart from the liver all the organs appeared to be normal. Thirdly, the degree of tissue oedema was such that a 26-weeks foetus was distended to a size equivalent to that of a full-term infant, the scalp floated on the skull, and the ascites was so marked that the abdomen had to be punctured before the child could be delivered. All these factors are unusual in hydrops due to the rhesus factor.

In my own limited experience, I have twice encountered dystocia due to the size of a hydroptic baby, and in both these cases there was no rhesus incompatibility. On the first occasion I was called to a confinement where the child's head had been delivered with forceps and the shoulders could not be extracted. I found a tense foetal ascites as the cause of the obstruction, and after puncture of the abdomen across the diaphragm an oedematous foetus was delivered. There was no autopsy. The mother, who had had one previous abortion, was found to be blood group A, rhesus positive, with no agglutinins, and W.R. negative. She has subsequently had a normal confinement of a healthy baby. On the other occasion the patient had been booked for her second confinement in hospital on account of hydramnios. A large infant became impacted in the pelvis as an extended breech and embryotomy was necessary before it could be extracted. There was gross oedema, the scalp floated on the cranium, the serous cavities were all distended with effusions, and the placenta was large and pale. The mother was W.R. negative, group O, rhesus negative, without demonstrable antibodies, and the foetus and also the father were rhesus negative.

There is little available information about those cases of hydrops foetalis in which rhesus incompatibility is not to blame, but Potter (1943) has given an excellent clinical description without throwing any light on the aetiology. She records 17 cases of hydrops without erythroblastosis and without splenic enlargement; six of the mothers were primiparas, and six

subsequent pregnancies produced seven normal babies. The blood groups of the parents are not recorded in these cases, but it is unlikely that serological tests were made in an effort to incriminate ABO incompatibility.

Two interesting speculations emerge. Has Dr. Franklin discovered the cause of a significant number of the unexplained cases of foetal hydrops; and is the gloomy prognosis for his patient entirely justified on the evidence?—I am, etc.,

Birmingham. W. G. Mills.

Should Pregnant Women receive Streptomycin?

Sir,—I read with interest Dr. P. N. Swift's account (*Journal*, September 30, p. 787) of the successful delivery of a live baby to a woman under treatment for tuberculous meningitis. He states that the progress of the infant has been very satisfactory. However, it is too early to be confident that there will be no latent toxic effects from streptomycin. The effects on the vestibular apparatus after large doses of streptomycin are likely to be permanent, and it is obviously impossible to assess these satisfactorily in an infant until at least the stage of walking is reached. In this case the concentration of streptomycin in the placental cord blood was as high as that of the mother, so it would be reasonable to expect considerable toxic effects on the vestibular apparatus of the infant.

This raises the question of the advisability of treating pregnant women with streptomycin. In tuberculous meningitis death would otherwise ensue, so there is definite justification; however, in pulmonary tuberculosis, where there may be alternative methods of treatment, judgment of the advisability of streptomycin therapy should be withheld until it is certain that there will be no delayed toxic effects on the child.—I am, etc.,

Manchester. M. J. Greenberg.

POINTS FROM LETTERS

The Common Cold

Dr. E. Wrigley Braithwaite (Leeds) writes: In 1943 (*Journal*, **2**, 433) you published a letter from me in which I made a number of statements about the pathology of the common cold. . . . It only develops when the individual is in a particular emotional state, which can be clearly defined during the course of psycho-analytic treatment. Cold and wet do not cause a common cold. Cold "proneness" disappears completely as a result of successful psychological treatment. The specific factor is psychological; the microbic secondary. I am glad to see that the Common Cold Research Unit has proved by experiment on a large scale that cold and wet do not cause colds. . . . Last year you reported a speaker at the International Congress of Otolaryngology as saying, "The occurrence of the honeymoon cold, that following a domestic row, and that occurring before or during an examination are well known." He gave it as his view that the best prophylactic against the common cold is a state of emotional balance. In your issue of September 16 (p. 662) the reviewer of a book by Dr. T. H. Holmes under the title "The Sensitive Nose" regarded the evidence that emotional states affect the nasal mucous membrane (and the gastric) as beyond dispute.

Treatment of Sea-sickness

Dr. J. H. D. Webster (London, W.1) writes: In the *Aquitania* in the spring of 1926 leaving New York it was quite rough for a few days, and, though sceptical of all remedies then used, I was able to see the most striking effects of the ship surgeon's remedy, which he found cured or prevented sickness in about 99% of all cases. . . . Dr. B. S. Jones's and Dr. Marmaduke Fawkes's letters on the subject, with acidosis as the cause and alkalis as the remedy, are to be found in the *Journal* (1925) **1**, 139, 240. No remedies can be simpler or cheaper. In many North Sea crossings I have found 20 gr. of sodium bicarbonate and 10 gr. of sodium citrate taken before the boat sails, and hourly or two-hourly for two or three times, and on the second day, say, thrice (unless it is very rough), are sufficient to give a comfortable crossing, taking all meals. . . . On a recent trip back from Paris a passenger in the same compartment was quite incapacitated and in a daze, unable to take food, and we found his wife had "doped" him in view of what she thought would be a four hours' crossing from Calais to Dover. They were non-Europeans on a first visit to England. It seems a pity that nervous theories of sickness should now almost obliterate a proved chemical theory, with a simple and almost invariably effective remedy,

Obituary

Sir ERNEST GRAHAM-LITTLE, M.D., F.R.C.P.

Sir Alexander Fleming writes: By the death of Sir Ernest Graham-Little we have lost a great citizen. For 50 years he was in the forefront of dermatology, and there must be very many students of St. Mary's Hospital, like myself, who have blessed him for his straightforward and sensible teaching of skin diseases. In his own field he had few equals in the healing art. But that was only one of his many activities which have been detailed in the obituary notices (*Journal*, October 14). Here I would like to pay tribute to his kindliness. The student or the recently qualified man never went to him in vain for help and advice, and his wide range of interests made his counsel worth while. Everyone who was intimately associated with him will sorrow at his passing. He was a great character, a likeable character, and one who would go to great lengths to uphold what he considered to be right.

Sir JOHN McINTYRE, K.B.E., C.B., M.C., M.B.

Air Vice-Marshal Sir John McIntyre, who was Director of Medical Services, R.A.F., from 1930 to 1935, died in Tunbridge Wells on October 7, aged 70 years.

McIntyre came of Northumbrian stock, his father being in the shipping business in Newcastle. He was educated at Clifton College, and studied medicine at Cambridge University, where he won the Vintner Exhibition to King's College, and St. Mary's Hospital. He graduated B.Ch. in 1906 and M.B. in 1908. After holding a number of resident appointments at St. Mary's Hospital he went into general practice for some years. He joined the R.A.M.C. in 1915 and was awarded the M.C. a year afterwards while on active service. He transferred to the Royal Air Force when it was formed in 1918 and took a permanent commission in 1919. He devoted the rest of his professional career to the new Service.

We are indebted to Sir David Munro, K.C.B., for the following appreciation: John McIntyre became Director of Medical Services, R.A.F., in 1930 (the title is now Director-General of R.A.F. Medical Services). At the time when he came into office the Air Force Medical Service was still in a formative stage. A false move in the relations already established between two older—centuries older—medical services of the Navy and Army, or, even more important, between the leaders of the medical profession, might have meant a loss of ground patiently won by his two predecessors—in particular by Lieutenant-General Sir Matthew Fell. A failure to co-operate successfully with the rank and file of the R.A.F., especially the high-ranking officers in the Air Ministry and the senior Civil Servants, would have had the same effect. John McIntyre made no such false move: the progress of the infant service remained steady under his direction. Before the 1914–18 war McIntyre had been a general practitioner in Croydon, and a very successful one. He was unlikely, therefore, in his administration to be influenced by customs or traditions handed down from the two older Services. Nor was he. His outlook remained fresh, and he was a born administrator. To common sense he added knowledge, a level head, and an even temperament. If anything, he was too coldly logical. Seldom, I imagine, was he ever bested in verbal or written argument, for he was a careful listener, and, having once grasped the essentials of a problem, his judgment was seldom at fault. Had he

chosen to study law rather than medicine, and had he been able to overcome his natural North-country reserve, he might, I believe, have made a notable career at the Bar. If these remarks seem to present John McIntyre as slightly inhuman, the reverse is the truth. He was a staunch friend, and one of the best and most amusing of hosts—until his wife died. They had no children, and after a long and happy married life he was left a lonely man just about the time when he had reached another unhappy landmark, retiring age.

S. ROODHOUSE GLOYNE, M.D.

Dr. Cecilia Shiskin writes: I should like to add to what has already been published (October 7, p. 841) my tribute to the memory of the late Dr. Stephen Roodhouse Gloyne, whose passing has saddened all who were privileged to know him. I had the good fortune to work in his department at the London Chest Hospital for a number of years. He was not only the expert pathologist who taught and guided his staff, but he also stimulated them in their work. He radiated a warmth and friendliness that made working with him a real pleasure. He took a fatherly interest in each one of us and our personal affairs, so that we felt we were members of one happy family. His kindliness embraced all connected with the hospital—the nurses, the domestic staff, and the patients. When the hospital was bombed in 1941 Dr. Gloyne transported some of the patients to their homes in his own car and saw that they were comfortably placed. He maintained contacts with many former residents of the hospital who came from the Dominions. All sought his guidance and appreciated his advice. The morning-coffee interval afforded a pleasant break, during which Dr. Gloyne would expatiate expertly on a wide range of subjects—music, archaeology, history, and even the culinary art. He enriched the lives of those who were privileged to be associated with him. Our heartfelt sympathy goes out to his widow, his daughter, and his son and family.

Dr. Francis Kenneth Kerr, who was in general practice in Leith for 46 years, died in Edinburgh on August 15 in his 73rd year. He was educated at Daniel Stewart's College, and he spent two years in a merchant's office before taking up the study of medicine at Edinburgh University. He graduated M.B., Ch.B. in 1900. His enterprising and adventurous nature was exemplified by his volunteering for service in the South African War as a civil surgeon. For his services in that campaign he received the Queen's Medal with four bars. On returning to civilian life he practised in Cumberland for two years and then moved to Leith in 1904. He was appointed clinical assistant in the *x*-ray department of the Edinburgh Royal Infirmary, and later he took charge of the *x*-ray and electrical department of the Leith Hospital for seven years. In the first world war he served with great distinction in France—where he was awarded the M.C. for conspicuous gallantry in "steadying troops under heavy and accurate hostile fire"—Gallipoli and Salonika. In 1919 he was made consulting physician to troops in Turkey and in the Army of the Black Sea. He attained the rank of lieutenant-colonel and was elected an esquire of the Order of St. John of Jerusalem for his work in the Near East. He resumed practice in Leith after he was demobilized, and in the course of time held many local medical appointments, including membership of the board of management of the Leith Hospital, in the work of which he took an active and lifelong interest. He was a keen member of the British Medical Association and took a leading part in the activities of the local division, both in connexion with the introduction of the National Health Insurance Act and the National Health Service Act. In spite of an inherently modest disposition he was an incisive speaker, with a definite gift of getting down to essentials. Many members of the Edinburgh and South-east of Scotland Branch of the B.M.A. have happy memories of the day when, as president of the Branch, he entertained the members to an excursion to the Island of Inchcolm in the Firth of Forth. He was a representative of the City of Edinburgh Division at a number of Annual Meetings, and a member of the Insurance Acts Committee for some years. He was also a member of the Edinburgh Insurance Committee and of the Panel Committee. He found relaxation from his professional work in amateur acting, football, and swimming. As a practitioner his conscientiousness, ability, and kindness endeared him to his patients, and their sympathy, with those of his colleagues and friends in Edinburgh, will be extended to his widow.—R. W. C.

Dr. Arthur Williamson Brodribb, for many years physician to the Royal East Sussex Hospital, died at St. Leonards-on-Sea on September 16 at the age of 71. He studied medicine at Oxford and St. Bartholomew's Hospital, and graduated M.B., B.Chir. in 1905. He joined his father in general practice in Hastings a year later, and remained in this practice all his life, except for a time in the first world war when he was a captain in the R.A.M.C. Arthur Brodribb came of a line of doctors, traceable from about 1800 (and still continuing in his eldest son). He was held in high esteem by his colleagues, and was for 38 years physician to the Royal East Sussex Hospital, being a senior member of the staff for much of this time. He took an active part in the affairs of the town, having been at one time a town councillor and later a J.P. It might be suspected that this was due to pressure from without rather than love of office, since he disliked publicity. His hobbies were gardening and carpentry; and in his active days he was a keen footballer and golfer, being chairman of local clubs in both these branches of sport. It was, however, as a family doctor that Brodribb was supreme, and here he had a touch all his own. He did not appear ambitious to amass a very large practice, but to his patients he gave all that he had of skill, care, and friendship, and they repaid him with their devotion. Thus was established a bond which made him, in their eyes, irreplaceable. He had a quiet voice and courtly bearing—the right sort of bedside manner. The last war came at a time when he might otherwise have thought of easing off: instead, his work was much increased, in conditions which were difficult and often dangerous. The National Health Service also was most uncongenial to one cast in his mould, and after a brief trial he withdrew from it. So he was latterly a tired man; but those who knew him at his best saw something which is not taught in the schools and is now seldom found anywhere.—C. M. C.

Dr. Andrew Edgar Struthers, of Paisley, died suddenly on September 16 while on holiday in Arran. It was known to all his colleagues that, since a coronary thrombosis fifteen years ago, he was sensibly and realistically carrying on his daily round and a full and active public life with characteristic fortitude and good humour. Struthers graduated M.B., Ch.B. at Glasgow University in 1910, and started practice in Paisley in 1919 after service in the Navy in the first world war. Before that war he had a short but intensive experience of practice in Coatbridge. Throughout all his years in Paisley he was associated with the Royal Alexandra Infirmary, and he applied his scientific and well-ordered mind diligently and earnestly to his work as physician there. In the public life of the town he was an enthusiastic member of the learned societies and was a past president of the Paisley Burns Club. He was much in demand as an after-dinner speaker, and his original and independent habit of thought made him a most entertaining and provocative raconteur. He was from 1922–45 secretary of the Renfrewshire and Buteshire Division of the B.M.A. He was also a representative on the Scottish Committee. He held many public appointments, including that of honorary secretary of the local medical committee, and he was the area medical officer under the Factory Acts. His pleasing nature and cultivated mind endeared him to a large and appreciative number of patients. Paisley has lost a sound physician and an independent and outstanding personality. His wife predeceased him a few years ago. Sincere sympathy is extended to his only daughter.—J. W. H.

Dr. DANIEL CHARLES EDINGTON died at his home in Penrith on September 23. He was born in 1865, and received his education at the Edinburgh Royal Academy. He commenced his career as a chemist at the Edinburgh Royal Infirmary, but later he decided to study medicine and graduated M.B., C.M. in 1892, proceeding M.D. in 1901. After holding posts at the Royal Infirmary, including that of assistant to the professor of clinical medicine, he was for a short time in practice in Bridge of Allan and also Clackmannanshire before moving to Penrith in 1895, where he continued in active practice till his retirement in 1945. In his earlier years he was a man of catholic tastes and wide interests in sport, music, the theatre, and masonry. He was immersed in medical politics from the days of the heated controversy in the profession over the first National Health Insurance Act, and his level-headedness and clear vision helped to smooth over some of the local difficulties which occurred throughout Cumberland at that time. During the 1914–18 war, despite the departure of his partner to war service, he took on the additional work of medical officer to the Red Cross hospitals in Penrith with enthusiasm and zest. In recognition of his services he was made a life member of the B.R.C.S. His wise counsel was greatly appreciated by his colleagues in this area, and he was for many years chairman of the Cumberland Panel Committee and a member of the Cumberland Insurance Committee. A keen member of the B.M.A. from the outset of his career, he was president of the Border Counties Branch in 1922–3, chairman of the English Division in 1926–7, and chairman of the Cumberland Division in 1938–9. He will be remembered, however, for his fine clinical skill, an eager, receptive mind, a kindly heart, a fund of common sense, and a clear appreciation of his patient as a personality. He will long be mourned by a multitude of Cumbrians, to whom for over 50 years he rendered service tinged with humanity, and by his widow and two sons, to whom we render our sympathy.—J. S.

Dr. WILLIAM LOWSON, who practised in Tamworth for over forty years, died on September 27 at Tamworth aged 78 years. Lowson studied medicine at University College, Dundee, and University College, London, graduating M.B., Ch.B. (St. Andrews) in 1902. After holding a number of resident hospital appointments he came to Tamworth in 1909 as partner to the late Dr. Fausset. He was largely responsible for the formation in 1911 of the public medical service for Tamworth, and acted as its secretary and treasurer until 1947. For many years he was medical officer of health to the Tamworth Rural District Council and the medical superintendent of the Tamworth Isolation Hospital. He was also police surgeon and, during the last war, medical superintendent of Tamworth Infirmary. He was a member of the panel committees for both Staffordshire and Warwickshire, and served on the general and house committees of the Tamworth Hospital until the introduction of the Health Service in 1948. Lowson joined the B.M.A. in 1904, and represented the Nuneaton and Tamworth Division at the Annual Representative meetings for most years from 1923 until 1939. He was chairman of the Division for the 1925–6 session. A keen golfer, he was the captain of the Tamworth Golf Club, and was subsequently elected its president. The sympathy of all who knew Dr. Lowson goes to his widow in her bereavement.—D. S. P.

P. A. V. B. writes: The passing of William Lowson has brought a great sense of loss to his medical and lay friends. He had gained a reputation for his competence, integrity, and his dislike of the sham and meretricious. To those who did not know him well his austere manner was often awe-inspiring, but to those of us who were privileged to be his colleagues that manner was only a very thin disguise worn by a somewhat shy man who possessed a large store of human kindliness and a great sense of quiet humour. He was a staunch friend, and his advice, born of sound common sense, allied to a clear head and keen vision—whether given privately or at a conference—was always proved by time to be right. These qualities endeared him to his patients, and there are many who will mourn him.

Dr. Harold Balme writes: Absence from England during the past month has prevented me from hearing sooner of the death of my friend and former colleague, Edward Gillespie, but I would like to add my tribute to the fine appreciation by Dr. Hadfield which appeared in the *Journal* (September 16, p. 684). At the outbreak of the last war it fell to my lot to become medical superintendent of the Haymeads E.M.S. Hospital at Bishop's Stortford, the medical and surgical staff of which was largely drawn from the Prince of Wales Hospital, Tottenham. The buildings had previously been used as a poor law institution, and the task of converting it into an acute general hospital, capable of receiving all types of medical and surgical cases and of providing teaching facilities for the keen staff of young residents transferred from the London Hospital, demanded detailed preparation, careful organization, and expert hospital practice. In all these matters Gillespie made a notable contribution. His rugged individualism, independence of thought and expression, and fine surgical judgment and technique made an impression on every member of the staff, and I, personally, can never forget the splendid loyalty and wise counsel which I always received from him during those early, difficult years of the war. It was thanks to his influence and that of his confrères that the Haymeads medical staff became welded together into so happy and united a group, and it is a melancholy fact that already three of the most outstanding of them—Burton Wood, Robert Klaber, and Edward Gillespie—have now passed over to the great majority.

Medico-Legal

CLAIMS AGAINST HOSPITALS: A DIFFERENCE OF LAW

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

Three recent actions against hospitals illustrate the difference between the Scots and the English law in regard to the liability of a hospital. In the first of these[1] a girl of 5 was having her tonsils removed at the Glasgow Victoria Infirmary, and by some mishap sustained a burn of the cheek which left a disfiguring scar. The cause alleged by the father[1] was a hot gag. The board of management pleaded that they had provided a proper, sufficient, and adequately trained staff, and that under the Public Health (Scotland) Act, 1897, they were not liable for any irregularity committed by their officers in the execution of that Act. Lord Strachan, dismissing the action as irrelevant, held that the board was not liable for the actions of a nurse in her professional capacity, and that the National Health Service (Scotland) Act had made no difference in the common law.

In the second case,[2] also in Scotland, a father claimed damages for injuries to a newborn infant whose feet and legs, it was alleged, had been badly burnt in front of an open fire by the negligence of a nurse at the Henderson Memorial Nursing Home, Wick. The board maintained that the nurse had performed her duties competently, and also that it had acted in the bona-fide execution of its duties under the National Health Service (Scotland) Act. Lord Strachan held on the facts of this case also that the board was exempt from liability for any negligence of its own.

In the third case,[3] an English one heard at Leeds Assizes, a girl of 12, a promising pianist, was treated by radium for a birthmark on her right arm and developed a contracture during the after-treatment, so that her forearm was grossly and permanently disfigured. Mr. Justice Croom-Johnson dismissed the action against the radiologist, Dr. Frank Ellis, but was satisfied that the house-surgeon had been negligent, and held that the Ministry of Health was liable as that officer's principal. He awarded £5,000 damages to the girl and £51 4s. special damages to her father.

The reason for the divergence between Scots and English law is that the liability of hospital authorities is based on the common law and not on statute. Both the Scottish and the English National Health Service Acts provide that the regional boards shall be liable in cases in which hospital governors would have been liable before, and that liability has been transferred to the Minister in England and the Secretary of State for Scotland by the Crown Proceedings Act, 1947. But neither Act has altered the common law as to the liability of the responsible authority. The divergence dates from certain *obiter dicta* in Hillyer's case[4] in England in 1904 to the effect that hospital governors were not liable for the negligence of their staff in matters of professional skill. These *dicta* were in England taken to state the law correctly until the decision of the Court of Appeal in the Essex radiographer case.[5] In that case it was held that hospital governors were liable for the negligence of medical auxiliaries and probably for that of medically qualified employees also. This has been confirmed by later English decisions. However, as Scottish judges have been at pains to emphasize, the development of the English common law does not bind the Scottish courts, which have continued to follow Hillyer's case ever since.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

Horace Basil Barlow, M.B., B.Chir., has been elected to a Research Fellowship at Trinity College for research in physiology.

UNIVERSITY OF DURHAM

At a Congregation held on September 30 the Diploma in Public Health was granted to W. B. A. Smyth.

UNIVERSITY OF LIVERPOOL

The following candidates have been approved at the examination indicated:

FINAL M.B., CH.B.—*Part I*: E. D. Falla, M. N. Harrison, F. B. Hartley, H. Holden, J. Hosker, G. Ingram, E. M. Jackson-Moore, D. E. Phillips, W. A. Weston.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

At a meeting of the Royal Faculty of Physicians and Surgeons of Glasgow held on October 2, with the President, Dr. W. R. Snodgrass, in the chair, the following were admitted Fellows of Faculty *qua* Physician: J. D. H. Bankier, A. Meiklejohn, M. Mousiquddin.

A new 16-mm. sound film entitled "Oxygen Therapy" has been produced for medical, nursing, and other professional audiences by Kinocrat Films Ltd. for Oxygenaire Ltd. The film runs for 35 minutes and is in two parts. Part I covers the history of the clinical use of oxygen, depicts the physiological aspects of oxygen in the lungs, blood stream, and blood plasma, and explains the symptoms and classifies the main types of anoxia. Part II demonstrates the techniques of oxygen administration by face-masks, oxygen tents, etc., to infants, children, and adults, and shows in detail the construction of the latest forms of oxygen therapy equipment. Other essential factors in oxygen therapy, such as various fire precautions to take, are also included in this section. Many sequences were filmed at the Westminster and Queen Charlotte's Hospitals and the Hospital for Sick Children, Great Ormond Street, with the assistance of the medical staff. Arrangements for borrowing the film can be made by communicating with Oxygenaire (London), Ltd., 8, Duke Street, Wigmore Street, London, W.1.

No. '39

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended September 30.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.
Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.
A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1950 (a)	(b)	(c)	(d)	(e)	1949 (Corresponding Week) (a)	(b)	(c)	(d)	(e)

Rate per 1,000 total births (including stillborn)			26					22		

* Measles is not notifiable in Scotland, and the returns are therefore an approximation only.
† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.
‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.
§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.
‖ Includes puerperal fever for England and Wales and Eire.
¶ Primary pneumonia no longer notifiable in Eire.

EPIDEMIOLOGICAL NOTES

Poliomyelitis

Notifications of poliomyelitis in the week ending October 7 were: paralytic, 241 (222); non-paralytic, 112 (109); total, 353 (331). The figures for the previous week are in parentheses.

Total uncorrected notifications for 1950 up to and including the week under review were 6,704. The corresponding figures for 1947, 1948, and 1949 were 7,094, 1,735, and 4,015 respectively.

The chief increases compared with the preceding week were in Devon 6, Gloucester 10, and Stafford 11. Decreases were generally distributed in small numbers. Non-paralytic cases in the week under review formed 23.5% of the total.

Compared with the week before, there was an increase in total notifications of 22—all except 3 of the paralytic type. This small rise in incidence is disappointing in view of the decreases in previous weeks, but there is reason to expect that the incidence will decline normally in the weeks to come to the lower levels of winter.

Discussion of Table

In *England and Wales* there were increases in the number of notifications of measles 290, scarlet fever 166; decreases were recorded for whooping-cough 319 and acute poliomyelitis 88.

A small rise in the incidence of scarlet fever occurred in all regions of the country. The largest rises in the number of notifications of measles were Lancashire 54 and Derbyshire 49. The notifications of diphtheria were 12 more than in the preceding week, the largest rises being Yorkshire West Riding 7, Durham 6, and Warwickshire 4. The largest falls in the incidence of whooping-cough were: Essex 74, Surrey 47, Yorkshire West Riding 39, and Gloucestershire 36.

A rise of 17 was recorded in the number of notifications of dysentery. The chief centres of infection were: Lancashire 61 (Bury C.B. 15); Leicestershire 25 (Leicester C.B. 25); Yorkshire West Riding 21; Surrey 13 (Surbiton M.B. 12).

The largest returns for acute poliomyelitis were: Lancashire 30 (Liverpool C.B. 10, Manchester C.B. 9); Yorkshire West Riding 29 (Leeds C.B. 6, Sheffield C.B. 6); Gloucestershire 21 (Bristol C.B. 18); Kent 17; London 16; Lincolnshire 16; Warwickshire 15 (Birmingham C.B. 13); Devonshire 13; Durham 12; Staffordshire 11 (Wolverhampton C.B. 5); Middlesex 10.

In *Scotland* the chief variations in the trends of infectious diseases were increases of scarlet fever 75 and measles 49. The rise in the incidence of scarlet fever occurred mainly in the western area, where the notifications were 60 more than in the preceding week, and an increase of 27 was reported from Glasgow. The largest number of notifications of dysentery were those from the cities of Glasgow 61, Dumfries 22, Edinburgh 11, and from Stirling county 11. The largest returns of acute poliomyelitis were: Glasgow 10, Dundee 6, Fife county 5, and Ayr county 4.

In *Eire* there was a decrease of 13 in the number of notifications of scarlet fever. A decrease of 14 occurred in the number of notifications of whooping-cough in Dublin C.B., but a slight rise occurred in the remainder of the country.

In *Northern Ireland* the chief feature of the returns was a rise of 12 in the notifications of whooping-cough. The largest returns of acute poliomyelitis were Armagh county 3, Antrim county 2, and Down county 2.

Quarterly Returns for England and Wales

The birth rate for the second quarter of this year was 16.7 per 1,000 total population; this was 2.1 below the average rate for the five preceding second quarters. The infant mortality rate, 28 per 1,000 live births, and the stillbirth rate, 22.5 per 1,000 total live and stillbirths, were the lowest rates ever recorded for a June quarter. The general death rate was 11.1 per 1,000, being 0.1 above the rate for the corresponding quarter of last year and 0.5 above the average for the second quarters of 1944–8. There were 71 deaths attributed to acute poliomyelitis. People married numbered 161,082. This number was 38,084 below the average of the second quarters of the five preceding years.

Week Ending October 7

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,064, whooping-cough 2,445, diphtheria 40, measles 3,914, acute pneumonia 351, acute poliomyelitis 353, dysentery 187, paratyphoid fever 11, and typhoid fever 10.

Medical News

Visitor to Copenhagen

Dr. W. W. Mushin, of the Department of Anaesthetics, Welsh National School of Medicine, is soon to visit Copenhagen for three weeks to take charge of the anaesthesiology centre there. The invitation comes from the World Health Organization. There are about 20 W.H.O. Fellows from various European countries attending the centre. Until now the centre has been in the charge of anaesthetists from the U.S.A.

Honorary Medal

At a meeting of the council of the Royal College of Surgeons on October 12, with Sir Cecil Wakeley, president, in the chair, the Honorary Medal of the College was presented to Lord Webb-Johnson "in recognition of his many generous acts and continued labours in the interest of the College during his eight years of presidency."

Chelsea Clinical Society

The first ordinary meeting of the fifty-fourth session was held on October 10 at the South Kensington Hotel, with the new president, Mr. Geoffrey Parker, in the chair. There was a discussion on "Plastic Surgery and the Arts," which was opened by Mr. Henry Blake, F.R.C.S., followed by Mr. Adrian Hill, R.O.I.

Register of Speech Therapists

The names, addresses, and qualifications of speech therapists are listed in the *National Register of Medical Auxiliary Services (Speech Therapists)*, the eighth edition of which has recently been published. Medical practitioners may obtain a copy free on application to the Registrar, Board of Registration of Medical Auxiliaries, B.M.A. House, Tavistock Square, London, W.C.1.

Mountain Air for Asthma

Twelve London school-children suffering from asthma left on October 10 to spend six months in Switzerland as the guests of the Swiss Economic Council. The whole cost is borne by the council, which hopes later to send children from other parts of Britain.

32nd British General Hospital

A successful reunion dinner of the 32nd British General Hospital was held at Birmingham on September 30. Dr. J. F. Wilde presiding. Next year this reunion dinner will be held at the same time and place on the last Saturday in September. Inquiries should be addressed to Mr. W. C. Marsh, 126, Cob Lane, Bournville, Birmingham, 30.

Death Certificates

Under regulations that come into operation on November 1 certain notices of death have been altered to bring them into conformity with the death certificate in general use. The notices are those given under the Mental Deficiency Regulations, 1948, the National Health Service (Emergency Treatment) Regulations, 1948, and the Mental Treatment Rules, 1948.

International Course in Audiology

A course of instruction in audiology was held in Stockholm under the chairmanship of Professor Gunnar Holmgren on September 11–20. The first of its kind ever to be held, this "International Course in Audiology" was opened by H.R.H. Princess Sibylla of Sweden in the presence of 258 participants, of whom 34 came from Great Britain. On the opening morning there were introductory lectures by Professor Holmgren, Dr. Julius Lempert, and Mr. Terence Cawthorne. In all, 24 countries were represented, and the 258 doctors attending included 41 teachers from 13 countries. The course of instruction was divided into lectures in four parallel series, there being some 80 lectures in all, and five practical courses or seminars. These were on audiometry and hearing-aids, hard-of-hearing children, basic audiology, and temporal bone surgery, with special reference to the fenestration operation. They were so arranged that each participant could attend two practical courses each day in addition to three lectures. Films, demonstrations at the Royal Institute of Technology, and demonstrations of operations by Professor Torsten Skoog and Dr. Paul Frenckner at the Karolinska and the Southern Hospitals were also arranged. There was also a visit to the new ear, nose, and throat clinic at Uppsala, which is under the direction of Professor C. O. Nylen. Both teachers and pupils gained much from the course, which proved to be very popular, and plans for another are already being considered.

Royal Academy of Medicine in Ireland

The following officers of the Royal Academy of Medicine in Ireland were elected at the annual general meeting of the Academy: president, Dr. E. T. Freeman; general secretary and treasurer, Professor T. Percy C. Kirkpatrick; secretary for foreign correspondence, Mr. William Doolin.

Chartered Society of Physiotherapy

Professor J. Whillis has been elected to the chairmanship of the council of the Chartered Society of Physiotherapy, in succession to Dr. W. S. C. Copeman, who, owing to pressure of work, has retired from the office after serving for five years.

Dr. Philip Hench's Visit to Britain

Dr. Philip Hench and Mrs. Hench have been visiting Britain at the invitation of the Royal Society of Medicine, the Nuffield Foundation, and the Ciba Foundation. The purpose of the visit is to enable Dr. Hench to discuss the development of cortisone and A.C.T.H. therapy with doctors in this country. On October 10, when Dr. Hench addressed a crowded meeting of the Royal Society of Medicine (see p. 942), the president of the Society, Lord Webb-Johnson, and Lady Webb-Johnson entertained Dr. and Mrs. Hench and other distinguished guests to dinner in the council room. The dinner was informal, but a speech of welcome was given by the president. Sir Henry Dale proposed the health of Dr. Hench, who replied.

Wills

Dr. Ronald Grey Gordon, physician to the Royal United Hospital, Bath, and formerly chairman of the Journal Committee of the B.M.A., left £13,587. Professor Harold John Hutchens, formerly Heath professor of comparative pathology and bacteriology, University of Durham, left £18,621. Dr. Sydney Henning Belfrage, formerly medical inspector of the Divorce Registry, left £11,911. Dr. John Lindsay, of Hebburn, Co. Durham, left £25,612.

COMING EVENTS

West Midlands Physicians' Association

A meeting will be held on Saturday, October 21, to inaugurate the West Midlands Physicians' Association. The Clinical Section will be held at Selly Oak Hospital, Birmingham, at 11 a.m., and the afternoon session will be devoted to general and scientific business and will be held in the medical school of the University of Birmingham at 2.15 p.m.

Professional Nurses and Midwives Conference

The 35th Annual Professional Nurses and Midwives Conference will be held at the Seymour Hall, London, W.1, from October 23 to 27 under the presidency of the Viscount Addison, with, as his vice-presidents, the President of the Royal College of Surgeons, Surgeon Rear-Admiral Sir Cecil Wakeley, and the Right Hon. Walter Elliot, M.P. On the first day Professor Hilda Lloyd, President of the Royal College of Obstetricians and Gynaecologists, will deliver the principal lecture, and on the succeeding days other well-known authorities will be speaking.

Renal Association

The third general meeting of the Renal Association will be held at the Ciba Foundation, 41, Portland Place, London, W.1, on Thursday, October 26, at 4.30 p.m. The subject will be "Renal Innervation"; the speakers will be Dr. de Muylder and Dr. El Asfoury. The opening papers will be followed by a discussion. The meeting will be preceded by a demonstration of slides starting at 3 p.m.

British Orthopaedic Association

The annual meeting of the British Orthopaedic Association will be held on October 26–28 under the presidency of Mr. S. L. Higgs at Friends House, Euston Road, London, N.W.1.

Edinburgh Lectures

In connexion with the postgraduate courses in internal medicine and surgery the Edinburgh Postgraduate Board for Medicine has arranged a series of open lectures starting on Friday, October 27, in the Anatomy Lecture Theatre, Edinburgh University, New Buildings. All students and graduates are invited to attend. Details will be published under "Societies and Lectures" in the *Journal*.

Pneumoconiosis Research Unit

The Lord President of the Council, the Rt. Hon. Herbert Morrison, M.P., will open the new laboratories of the Pneumoconiosis Research Unit of the Medical Research Council at Llandough Hospital, near Cardiff, on Saturday, October 28, at 2.45 p.m.

Royal College of Obstetricians and Gynaecologists

A postgraduate course of advanced lectures for those studying the special practice of obstetrics and gynaecology will be held at the Royal College of Obstetricians and Gynaecologists, 58, Queen Anne Street, London, W., the first session on November 3 and 4, and the second session on November 17 and 18. The fees are £3 3s. for the two sessions; £2 2s. for one session; and 10s. 6d. for single lectures. Admission is by ticket only, obtainable from the secretary of the college. Details of the lectures will be published in the "Societies and Lectures" column of the *Journal*.

Westminster Hospital Students' Union

The annual ball of the Westminster Hospital Students' Union will be held at Dorchester Hotel, Park Lane, London, W., on Friday, November 3, with dancing from 9 p.m. until 2 a.m.

Manchester Ball

The Manchester Medical Students' Representative Council is organizing a Winter Medical Ball to be held in the Whitworth Hall of the University of Manchester on Friday, November 10. This function has the support of the Manchester Medical Society and the Medical Board of the Manchester Royal Infirmary. It is hoped that this social occasion will become again an annual feature in the medical life of Manchester. Dancing: 8.30 p.m. to 2 a.m. Buffet: 10 p.m. to 12.30 a.m. Double ticket: one guinea. Further information and tickets may be obtained from the Dance Secretary, the Medical School, Manchester, 13.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday

●HUNTERIAN SOCIETY.—At Talbot Restaurant, 64, London Wall, London, E.C., October 23, 7 for 7.30 p.m., dinner meeting. "*A Gastric Gossip*," presidential address by Sir Arthur Porritt.

●INSTITUTE OF NEUROLOGY, National Hospital, Queen Square, London, W.C.—October 23, 5 p.m., "*Poliomyelitis*," by Dr. F. M. R. Walshe.

INSTITUTE OF PSYCHIATRY, Maudsley Hospital, Denmark Hill, London, S.E.—October 23, 4.30 p.m., lecture-demonstration for postgraduates by Dr. E. Stengel.

MEDICAL SOCIETY OF LONDON, 11, Chandos Street, Cavendish Square, W.—October 23, 8.30 p.m., "*Pancreatitis*," discussion to be introduced by Professor Ian Aird and Dr. H. T. Howat.

●ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.—October 23, 3.45 p.m., "*General Pathology of the Central Nervous System*," by Professor T. Crawford; 5 p.m., "*Surgical Treatment of Some Types of Urinary Incontinence*," by Dr. Terence Millin.

Tuesday

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C., October 24, 5.30 p.m., "*Renal Function in Early Life*," by Professor R. A. McCance, F.R.S.

CHADWICK TRUST.—At Westminster Medical School (Sir Edward Meyerstein Lecture Theatre), 17, Horseferry Road, Westminster, London, S.W., October 24, 4.30 p.m., "*Public Health Administration in Western Union Countries: A Comparative Synthesis*," by Dr. Neville M. Goodman (Ministry of Health).

●INSTITUTE OF DERMATOLOGY, Lisle Street, Leicester Square, London, W.C.—October 24, 5 p.m., "*Newer Antibiotics in Dermatology*," by Dr. F. R. Bettley.

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—October 24, 5 p.m., "*Genetics in Ophthalmology*," by Professor Arnold Sorsby.

UNIVERSITY COLLEGE, Gower Street, London, W.C.—October 24, 5.15 p.m., "*Some Recent Advances in the Physiology of Vision*," by Professor Hamilton Hartridge, F.R.S.

Wednesday

GLASGOW UNIVERSITY.—In Department of Ophthalmology, October 25, 8 p.m., "*Biological Action of Radiation*," by Dr. J. M. A. Lenihan.

●INSTITUTE OF DERMATOLOGY, Lisle Street, Leicester Square, London, W.C.—October 25, 5 p.m., "*Medical Mycology*," lecture-demonstration by Dr. R. W. Riddell.

●INSTITUTE OF PHYSICS: EDUCATION GROUP.—At Fyvie Hall, The Polytechnic, Regent Street, London, W., October 25, 3 p.m., "*Technical Universities*," by Lord Eustace Percy.

●ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.—October 25, 3.45 p.m., "*Anatomy of the Mouth and Pharynx*," by Professor J. Whillis.

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—October 25, 5.30 p.m., "*Ophthalmic Neurology*," by Mr. L. H. Savin.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE, 28, Portland Place, London, W.—October 25, 3.30 p.m., "*Modern Methods of Refuse Disposal*" (illustrated), by Mr. H. Ardern, A.M.I.Mech.E., F.Inst.P.C.

SOCIETY OF CHEMICAL INDUSTRY: FOOD GROUP: NUTRITION PANEL.—At Chemical Society's rooms, Burlington House, Piccadilly, London, W., October 25, 6.15 p.m., "*Factors in Distribution Affecting the Quality and Nutritional Value of Foodstuffs: Fish and Meat*." Speakers, Drs. G. A. Reay, E. H. Callow, and M. A. Pyke.

Thursday

ALFRED ADLER MEDICAL SOCIETY.—At 11, Chandos Street, Cavendish Square, London, W., October 26, 8 p.m., "*The Influence of Adlerian Principles on Modern Psychiatry*," by Professor R. Dreikurs (Chicago Medical School). Discussion to be opened by Drs. E. B. Strauss and E. Weissmann.

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C., October 26, 5.30 p.m., "*Experimental Research in Chemotherapy*," by Sir Charles Harington, Ph.D., F.R.S.

HONYMAN GILLESPIE LECTURE.—At University New Buildings (Anatomy Theatre), Teviot Place, Edinburgh, October 26, 5 p.m., "*Filariasis*," by Dr. John M. Bowie.

MEDICO-LEGAL SOCIETY.—At 26, Portland Place, London, W., October 26, 8.15 p.m., "*Doctors and the Law*," by Rt. Hon. Sir Travers Humphreys.

ROYAL ARMY MEDICAL COLLEGE.—At Lecture Theatre, John Islip Street, London, S.W., October 26, 5 p.m., "*The Maintenance of Fluid Balance*," by Dr. H. L. Marriott.

●ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.—October 26, 3.45 p.m., "*Arteries and Veins*," by Professor H. A. Harris.

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—October 26, 5.30 p.m., "*Visual Fields: Normal and Pathological*," by Mr. C. Taylor.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, Hyde Park Corner, London, S.W.—October 26, 4.30 p.m., lecture-demonstration on psychiatry by Dr. M. A. Partridge.

TORQUAY AND DISTRICT MEDICAL SOCIETY.—October 26 (1) at Torbay Hospital, 4.30 p.m., "*Tuberculous Lymphadenitis*," by Sir James Paterson Ross; (2) at Palace Hotel, Torquay, 7.30 for 8 p.m., dinner and dance.

WINGFIELD-MORRIS ORTHOPAEDIC HOSPITAL; NUFFIELD ORTHOPAEDIC CENTRE, Oxford.—October 26, 8.30 p.m., "*Personal Experience of Tuberculosis of Hip*," by Mr. J. Agerholm.

Friday

EDINBURGH POSTGRADUATE BOARD FOR MEDICINE.—At University New Buildings (Anatomy Lecture Theatre), Edinburgh, October 27, 5 p.m., "*Some Aspects of Heart Surgery*," by Mr. R. C. Brock.

INSTITUTE OF LARYNGOLOGY AND OTOLOGY, 330, Gray's Inn Road, London, W.C.—October 27, 4.30 p.m., "*Otitic Baratrauma*," by Air Commodore E. D. D. Dickson.

KENT AND CANTERBURY HOSPITAL, Canterbury.—October 27, 5 p.m., clinical meeting.

MAIDA VALE HOSPITAL MEDICAL SCHOOL, London, W.—October 27, 5 p.m., clinical neurological demonstration by Dr. W. Russell Brain, F.R.C.P.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES, 11, Chandos Street, London, W.—October 27, 8 p.m., "*A Survey of Radiological Changes Encountered in Venereal Disease*," by Dr. K. H. Gaskell. A discussion will follow.

●ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.—October 27, 5 p.m., "*Surgical Aspects of Tabes Dorsalis*," by Dr. R. Lees.

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, London, S.E.—October 27, 4.30 p.m., "*Medical Ophthalmology*," by Mr. A. J. Cameron.

ROYAL MEDICAL SOCIETY, 7, Melbourne Place, Edinburgh.—October 27, 8 p.m., "*The Surgery of the Heart*," address by Mr. R. C. Brock.

APPOINTMENTS

CROYDON GROUP HOSPITAL MANAGEMENT COMMITTEE.—*General Hospital:* J. C. Tainsh, M.B., Ch.B., D.R., Full-time Radiologist, and to carry out part-time duties at Purley and District War Memorial Hospital: L. R. Spencer, M.B., B.Chir., Casualty Officer. *Mayday Hospital:* S. Oram, M.D., F.R.C.P., Cardiologist, with sessions at Mayday and General Hospitals.

HOSPITAL FOR SICK CHILDREN, Great Ormond Street, London, W.C.—*Senior Casualty Physician* (*Senior Registrar Grade*), D. J. Conway, M.D., D.C.H., D.T.M.&H. *Assistant Radiologist* (*Senior Hospital Medical Officer*), John Sutcliffe, M.B., B.Ch., M.R.C.P., D.M.R.D. *House-physicians* (*Junior Registrar Grade*), L. C. Harris, M.D., M.R.C.P., S. N. Nabarro, M.B., Ch.B., M.R.C.P., R. G. Welch, M.B., B.S., M.R.C.P. *House-surgeon to the Orthopaedic and Plastic Departments* (*Junior Registrar Grade*), D. Duncan, M.B., Ch.B. *Assistant Resident Medical Officer, Tadworth Court* (*Junior Registrar Grade*), M. G. Martin, M.B., Ch.B.

MAW, T. STAFFORD, M.B., Ch.B., D.O.M.S., Senior Registrar, Ophthalmic Department, Royal Victoria Infirmary, Newcastle-upon-Tyne.

RATNER, EDWIN, M.D., D.P.H., Consultant Chest Physician, Oldham and Ashton Area, Manchester Regional Hospital Board.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Cooper.—On October 2, 1950, at Queen Charlotte's Hospital, Hammersmith, to Frieda (formerly Bell), wife of Dr. J. R. Cooper, a daughter—Monica Frieda.

Fallon.—On October 7, 1950, at Royal Infirmary, Edinburgh, to Hazel (formerly Spink), wife of Martin Fallon, O.B.E., M.Ch., F.R.C.S.I., a son.

Gwynne Williams.—On October 5, 1950, at The Infirmary, Denbigh, to Peg, the wife of Dr. T. Gwynne Williams, a brother for Ann.

May.—On September 13, 1950, at Newbury House Nursing Home, to Sylvia, wife of Surgeon Lieutenant C. R. May, R.N., a son—Nigel.

Morrison.—On October 8, 1950, at Bankhall Hospital, Burnley, to Dr. Agnes, wife of Dr. A. B. Morrison, a son.

MARRIAGES

Mathers—Mould.—On September 16, 1950, at Stroud, George Crosthwaite Mathers, M.B., D.R.C.O.G., of Lezayre, Whitehaven Road, Workington, Cumberland, to Diana Mary Mould, S.R.N., of Rowcroft House, Stroud, Gloucestershire.

DEATHS

Binns.—On October 12, 1950, at Little Holland, Ludham, Norfolk, John Braybrooke Binns, M.R.C.S., L.R.C.P.

McIntyre.—On October 7, 1950, at the Kent and Sussex Hospital, Tunbridge Wells, Sir John McIntyre, K.B.E., C.B., M.C., M.B., B.Ch., Air Vice-Marshal, R.A.F., retired.

Rowling.—On October 12, 1950, at 15, Blenheim Terrace, Leeds, Samuel Thompson Rowling, M.D., D.A.

Scoresby-Jackson.—On October 3, 1950, at East Hill Lodge, Dunsford, Exeter, Thomas Scoresby-Jackson, M.B., Ch.B., D.P.H.

Simmons.—On October 8, 1950, at Monxton, Andover, Hants, Stewart Septimus Simmons, M.R.C.S., L.R.C.P., late of South Norwood, London, S.E., aged 80.

Tait.—On October 9, 1950, at the Royal Infirmary, Edinburgh, Robert Horsburgh Tait, M.D., D.P.H., of 55, Argyle Crescent, Portobello, Midlothian.

Thomson.—On October 3, 1950, at 1, Newlands Road, Horsham, Sussex, William Thomson, M.B., C.M., late of Waltham Abbey, Essex.

Webber.—On October 4, 1950, at Headington Hospital, Oxford, Henry Woolmington Webber, M.D., M.S., F.R.C.S.Ed.

White.—On October 11, 1950, at the Royal Infirmary, Edinburgh, James Hunter White, M.B., C.M., aged 81.

Any Questions?

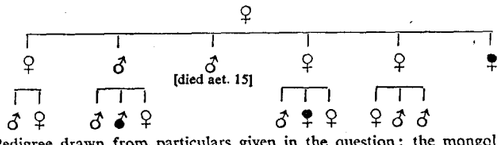
Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Familial Incidence of Mongolism

Q.—*What is known about the mechanism of the inheritance of mongolism? The history of the family with whom I am concerned is as follows:*

Grandmother.—Normal, but with a bad family history of mental and nervous troubles.

First generation.—Two sons and four daughters, the youngest a mongol, the other five normal.



Second generation.—Eldest son: three children, one a mongol. Eldest daughter: two normal children. Second daughter: three children, two normal, one a mongol. Third daughter: three normal children.

The diagnosis in all three cases has been confirmed by experts.

The mothers of the mongol children were respectively aged 44, 40, and 39 when their mongol children were born. The maternal ages at which the unaffected children of the second generation were born were, in order, 35, 37; 38, 43; 34, 42; 31, 33, 38.

What are the probabilities of the normal children of the second generation, when they marry, producing a mongol child? Two mental specialists whom the parents of these children consulted before their marriage told them that mongolism was not inherited—an opinion which does not seem to be borne out by the above facts.

A.—The role of heredity in the production of mongolism is still obscure. A few writers deny that hereditary constitution is involved at all, but this seems too extreme a view. Large collections of data show that amongst the sibs of mongols the occurrence of similar cases is slightly but definitely higher than would be expected by chance, given the incidence of the condition in the general population. Familial incidence, however, is not necessarily a proof of the existence of a genetic mechanism; it might conceivably be due to some non-genetic abnormality in the mother. Much more convincing evidence is the raised incidence amongst more distant relatives of mongols. The practical importance of genetic constitution must be relatively small compared with that of other factors. One could imagine a dominant gene whose possession is necessary before the subject suffers from mongolism, but of the possessors of the gene only a small proportion would actually be mongols.

Pedigree drawn from particulars given in the question: the mongol children are shown in black.

The only other aetiological factor identified with certainty is the age of the mother; the incidence of mongolism rather more than doubles with each advance of five years after the age of 25, and in the oldest age groups may reach quite a high figure.

The pedigree described in the question is highly unusual. The specialists who were consulted were perfectly correct in advising that the risk was negligible that the brothers and sisters of a mongol might themselves have mongol children. The experience in this family does emphasize, however, that it is wise to guard oneself by explaining that the risk, though very small indeed, is nevertheless somewhat greater than for the ordinary person with no close mongol relative. In spite of what has happened the chances for the children of the normal persons of the last generation are probably still good and the risk, though definitely increased as against the chance of 1 in 700 or so that any random pregnancy will end with a mongol child, is likely to be quite small. In all probability it is less likely that one of these persons having a child when the mother is 25 will produce a mongol than that any random woman of 40 or over will do so.

Fibrocystic Disease of the Pancreas

Q.—*The first and third children of a healthy woman have fibrocystic disease of the pancreas. What are the chances of further children being affected?*

A.—The evidence has now become very strong that fibrocystic disease of the pancreas is due to a recessive gene. At all events once the condition has appeared in a sibship the empirical chance of any subsequent child being affected is close to the theoretical figure of one-quarter. Should this mother become pregnant again, the chance is one in four that the child will suffer from the disease.

Prefrontal Leucotomy

Q.—*(a) What are the indications for prefrontal leucotomy, and what is the prognosis? (b) Has the operation been used to alleviate craving in drug addiction?*

A.—*(a)* Prefrontal leucotomy is a symptomatic treatment used in a wide variety of conditions ranging from major forms of insanity, through chronic neurotic illnesses involving tension and distress of mind, to the states of demoralization that can be induced even in normal personalities by intractable pain. It is therefore impossible to state the operative indications succinctly, but (1) the patient should be severely incapacitated before the operation is contemplated, (2) other appropriate treatments, if any, should have been tried, and (3) the best results occur in conditions specially characterized by emotional excess in the form of agitation with tension and distress. The outcome depends on the nature, severity, and duration of the underlying condition, and on the personality of the patient. The better the patient's personality the better is the outcome likely to be. At best after the operation the patient may be a normal person without appreciable handicaps. But where the pre-operative condition has become so fixedly established as to show variation neither spontaneously nor in relation to circumstances, it will persist after operation, though usually in a modified and less distressing form so that the symptoms will be more easily tolerated. It is advisable to seek a second, and preferably expert, opinion before recommending the operation, and in the present state of our knowledge the prognosis should be guarded rather than confident.

(b) Yes, with variable results. The prevailing opinion is that there is some hope of success where the addiction has been more rather than less symptomatic in the sense that it has arisen from attempts to meet undue stress (whether psychic, as in drinking to alleviate depression, or somatic for intractable pain). The less obvious the cause and the less excuse for the addiction, the less good are the operative results. Indeed, where a personality is essentially an unsatisfactory one and the patient has taken to drugs apparently for little reason, the post-operative state is, if anything, liable to be worse, since the post-operative reduction of worry and of restraint is liable to encourage the search for even more immediate gratification of the desires. On the other hand, where drug addiction has arisen more excusably from intolerable pain or even in the hope of quieting a genuine psychic turbulence, the outlook is more hopeful. Quite a number of addicts subject to intolerable pain have been enabled to dispense with drugs altogether after this operation, and so have a few who drifted into the habit through genuine psychic stress.

The Hymen

Q.—*What is the origin of the human hymen?*

A.—The hymen is functional only in female mammals possessing a urogenital sinus (such as the sow), and in these it constitutes a barrier to the flow of urine into the vagina. The human female has no urogenital sinus, but the hymen persists, just as the male nipple persists, because it is part of the hereditary make-up of the mammalian body.

Anoxia and Liver Damage

Q.—*Is it true that the anoxia accompanying severe anaemia can cause liver damage?*

A.—It is important not to confuse anoxic anoxia—i.e., anoxia associated with low oxygen tension—with that due to anaemia, in which the oxygen tension is usually normal. The former cannot be compensated by an increased blood flow, whereas in the latter increased cardiac output may largely make good the deficiency. That anoxic anoxia may lead to liver damage has been undoubtedly established both in men and animals (Buchner, H., *Klin. Wschr.*, 1942, **21**, 721), severe cases resulting in extensive centrilobular necrosis. Uncomplicated anaemia, however, does not generally lead to necrosis: the more usual finding is some degree of fatty infiltration, as, for example, in inadequately treated cases of pernicious anaemia. On the other hand, a degree of circulatory impairment which might be innocuous in a subject with a normal haemoglobin level may well lead to anoxic liver damage in a severely anaemic subject whose liver cells have been dependent for adequate oxygenation upon an increased blood flow. Any increased metabolic activity of the liver in these circumstances may also upset the balance between supply and demand. Such an increased demand may well result from the metabolic disturbance engendered by major surgery and its accompanying anaesthetizing agents.

Vitamin D and Bronchitis

Q.—*An otherwise healthy boy of 9 years living under first-class conditions suffers from recurrent attacks of bronchitis during the winter. Would vitamin D be beneficial and; if so, has an ultra-violet lamp any advantages over direct administration? What, besides burns, are the dangers of such a lamp?*

A.—Scientifically conducted experiments with groups of children in Great Britain have so far failed to show that ultra-violet light externally or vitamin administration has any beneficial effect in reducing the incidence of respiratory tract infections. This does not exclude the possibility of an individual child receiving some benefit, but it makes it unlikely. The main danger of ultra-violet light, apart from burns, is the well-recognized risk of lighting up a tuberculous infection in the lungs—an unlikely event, however, in a boy of 9. There is also the point that the warming of the skin which occurs, if followed by exposure to colder conditions, may be succeeded by the sort of "chilling" which seems to precede some of the respiratory tract infections.

It may be permitted to follow this largely negative answer with some comments on the condition described. There are three possibilities which might be usefully considered: First, where is the infection coming from? If the child is "otherwise healthy" the question of infection from some other member of the household should be investigated. A sinus infection, a throat infection in mother or father with whom the children are living so to speak in symbiosis may spread to a child. Does the term "otherwise healthy" exclude the chance that the child has infection of an antrum, of the tonsils, or even a small area of collapsed and infected lung only to be recognized on *x*-ray examination? Secondly, has the possibility of allergy been excluded? Some cases of recurrent bronchitis in the young are in effect really asthma. Thirdly, it is fair to ask what the "first-class conditions" really mean. Overheated rooms, lack of fresh air, too many clothes, lack of exercise, or absence of precautions to keep warm after exercise may all occur at the best economic levels. Over-protection may result in lack of immunity.

Bleeding Gums

Q.—*An otherwise healthy man suffers from bleeding gums. Every morning his teeth and gums are covered with a brown nasty smelling deposit. What is the best treatment?*

A.—There are numerous forms of gingivitis due to many causes, and any treatment prescribed without investigation of possible causes is bound to be empirical. In general, local scaling and cleaning are indicated to keep the teeth clean and polished, thereby preventing food sticking to them, with finger-massage to restore tone in the gums. If the pockets round the teeth are deep, gingivectomy—i.e., trimming away superfluous and swollen gums—may be undertaken. Local penicillin in the mouth is of use in acute cases, but it is not much good in long-standing cases.

Treatment of Leucopenia

Q.—*A woman aged 55 has been taking "tridione" for several months for petit mal. In four months her total leucocyte count has fallen from 5,000 per c.mm. to 3,500 per c.mm. The tridione has now been stopped. What other measures should be adopted to increase the number of leucocytes to normal?*

A.—It is questionable whether a fall of the total leucocytes from 5,000 per c.mm. to 3,500 per c.mm. is of any significance, unless repeated counts showed the second figure to be constant. The range for 95% of normal individuals is 4,000–11,000 per c.mm.; thus it is possible that the count of 3,500 is a solitary low reading. If it is established that there is persistent leucopenia, tridione should be stopped and the patient kept under observation. The count will almost certainly rise spontaneously after withdrawal of the toxic agent. Folic acid, pyridoxine, and crude liver extract have all been thought at one time or another to stimulate leucopoiesis; it is more than doubtful whether they exert any such action, but they are worth a trial. There is, in fact, no drug known which increases the formation of leucocytes. The most important part of treatment is the immediate control of any infection should evidence of such occur.

NOTES AND COMMENTS

Splenomegaly in Thrombocytopenic Purpura.—Dr. BERNARD MYERS (London) writes: In your reply ("Any Questions?" September 30, p. 793) you state that "palpable enlargement of the spleen occurs in about one-third of patients with primary or idiopathic thrombocytopenic purpura." In a series of cases which Mr. Rodney Maingot and I had together which from the tests and clinical observation were essential thrombocytopenic purpura, there was not a single case, clinically or at the operation of splenectomy, in which the spleen was in any degree enlarged. I found when I made this statement to medical societies in the United States that the same was the experience of the profession there.

"Hospital Improvements."—This booklet by Miss Olive Matthews, which was referred to in an annotation last week (p. 878), is obtainable only from the author at 22, Harrington Gardens, London, S.W.7 (1s. 6d., post free).

Correction.—Dr. BYRON E. HALL (Rochester, Minnesota, U.S.A.) writes: In the *British Medical Journal* of September 9 (p. 585) a paper bearing the title "Studies on the Nature of the Intrinsic Factor of Castle" was published with my name as sole author. When the manuscript was submitted to Professor Justin Besançon, secretary-general for the First International Congress of Internal Medicine, last July, I was not cognizant of the fact that it would be published, especially prior to the meeting of the Congress. The manuscript was incomplete to the extent that the names of associates who had worked with me on this project and acknowledgments to certain pharmaceutical firms had been omitted. Dr. E. H. Morgan, formerly a fellow in medicine, Mayo Foundation, and Dr. D. C. Campbell, consultant in medicine, Mayo Clinic, should have been co-authors. Moreover, acknowledgments to Merck and Company, Rahway, New Jersey, for supplying crystalline vitamin B_{12}; to the Abbott Laboratories, North Chicago, Illinois, for extracts of hog gastric mucosa; and to the Upjohn Company, Kalamazoo, Michigan, for vitamin B_{12} concentrate and extracts of hog duodenum should have been included.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology, Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Britmedads, Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra, Westcent, London.*

"VERITIES YET IN THEIR CHAOS"*

BY

CHARLES McNEIL, M.A., M.D., F.R.C.P., F.R.C.P.Ed.

Professor Emeritus in Child Life and Health, University of Edinburgh

Thomas Hobbes, the philosopher, was a contemporary and familiar friend of William Harvey. Hobbes has described the life of man as "nasty, brutish, and short." He knew something both of life and of medicine. He had studied anatomy and read Vesalius in Paris; and he lived to the age of 90 by a health system of his own, and by keeping clear of doctors. A strong point in his system was exercise, and a favourite exercise was singing. This is described by Aubrey (*Lives of Eminent Men*): "At night when he was abed and the doors made fast, and was sure nobody heard him, he sang aloud (not that he had a good voice) but for his health's sake: he did believe it did his lungs good, and conduced much to prolong his life." Aubrey adds: "He seldom used any physique. He was wont to say that he had rather have the advice or take physique from an experienced old woman who had been at many sick people's bedsides, than from the most learned but unexperienced physician."

This story suggests the low state and repute of medical practice in 1602, when Harvey came back to London from Padua, like Portia, "a young and learned doctor." Yet he brought back with him from Padua the best medical science of that time. It was the system of Galen brought up to date: Galen's anatomy revised and added to by Vesalius and Fabricius; his physiology, hardly modified but brilliantly expounded by Fernel in his *Physiologia*. It was the physiology that specially interested the young Harvey, and that was to be his life-long study. There were the four elements and temperaments; the four humours; the three coctions; the three spirits derived from the three great organs—liver, heart, and brain. The blood, carrying nutriment to every part, flowed out and came back by the same vessels—veins and arteries: and the blood was also charged with innate heat. But almost nothing was known of the true function of the heart, lungs, brain and nerves, muscles, and digestion.

Although the human body with its great organs had been dissected for sixty years by the accurate standards of Vesalius, there was confusion and almost complete ignorance of how these organs worked. These humours and spirits and innate heat and the rest had truth in them; but they were dim shapes, "without form and void"; they were "medical verities yet in their chaos." And so pestilence raged, disease prevailed, and humanity suffered. Medicine was a learned science, but it was impotent in practice.

Harvey's Two Masterpieces

Harvey's life-work lay before him, a stretch of more than fifty years. His professional success as hospital physician, trusted official in his college, and physician to the Royal Court was rapid and distinguished. But what was extraordinary and immortal was his work as a thinker and discoverer; and the fruits of his genius were given to us in his two books, *De Motu Cordis et Sanguinis in Animalibus* (1628), and *De Generatione Animalium* (1651), the one appearing in the middle, the other towards the end, of his working life.

In both books the subject of study was physiology, the working of the human and animal body; and Harvey's general aim was a revision of the physiology of Galen. He wished, in fact, to bring out a new edition of this part of Galen's vast encyclopaedia of medicine, and for this immense task he chose his methods carefully. His first object was to bring data to "the cognizance of the senses": and he got these *sense*-data by anatomy—human anatomy, comparative anatomy in many kinds of animals, and experimental anatomy in living animals. Then, having got and verified his *sense*-data, he reasoned from them and tried to reach a physiological conclusion.

These famous Harveian methods seem to be paraphrased by Sir Thomas Browne, physician of Norwich and contemporary of Harvey, in a passage from his *Christian Morals*, the passage ending with the title of this address. "Fly not only on the wings of Imagination: join Sense unto Reason, and Experiment unto Speculation, and so give life unto Embryon Truths and Verities yet in their Chaos." Reading Browne's lovely prose and admiring the beauty and antique charm of the words, one can miss the depth and truth of his thought. For this passage exactly describes the methods used by Harvey in his *De Motu*. There is the evidence of *sense* given by anatomy and experiment; the use of inductive reason and the element of speculation as to the missing link of the capillaries. These four mental instruments used together in *De Motu* drew out of chaos into clear form the verity of the circular motion of the blood.

De Motu is a masterpiece, announcing a great discovery, and showing a method applicable to every field of medicine

*Oration given at the 155th Festival, Harveian Society of Edinburgh, on June 2.

and science. His second book, *De Generatione*, takes a lower rank in physiology. Here Harvey was dealing with more complex problems where his instrument of anatomy was not fine enough to give him the necessary *sense*-data (he needed the microscope); he overloaded his argument with speculation, and, flying "only on the wings of Imagination," he often went astray. But it is a classic, and in some ways is a greater book; it deals with bigger problems, and shows Harvey in a wider range as biologist and metaphysician.

Harvey's Unwritten Books

In the closing chapters of *De Motu* Harvey shows that he had in mind other problems than the motion of the blood and heart; these other problems covered the whole range of Galen's physiology. Years before *De Motu* was written he was studying the function of the lungs and the whole problem of generation. He had now shown by carefully chosen methods that the motion of the blood was a circulation. This discovery opened a wide range of new problems which he could examine and might solve in the same way. Harvey, impatient and irritable in the ordinary intercourse of life, showed in the writing of *De Motu* a firm mind disciplined and calm. But in the second last chapter the thought of his discovery raises him to an unusual excitement: "Finally reflecting upon every part of medicine, physiology, pathology, semeiotics, and therapeutics, when I see how many questions can be answered, how many doubts resolved, and how much obscurity illustrated, by the truth we have declared, the light we have made to shine, I see a field of such vast extent in which I might proceed so far and expatiate so widely that this my tractate might swell out into a volume which was beyond my purpose, but my whole life would not suffice for its completion." This was only a dream, and the great enterprise does not seem to have been seriously taken up.

But in *De Motu*, in the Two Letters to Riolan, and in *De Generatione*, he gives a list and names the titles of seven treatises which he proposes to write and for which he has already made experiments and collected observations. The list is: (1) On the Causes, Uses and Organs of Respiration; (2) On the Formation of the Foetus; (3) The Organs of Motion (Heart and other Muscles); (4) Medical Observations and Pathology; (5) The Loves, Lusts, and Sexual Acts of Animals; (6) Physiology and Particular Treatise on the Blood; (7) On the Soul and its Affections. The only one of the list to be completed was "The Formation of the Foetus," published as *De Generatione*. The other six unwritten books of Harvey's may be called his hyperaemic (unprolific) eggs, conceived in his brain, undergoing some gestation there, but never brought to birth. The one most nearly completed was his "Medical Observations and Pathology," which, he says in his First Letter to Riolan (1649), "I intend putting to the press," and which in *De Generatione* (1651) he hopes to complete, "if God grants me longer life."

This grand review of medicine and physiology which Harvey planned in these unwritten books was beyond his powers, because the means of acquiring the new knowledge were not available in his time. This rewriting of Galen's system of medicine and surgery was to be done not by one but by many men, written slowly page by page not in a single generation but over three hundred years; and the great volume is not finished yet. But about Christmas, 1650, Harvey handed over, rather reluctantly, to his friend, Dr. George Ent, the manuscript of *De Generatione*, and this great and strange book was published in 1651.

Harvey's Doctrine of the Soul

De Generatione contains seventy-two exercises on conception and development; and added essays on parturition, the uterine membranes and fluids, and his final theory of conception. But, mingled throughout, there is also much general biology, and, what is strange and disappointing to modern biologists, much metaphysical argument dealing with the soul. The book contains many references to his planned but unwritten treatises, and many passages showing his fine sense of poetry. It is an extraordinary book, interesting to read but not easy to understand, and it shows the range and depth of Harvey's mind. Even its mistakes, the mistakes of a great mind, are worth consideration. It made no substantial contribution to the physiology of development. But it firmly stated the doctrine of epigenesis as opposed to metamorphosis—a doctrine which was amply confirmed much later by Wolff and von Baer; and its influence upon the improvement of midwifery practice has been made clear by Professor R. W. Johnstone in his Oration to our Society two years ago. It again shows Harvey, as in *De Motu*, a great and accurate anatomist and a tireless and ingenious experimenter.

In it he reaches his full stature as a general biologist, dealing with all living creatures, man and animals, birds, fishes, insects, and plants—as Newton said of himself, "gazing at the ocean of being that lay before him." And for Harvey, in his study of being, there was something beyond biology, although joined with it. With this mysterious *beyond* Harvey's mind wrestled, and so in *De Generatione* Harvey passes from biology into metaphysics, and states his doctrine of the soul and the blood, of the soul in man and animals, and of the Soul of the Universe.

Harvey's mind and outlook were formed at Padua. Here he was trained in anatomy by Fabricius; he may well have heard the new teaching in physics by Galileo; and he came into deep contact with the towering mind of Aristotle ("master of them that know"), and read the Aristotelian treatises on biology, generation, and metaphysics. According to Aristotle and most of the great thinkers up to Harvey, there was in the living body something more than physical structure and physical process; and so alongside physics as a subject of study there lay metaphysics. Harvey had no shadow of doubt about this; and so he shows himself in *De Generatione* both as biologist and as metaphysician, and discourses again and again of the soul, how it is joined to the body, and how together they make up the lives of man and animals.

The Soul and the Blood

Harvey's final position was that the immediate link between soul and body was the blood. Throughout his life his mind was fascinated by the blood. In *De Motu* he had taken up and solved the path of the blood and the action of the heart in maintaining its circular course: and, following Aristotle, he at first gave primacy in the whole body to the heart, saying: "It is the heart by whose virtue and pulse the blood is moved, perfected, made apt to nourish, and preserved from coagulation and corruption . . .: [it] is indeed the foundation of life, the source of all action." But in *De Generatione* he has changed the emphasis from the heart to the blood, and he now puts the blood in the first place. He did this because, in his study of the early development of the hen's egg, he was satisfied that the blood appeared before the heart and every other organ and part. This appearance was the famous punctum saliens of Aristotle. This first sign of animal life

in the 4-day-old chick as a red "leaping point" had been seen nearly two thousand years before by Aristotle, who named it punctum saliens and proclaimed it to be the heart of the embryo chick.

Harvey confirmed the observation of Aristotle, but with a significant difference. This is Harvey's vivid description, given in the first English translation of *De Generatione* (1653). "If therefore you observe on the fourth day, you will meet a great metamorphosis and wonderful alteration, which are more evident almost every hour that day long: about which time the Egg beginneth to step from the life of a Plant to the life of an Animal. For now the Limbus or hemme of the colliquamentum beginneth to blush and purple, being encompassed by a slender bloody line: and in the centre almost of it, there leapeth a capering bloody point [Aristotle's punctum saliens] which is yet so exceeding small that in its diastole or dilatation it flasheth only like the most obscure and undiscernable spark of fire, and presently upon its systole or contraction it is too subtile for the eye and quite disappeareth." After careful and repeated observation Harvey was convinced that the red line (the embryonic blood) appeared *before* the red leaping point, and he therefore now transferred to the blood the primacy in the life of the body. He puts his new view plainly: "The blood is the prime part engendered, and the heart the mere organ destined for its circulation."

Continuing his study of the blood, he next takes up the old doctrines of Galen of humours and many kinds of spirits working in the blood, and of the innate heat; and dismisses them all with scorn: "Nothing is more uncertain and questionable than the doctrine of the spirits . . . we have found none of all these spirits by dissection. . . . There is in fact no occasion for searching after spirits foreign to or distinct from the blood, to evoke heat from another source, to bring gods upon the scene, and to encumber philosophy with fanciful conceits; what we are wont to derive from the stars is in fact engendered at home; the blood is the only innate heat." With the ground cleared, he goes on to describe the powers and properties of the blood in relation to the soul and the processes of animal life. "It [the blood] is the common bond between soul and body: it is the immediate instrument and principal seat of the soul . . . it is the instrument of the Great Workman . . . it is to be regarded as the substance whose act is the soul or the life . . . it therefore comes to the same thing whether we say the soul and the blood, or the soul with the blood, or the blood with the soul, performs all the acts in the animal organism."

This is Harvey's doctrine of the soul and the blood. It replaces the many spirits and innate heat of Galen with one spirit, the soul, which performs through the blood all the acts of life. It does not tell how the acts of life are performed; elsewhere he says that these operations "are carried out with such foresight and divine intelligence which indeed surpasses our understanding, and are in no way to be penetrated by the dull edge of our apprehension." With him physiology has now ended and metaphysics has begun; unable to search out physiological *process* any further, he goes on to speak of *cause* in man and in the universe. The soul of man, interfused through his blood and body, is linked with and dependent on "the first cause of all things, by whatever name this has been designated—the Divine Mind of Aristotle, the Soul of the Universe by Plato, the Natura Naturans by others." In the same argument he turns to and quotes his beloved Virgil—"in the same way as in the greater world we are told, 'All things are full of Jove—Omnia plena Jovis,' so in the slender body of the pullet, and in every one of its actions, the finger of God or Nature obviously appears."

This last sentence and many like it have the feeling if not the form of poetry, and show Harvey as poet as well as metaphysician. He did not express his thought in verse, but when he rises to the height of his argument he shows the true sense and quality of poetry. He combined anatomy and poetry—a strange combination. Anatomy divides, dissects, and looks at parts. Poetry looks at things undivided and whole, and, however small the thing is, in its widest relations. And poetry is also and essentially metaphysical. Its language is not that of metaphysics, for it uses words that are understood by all men, even the unlettered. In poetry deep is speaking unto deep; and this deep is the soul in man. The universal range and poetical quality of Harvey's thought are shown in this passage where he is speaking of the nesting of birds: "And it is indeed a thing most worthy of admiration to see these creatures selecting and preparing their nests with so much foresight fashioning and furnishing, and concealing them with such inimitable art and ingenuity, so that it seems imperative on us to admit in them a certain spark of the divine flame (as the poet says of bees)."

Fulfilment in Physiology and the Liquidation of the Soul

Three hundred years have gone since *De Generatione* was published. Harvey brought no more unfinished books to press, and died in 1657. In this long march of time, the medical *comoedia* has moved upwards, slowly but very far, from the inferno of unknown and uncontrolled disease in which it lay in Harvey's day; and this progress has been mainly due to the building up of physiology. The effort and achievement of one man are of little account compared with this gigantic task and the many who have helped to complete it. But Harvey was a Titan among men, both in his power of mind and in what he set himself to do. He gave the new physiology a splendid start in his discovery of the circulation, but beyond that he added little. Looking back, we can see the reason for his failure. He had to hand the two instruments of anatomy and the experimental method; and his anatomy, consisting of dissection, his trained eyes, and the occasional use of the magnifying glass, was not fine enough. But the range and penetrating power of anatomy were to be prodigiously increased by the gradual perfection of physics and chemistry. Optical physics soon produced the microscope, and much later the *x* ray; electrical physics; and the fine filter: all these inventions gave really a finer and deeper anatomy, put at the disposal of physiology. So also the perfection of chemistry, essentially a sublime anatomy, revealed the intimate and ultimate structure of cells and fluids and their components.

In the closing years of Harvey's life anatomy was becoming microscopical, and three years after his death Malpighi with his microscope saw blood flowing in the capillaries, and supplied the missing link in the circular chain of the blood. A few years later the microscope showed red corpuscles in the blood and spermatozoa in the seminal fluid. These were only the first fruits of a rich harvest to be reaped by the microscope: but these three discoveries all touched on, adding to or correcting, Harvey's work on the blood and generation.

About the same time, and in London, the new physics attacked the baffling problem of respiration. Boyle, Hooke, Lower, and Mayow demonstrated a new kind of "spirit" in the blood derived from the in-breathed air. This was called "igneo-aerial spirit," and after two hundred years

of further search it was isolated and named oxygen by *Lavoisier*. Innate heat and igneo-aerial spirit are akin in name and in nature: the one is the "embryon truth" of Galen; the other its further development, coming to maturity in the modern doctrine of oxidation and combustion. As for Galen's humours and spirits, the new chemistry has found the blood and body fluids to be teeming with humours, ferments, hormones, and spirits in greater numbers and complexity than Galen and Fernel imagined.

Harvey, you will remember, dismissed the doctrines of the spirits and innate heat, saying that *his* "dissection could show nothing of the sort." He emptied the old chaos of shadowy spirits, and into the void that was left he introduced the metaphysics of the soul, carrying out, through the blood, all the processes of life. The more perfect *dissection* of the microscope and of physics and chemistry has shown Harvey to have been wrong, and that Hippocrates and Galen have been justified by their modern children in physiology. The old Greeks were men of genius, and their guesses, vague and without form, were a dim foreshadowing of truth. Their doctrines, rejected by Harvey, were "verities yet in their chaos"; they have now come out of their chaos and stand in clear and delicate outline as chemical and physical processes. It is not beyond the mark to say that modern physiology is a new edition of the old Galen, revised, rewritten, and greatly enlarged.

Biology and Metaphysics

And how has it fared with Harvey's doctrine of the soul and the blood, and of the soul generally? We can see what happened to Harvey in his study of the blood. He was a profound student both of biology and of metaphysics. His instruments for the study of the blood and of biology in general were anatomy and experiment. But his instrument of anatomy was not fine enough; and, having got from it all that it could do, he took up metaphysics. This combination of biologist and metaphysician was now becoming dangerous.

Descartes, philosopher, brilliant amateur of physiology, and contemporary of Harvey, gave in his writings a firm warning that, in the study of man, the soul and the body, metaphysics and biology, should be kept apart. Since this warning was given most biologists have taken the lesson to heart and have fought shy of metaphysics. In their study of living bodies they have done what Descartes advised, and have used only physical methods, and have stated their results in strictly physical terms. In this concentration on physics and exclusion of metaphysics they have in three hundred years filled the void of Galen's physiology with a labyrinth of living processes, working under physical and chemical laws, and in so doing they have made the practice of medicine powerful and beneficent.

Indeed, biologists have gone beyond the lesson of the master. Finding the most intimate processes of life to be explained by chemistry and physics, and finding nothing else in life but chemical operations, they see no place in the living body for metaphysical spirit. They might well use Harvey's own words: "There is no occasion for searching after spirits . . . to bring gods upon the scene . . . to derive from the stars what is in truth engendered at home." Life, we are told, is a form of matter; and living matter is chemistry in action. The biologists have gained the whole world in physiology, and have lost the soul. Sir Charles Sherrington, in his deep, scholarly, and humane study, *The Endeavour of Jean Fernel* (1946), has concluded a fine commentary on the old physiology thus: "To-day physiology *is* chemistry and physics," and he calls for "the liquidation" of the life-soul and the other forms of spirit on Fernel's list.

It seems a hard and severe sentence; but the biologists have an old-standing grievance against the metaphysicians, and are not prepared to show mercy on their doctrines. They say that the metaphysicians, meddling with biology, have retarded its progress. Harvey's activities as a metaphysician they pass over in silence, or with an expression of mild regret, because in his case there are extenuating circumstances in his great physiological discovery of the circulation. And it must be granted that Harvey in his studies of the blood and male seminal fluid was in serious error, and allowed his doctrine of the soul to usurp the place of physiology. But he made fundamental statements about the rational soul in man and the Soul of the Universe—statements which in this general form have been held by the great majority of mankind in all recorded time and which have been the mainstay of their thought and action. Is this great doctrine of soul or spirit now to go into liquidation?

This great question cannot be dealt with now; but, with Harvey's affirmations about the soul in our mind, it can be looked at in its broad significance and implications. It is more than a question of doctrine for debate between biologists and metaphysicians; it is of deep concern for all men in their daily lives.

Life Without Soul

This new, or rather old-new, theory of life without soul promises great benefits, but it seems to carry practical losses and risks. The biologist tells the ordinary plain simple man to forget the old fairy-tales about spirit and to accept the new and true chemical story about life, and the dialogue goes on:

Biologist: "The world, yourself, even your thoughts, all are a marvellous chemistry which has been operating the whole universe of things alive and dead, and for thousands of years past until now."

The Plain Man interrupts with a question: "Must there not be a great Chemist, who has made all this chemical stuff, and who directs this tremendous chemical operation?"

The Biologist: "That question raises the old hare of the First Cause, and I am not going to chase it. Such a question is beyond chemistry. In any case, you don't *need* a First Cause; and I can give you all you do need. As yet I can't make the stuff; but my power of destroying it gets greater and greater. I have come to know most of the secrets of the chemistry. So far as you are concerned, I am the manager; and if you do what I tell you I shall give you in abundance everything necessary for your life—every chemical need. But all this nonsense about spirit, you must cut it out of your life—to use a good chemical term, you must liquidate it."

The Plain Man: "About music; must I give up the spirit in my music?"

The Biologist: "There is a good story about an old man, Thomas Hobbes, who sang himself to sleep every night, singing out of tune and without spirit. His music was mainly chemical—noise and exercise, and for a chemical end—the promotion of his health, and yet his music without spirit helped him to live till the age of 90. Isn't that good enough?"

The Plain Man: "The loss of soul in music would be a heavy one for me. Another question: What about poetry, which means a great deal to me?"

The Biologist: "Poetry is full of soul-stuff too: its essence is spirit. Poetry would keep alive the false doctrine of spirit, and would have to be repressed or severely controlled."

The Plain Man: "This would be a dreadful loss. One more question: What about religion in the new chemical world?"

The Biologist: "Religion is a fairy tale which must be told no more, not even to your children. You are a grown man now; and you can and must do without it. Religion must go: it has done you grievous harm."

At this the plain man drops his head and is silent.

The Biologist (continuing): "Only look at what I have to offer you in exchange for your soul. In the language of an old book which you seldom read and which is now obsolete, I will pull down your old barns and build you bigger and better ones; and I will fill them to the roof with 'goods' that our newest chemistry will provide—food, clothing, health, long life, ease, and pleasure. The loss of your soul is nothing to what you will gain."

The Plain Man: "What you offer tempts me. Many of us plain folk need these chemical goods badly. But the idea of life without soul frightens me; it would be so flat and cold and dreary, and it might be dangerous. We have always been told that our souls are the best part of us. And yet your best chemists have searched every corner of us, and have found no chemical trace of soul. Could it not be that soul is of different and non-chemical stuff, that if you used other long-tried non-chemical methods of search, at once and everywhere, within our bodies and without, you would find soul?"

Conclusion

To sum up: Harvey's discovery of the circulation of the blood was the beginning of a new chapter in physiology. It may be compared to the appearance of the punctum saliens in the 4-day-old chick; "like a spark darting from a cloud" (his own words), it was the first sign of new life in European physiology, and was followed in a kind of epigenesis by a succession of other discoveries. Much of what he wished to do he left undone; but his unfinished work has been brought to fulfilment by others, and the verities of physiology are now no more in their chaos.

As to his teaching on the soul, both his particular doctrine of the soul and the blood, and his general statement of the soul in man and in animals, and the Soul of the Universe—all this has been rejected by modern biology. But biology has not said its last word, and is struggling even now to find its own metaphysic on the question of cause. Meantime Harvey's general statement on the soul is worth setting alongside those of other great minds in ancient times. *The Book of Wisdom*: "The Spirit of the Lord hath filled the whole earth." Aristotle: "All things are full of Soul." Virgil: "All things are full of Jove." Last, Harvey, speaking as a biologist: "For, as the same intelligence or spirit which incessantly actuates the mighty mass of the Universe . . . so also is there a *vis enthea*, a divine principle, inherent in our common poultry."

At the third annual general meeting of the British Rheumatic Association held on September 28 it was reported that the association is now established as a national organization and a registered charity. It maintains helpful connexions with the Ministry of Health and regional hospital boards. As the result of these, spa treatment can now be authorized under the National Health Service by a consultant in rheumatism, and those who can find their own accommodation can be treated as out-patients in any hospital rheumatic unit, subject to the recommendation of their own doctor and a recognized consultant. To meet the difficulties of rheumatics in finding accommodation close to centres where they can get urgently needed treatment, the association has promoted the formation of a housing society with charitable status under the title of B.R.A. Homes Limited to provide accommodation on a voluntary basis. Another of its activities is to provide flatlets for the old and disabled rheumatics within a certain income group. This will make it possible to combine geriatric with rheumatic treatment, which recent experience shows can relieve pressure on hospital beds.

ANTICOAGULANTS IN TREATMENT OF CORONARY THROMBOSIS

BY

JOHN A. TULLOCH, M.C., M.D., M.R.C.P.Ed.*

A. RAE GILCHRIST, M.D., F.R.C.P., F.R.C.P.Ed.
Physician, Royal Infirmary, Edinburgh; Reader in Clinical Cardiology, Edinburgh University

Adequate care for the patient suffering from acute coronary occlusion is one of the most urgent problems in present-day therapeutics. A disease which statistics prove to be on the increase, which is afflicting younger lives (Ryle and Russell, 1949), and which after 25 years' study can still be shown to have a mortality rate of 40% among hospital patients within the first six weeks, is a challenge that for too long has been neglected.

Myocardial infarction, the result of coronary artery occlusion, now constitutes a large part of cardiological practice. The exact incidence of the condition throughout the general population is difficult to assess. All grades of severity are encountered, from the most severe cases dying immediately or within a few minutes or hours from the onset, to the very mild which experience little upset and have no ensuing disability. It is therefore the moderately severe or the complicated cases which provide the greater part of hospital experience. Statistics gathered from the hospitals cannot be applied to the population as a whole, but in this disease they certainly indicate the course followed by the moderately severe case treated, as we believe, under the best available conditions.

A study of the literature indicates that the immediate mortality following myocardial infarction varies widely in different centres and perhaps in different hospitals in the same city. In Table I the mortality rate ranges from the 78% of Newman (1946) to the 16% of Conner and Holt (1930). Our current Edinburgh experience has been assessed from two series of hospital patients, the first being composed of 100 consecutive cases of coronary thrombosis observed during the period 1939–46, before the introduction of anticoagulants; their mortality rate was 43%. A second series of 84 consecutive patients, forming the present control group and observed concurrently with a similar number receiving anticoagulants, had a mortality rate of 41%. Through the courtesy of physicians elsewhere in

therapeutic measures, coronary thrombosis has a mortality rate in the neighbourhood of 33% among hospital patients in this country.

Embolic and thrombotic episodes, which may handicap a convalescent patient or prove immediately fatal, are common after myocardial infarction. Such episodes comprise: (1) the sudden occlusion of a systemic artery; (2) the development of a fresh myocardial infarct or the spread of the occlusive process to adjoining branches of the affected artery, and hence an extension of the original damage; (3) peripheral phlebothrombosis, notably in the calf veins; and (4) pulmonary infarction. In recent years a much higher clinical incidence for thrombo-embolic phenomena after coronary occlusion has been recorded, suggesting that in earlier reports minor episodes had been overlooked. This is demonstrated in Table III. Mural thrombus formation

TABLE III.—*Showing that the Frequency with Which Thrombo-embolic Incidents after Coronary Thrombosis are Recognized has Apparently Increased in Recent Years*

on the endocardial surface of the infarcted area of the ventricle is present in 44% of necropsy cases, but all peripheral arterial occlusions are not necessarily embolic in origin (Hellerstein and Martin, 1947). It is during the first three weeks after the acute occlusion that thrombo-embolic incidents are most apt to occur (Nay and Barnes, 1945), and it is during this same period that an upset in the control of intravascular blood-clotting has been demonstrated (Ogura *et al.*, 1946). Using the Waugh–Ruddick (1944) heparin-retarded clotting test, Ogura and his colleagues observed the development of an enhanced clotting tendency in 75% of cases of recent myocardial infarction. An increased coagulability of the blood appeared during the first week, reached a maximum towards the end of the second week, and disappeared during the third week. Our own experience has been that there is considerable individual variation in the time of onset, duration, and degree of this change.

In the treatment of myocardial infarction the possibility of controlling this enhanced clotting tendency and preventing thrombo-embolic complications appeared attractive. The introduction of the anticoagulant dicoumarol made this supposition a practical measure. The earliest reports on anticoagulant therapy by Wright (1946) and Peters *et al* (1946) indicated that not only was the incidence of thrombo-embolic complications greatly lessened, but the immediate mortality rate was strikingly reduced. With the accumulation of further reports in the American literature, supplemented by the large-scale investigation at 16 leading hospital centres sponsored by the American Heart Association, the evidence is overwhelmingly in favour of this method of treatment. Table IV, constructed from American statistics, suggests that anticoagulants are capable of reducing the mortality rate by one-half.

* Cases dying within 48 hours of admission are not included.

Whether all cases derive equal benefit has not been adequately investigated. Wright *et al.* (1948) indicated that males aged 60 years and over showed greatest improvement, and Greisman and Marcus (1948) in a small series reported a greater improvement among males than among females. The present investigation, now to be reported, was begun in 1947 with the object of assessing the value of anticoagulant therapy in myocardial infarction and of determining, if possible, the type of case most likely to benefit from this form of treatment.

Material

During the past three years 154 cases of myocardial infarction have been observed and treated. These comprise two series of cases: one series, consisting of 84 cases, was treated by conventional conservative measures and constitutes the "control" series; the second series, consisting of 70 cases, received anticoagulant therapy during the first three weeks after admission in addition to the standard forms of treatment, and constitutes the "treated" series. All cases were unselected, their inclusion in one or other series being determined by the day of their admission to hospital. All cases admitted to one medical block were treated conservatively, whereas all cases admitted to a second block received anticoagulants—unless some contraindication to their use existed. Both series comprise, therefore, the everyday emergency admissions to a medical ward. No case was admitted specifically for anticoagulant therapy. All cases admitted and dying within six hours of admission have been excluded from both series, as insufficient time had elapsed for any benefit to result from the treatment given.

Diagnosis was based on the history and the usual signs, supported by positive electrocardiograms in 134 of 136 patients thus examined, and by the course of the illness. Cases in which a doubt existed regarding the presence of a recent myocardial infarct have been rigorously excluded from the series under review.

Treatment

The routine treatment adopted for all cases consisted in rest in bed for five to six weeks, morphine for relief of pain, sedation with phenobarbitone, low calorie intake, graduated exercises from the fourth week, and treatment of complications as and when they arose. The "treated" series received in addition heparin and dicoumarol (64 cases) or dicoumarol alone (6 cases). Heparin was given by the interrupted intravenous injection method, the interval between injections being 8 hours in 62 cases and 6 hours in two cases, the later two cases having both experienced thrombo-embolic complications before their admission to the ward. Except in the first few cases, each injection consisted of 10,000 units of heparin. Adequacy of dosage was assessed by estimation of the clotting time one hour after the injection, using the Lee–White (1913) method. A time of 20 minutes, three or four times the normal value, was regarded as satisfactory. The injections of heparin were stopped as soon as a therapeutic reduction in prothrombin content had been achieved with dicoumarol. The object in using the latter drug was to obtain a prothrombin content less than 30% of normal (Allen, 1947). This level was seldom attained before the fourth or fifth day of treatment. Dicoumarol was therefore started on the day of admission, the dose being 300 mg. on the first day, 200 mg. on the second day, and 100–200 mg. on the third day. All subsequent doses of dicoumarol were determined in relation to the daily estimation of the prothrombin time. The Fullerton (1940) modification of the Quick method, using venom as the source of thrombokinase, was the technique employed. It was appreciated that at low concentrations of prothrombin this method is less sensitive than the original Quick method in detecting minor variations in prothrombin content, but the same technique was used throughout this series.

The daily dose of dicoumarol was regulated approximately by the following guide: using a control prothrombin time of 19 seconds, 100–200 mg. of dicoumarol was given if the patient's prothrombin time was under 28 seconds, but if the prothrombin time was over 28 seconds a dose of 0–100 mg. was given. In regulating the dicoumarol dosage, Wright (1950) commends the Sterling Nichol formula whereby the ideal prothrombin therapeutic level is maintained between two and two-and-a-half times the control prothrombin-time for that day in the laboratory (Nichol and Borg, 1950). It is important to note that, unfortunately, there is no clinical guide to the regulation of dosage with this drug. Individuals vary greatly in their susceptibility to it, and the appropriate dose on any one day can be ordered only when the laboratory has reported on the prothrombin-time existing on that date. Patients given dicoumarol without laboratory control may bleed heavily. Even 150 mg. daily may lead to serious haemorrhage in a short period of time.

A minimum period of three weeks of dicoumarol therapy was decided upon for three reasons: (1) the great majority of thrombo-embolic phenomena occur during that period; (2) the clotting tendency previously mentioned tends to disappear towards the end of the third week; and (3) the effect of dicoumarol persists for several days after administration of the drug has ceased.

In this series the total dicoumarol dosage in the three weeks of treatment ranged from 1,100 mg. to 4,200 mg., the majority of cases receiving 2,000 to 3,000 mg. Haemorrhagic complications were treated by stopping the drug, and, if severe, by administration of vitamin K, 50 mg. intravenously as a single dose, with 100 to 150 mg. daily by mouth.

Comparison of Two Groups

Before drawing any conclusions regarding the efficacy of anticoagulant therapy it is necessary to compare the two series of cases in respect of similarity in important details. The immediate prognosis in myocardial infarction depends on a number of factors, which should be equally distributed between the two groups. Both series have therefore been analysed in respect of (1) age, (2) sex, (3) pre-existing hypertension, (4) pre-existing angina pectoris, (5) number of previous myocardial infarcts, (6) obesity, (7) myocardial state prior to the infarct, (8) duration from onset of symptoms to admission to hospital, (9) degree of shock at the onset, (10) incidence of heart failure, thrombo-embolic phenomena, and arrhythmias after the infarct, and (11) mortality rate within the first six weeks after the infarct.

Details of the age and sex incidence are given in Table V.

TABLE V.—*Presenting Details of the Age and Sex Incidence of the 154 Cases of Coronary Thrombosis Comprising the Present Series. The "Control" Series Consisted of 84 Patients and the "Treated" of 70 Patients Receiving Anticoagulants*

Age	Male				Female			
	Total		Died in Ward		Total		Died in Ward	
	Control	Treated	Control	Treated	Control	Treated	Control	Treated
35– ..	1	1	1	—	—	—	—	—
40– ..	—	2	—	—	—	—	—	—
45– ..	9	4	1	—	1	—	—	—
50– ..	5	11	1	1	1	2	—	—
55– ..	8	8	2	1	6	1	4	2
60– ..	15	13	4	3	8	10	5	2
65– ..	9	3	3	1	7	9	4	3
70– ..	6	4	5	1	4	2	1	—
75+ ..	1	—	1	—	3	—	2	—
Total	54	46	18	7	30	24	16	9

In the control series the males averaged 60 and the females 64 years of age, while in the treated series the males averaged 57 and the females 64 years. So far as sex and age distributions are concerned, it appears that the two samples—control and treated—are sufficiently homogeneous to warrant comparison. As shown in Table VI, the incidence of hypertension and previous angina pectoris did not differ widely in the two groups, though the incidence of obesity

TABLE VI.—*Showing that the Incidence of Hypertension and Previous Angina Pectoris did Not Differ Widely Between the Two Groups, Though the Incidence of Obesity was Almost Twice as Great in the "Treated" Series*

	Male		Female

Fourth	—	1	—	1	—	1	—	—
Fifth..	—	—	—	—	—	1	—	—

was almost twice as common in the treated series. Table VII demonstrates that multiple attacks of coronary thrombosis had been more commonly experienced in the treated series. One remarkable woman among those receiving anticoagulants had survived five myocardial infarcts.

In all cases in which a satisfactory history was obtained an attempt was made to gauge the state of the myocardium before the onset of the acute coronary occlusion. In some patients the attack was preceded for months or years by definite angina of effort; others had had no exertional pain but were restricted by dyspnoea; others again admitted to no cardiac symptoms previous to the occlusion. By applying the standards of functional capacity adopted by the New York Heart Association (1939) we placed our patients in the following broad categories:

Grade I patients are symptom-free, ordinary physical activity causing no discomfort.

Grade II A patients experience a slight-to-moderate limitation of physical activity. Walking on the flat out of doors at an average pace constantly reproduces ischaemic pain or dyspnoea after a few hundred yards.

Grade II B patients have a moderate-to-great limitation of activity. Less than ordinary activity causes discomfort. In this group we include those people who experience angina on light household activity or walking 20 to 50 yards out of doors, and those who have recurrent spontaneous attacks at rest, perhaps awakening them from sleep.

Grade III patients are those unable to carry on any physical activity without discomfort. As a rule they are confined to bed, congestive failure in some form being already present.

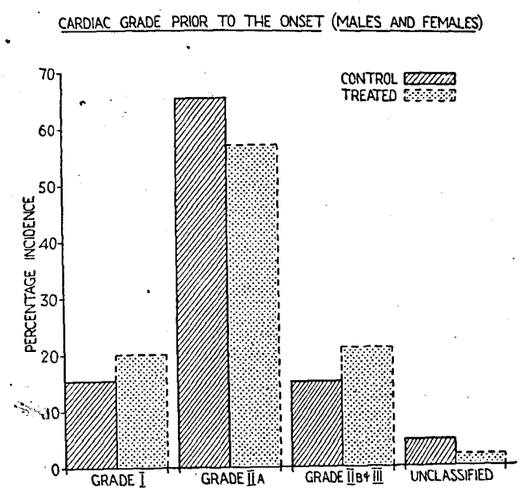

Fig. 1.—Incidence of various grades of functional capacity of the heart existing in the two series of cases of coronary thrombosis, previous to the onset of the acute occlusion. There is little difference between the "control" and the "treated" cases.

In applying this rough-and-ready measure of cardiac efficiency, we regarded symptoms developing comparatively suddenly during the two weeks immediately preceding the infarction as premonitory in nature and have not taken them into account in assessing the cardiac grade. The incidence of the various grades, which are evenly distributed between the two series, is shown in Fig. 1. Only in the treated series were there patients actually in congestive heart failure prior to the infarct.

For statistical purposes it is difficult to grade cases of myocardial infarction according to their severity. Clinically, the actual size of the infarct cannot be determined with much precision, nor does its extent determine the degree of shock. In an admittedly arbitrary fashion, the grade of shock, expressed according to clinical experience as severe, moderate, and mild or absent, may be taken as a measure of the severity of the illness. In a number of patients admitted some days after the onset the degree of shock could not be estimated, but Fig. 2 shows that the

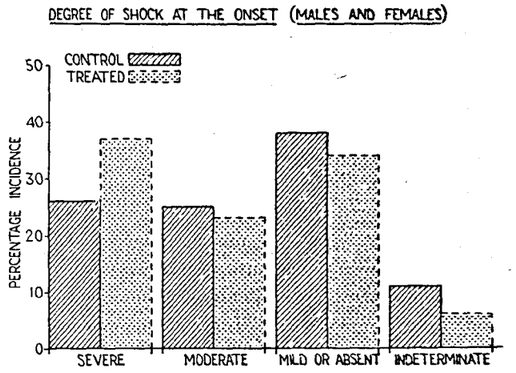

Fig. 2.—When the degree of shock is taken as a rough-and-ready measure of the severity of the attack of coronary thrombosis, the three grades—severe, moderate, and mild—were fairly evenly distributed between the two groups of patients.

three grades were fairly evenly distributed between the two series, with a preponderance of more severe cases in the treated group.

Finally, in the estimation of comparative mortality rates a further and commonly neglected factor has to be taken into consideration. A moment's reflection indicates that the mortality rate in a hospital series of cases of coronary thrombosis will be all the less the greater the delay in securing admission. It is known that the mortality rate in coronary thrombosis is highest in the first few days, and therefore the longer patients are excluded from the hospital the lower will be the death rate for the series, the more severe cases dying before admission. When the duration of illness before admission to hospital is compared, the two series—control and treated—are strikingly similar, 32% of the former and 34% of the latter arriving in hospital within 24 hours of the onset of the coronary occlusion (Fig. 3). Our two groups bear a close resemblance in this respect.

We may therefore conclude that the two samples—control and treated—in respect of sex and age distribution, pre-existing state of the heart muscle, severity of the acute attack, and duration of the illness before hospital treatment, are sufficiently homogeneous to warrant comparison.

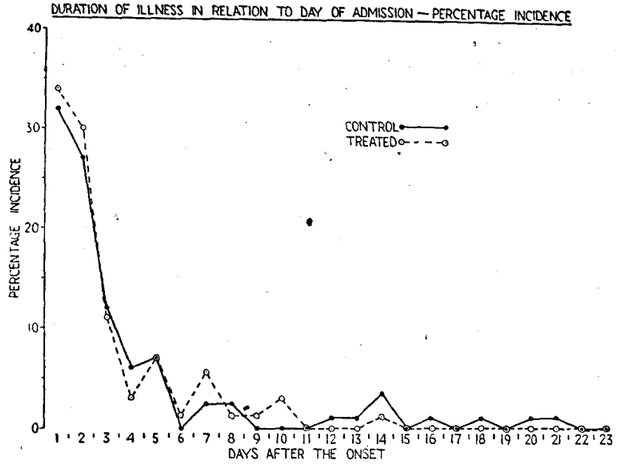

Fig. 3.—The duration of the illness as measured from the time of onset until admission to the ward is strikingly similar in the two groups, 32% of the "controls" and 34% of the "treated" arriving in hospital within the first 24 hours.

Results of Anticoagulant Therapy

In as severe an illness as coronary thrombosis it is natural to assess the results of treatment on the basis of (1) mortality rates and (2) incidence of thrombo-embolic complications.

Our experience is that 34 of the control group of 84 persons died within six weeks of the onset, giving a mortality of 40.5%. This contrasts with the 16 deaths among 70 persons in the treated series, with a mortality rate of 22.8%. It would appear that by efficient anticoagulant therapy during the first three weeks after the myocardial infarct the mortality rate in the first six weeks may be almost halved. Our experience confirms the American conclusions to which reference has already been made.

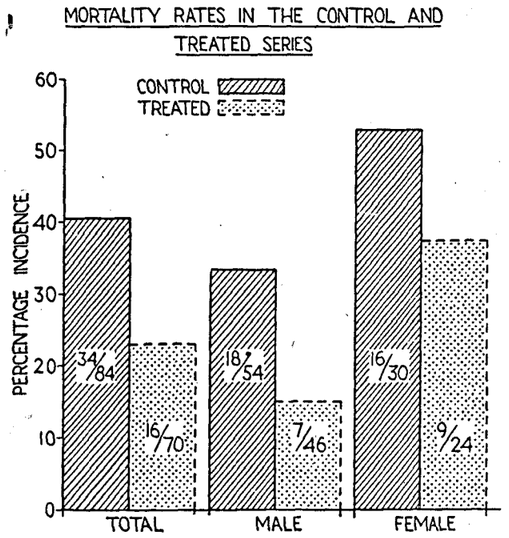

Fig. 4.—Efficient anticoagulant therapy reduces the total mortality rate by half. The difference is statistically significant among men. The smaller experience, based on 30 "control" and 24 "treated" females, does not justify similar conclusions among women.

When the sexes are considered separately it is apparent that the males show a greater improvement than do the females. The reduction in male mortality rate is of statistical significance, the degree of probability (P) being less than 0.05. In the control group of males the death rate was 33.3%—18 deaths among 54 men. In the treated group, composed of 46 males, 7 died, giving a mortality rate of 15.2% (Fig. 4). This is a striking difference, and, being of statistical significance, we conclude that in males, during the first six weeks after a myocardial infarct, the death rate can be reduced by half. Analysis of the figures for females does not allow similar deductions, largely owing to the smaller number of cases observed. In the control series 16 of the 30 females died, giving a mortality rate of 53.3%; whereas 9 deaths occurred among the 24 females in the treated series, the mortality rate being 37.5%. Such a difference is not of statistical significance.

In estimating the prognosis after myocardial infarction, one factor of great importance is the state of the heart muscle at the time when the acute coronary occlusion was sustained. By using the method of functional grading to which reference has already been made, it becomes apparent that those patients referred for treatment in the hospital who have been in Grade I immediately prior to their coronary occlusion seldom die, provided they survive the immediate effects of the occlusion long enough to be admitted to the ward. In contrast to this, patients in cardiac Grade II B when the infarct is sustained seldom recover. Grade III cases, already seriously handicapped, never recover. Fortunately, the majority of victims fall into the Grade II A capacity, and it is in this grade that every aspect of the case must be carefully considered.

Our patients classified as Grade II A prior to the infarct total 55 in the control group and 40 in the treated group, including 38 and 23 males respectively. The most striking difference is observed in the mortality of these Grade II A males. Among the control group the mortality was 31.6%, whereas among the treated males 1 of 23 died—a mortality of 4.4%. This improvement is of statistical significance, P being almost 0.01. We make no claim for any betterment in the other groups, male or female, but we suggest that when a larger series of some hundred cases is presented for statistical analysis it would be advantageous to have these patients assessed in regard to their functional capacity before the myocardial infarct was sustained. We have proof that it is possible to influence the course of events favourably in regard to males classified in Grade II A. Our figures do not suggest that one particular age group in either sex derives greater benefit than any other age group.

As a further test of the efficacy of anticoagulant therapy, the incidence of thrombo-embolic episodes in the two groups has been analysed (Fig. 5). No fewer than 24 patients (28.6%) in the control series developed thrombo-embolic complications of one kind or another while under observation, and 13 of these died. Ten deaths were the outcome of the thrombo-embolic complication, while in three cases death was unrelated to the complication. On the other hand, 9 (13%) of the 70 patients in the treated group developed thrombo-embolic complications, and of these 4 died. No death followed immediately on any such

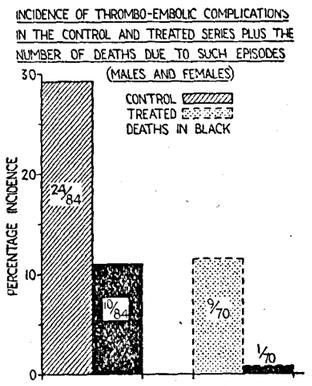

FIG. 5.—The incidence of thrombo-embolic complications was reduced from 28.6% in the "controls" to 13% in the anticoagulant "treated" group. In the "control" group 10 deaths were attributable to these complications, in contrast with one death in the "treated" series.

complication, but in one patient death was related to an embolic incident. The incidence of complications was 13% in the treated group—less than half that observed amongst the controls. Taking the incidence of complications separately between males and females, no significant reduction is observed statistically. However, as the data show no significant difference in the incidence of complications as between males and females, they may reasonably be taken together as one group, and if this is done there is then a significant difference in the incidence of complications between the treated and control groups (P being 0.01). We can therefore confirm the observation of Wright *et al.* (1948) that the incidence of thrombo-embolic complications in myocardial infarction can be reduced by half by the proper use of anticoagulants.

Marple and Wright (1948) have drawn attention to the possible relationship of a lapse in dicoumarol therapy to the occurrence of thrombo-embolic episodes. In this series seven patients sustained thrombo-embolic complications during the first four to five days of treatment, either while heparin was being given or during the 24 hours after the heparin had been stopped. The two episodes occurring at a later date developed in adequately treated males.

Other Complications

Other complications of significance occurring during the period of treatment in hospital were the development of heart failure and the occurrence of arrhythmias. Heart failure developed in 23 cases in each series—an incidence of 27% in the control series and 33% in the treated series. In the control series 17 of the 23 patients died—a death rate of 74%, but in the treated series only 13 died—a death rate of 56.5%. Arrhythmias occurred in seven cases of each series; four deaths occurred in the control group and five in the treated series.

The causes of death in the two series are listed in Table VIII. It will be seen that in the control series death resulted from a variety of causes, while in the treated series the great majority of patients died in heart failure. One patient in each series died suddenly from rupture of the infarcted area. Our necropsy experience in both series is small and unsuited for statistical analysis. In the control series 12 cases came to necropsy. Six showed mural thrombus formation; of these, four had had thrombo-embolic complications. In the treated group there were nine post-mortem examinations. Mural thrombus was found in the ventricles in two patients and thrombo-embolic phenomena were limited to one of these—the first female to be treated—in whom the anticoagulant therapy then employed would now be regarded as inadequate.

TABLE VIII.—*Causes of Death in the Two Series of Patients*

Cerebral embolus	3	1
Sudden death	10	7
Coma	1	—
Death within 24 hours of onset	6	—

General Considerations

All the reports in the literature substantiate the claim that anticoagulants are at the present day a remedy of outstanding value in the treatment of coronary thrombosis By their proper use the death rate and the incidence of thrombo-embolic complications can each be reduced by half—a very substantial contribution to the treatment of this serious disease.

Unfortunately, with the anticoagulants at present available, it is a tedious and difficult form of therapy, depending upon laboratory facilities, a reliable technique, and trustworthy technicians in whose hands is the life of the patient. More laboratory assistants require to be trained for this work so that this particular treatment can be made available to larger sections of the community, even outside the walls of the hospital. Until a domiciliary service can be arranged, the only alternative is to refer such cases of coronary occlusion as are fit to be moved, to those institutions where appropriate laboratory facilities exist for the control of anticoagulant therapy. The practitioner can always begin treatment with heparin in the patient's home, but at present the coumarol compounds cannot be used without daily estimations of prothrombin time. The mortality rate for coronary thrombosis throughout the general population will fall when a larger number of hospital beds are made available for its treatment and when a domiciliary laboratory service provides the practitioner with technical help, without which this particular treatment cannot be undertaken.

No doubt the use of anticoagulants may be simplified in the future. At the present time they are difficult to handle A painless, inexpensive, slow-acting but reliable substitute for intravenous heparin would be a great advantage. We have been disappointed in depot-heparin and heparin-retard, partly on account of the intense and persistent local pain after the intramuscular injection and partly on account of irregular absorption. "Heparin-Evans" (25,000 units per ml.) has proved more satisfactory when given at eight-hour intervals intramuscularly in doses of 20,000 units. This amount will usually maintain a clotting time in excess of 20 minutes throughout an eight-hour period. We have no personal experience of new synthetic heparin-like substances, such as "paritol," which have the virtue of cheapness and are now under clinical trial (Sorenson *et al.*, 1949). "Tromexan" (Burt, Wright, and Kubik, 1949) possesses certain advantages over dicoumarol in that it comes into action more quickly and is less cumulative The oral dose being larger, it can be more easily adjusted from day to day. It should be given in divided amounts at 6-hour to 12-hour intervals according to the morning prothrombin-time.

Finally, it is worth emphasizing that there are definite contraindications to dicoumarol and tromexan. In view of the risk of serious haemorrhage, they should not be used in the presence of hepatic or renal disease, or the severer anaemias, pregnancy, or vitamin deficiencies. Any ulcerated surface, particularly of mucous membranes, such as a peptic ulcer or a diverticulitis, may bleed profusely when these drugs are used.

Conclusions

Anticoagulant therapy, suitably controlled by specialized techniques, reduces by one-half the mortality rate during the first six weeks after myocardial infarction. Our experience is that it appears to benefit males to a greater extent than females, particularly men whose myocardial efficiency was only slightly impaired before the acute damage was sustained.

Thrombo-embolic complications are reduced by half, and, when they do occur, fatalities are lessened.

Anticoagulant therapy cannot succeed in the absence of strict attention to the established methods of treatment. It does not shorten the stay in bed.

It should be considered for every sufferer from myocardial infarction. This implies an extension of laboratory facilities for the regulation of treatment and a greater number of hospital beds set aside for this purpose. A scheme for domiciliary laboratory control is desirable if the practitioner is to continue to care for these patients.

For the purposes of this investigation Professor Stanley Davidson, Dr. W. D. D. Small, and Dr. W. A. Alexander have kindly given us access to patients suffering from coronary thrombosis under their immediate charge in the Royal Infirmary. We are also indebted to Mr. George Waugh, F.F.A., of the Scottish Statistical Research Bureau, for help in the statistical analysis of our findings.

CAPILLARY RESISTANCE AND ADRENO-CORTICAL ACTIVITY

BY

H. N. ROBSON, M.B., M.R.C.P.Ed.

AND

J. J. R. DUTHIE, M.B., F.R.C.P.Ed.

(From the Department of Medicine, University of Edinburgh; Rheumatic Unit, Northern General Hospital; and the Eastern General Hospital, Edinburgh)

The starting-point of the present investigation was the observation that the resistance of skin capillaries to rupture by negative pressure rises sharply after many types of surgical operation (Scarborough, 1944). It was decided to study the effects on capillary resistance of other types of tissue damage. The variety of such types of damage which produced increased capillary resistance led to the possibility that this rise might be produced by any form of non-specific stress. Positive results were obtained after the application of various forms of stress. Interest was then stimulated by recent work on the physiology of the pituitary – adrenal axis, and it seemed possible that all the conditions which had been investigated were such as would lead to activation of this axis through the release of endogenous adrenaline or through some other pathway as yet unknown. This paper describes the investigations outlined above, leading to the study of the effects of the injection of adrenocorticotrophic hormone (A.C.T.H.) on capillary resistance.

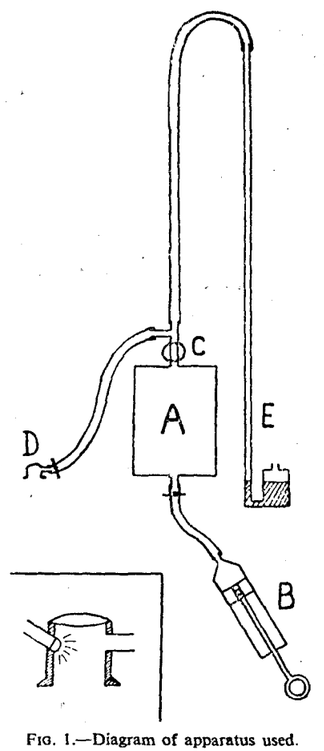

FIG. 1.—Diagram of apparatus used.

Methods

Capillary resistance has been measured throughout these studies by a negative pressure method. The apparatus (Fig. 1) was the same as that used by

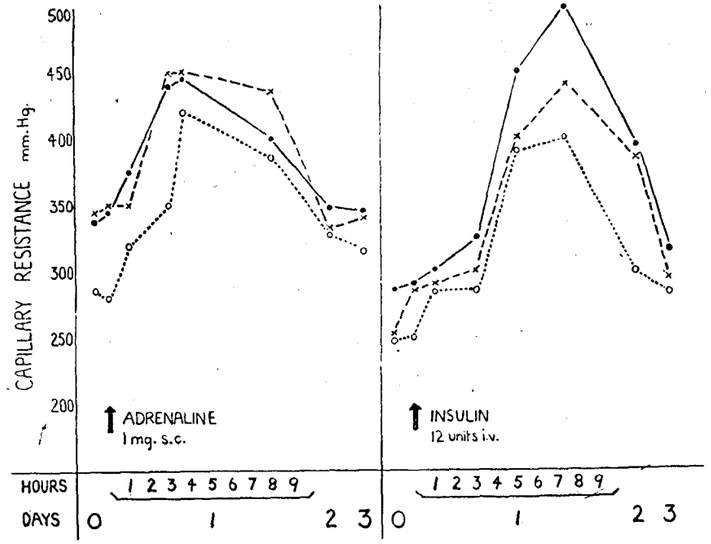

FIG. 2.—Changes in capillary resistance following (*a*) the injection of adrenaline, and (*b*) the production of insulin hypoglycaemia.

Scarborough (1941). Negative pressure is created in the reservoir (A) by means of a suction pump (B). The control valve (C) allows suction to be applied to the skin in the test area through the cup (D). The degree of negative pressure is recorded on the mercury manometer (E). The suction cup used has an internal diameter of 20 mm. A lens of ×10 is incorporated in the roof of the cup. Standard illumination is obtained from an endoscope bulb which projects from the wall of the cup and is lit by a 2-volt dry battery.

The principle employed in using this apparatus was the determination of the "critical petechial pressure"—that is, that negative pressure which when applied for 30 seconds would produce one or two petechiae only in the test area. At each estimation three standard areas on the volar aspect of the forearm were tested (Scarborough, 1941), the same arm being used throughout studies on any one patient, and, when recorded daily, readings were taken at approximately the same hour. In order to reduce the number of trial readings at any one estimation, alterations in pressure were usually made at intervals of 500 mm. Hg. It has been found by experience that when any given pressure produces up to but not more than 10 petechiae it is usually unnecessary to make further trial, since a pressure of 50 mm. less will not produce any petechiae. If more than 10 petechiae are produced, then it is necessary to repeat the observation at a lower pressure in an immediately adjacent area. For the purposes of graphing results only, it has been assumed that between the intervals of 50 mm. of pressure the "critical petechial pressure" is proportional to the number of petechiae produced.

With the technique described here the average range of normal capillary resistance is 250 to 350 mm. Hg, but occasional wide variation in normal individuals is encountered within a range of 200 to 450 mm. Hg (Bell, Lazarus, Munro, and Scarborough 1942).

Factors Influencing Capillary Resistance

Physical Agents—Heat, Cold, and Ultra-violet Light.—The environmental temperature is known to affect capillary resistance. Von Borbély (1930) showed that immersion of the body in a warm bath caused a fall in resistance, while a cold bath gave rise to increased resistance. Rossman (1940–1) showed that heating of the whole body in an inductotherm caused lowering of resistance during the period of heating, followed by a rapid rise to supranormal levels when heating was discontinued. Patients undergoing inductotherm treatment have been studied here. No observations were possible during the period of heating.

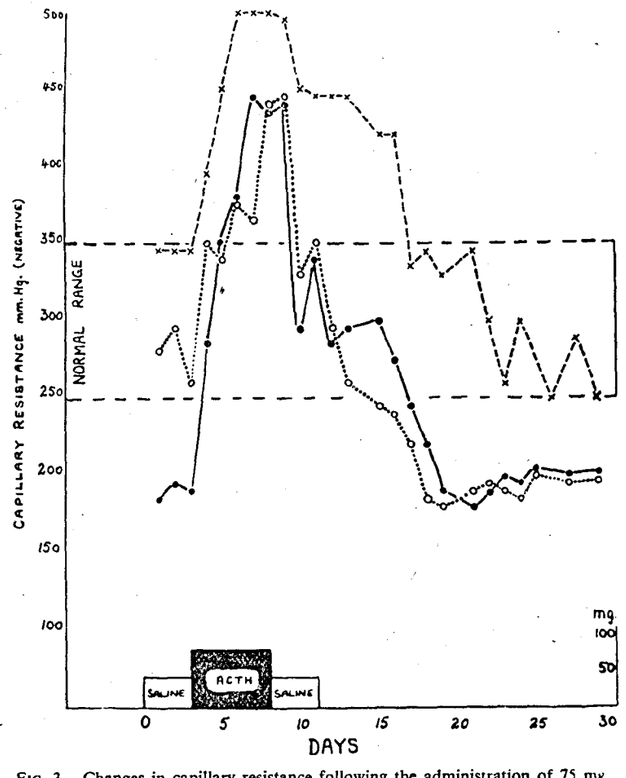

FIG. 3.—Changes in capillary resistance following the administration of 75 mg. A.C.T.H. daily for five days in a case of rheumatoid arthritis.

Table Showing Results in Cases of Rheumatoid Arthritis

Case No.	Area	Range of Readings in Control Period		Readings at 4 hr. after 25 mg. A.C.T.H.		Readings at 8 hr. after 25 mg. A.C.T.H.		Maximum Resistance Attained (mm.Hg)	Time to Reach Maximum (hr.)	Time Taken to return to Control Levels (days)	Total Dose of A.C.T.H. (mg.)

but readings taken after removal of the patient from the inductotherm confirmed Rossman's observation that a marked increase in resistance occurs. Franke (19) reported that exposure to ultra-violet light gave rise to diminished resistance during the period of skin erythema, but that if exposure was continued resistance rose to supranormal levels.

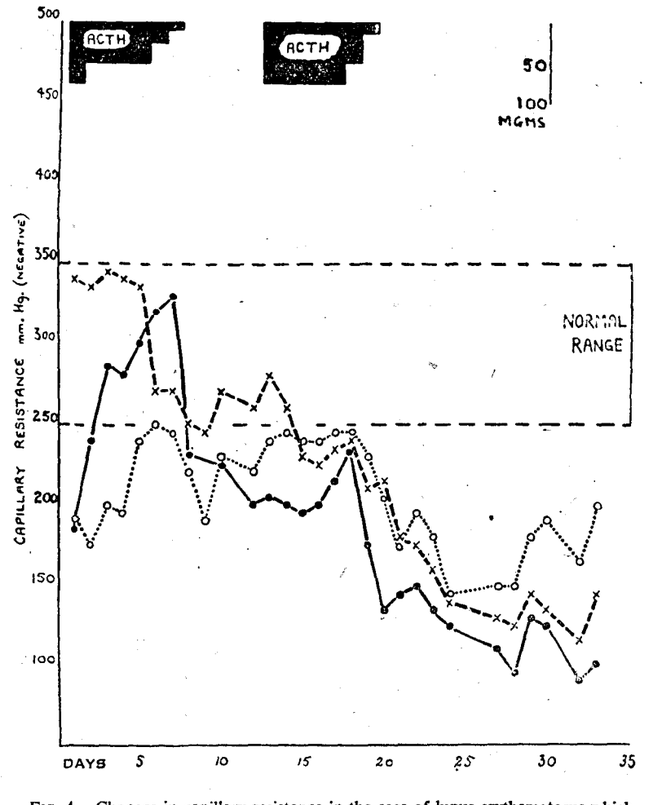

FIG. 4.—Changes in capillary resistance in the case of lupus erythematosus which showed a poor clinical response to A.C.T.H., and in which there was a fatal termination.

X-ray Irradiation.—Capillary resistance has been measured in patients having radiotherapy for various types of malignant disease. In most cases a marked rise in capillary resistance occurred within three to four days of the beginning of therapy and was maintained during the course. These findings are to be fully described elsewhere (Robson and Court Brown, to be published).

Mitotic Poisons: Nitrogen Mustard.—The intravenous injection of nitrogen mustard in cases of reticulosis has also been found to cause a sharp rise in capillary resistance, sustained for some days after completion of the course of injections.

It seemed possible that, since the agents described above caused some degree of tissue damage, their effects on capillary resistance might be due to the action of histamine or histamine-like substances released by tissue breakdown.

Histamine.—Franke (1943) reported that 1 mg. of histamine injected subcutaneously caused an initial fall in capillary resistance, which was maximal in about 20 minutes, with a return to basic readings in about 45 minutes. He did not record observations beyond that point. Wyss and Gianoli (1946) confirmed these findings. The technique employed in the present investigation was the intravenous infusion of 3 mg. of histamine in a saline drip over a period of one to two hours, usually in cases of rheumatoid arthritis. Capillary resistance was found to fall during the period of infusion of the drug, returning to basic levels in about two hours, and rising thereafter to supranormal levels, the increase being sustained for about 24 hours. The pattern of change in capillary resistance following the infusion of histamine, while bearing some resemblance to the effects of heating and burning, was not the same as that produced by cold, or by surgical operations, irradiation, or mitotic poisons.

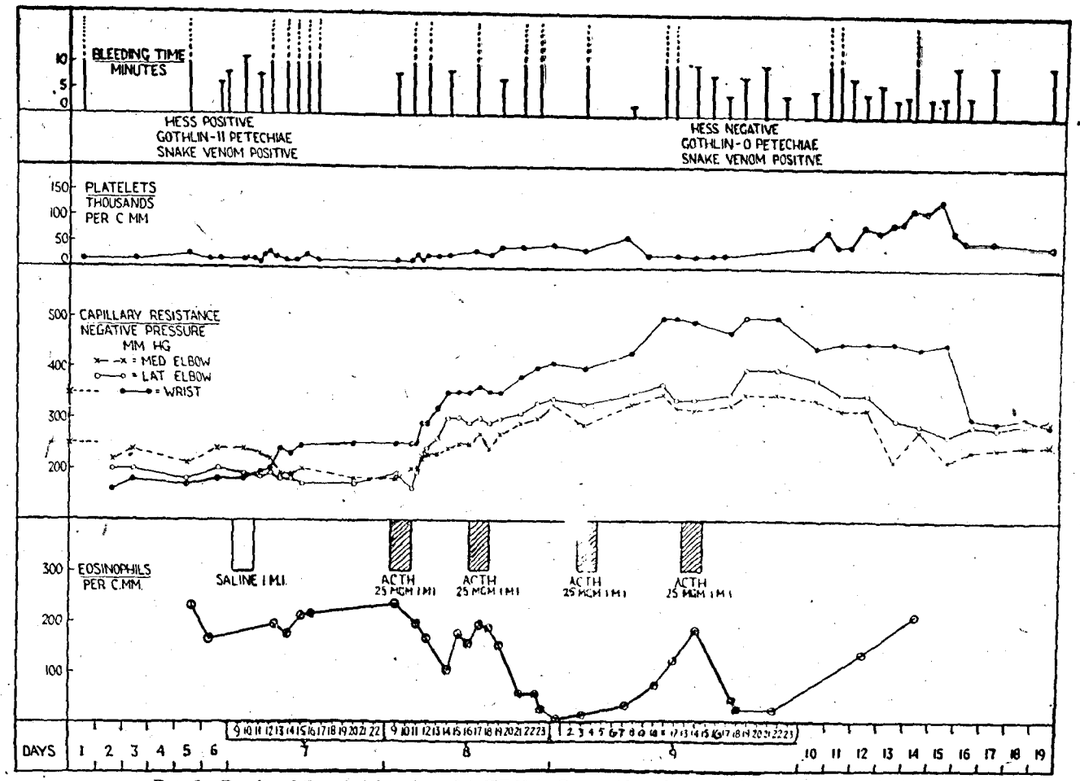

Fig. 5.—Results of the administration of A.C.T.H. in Case A (thrombocytopenic purpura)—first course.

Protein Shock by T.A.B. Vaccine.—Protein shock produced by the injection of T.A.B. vaccine was studied. A fall in resistance was generally recorded during the period of mounting pyrexia, but this was followed by a rapid rise to supranormal levels, reaching a maximum in three to four hours and thereafter slowly returning to the baseline in 36 to 48 hours.

Adrenaline.—It was decided to observe the effects of the injection of adrenaline, since the "alarm reaction" of Cannon is produced by the endogenous release of this substance. Observations were made following the injection of 1 mg. of adrenaline intravenously or 1 to 2 mg. subcutaneously. With either route a rise in capillary resistance has constantly been found, detectable within two hours of the injection, reaching a maximum in four to six hours, and thereafter returning to base levels in 24 to 36 hours. An example is shown in Fig. 2. Similar results have been described by Parrot, Lavollay, and Galmiche (1944) and by Lavollay (1944).

Insulin Hypoglycaemia.—The results obtained by the injection of adrenaline prompted the study of the effects of hypoglycaemia, since this is known to be an effective stimulus to the endogenous release of adrenaline. Observations were made following the injection of soluble insulin, either intravenously in doses of 10 to 15 units, or subcutaneously in doses of 30 to 50 units. One example of the result is shown in Fig. 2. An increase in capillary resistance is usually detectable about one to two hours after the hypoglycaemia is manifest, reaching a maximum in four to six hours, and returning to control levels in about 48 hours.

The observations, when considered in the light of recent work which suggests that adrenaline stimulates the production of A.C.T.H. from the anterior pituitary, led to the idea that increased capillary resistance might be a manifestation of increased adrenocortical activity.

A.C.T.H. and Capillary Resistance

In the course of wider clinical investigations an opportunity arose to study the effects of A.C.T.H. on capillary resistance. Among the cases which have been studied were six examples of rheumatoid arthritis, two of ankylosing spondylitis, two of disseminated lupus erythematosus, and two of idiopathic thrombocytopenic purpura.

Rheumatoid Arthritis

Six patients suffering from this condition have been studied. Fig. 3 illustrates the changes in capillary resistance resulting from the administration of 75 mg. A.C.T.H daily for five days in one of these cases. The accompanying Table gives brief details of the findings in the six cases. Illustrated are the changes in response to the first dose (25 mg.), the time taken to reach maximum resistance on a dosage of 25 mg. eight-hourly, and the time taken for capillary resistance to return to control levels after the course was completed. It may be seen that a single dose of 25 mg. of A.C.T.H. produced a significant rise in one or more areas within four hours in all except one case, in which the response was delayed. In this latter case resistance was raised at eight hours after the injection, by which time the others had in general shown a tendency to return to base levels. In all cases, continued administration of A.C.T.H. in doses of 25 mg. eight-hourly resulted in a marked elevation of capillary resistance, reaching a maximum in about 72 hours. Resistance was maintained at this high level for the remainder of the period of administration. When A.C.T.H. was stopped the resistance fell at varying speeds, reaching base levels again in 10 to 14 days. (In Cases 4 and 6 the return was much slower.) No case has been encountered in which a significant fall in eosinophils has not been accompanied by a definite rise in capillary resistance. The extent and speed of the increase in resistance, however, have not necessarily corresponded exactly with the percentage fall in eosinophils. The extent and duration of the increased resistance have borne only a rough correspondence to the clinical effects achieved by the A.C.T.H.

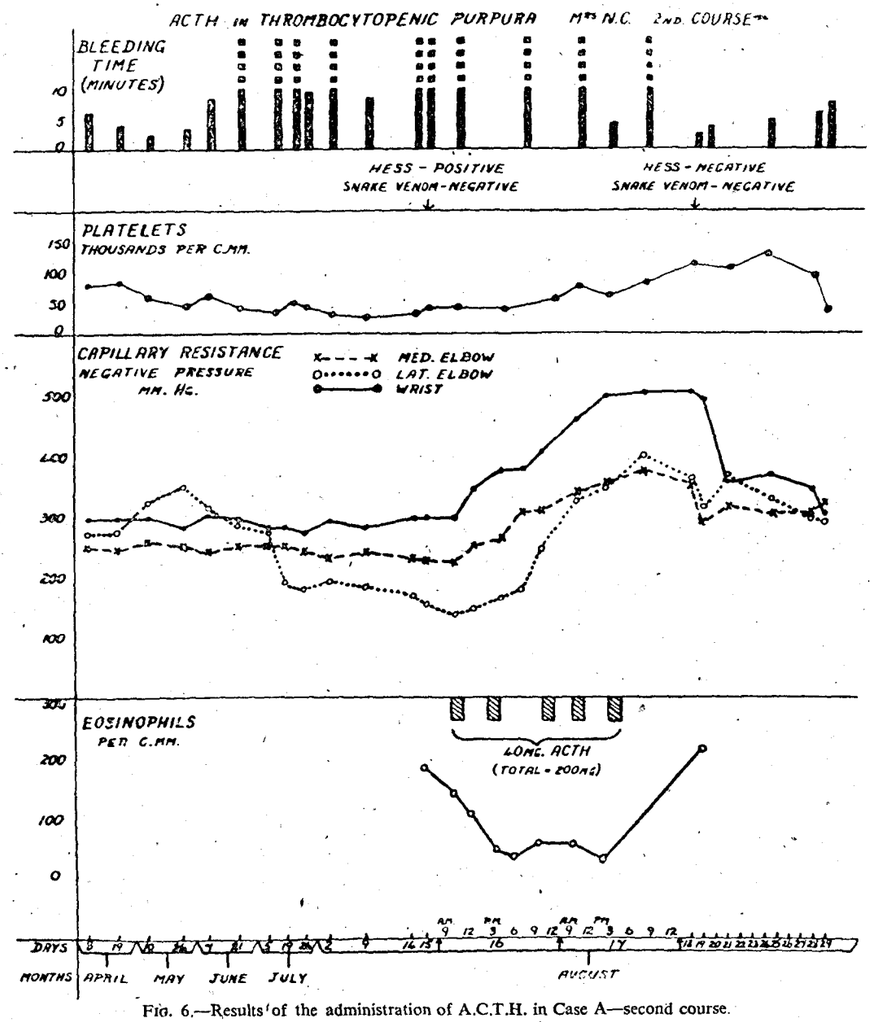

Fig. 6.—Results of the administration of A.C.T.H. in Case A—second course.

Spondylitis Ankylopoletica

Two patients suffering from this condition have been studied. In both a marked increase in capillary resistance was observed following the administration of 75 mg. daily. Resistance reached maximum level in both about 48 hours after the first injection. In both cases resistance fell quickly on completion of the five-day course of A.C.T.H.

Disseminated Lupus Erythematosus

Two patients suffering from this condition have been studied. In both cases capillary resistance was low in the observation period. In one case, eosinophils, which had been entirely absent from the peripheral blood, reappeared before A.C.T.H. was given. A course of A.C.T.H. lasting seven days (total dose 340 mg.) resulted in a marked clinical improvement, a reduction in circulating eosinophils, and a definite increase in capillary resistance. This increase was not long sustained after A.C.T.H. was discontinued, and resistance returned to base levels in four days. Clinical relapse was also quickly evident. The findings in the second case are illustrated in Fig. 4, where it may be seen that the expected increase in resistance did not take place. The patient showed a poor clinical response to A.C.T.H.; her condition steadily deteriorated and death occurred. Eosinophils were absent from the peripheral blood in this case throughout the entire period of observation, before, during, and after the administration of A.C.T.H. At necropsy both adrenals were found to be small, and on section it was noted that lipoid was extremely scanty in the zona fasciculata.

Idiopathic Thrombocytopenic Purpura

Since low capillary resistance is generally regarded as one of the principal features of idiopathic thrombocytopenic purpura, it seemed of interest to ascertain the effect of giving A.C.T.H. in this condition. Reports of two cases follow.

Case A.—A woman aged 33 had had a prolonged episode, starting in 1946 and continuing until spontaneous remission occurred in 1948. During this time she had suffered from ecchymoses and recurrent petechial rashes, but no haemorrhagic incidents had occurred. In December, 1949, on the twelfth day of the puerperium of a normal pregnancy and delivery, ecchymoses and petechiae reappeared. These, together with thrombocytopenia, continued without remission up to the time of the present investigation. The results of the initial administration of 100 mg. of A.C.T.H. in four divided doses are shown in Fig. 5. It may be seen that a definite rise in capillary resistance occurred, reaching a maximum after 75 mg. had been given. When the drug was discontinued, capillary resistance returned slowly towards the control levels in approximately seven days. During the period of elevated resistance the Hess test became negative, but the snake-venom test remained positive; no significant change occurred in platelet counts and the bleeding-time was little altered. It must be noted, however, that a moderate increase in platelets was recorded (maximum about the seventh day) after A.C.T.H. had been given, and that a tendency towards reduction in bleeding-time had become apparent about this period. Clinically, a definite remission resulted, and this persisted for three months, though platelet counts and capillary resistance had returned to low levels. Ecchymoses and petechiae then reappeared and the clinical condition rapidly reverted to that found before the first course of A.C.T.H. As shown in Fig. 6 a second course of A.C.T.H., totalling 200 mg., was given in 40-mg. doses over a period of 48 hours. This resulted in changes similar to those observed previously in capillary resistance, bleeding-time (more definitely reduced on this occasion), and platelets (again a delayed slight increase). Clinical remission has again been produced, although at the time of writing this had been followed for only three weeks. It must be noted that, although the amount of A.C.T.H. given was doubled in the second course, the effects produced were no greater than, if indeed as great as, in the first course.

Case B.—A man aged 32 presented with a history of bruising and petechial haemorrhages for three months, and of bleeding from the gums for one week. The clinical and haematological findings conformed to the diagnosis, and during observation over a period of three weeks there was no sign of remission. As shown in Fig. 7, A.C.T.H. was given in doses of 40 mg. eight-hourly to a total of 340 mg. This resulted in a marked increase in capillary resistance, a definite reduction in bleeding-time, conversion of both the positive-pressure and the snake-venom tests to negative, and a moderate thrombocytosis which was maximal about nine days later. Bleeding from the gums stopped on the second day of A.C.T.H. administration, no further bruises or petechiae appeared, and the patient has remained in complete clinical remission for five weeks. In contrast to Case A, capillary resistance and platelets have remained above the pre-A.C.T.H. levels and the bleeding-time has been maintained within the normal range.

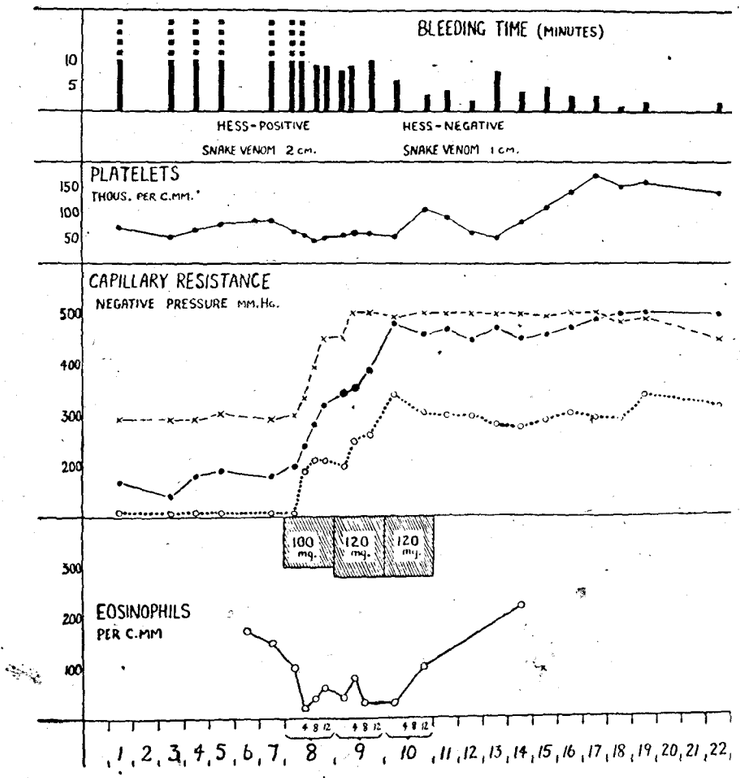

FIG. 7.—Results of the administration of A.C.T.H. in Case B (idiopathic thrombocytopenic purpura).

Discussion

The negative-pressure method of estimating capillary resistance has not been so widely employed as have positive-pressure methods such as the Hess, Rumpel-Leede, or Göthlin tests. First suggested by Hecht in 1907, the suction method has been used by such authors as da Silva-Mello (1929, 1930), Mengler (1930), Von Borbély (1930), Adant (1936, 1938), Franke (1943), and Parrot, Lavollay, and Galmiche (1944) on the Continent; by Dalldorf (1933), Dalldorf and Russell (1935), Cutter and Johnson (1935), and Elliott (1938) in America; and by Scarborough (1941, 1943, 1944) and Robson (1949) in this country. The merits and demerits of the method are reviewed by Munro, Lazarus, and Bell (1947).

In the present study, the use of the negative-pressure method has permitted the detection of an increase in capillary resistance, often to markedly supranormal levels, occurring as a result of several different stimuli. These preliminary observations suggest strongly that this rise in resistance is mediated by adrenocortical activity. The number of cases treated with A.C.T.H. is not great, but it seems probable that the extent and duration of the increase in resistance are roughly proportional to the degree of adrenocortical stimulation. In the cases of rheumatoid arthritis, however, the capillary changes did not necessarily reflect accurately the clinical response of the patients to A.C.T.H. In the sixth case of rheumatoid arthritis (see Table), a dramatic clinical remission was produced by A.C.T.H., but this was short-lived. The capillary resistance, however, which was raised to high levels, remained elevated for a considerable period, though complete clinical relapse had occurred. In the fifth case, on the other hand, a prolonged clinical remission was produced by A.C.T.H., but capillary resistance returned quickly to previous levels after the course was completed. In these six cases of rheumatoid arthritis, and in two cases of ankylosing spondylitis, the correlation between capillary resistance and eosinophil counts was fairly close.

The two cases of disseminated lupus erythematosus provide an instructive comparison. In one case a definite rise in capillary resistance was recorded after the administration of A.C.T.H. in a dosage which resulted in a decided clinical remission and a depression of eosinophils. In the second case, however, no such increase in resistance was recorded, clinical response to A.C.T.H. was poor, and the progressive deterioration was reflected by the falling capillary resistance. Since no eosinophils were found at any time in the peripheral blood in this case, the capillary resistance findings were of great value as an index of the lack of response to A.C.T.H.

The results in the two cases of thrombocytopenic purpura are of interest. It is noteworthy that capillary resistance rises in response to A.C.T.H. in this condition where the capillaries are believed to be abnormal. The moderate increase in platelets which was found to follow this increased resistance occurred at about the same time interval as the maximum thrombocytosis observed after splenectomy. While it would be unwise to draw more than tentative conclusions from such limited experience, definite clinical remission was induced by A.C.T.H. on three occasions in these two cases. Further study of the effects of A.C.T.H. in this and similar conditions would appear to be indicated.

It seems likely that the increase in capillary resistance which has been found to follow the administration of A.C.T.H., adrenaline, and insulin is due to adrenocortical activity. Such activity would account also for the changes in resistance which follow tissue damage and bodily stress. It is suggested that the measurement of capillary resistance provides a fairly simple and rapid method of following the response to A.C.T.H. or to substances which might be expected to have a similar effect.

Summary

It has been observed that an increase in capillary resistance, as measured by a negative-pressure method, occurs after the infliction of various types of tissue damage and after the application of various forms of bodily stress.

The results obtained suggest that this rise in resistance might be due to adrenocortical stimulation by the release of endogenous adrenaline or some similar mechanism.

Patients receiving adrenocorticotrophic hormone (A.C.T.H.) have been studied and the predicted increase in capillary resistance observed. The features of this response are described.

These observations led to the study of the effects of A.C.T.H. in two cases of idiopathic thrombocytopenic purpura; the results are described. Definite clinical remission was induced on three occasions.

It is suggested that capillary resistance estimations may be used in the measurement of the response to stimulation of the adrenal cortex.

Gratitude is expressed to Drs. E. B. French and A. G. S. Hill for much valuable assistance. We wish to thank Professor L. S. P. Davidson for helpful criticism and advice.

THREE CASES OF SEVERE BURN TREATED WITH CORTISONE*

BY

P. O. CRASSWELLER, M.D.

A. W. FARMER, M.D.

W. R. FRANKS, M.D.

(From the Royal Canadian Air Force Institute of Aviation Medicine and the Department of Surgery, Hospital for Sick Children, Toronto)

AND

A. D. McLACHLIN, M.D.

Professor of Surgery, University of Western Ontario, London, Canada

In a former study (Crassweller, Farmer, and Franks, 1950), experimental evidence was presented suggesting that the mortality of experimentally burned mice was reduced by the administration of urinary extract fractions such as are known to contain the cortisone-active material. It thus seemed justifiable to consider giving cortisone in the treatment of severe clinical burns. In this paper three cases of severe burn are presented in which routine burn-therapy was supplemented by the administration of cortisone acetate in varying amounts. One case of 70% burn in an adult has done well. The other two patients (both children) died—one, however, 24 days after the burn and following a most promising early clinical response.

In reporting surface area of burns the modification of Berkow's formula (Lund and Browder, 1944) was used. Simple erythema has not been included.

As routine treatment all received occlusive pressure-dressings with light plaster casts. In Case 1 the burned surface was covered with aluminium foil (Brown, Farmer, and Franks, 1948), while in the other two vaselined gauze was used. Fluid requirements were maintained intravenously and by mouth in all cases.

Case 1

A well-nourished male child aged 23 months was admitted to the Hospital for Sick Children, Toronto, on June 8, 1950, in a moribund condition. He had suffered second-degree burns due to scalding, involving approximately 55% of his body-surface, including the legs, thighs, genitalia, and lower two-thirds of the trunk.

Treatment was started within one hour after the accident. To combat severe shock, 250 ml. of plasma was syringed at once into the radial artery. This resulted in an immediate return

*This work was carried out through a grant-in-aid supplied through the Defence Research Board of Canada.

to consciousness. 150 mg. cortisone acetate was administered intramuscularly at this time. In addition to the immediate shock therapy, plasma and normal saline were given intravenously to control haemoconcentration throughout the next few days. The haemoglobin fell on the third day to 7.2 g. per 100 ml., after which 500 ml. of whole blood was given. Daily injections of cortisone were continued to a total of 450 mg. (Fig. 3). In addition, 400,000 units of penicillin were given intramuscularly daily.

Considering his severe burn the child appeared to be doing well clinically, although his urinary output was small and bloody for the first 36 hours. On reduction of protein intake while fluids (glucose and saline) were maintained, his output suddenly increased and his urine became clear. Despite this turn and a normal non-protein nitrogen, he became comatose, with generalized twitchings and mounting fever at the end of the second day. On the third day his condition improved, with return of consciousness and good voluntary oral intake. However, at the end of the fifth day he lapsed into coma and died in respiratory failure with twitchings and hyperpyrexia.

Necropsy failed to reveal any significant findings apart from the burn. The adrenal glands contained adequate sudanophilic material.

Case 2

A girl aged 7 years was admitted to the Hospital for Sick Children, Toronto, on May 28, 1950, showing no evidence of shock other than rapid pulse and thirst. She had suffered flame burns to the extent of 30% of her body surface, involving the dorsum and left side of the trunk, the left arm, and left thigh. About one-third of the damaged area had second-degree burns and the remainder third-degree burns.

Treatment was begun 45 minutes after the accident. Haemoconcentration was controlled by the administration of 5,420 ml. of plasma in the first three days. Oral fluid intake was good throughout, as was also the calorie intake. She received penicillin, 400,000 units daily, beginning on admission.

On the first day the patient was bright and co-operative, but on the second day she began to appear ill, with a rising temperature and increasing pulse and respiratory rates (Fig. 1). Cortisone acetate 100 mg. was administered intramuscularly at this time and continued daily until the eighth day (Fig. 3). The temperature dropped and she remained remarkably well clinically. Dressings were changed on the tenth day. There was complete healing of the second-degree areas. Separation of slough was progressing normally. The dressings were heavily contaminated with *Ps. pyocyanea*. From the eleventh day her condition deteriorated; she had a slowly rising and swinging temperature and showed signs of toxicity suggestive of a septicaemia. Blood cultures were negative. From the twelfth to twenty-second days sulphadiazine and streptomycin were given, with no apparent benefit. Her burned surfaces were examined with the hope of finding a localized focus of infection, but none was found. Granulations were well formed and appeared healthy. She received aureomycin from the twenty-third day. She became comatose and cyanotic, with a rising temperature which terminally reached 107° F. (41.7° C.). Death ensued with respiratory failure on the twenty-fourth day.

On removal of the dressings at necropsy a red macular rash was found over the abdomen and buttocks which had not been present 24 hours previously. The burned surface and dressings were heavily contaminated with *Ps. pyocyanea*, and this organism grew profusely in the culture of heart blood collected at necropsy. Since no other focus of infection was found, it is presumed that she died with a *Ps. pyocyanea* infection.

Case 3

A strong wiry man aged 21 was admitted to Victoria Hospital, London, Ontario, on May 8, 1950, suffering from severe flash burns sustained while working with high-tension wires. There were burns of most of the trunk, face, and neck, most of the left arm, and of the right arm to the elbow. The pubic hair and all the hair of the legs were singed, and there were burns of less intensity over these areas. The overall area of burn, excluding simple erythema, was estimated to be 70%. The total area of third-degree burn was estimated to be 15% of the body surface.

The face and neck were excluded from the occlusive pressure-dressings and were treated with penicillin cream. During the first 90 hours the patient required 24,750 ml. of plasma (Fig. 2) to maintain normal haemoglobin concentration. In addition he received 900 ml. of whole blood and 2,000 ml. of Ringer-lactate solution. He took fluids well by mouth throughout and received high-protein drinks from the second day on.

The patient was seen in consultation on the third day and cortisone therapy was suggested. This phase of the treatment was supervised by Dr. H. McAlpine. Daily cortisone injections were started on the fourth day (Fig. 3) and discontinued on the twenty-seventh day, following a total dose of 2,750 mg. 50,000 units of penicillin were administered intramuscularly every three hours. The patient remained well throughout and showed none of the stigmata of the so-called toxic phase.

Skin grafts were performed on the twenty-sixth, thirty-third, and fortieth days; all of these were successful. Because of the limited undamaged skin available, stamp grafts were used so as to cover a greater area. At the time of writing (seventieth day) the patient is still in hospital awaiting grafting of residual areas.

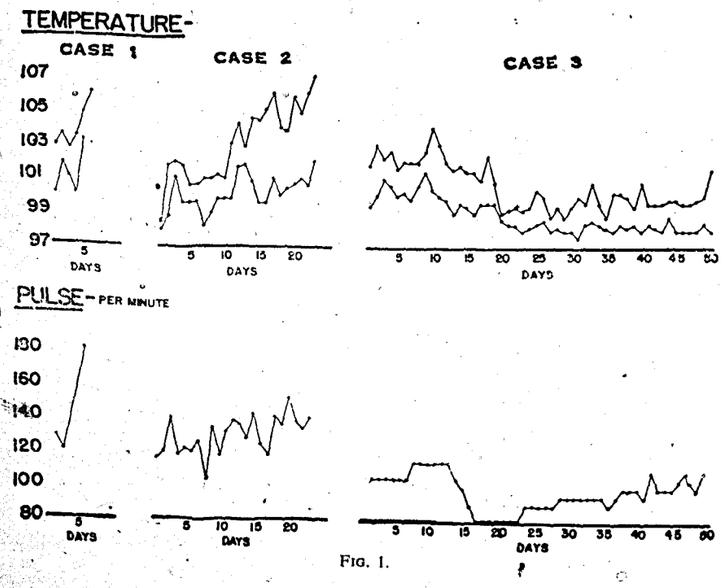

FIG. 1.

Discussion

The first patient (Case 1), according to the tables of mortality probabilities in burns prepared by Bull and Squire (1949), had less than a 40% chance of survival. He received a total of 450 mg. of cortisone over a five-day period. Temperature, pulse, and respiration recordings followed the usual pattern for burns of this severity (Fig. 1). The initial marked depression in the eosinophil count (Fig. 3) was consistent with the severity of the burn (Crassweller, Farmer, and Franks, 1950). With cortisone therapy the initial rise was followed by a return to low levels.

Because of the oliguria, protein restriction seemed indicated and whole-blood transfusion was withheld at this time. Under this treatment an anaemia developed rapidly. The fluid intake, while adequate, was not excessive, so that dilution was not the cause of the low haemoglobin levels. The peripheral-blood smear showed large numbers of microspherocytes, as has been described in severe burns by Brown (1946). The depressed haemoglobin levels may thus have been secondary to haemolysis. Following the return of renal function, 500 ml. of whole-blood transfused on the third day failed to restore the haemoglobin level. Fear of renal complications prevented further transfusion, although it is evident, in retrospect, that transfusions were probably indicated. The anticipated drop in total plasma protein levels did not occur (Fig. 4), and the non-protein nitrogen values remained within normal limits throughout. It is difficult to account for the low total-urinary-nitrogen excretion (Fig. 5) in the face of the usual burn response, coupled with adequate fluid intake and cortisone therapy. As reviewed by Crassweller, Farmer, and Franks (1950), all of these might be expected to result in increased nitrogen excretion. Early hyperglycaemia did not occur, but rising non-fasting blood-sugar levels (Fig. 5), unaccompanied by ketonuria, and in the presence of a relatively constant glucose intake, are perhaps associated with the cortisone therapy. A rising 17-ketosteroid excretion level also suggests a cortisone effect. At necropsy the normal quantity and distribution of sudanophilic material found histologically in the adrenal cortices probably indicates that death was not secondary to adrenal exhaustion (Sayers and Sayers, 1949; Cain and Harrison, 1950).

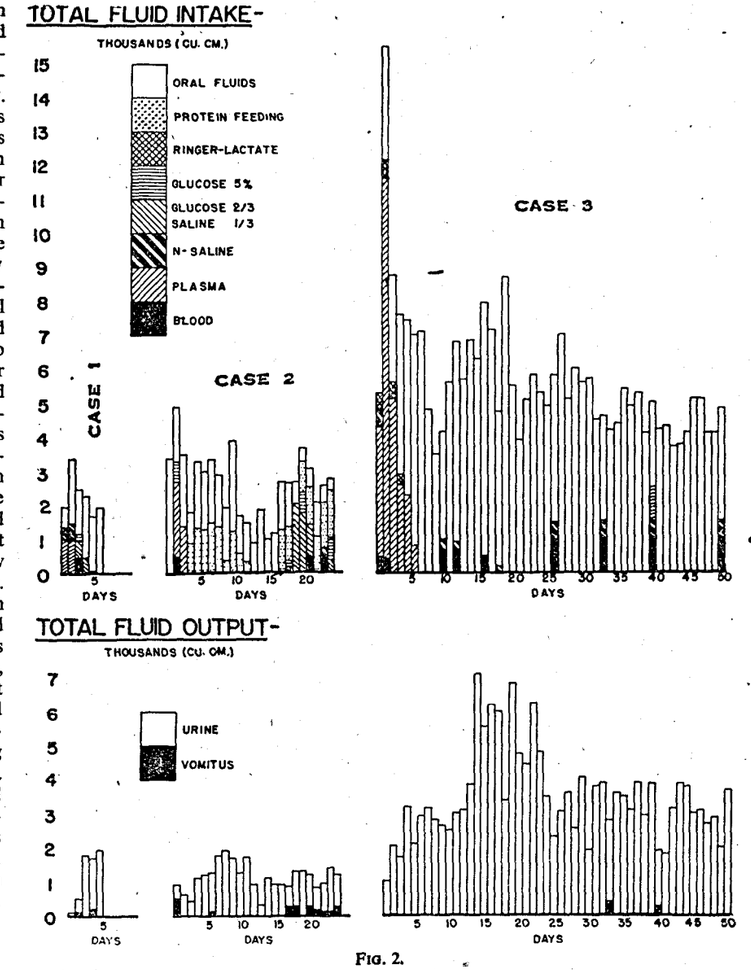

FIG. 2.

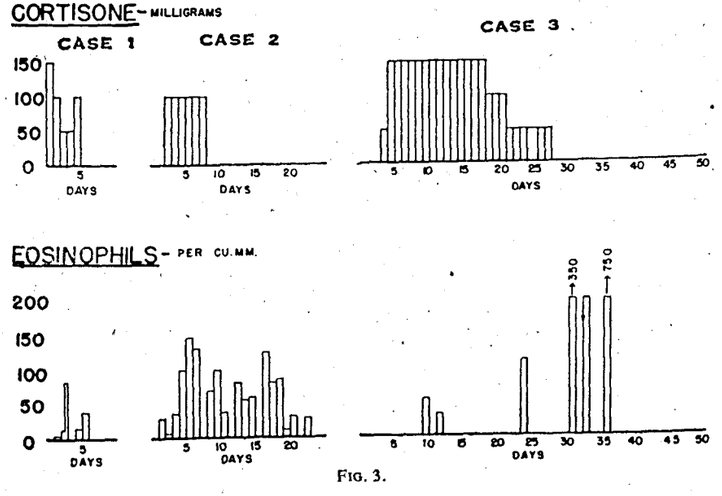

FIG. 3.

The second case received cortisone 100 mg. daily, beginning on the third day (Fig. 3), following which she improved, and her clinical course was most encouraging. The temperature dropped almost immediately. She was bright and cheerful and displayed a keen appetite. Cortisone was stopped on the eighth day after a total dose of 600 mg. had been given.

After the first change of dressings on the tenth day there followed a slow progressive clinical deterioration. The appetite vanished and it became necessary to feed through a stomach-tube. The temperature

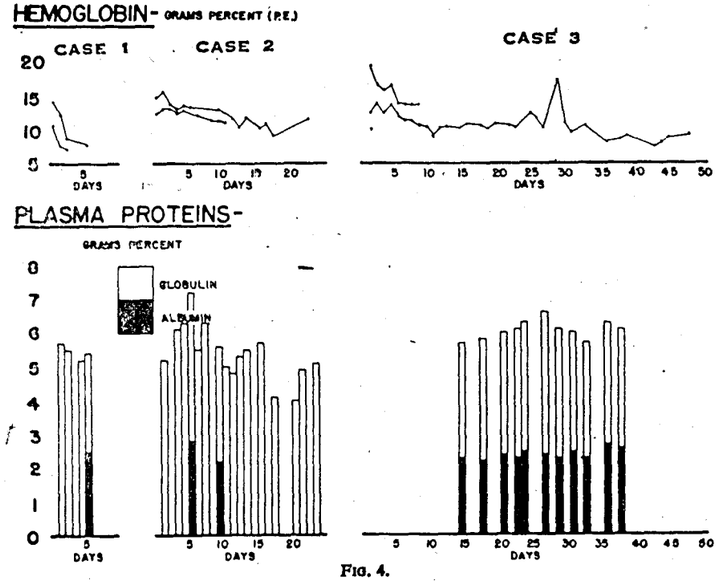

Fig. 4.

assumed a typical septic course and this was reflected in the pulse (Fig. 1) and respirations. A retrograde urinary infection was feared and the catheter was removed. The white blood count reached a level of 32,500 per c.mm. on the eleventh day. Repeated blood cultures were sterile.

During the period of cortisone therapy the eosinophils increased somewhat over the initial depression secondary to the burn (Fig. 3) but remained below the lower limit of normal, suggesting to us at the time that adequate cortisone was being used. However, a steady drop in the daily excretion of 17-ketosteroids in the urine from the third to the tenth day would suggest, from this criterion (Sprague *et al.*, 1950), that the total cortisone dosage was inadequate. A further drop from the eighth to the twelfth day suggests that the production of endogenous corticoids was depressed and remained so during this period. Unfortunately, owing to withdrawal of the catheter, 17-ketosteroid determinations were not available after the tenth day. (Because of the involved nature of the urinary 17-ketosteroid determination (McGill University Clinic modification of the Zimmermann reaction—Hawk *et al.*, 1947), the results were not available to us on a day-to-day basis. Eosinophil counts were therefore followed as the immediate criterion of cortisone therapy (Sayers, 1950). We are now attempting to apply the skin test described by Shuman and Finestone (1950) as a rough measure of corticoids in the circulation.) Continued depression of the eosinophil counts between the eleventh and fifteenth days suggested that the patient was able to respond to the increased stress associated with the onset of infection. Eosinophil counts from the twentieth day onwards led us to believe that the patient was producing adequate corticoids. However, despite the trend of the eosinophil count, post-mortem sections of the adrenal cortices showed a marked decrease in sudanophilic material in the fasciculata and reticularis, and to a smaller extent in the glomerulosa. This suggests adrenal exhaustion (Sayers and Sayers, 1949; Cain and Harrison, 1950) and possibly indicates that 17-ketosteroid excretion estimations are a more reliable guide to adrenal function than the eosinophil count.

The question arises whether or not the administration of cortisone bore any relation to the development of the subsequent infection in the burn. With this in mind, a fractionation of the plasma proteins from a post-mortem sample of heart blood was carried out through the kindness of Dr. A. G. Gournall, Department of Pathological Chemistry, University of Toronto. Using solutions of sodium sulphate of varying percentage as precipitant, the total plasma protein was found to be 4.85 g. per 100 ml. With a 26% solution of sodium sulphate the yield was 2.55 g. of globulin and 2.30 g. of albumin per 100 ml. Using 15% sodium sulphate, the total globulin fraction amounted to only 0.25 g. per 100 ml. Further work is required to determine the significance of this apparently low value. The clinical course in this case, however, was fairly typical of

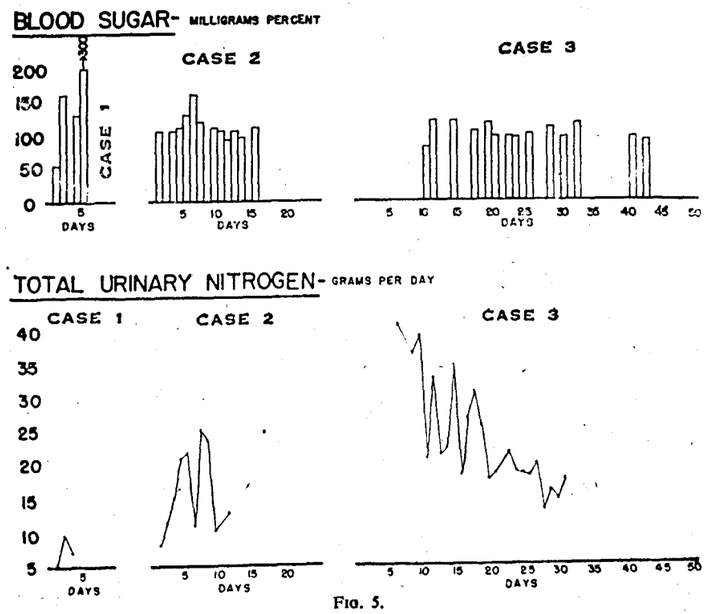

Fig. 5.

Ps. pyocyanea infection as reviewed by Stanley (1947).

According to the tables of mortality probabilities in burns, Case 3 had less than a 5% chance of survival under modern burn therapy. He responded well from the start, even before the administration of cortisone. He did not develop any evidence of pulmonary oedema, despite the fact that on the second day he received 15,500 ml. of fluid (Fig. 2). He did, however, develop marked peripheral oedema, making it necessary by the third day to split the body cast. This oedema probably accounts for the marked positive fluid-balance at this time. Cortisone therapy was begun on the fourth day and continued to the twenty-seventh day. Eosinophil counts were found to be depressed on the tenth, twelfth, and twenty-fourth days (Fig. 3). The cortisone dosage was tapered off on the nineteenth and finally stopped on the twenty-seventh day. The very high counts on the following days may indicate that the endogenous production of corticoids was somewhat depressed. The patient experienced a remarkable state of well-being, almost euphoria, during the period of cortisone administration and after its cessation. Also, he managed a sizeable calorie intake, averaging over 4,000 calories daily and on three occasions reaching 7,000 calories. Although it has been reported (Ragan *et al.*, 1950) that too much cortisone may delay wound-healing, no such difficulty was encountered in this case, despite the fact that the first graft was made during the period of cortisone administration.

Summary

Three cases of severe burn are presented in which routine burn therapy was supplemented by the administration of cortisone acetate.

The first patient, who suffered a 55% burn, died despite cortisone therapy. He had a normal histological distribution of lipoid material in the adrenal cortices at necropsy.

The second patient, who suffered a 30% burn, received cortisone from the third to eighth days, during which period she was remarkably well. Her condition deteriorated clinically after the initial change of burn dressings on the tenth day. She died on the twenty-fourth day, death apparently being due to sepsis. The finding of markedly decreased sudanophilic material in her adrenal cortices suggests adrenal exhaustion at the time of death.

The third patient, who suffered a 70% burn, has done well. He received cortisone from the fourth to twenty-seventh days and displayed a remarkable state of well-being and a keen appetite. This unusual recovery may be related to the cortisone therapy.

We wish to acknowledge the assistance of M. D. Maxmen and A. G. Stocks in the preparation of this paper.

AN UNUSUAL COMPLICATION OF MYANESIN THERAPY IN THE TREATMENT OF TETANUS

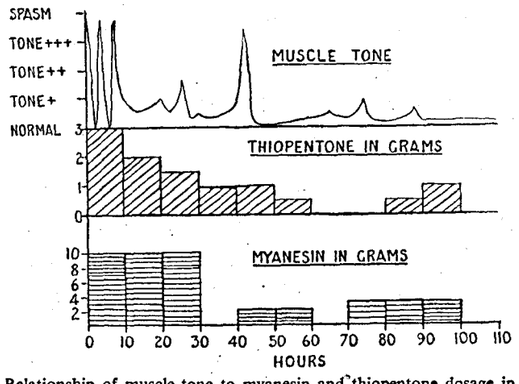
BY

M. L. NEWHOUSE, M.B., M.R.C.P.
Assistant Physician, Barnet General Hospital

J. D. ROCHFORD, M.B., B.S., D.A.
Anaesthetist, Barnet General Hospital

AND

G. RIDDELL ROYSTON, M.D., M.R.C.P., D.C.H.
Physician, Barnet General Hospital



"Myanesin" (α-β-dihydroxy-γ-(2-methylphenoxy)-propane; mephenesin) was introduced into clinical use by Berger and Bradley (1947), and was first used for relief of spasm in two cases of tetanus by Belfrage (1947), with encouraging results. Torrens, Edwards, and Wood (1948) treated a moderately severe case of tetanus with a combination of intramuscular and intravenous injections of myanesin, giving 22 g. in nine days, with considerable benefit to the patient. Davison, Ward, and Pask (1949) also treated two cases. The first case, after a period of treatment with curare and sedatives, was given intermittent intravenous injections of myanesin and recovered. The second was more seriously affected, and myanesin was used from the beginning of treatment. When it was found that a single intravenous injection controlled the spasms for only about 30 minutes, an intravenous glucose-saline drip was set up and myanesin added in varying amounts according to the condition of the patient. After 26½ hours of continuous myanesin treatment haemoglobinuria was observed and the myanesin was discontinued, but the patient immediately relapsed and died from violent spasms two hours later. Macdonald (1949) combined intravenous myanesin with intravenous thiopentone, giving 1–1.5 g. myanesin and 0.5–0.75 g. thiopentone in each 600 ml. of glucose-saline. In 23 days he gave a total of 40 g. myanesin and 32.75 g. sodium thiopentone. No haemoglobinuria occurred, and the patient, a child aged 8, recovered. Godman and Adriani (1949) used the American oral preparation "tolserol" in eight cases of tetanus; all but one of their cases were mild. They found that in doses ranging from 62.5 to 750 mg. in children, and up to 3,500 mg. in adults, it was an extremely satisfactory relaxing agent.

Case Reports

The following are reports of two cases of tetanus in which oral myanesin was used. Rectal thiopentone was also given in the first case.

Case 1.—A man aged 38, an inmate of a colony for mental defectives but of fairly high mental grade, was employed as an agricultural labourer. He gave no history of recent injury. On March 12, 1950, he complained of a painful stiff neck, which was thought to be due to fibrositis; he remained in bed but had no special treatment. The pain increased in severity and spread from the neck to the trunk and legs, and on the morning of March 16 he had a generalized convulsion. He was admitted to hospital, under the care of M. L. N. and J. D. R., at 2.30 p.m. on that day. On examination he was seen to be a well-built muscular man; there was no external injury, and he was fully conscious, flushed, and sweating profusely. There was rigidity of the neck and shoulder muscles with trismus and risus sardonicus. The erector spinae, the anterior abdominal muscles, and all muscles of the legs were in persistent spasm, and clonic contractions of the legs occurred on attempts to flex the knees. The arms were unaffected. No abnormalities were found in the heart, lungs, or central nervous system.

It was decided to treat the patient with a combination of myanesin and rectal thiopentone. At 3.50 p.m. 1 g. of myanesin dissolved in 10 ml. sterile water was given intravenously. Within two or three minutes complete relaxation had occurred, and the change in expression of the patient was most striking as his anxious frown and "risus" relaxed. The patient was given 250,000 units of tetanus antitoxin intramuscularly, and appeared to be comfortable, but by 5 p.m. generalized rigidity had recurred and a further 1 g. myanesin was given intravenously and 2 g. myanesin in tablet form by mouth. Again the intravenous myanesin had a rapid effect, but within half an hour spasms had recurred. At 5.50 p.m. the first dose of 2 g. sodium thiopentone was given per rectum; within 10 minutes the patient had completely relaxed and fallen asleep, but he was disturbed by several sneezing attacks (which are not unknown under light thiopentone narcosis), though these did not precipitate any tetanic spasms. At 8 p.m. there was again generalized rigidity, and the patient was given a further 1 g. myanesin intravenously. He was now ordered 2 g. myanesin by mouth and 0.5 g. sodium thiopentone per rectum, both every two hours. These were given regularly between 11.30 p.m. and 9.30 a.m. the next morning. At 8.50 p.m., about two hours after his third injection of myanesin, he passed

Relationship of muscle tone to myanesin and thiopentone dosage in Case 1.

"port-wine" urine, and the next two specimens of urine, passed at 3.30 a.m. and 4.30 a.m., were also heavily stained. Spectroscopic examination confirmed the presence of haemoglobin, but the specimen passed at 9 a.m. was clear both to the naked eye and on spectroscopy; there was no recurrence of haemoglobinuria.

The following day there was only moderate neck stiffness and the patient was able to speak and swallow without difficulty; he had, however, developed a cough with purulent sputum and there were scattered rales and rhonchi on both sides of the chest. The same dosage of myanesin and rectal thiopentone was continued, but the myanesin elixir was substituted for the tablets. During the day there were only two spasms, both affecting the right leg. The chest condition worsened. Through a misunderstanding the myanesin was omitted during the second night in hospital, though three doses of rectal thiopentone were given. At 7.30 a.m. on the third day the patient had a severe generalized spasm with opisthotonos. Rectal thiopentone was given, followed by oral myanesin, and complete relaxation was obtained within 10 minutes. After this there was no return of major spasms, though rigidity of the neck and abdominal muscles recurred from time to time; this was easily controlled by oral myanesin. The accompanying Graph shows the time-relationship between the spasms and muscular rigidity and the dosage of myanesin and sodium thiopentone

In spite of decreased dosage of sedatives, the chest condition deteriorated rapidly and the patient died on the evening of his fifth day in hospital. The total dosage of myanesin was 3 g. intravenously and 40 g. by mouth. Altogether 11 g. sodium thiopentone was given per rectum.

At necropsy the body was reported to be that of a well-nourished male. A healing abrasion was present over the left scapula, and there were several splinters in the hands—one 4 mm. long with a surrounding inflammatory reaction and deeply embedded. Anaerobic cultures from this splinter were negative for *Cl. tetani*. No abnormalities were noted in the heart, the central nervous system, or the alimentary system. The lungs showed suppurative bronchitis with early hypostatic pneumonia. The kidneys showed some evidence of old-standing chronic nephritis; otherwise the urinary tract was normal.

Case 2.—A man aged 45 was admitted under the care of G. R. R. on June 7, 1950, at 8.45 p.m. Six days previously while pushing a wooden tomato-stake into the ground he drove a splinter into his left antecubital fossa. He immediately boiled a pair of forceps, pulled out the splinter, dressed the small puncture wound with "dettol," and applied a bandage. Four days later, in the morning, while driving his bus, his back became stiff. The following day, 36 hours before admission, he noticed that his "gums were stiff"; there was some difficulty in chewing. On the day of admission he complained that while walking "something seems to run up and down my spine, and every now and then everything seems to stiffen up—throat, jaws, and back." For the last 12 hours he had been unable to swallow anything.

He was a well-built muscular man, alert and euphoric. He was lying quietly on his back with a stiff neck. There was no neck retraction. His spine was rigid and he was unable to sit up. He was edentulous and could separate his gums by only ¼ in. (1.58 cm.). There were no other abnormal signs, except for the presence of a small unhealed puncture-wound in the left antecubital fossa which appeared moist and unhealthy. There was no lymphangitis nor were there palpable lymph nodes.

A diagnosis of tetanus was made and treatment instituted as follows: Antitetanic serum, 100,000 units intravenously and 50,000 units intramuscularly, was given and sodium penicillin. 250,000 units six-hourly, begun. Myanesin, 1 g. in 20 ml. distilled water, was then given intravenously at 11.10 p.m. Within 30 seconds the patient smiled, said he had not felt so well for days, and asked for a drink. He sat up in bed and could bend his neck so that his chin almost reached his chest. His trismus disappeared and he could separate his gums by about 1½ in. (3.75 cm.). He was then given 2 g. of myanesin in 2 oz. (57 ml.) of the elixir by mouth. He took one sip and complained of a burning sensation in the mouth; the elixir was therefore diluted with an equal quantity of water. He still found it rather hot and sipped it slowly. At the fifth sip he clutched his throat, had a violent attack of coughing, and, with his eyes bulging and tears streaming down his cheeks, rapidly became greatly distressed. The paroxysm lasted about two minutes, and on his recovery he said, "It went down the wrong way, doctor." It was noticed that though he had stopped coughing a rattling noise was coming from the trachea. From then on until his death signs in the chest became progressively more prominent. The patient was encouraged to finish his elixir and was given a further 2 oz. half an hour later. With this second dose there was again a paroxysm of coughing. With neither of these paroxysms was there any return of spasticity. At 12.30 a.m. he was taken to the theatre and his wound excised under nitrous oxide, oxygen, and "trilene" anaesthesia. A swab from the wound failed to yield any *Cl. tetani* on culture. Unfortunately the tissue removed was not examined. More myanesin was then given—2 oz. of the elixir at 2 a.m. and 4 a.m., the latter dose being swallowed slowly and with difficulty. At 5.15 a.m. abdominal cramps and dysphagia necessitated a further 1 g. myanesin in 20 ml. distilled water intravenously. Relaxation was immediate, and at 6 a.m. the patient managed to drink a further 2 oz. of the elixir. At 9 a.m. he objected to the elixir, so crushed tablets (2 g.) were substituted. At 9.15 a.m. he tried to cough up some mucus, became intensely cyanosed, and had a generalized clonic convulsion with loss of consciousness. Mucus was sucked from his pharynx, and after artificial respiration and the administration of oxygen with 5% carbon dioxide he

recovered. Postural drainage then produced a good deal of thick mucopus. Numerous rales could now be heard at both bases and in the left axilla. At this stage lumbar puncture yielded normal fluid. The urine was clear. At 11.15 a.m. a further 2 g. crushed tablets of myanesin was prescribed, but he was unable to swallow the powder, and it was noticed that some of the previous dose was still adhering to the tongue and the pillars of the fauces. It was therefore decided to give 1 g. myanesin intravenously and then pass a stomach tube. However, every effort to pass a Ryle's tube or an oesophageal catheter (12E) resulted only in tracheal intubation. It is noteworthy that this caused no distress or cough. The attempt was then abandoned. A further 1 g. myanesin was given intravenously at 3 p.m., and soluble phenobarbitone 3 gr. (0.2 g.) intramuscularly as he had not slept since admission. A quarter of an hour later he again started to cough, became cyanosed, and had clonic convulsions. Resuscitation failed, and he died.

At necropsy the brain was intensely congested, but apart from this appeared normal. The trachea and bronchi contained a moderate amount of mucopurulent fluid, and there was marked congestion of both lungs with bronchopneumonia at the bases. The heart showed no macroscopic abnormality. The liver was congested. The spleen and kidneys appeared normal.

Discussion

Cole and Spooner (1935) describe four degrees of severity of tetanus. In the second degree there is generalized tonic rigidity; in the third the tonic rigidity passes on to the stage of reflex spasms. Our Case 1 corresponds to the third category, and according to those authors this bears a poor prognosis. Case 2 corresponds to the second category, in which the prognosis is better; but the short incubation period in this case indicates a severe attack. Both patients responded extremely well to intravenous myanesin, and in the first case the oral myanesin was of considerable value in controlling spasm.

In the first patient it appeared that during the last three days of his illness the tetanic symptoms were under control and required only small doses of antispasmodics and sedative, but he had already developed signs of bronchitis by the second day in hospital, and it seems likely that he was too heavily sedated during his first 15 hours of treatment. It is not thought that the myanesin was responsible for the development of the chest complication, as even when given intravenously it did not depress respiration. The two drugs appeared to have a synergistic action, as when both drugs were given the patient was easily controlled; but when, as during the second night in hospital, the myanesin was withheld, a very violent spasm occurred (see Graph). Both drugs were easily administered. The sodium thiopentone was given rectally in 10% solution. The patient could swallow freely, or the elixir could easily have been given by tube.

With the second patient, although the elixir was diluted with an equal quantity of water after the initial sip, it still burnt his throat and he was unable to swallow it as a draught. After a few minutes he found that the solution no longer burnt him. This we now believe to have been due to the local analgesic action of the elixir on the pharynx. It was at this stage that there was the first violent fit of coughing: quite clearly some of the elixir entered the trachea. From this point a rapidly progressive purulent bronchitis developed. With the second dose further elixir was inhaled. The substitution of powdered tablets for the elixir, coming at a time when swallowing was again difficult, resulted in the powder adhering to the tongue and the mucous membrane of the mouth and fauces, where it exerted its local analgesic action. It was this analgesia that accounted for the stomach tube passing straight into the trachea at every attempt without producing any cough or distress. It is probable that during this period saliva containing dissolved and undissolved myanesin was trickling down the trachea. This would account for the very rapid development of the severe bronchitis in a man with no previous chest history who was receiving penicillin and was nursed sitting upright throughout his illness.

The asphyxial attacks seemed to be due to mucopus being coughed up and accumulating at the back of the pharynx. The presence or absence of laryngeal spasm could not be determined, but it was noticed that there was no trismus or neck stiffness. The convulsions followed the intense cyanosis and were presumably anoxaemic in nature rather than tetanic.

Myanesin has two properties. It causes muscle relaxation by an action on the central nervous system: this may be a depressant action on the reflex excitability of the spinal cord. Its second property, on which no emphasis has been placed in the literature to date, is its local analgesic action. This we believe to be important, and indeed consider it to be directly responsible for the fatal outcome in Case 2. In view of this local analgesic property we feel that myanesin should not be given by mouth to patients with tetanus, in which dysphagia is a common occurrence.

A suggested scheme of treatment would be to begin with an intravenous injection of myanesin, 1 g. in 20 ml. distilled water. This should cause relaxation and enable a Ryle's tube to be passed into the stomach. Two ounces of myanesin elixir could then be given via the tube and repeated half an hour later. In the early stages two-hourly doses of 2 oz. (57 ml.) myanesin elixir by stomach tube would probably be needed, and it might be necessary also to give 0.5 g. thiopentone per rectum. Later the dose of myanesin could cautiously be reduced and the time interval between doses increased. It is felt that the intravenous preparation is of considerable value in the rapid control of severe spasms. The risk of haemoglobinuria after oral myanesin appears to be remote, as it did not recur in our patient after a further 40 g. by mouth, nor did Godman and Adriani (1949) report it in any of their eight cases. In those cases in which oral intubation is difficult or poorly tolerated myanesin could be given in doses of 1 g. intramuscularly.

It is stressed that myanesin should be used solely as an adjunct to treatment with antitetanic serum, penicillin, and local wound excision. The patient should be sedated as little as possible and nursed in the sitting position.

Summary and Conclusions

Two fatal cases of tetanus treated with myanesin are described. The first case also received rectal thiopentone.

Investigation showed that myanesin, given intravenously and orally, is a useful relaxant and controls tetanic spasms satisfactorily; and that when used in therapeutic doses it does not depress respiration.

Myanesin has a local analgesic action and should never be given in powder form by mouth. The elixir should not be given when there is dysphagia. When administered intravenously the risk of haemoglobinuria is diminished by adequate dilution, and may be ignored.

In the second case death occurred from lung complications due to the inhalation of myanesin elixir.

We wish to thank Dr. A. Lisle Punch for permission to treat and publish the first case.

CASE OF TETANUS TREATED WITH DECAMETHONIUM IODIDE

BY

R. McD. S. KEIR, M.B., D.A.

Anaesthetist to the Belfast City Hospital and the Samaritan Hospital

In the treatment of tetanus the efficacy of muscle relaxants in preventing exhaustion of the patient from excessive muscular activity has already been shown. Curare has been used by several workers (Hoche, 1894; Cole, 1934; Mitchell, 1935; West, 1936; Cullen and Quinn, 1943; Adriani and Ochsner, 1947; Ory and Grossman, 1948); more recently the use of "myanesin" (mephenesin) has been reported (Belfrage, 1947; Davison, 1949; Davison *et al.*, 1949). It may be of interest to report a case of tetanus in which the relaxant used was the much discussed bistrimethylammonium decane di-iodide (decamethonium iodide, or C10). There were four main reasons for the choice of C10: (1) Both D-tubocurarine chloride and "flaxedil" had been tried by the physicians in charge of the case, with the production of marked respiratory depression and profuse salivation. (2) Myanesin was considered, but, in view of its tendency to produce haemoglobinuria, was rejected. (3) Experience with C10 in anaesthesia has shown that adequate relaxation of the larger skeletal muscles could be achieved without profoundly depressing respiration, and without relaxing the pharyngeal muscles. (4) C10 has less power to liberate histamine than D-tubocurarine chloride and therefore to produce bronchospasm.

Case Report

A girl aged 19 was admitted to the Belfast City Hospital on April 28, 1950, with a history of trismus and severe backache for four days, and opisthotonos and spasms, with very severe pain since the previous day. Two weeks previously she had got a wooden splinter under her finger-nail.

On examination she was seen to be a healthy, well-nourished girl, with a typical risus sardonicus, moderate opisthotonos, and marked trismus—being unable to put out her tongue, and spasms lasting 20 seconds occurring every two minutes; between spasms the muscles were rigid. A clinical diagnosis of tetanus was made (unfortunately the splinter was thrown out with the soiled dressings and a piece of loose nail which separated), and the patient was treated with massive intravenous doses of A.T.S., penicillin, and sedatives. This treatment was successful at first, but spasms returned as soon as the effect of sedation lightened and she became restless.

On the third day small injections of curare in oil were tried, with no effect. Intravenous D-tubocurarine chloride was then tried in 10-mg. doses, and flaxedil in 40-mg. doses, both achieving profound relaxation with respiratory depression for periods of about 30 minutes, after which rigidity and spasms returned as before. The pulse rate and temperature remained high, and the patient's general condition was poor. The physicians in charge of the case decided to seek my opinion as an anaesthetist, and the following treatment was carried out.

On examination the patient was distressed, crying out with the pain of the spasms, flushed, and sweating profusely, and the muscles of the trunk and limbs were rigid. It was decided to try the effect of C10. At 11.45 a.m. on May 2 a slow intravenous injection of C10 was started, 1 mg. at a time. During half an hour 5 mg. was given, producing some relaxation and no respiratory depression. A further 3 mg. was given over the next 15 minutes. The respirations became shallow and cyanosis developed. The injection was stopped and the patient was turned on to her side with her head over the side of the bed, and oxygen was administered by mask. The pharynx filled with sticky mucus, which was periodically swabbed out. She remained unconscious for one hour. The breathing then became noticeably deeper, and she opened her eyes. Fifteen minutes later she was sitting propped up, coughing, and blowing out mucus. After another 15 minutes 1 mg. of C10 was given intramuscularly with 50 mg. of pethidine intravenously and 50 mg. intramuscularly. She was then put in an oxygen tent at 2 p.m.

Small intramuscular doses of C10 and pethidine were given at 7 p.m. and the patient remained comfortable until 9.45 p.m., apart from slight tremors which were seen mainly on effort. Spasms then returned, and a further intravenous injection of 2 mg. of C10 with 50 mg. of pethidine was given, followed by the same dose intramuscularly. An extract from the notes summarizes the effect of these injections. "10 p.m.: Patient restless, crying out, tearful, and frightened. After injection: Quiet, rational, grateful."

In 48 hours 50 mg. of C10 and 950 mg. of pethidine were given. Spasms returned as the effect of the injections wore off, but were easily controlled, and the patient's general condition was much improved. On the evening of the third day of treatment her temperature rose and coarse crepitations were heard at the left lung base. C10 was withheld and a course of streptomycin started. She was encouraged to cough, and postural drainage, with deep percussion, was instituted. With the energetic co-operation of patient and nursing staff the chest was cleared in less than 24 hours. During this time it was necessary to increase the dosage of pethidine to 600 mg. a day. Pain was fairly well controlled, but spasms were troublesome and sleep was disturbed.

After this incident 1/100 gr. (0.65 mg.) of atropine was given six-hourly to cut down secretions. Treatment with C10 was restarted and continued for a further five days, dosage and frequency being judged by the response of the patient. The usual requirement was 2–3 mg. every four to five hours. It was found that, even with the large amounts of pethidine being given, a soporific was necessary at night. The chest remained clear, the spasms became less frequent and less severe, and her general condition improved.

On the evening of the tenth day of the treatment (the fourteenth day since admission) it was noticed that the occasional spasms now coincided with the appearance of the medical attendants. We came to the conclusion that the patient had probably

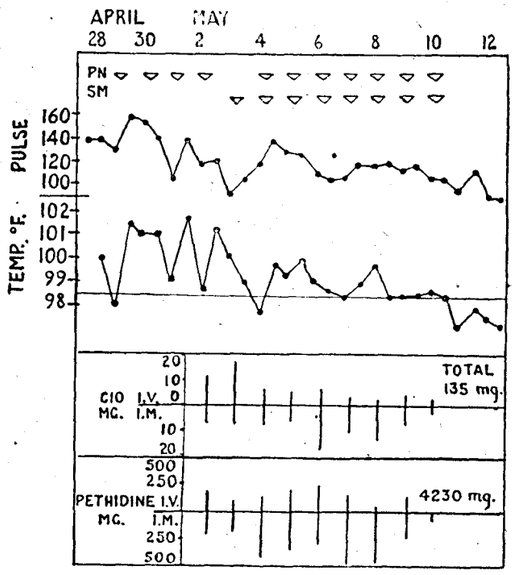

Chart showing dosage. PN = Penicillin. SM = Streptomycin.

developed a mild addiction to pethidine. Paraldehyde, 4 mg., was given intramuscularly. This raised a storm of tearful protest, but the patient slept soundly and no further spasms were seen. On May 15 she was up in a chair, and on May 23 walked with assistance. The muscles were still sore and stiff, but recovery was helped by physiotherapy. She was discharged on June 8.

The total dose of C10 was 135 mg., representing a daily average of 15 mg., and of pethidine 4,230 mg., with a daily average of 470 mg. The distribution is shown in the Chart.

Discussion

The treatment of tetanus with relaxants is not curative. It is still necessary to give A.T.S. and penicillin in massive doses and to build up the patient's general resistance. The experience gained in the treatment of this case, together with a study of the literature, enables certain general principles to be stated.

Sleep.—Even when painful spasms are abolished there may be a fair amount of residual pain from aching and torn muscles, so that an analgesic must be prescribed as well as sedatives to ensure sufficient sleep.

Secretions.—It is futile to abolish the spasms of tetanus, only to let the patient drown in his own secretions. Atropine is useful to cut down secretion. The cough reflex must not be dulled by sedatives, and the patient must be encouraged to cough. If necessary, curarization must be lessened to enable the patient to cough.

Oxygen.—Adequate oxygenation must be ensured. Anoxaemia increases the permeability of the capillaries in the lungs, allowing fluid to escape into the alveoli. If respiratory depression is present, oxygen must be administered. It is suggested that if adequate ventilation cannot be maintained by other means the patient might be nursed in an iron lung.

Nutrition.—Feeding presents no difficulty, since with C10 the patient is usually able to swallow. If, however, the effort proves exhausting, a fine plastic tube, as recommended by Bull *et al.* (1949), can be passed into the stomach with remarkable ease.

Fluids.—Fluid intake and output should be checked and an adequate balance maintained. If the temperature is high, much fluid may be lost by sweating and through the lungs. Haemoconcentration should be watched for by repeated haemoglobin estimations. Urinary chlorides should be estimated and any deficiency made good.

There should always be available a supply of oxygen, with a facepiece and reservoir bag, a mouth gag, tongue forceps, a sucker, and a supply of gauze wipes, a laryngoscope, and endotracheal tubes.

Comparison with Other Relaxants

The causes of failure with curare in the treatment of tetanus are the inadequate margin between the lissive dose and that causing respiratory paralysis, bronchial spasm, and accumulation of secretions.

Myanesin seems to have none of the disadvantages of curare. It has, however, two of its own: a tendency to cause venous thrombosis at the site of injection, and the production of haemoglobinuria. Davison (1949) makes out a very good case for the use of this drug in tetanus. He points out that proof of haemoglobinuria is lacking, since the breakdown products of the drug may produce a positive reaction to the benzidine and guaiac tests, and, further, that in no case has the so-called haemoglobinuria been shown to have any adverse effect on the patient.

C10 has the disadvantages of neither curare nor myanesin. In the above case, on only one occasion was respiration depressed to such an extent as to require inflation of the lungs with oxygen. This occurred with a very large dose —9 mg.—given initially. It is of interest to note that this amount was required to produce relaxation after two intravenous injections of 5 mg. of D-tubocurarine chloride had been given 50 minutes and 1 hour previously. This confirms the experimental finding of Paton and Zaimis (1948) that, although the potency of D-tubocurarine is not affected by the previous administration of C10, twice as much C10 is required after a previous dose of D-tubocurarine. Subsequently, the dosage averaged 2–4 mg. at three- to four-hourly intervals. On one occasion 5 mg. was given, but this dose paralysed the intercostals, and, though no cyanosis was seen, the patient was put in the oxygen tent.

West (1936) expressed the opinion that the development of bronchial spasm was a very real danger in the use of curare. The occurrence of this complication is probably less likely with the pure D-tubocurarine chloride now available, but even with this material it is still seen fairly often. Paton and Zaimis (1948) found that the power of C10 to liberate histamine was one-quarter that of an equivalent dose of D-tubocurarine. This leaves an adequate margin of safety.

Accumulation of mucus was seen after the first dose of C10, and on the third day there were signs of fluid at the base of the left lung. Otherwise there was no trouble with excessive secretion. Coughing and swallowing were possible throughout the treatment. I feel that the choice of analgesic helped to achieve this result.

Pethidine is structurally related to atropine, and has mild atropine-like properties (Batterman and Himmelsbach, 1943). In addition to its analgesic and sedative action, it has, in contrast to morphine, an antispasmodic effect on smooth muscle, including bronchial musculature, and causes very little depression of respiration or of the cough reflex. Despite the enormous amount given, no ill effects were seen, and there were no withdrawal symptoms.

Summary

A case of tetanus treated with C10 and pethidine is presented.

It was found possible with these two drugs to control the spasms, abolish the rigidity, and relieve the pain of tetanus without unduly depressing either respiration or the cough reflex.

The advantages of pethidine as an adjuvant to the relaxant treatment are commented on.

The case is reported in the hope that others may be encouraged to give C10 a further trial. I should be interested to hear of any other cases.

I wish to thank Dr. T. Howard Crozier and Dr. F. Pantridge for allowing me to co-operate in the treatment of this case, and for their help and encouragement; Dr. T. Leitch for his help in carrying out the treatment; and the sisters and nursing staff of ward 15 for their invaluable assistance.

PROLONGED INTERCOSTAL PARALYSIS DUE TO A RELAXANT

BY

H. BARRIE FAIRLEY, M.B., B.S.

Junior Registrar, Department of Anaesthetics, Westminster Hospital

The following case may be of interest to anaesthetists. As relaxants are only a recent addition to the anaesthetist's armamentarium, any complication following their administration is worthy of record.

Case Report

A woman aged 33 was recently admitted to hospital for hysterotomy and sterilization. Seven years ago, following lobar pneumonia, she contracted acute nephritis, which has since become chronic. Three years ago a pregnancy was artificially terminated owing to the onset of incapacitating symptoms related to her nephritis; and for the past two years she has been subject to intermittent attacks of blurred vision.

Six weeks before admission investigations made at another hospital were reported to her doctor as follows: blood urea, 60 mg. per 100 ml.; urea concentration, less than 2 g.% on all readings; urea clearance test, "very low percentage"; renal function "very poor."

On admission the patient looked well. She had oedema of the ankles; albuminuria ++; her blood pressure was 180/110 and haemoglobin 55%. There was no evidence of cardiac failure or respiratory disease. Pre-operatively, 1 pint (570 ml.) of whole blood was given.

Anaesthesia was induced with sodium thiopentone, 0.4 g. The nose was sprayed with cocaine 15%. Hyperventilation was achieved with nitrous oxide, oxygen, and carbon dioxide, and a No. 8 nasal tube was passed blind. "Flaxedil," 100 mg., was then given, anaesthesia being maintained with a mixture of nitrous oxide and oxygen with minimal cyclopropane. After half an hour the abdominal muscles were beginning to tighten; a further dose of flaxedil, 40 mg., was therefore given. After each dose of relaxant the respirations returned in approximately two minutes. The patient being in the Trendelenburg position, assisted respiration was continued throughout.

After 55 minutes the operation was completed. The patient appeared to be maintaining a good colour, though the respirations were only diaphragmatic. She coughed slightly on extubation and was returned to the ward with an oral airway.

About 10 minutes post-operatively she appeared cyanosed. The colour improved immediately on reintubation and administration of oxygen.

About 1½ hours post-operatively, and shortly after extubation, consciousness returned and the patient asked for a drink. Shortly after this she became unconscious and was breathing "very shallowly." Breath sounds were present in all areas. She was slightly cyanosed. Pulse 130 a minute. Her colour improved with oxygen.

2 Hours Post-operatively.—Blood pressure 260/150. Eyes directed upwards (pupils equal and reacting minimally to light). A provisional diagnosis of hypertensive encephalopathy was made. Respirations diaphragmatic; chest wall sucked in on inspiration. Owing to the presence of moist sounds in the trachea and main bronchi, blind intubation and tracheo-bronchial suction were carried out. Oxygen was given. Magnesium sulphate was introduced rectally and hypertonic sucrose intravenously.

3¼ Hours Post-operatively.—Consciousness returned. Blood pressure 180/110. Patient a little distressed by tube.

3¾ Hours Post-operatively.—Extubated, as good colour was being maintained. Respirations still only diaphragmatic.

5 Hours Post-operatively.—Slightly cyanosed. No improvement in respiratory excursions. Chest wall still indrawn on inspiration. Accessory muscles still active. Conscious. No. 6 tube passed blind after cocainization of nose and pharynx. Tracheo-bronchial tree again sucked out. Patient indicated immediate subjective improvement. From this point onwards the nasal tube was left *in situ* and intermittent tracheo-bronchial suction performed, mucoid material always reaccumulating. The patient's condition appeared to be gradually deteriorating.

9¼ Hours Post-operatively.—Blood pressure 220/150. Patient very distressed. Otherwise no change.

10¾ Hours Post-operatively.—E.C.G. showed sinus tachycardia only. Lumbar puncture revealed normal pressure.

12¼ Hours Post-operatively.—Bronchoscopy performed: small amount of mucoid material removed.

13 Hours Post-operatively.—Atropine, 1/100 gr. (0.43 mg.) and neostigmine, 1.25 mg., given. Immediate improvement. Intercostal muscles came into action. Patient quickly returned to "normal." No further post-operative complications.

Comment

Whilst one would not presume to dogmatize about the reason for this occurrence, the following points of interest emerge: (1) Even excessive doses of flaxedil are known (in animals) to be excreted unchanged in the urine—30–100% in two hours (Mushin *et al.*, 1949). (2) The dosage of relaxant, though generous, was not excessive. (3) This patient has very poor renal function. (4) It would appear that the return of diaphragmatic respirations after the administration of flaxedil is not necessarily followed soon by the return of intercostal muscular tone. (5) Further confirmation is given of the fact that inadequate respiratory excursions are not detrimental to the patient provided adequate oxygenation is maintained.

The giving of neostigmine was delayed for two reasons: (*a*) The uncertainty whether it was indicated. Initially, the recovery of consciousness followed by a period of coma with concomitant increase in hypertension confused the picture from the anaesthetic aspect. (*b*) Following this, one was hesitant to administer neostigmine in view of its possible effects on the cardiovascular system.

We await the results of further renal-function tests.

Summary

A case is reported of prolonged loss of respiratory muscular tone following intravenous injection of 140 mg. of flaxedil in a woman with severe renal damage.

The picture is complicated by symptoms suggestive of hypertensive encephalopathy.

I wish to thank Mr. A. Briant Evans and Dr. J. B. Wyman for permission to publish this case.

In consultation with the Invalid Children's Aid Association, the British Rheumatic Association is now determining how much it should be responsible for the care of children with rheumatic hearts. Local authorities in most areas operate a scheme providing for the medical and educational needs of these children, and, while most can return to their own homes after treatment and convalescence, there remain a small and at present unknown number of children who have either unsuitable homes or none at all. These sufferers, together with mothers of several young children, one of whom may need continuous care, need domestic help to prevent the suffering of either the invalid or the rest of the family. This problem is being taken up by the British Rheumatic Association's local branches. A threefold line of sociological inquiry is now being conducted: one forms part of the research by the Medical Research Council at the London Hospital; another will be based on information provided by the Registrar-General.

Medical Memoranda

Hypertrophy of the Little Finger

In these days, when "compensationitis" is so prevalent and when the examination of patients for insurance claims tends to give the surgeon a somewhat disillusioned opinion about the recovery powers of the average person following trauma, it is refreshing to meet a case such as is described here.

Case Report

A man aged 54 came to the Leith Hospital surgical out-patient department on June 17, 1949. He had fallen off his cycle and bruised his right hand. A radiograph showed a small crack in the metacarpal surface of the right trapezium bone. The injury was of a minor nature, and he made a good recovery with no special treatment beyond supporting strapping for a fortnight.

Radiograph of the patient's hands. Note the thickness of the fifth right metacarpal and the increase in size of the fifth right finger compared with the left.

Attention was drawn, however, to the deformed condition of the right hand, from which the fingers and thumb were absent with the exception of the fifth finger. The patient said that this was the result of a shrapnel wound in France in September, 1918. He had been treated in a field hospital, had had one operation, and had been discharged within a month. When the wound had healed he started work as a miner, and had been employed in the pits for over three years. The scar had not been painful, and he had been able to grip the handle of a shovel firmly between his little finger and the remaining portion of his right hand. After leaving the mines he had continued at various forms of labouring, and had been able to work without difficulty; his present job is lifting bales of paper, etc., in a stationery office. Examination of the right hand showed the little finger to be almost as long as, and actually thicker than, the middle finger of the left hand; it was much larger in every dimension than the left little finger. The patient demonstrated the surprising strength of the grip of his right hand, in spite of the tenderness due to the recent injury. This power was largely owing to the great development of the "opposition" element in the movements of the fifth finger. The fifth metacarpal segment had become hypermobile, with excessive development of the muscles of the hypothenar eminence, so that the fifth finger could be swung across the palm to the first metacarpal, which was relatively fixed.

The scars of the traumatic amputation had healed cleanly without becoming adherent to the stumps of the third and fourth metacarpals, and there had been no development of stump neuromata. The patient had therefore been able to use the hand vigorously from the start without pain. Shorn of all its members save the weakest, the hand nevertheless had been used unsparingly in the one way it could—namely, gripping—and it had responded. The bones of the fifth finger could not grow in length, as the epiphyses were already ossified, but they became thicker and stronger, especially the metacarpal, to which the opponens muscle is attached. The right hand, though only a remnant, is to-day the hand of a strong labouring man. The accompanying radiograph demonstrates the features noted above, particularly the hypertrophy of the soft tissues of the fifth right finger.

This case illustrates the truth of the old adage, "Where there's a will there's a way." It shows how well Nature responds to the demands of a determined man in overcoming gross mutilations. It makes one more than ever sceptical of those patients who come for examination on compensation claims, months after some comparatively minor injury, holding their fingers stiff and useless and their healed scars still swathed in bandages.

James A. Ross, M.D., F.R.C.S.Ed.,
Assistant Surgeon, Edinburgh Royal Infirmary and Leith Hospital.

Status Epilepticus: A Symptom Complex of African Trypanosomiasis

The following case, in which the cerebral stage with meningo-encephalitis was complicated by an attack of status epilepticus, is of interest. Few patients present themselves for treatment during the incubation or febrile stage.

Case Report

The patient, a married man aged 33 with two children, was a native of Georgetown, which is in the tryanosomiasis endemic area (138 cases in the first eight months of 1949). He had been a ferryman at the southern crossing of the river at Sankuli Kunda for ten years. He had been in fairly good health, with only irregular attacks of some of the more common diseases—malaria, yaws, etc. The present illness started on June 1, 1949. He had attended the funeral of a friend, and on his return home he suddenly became confused, exhibiting abnormal behaviour and a tendency to sleepiness. Later he grimaced, became apathetic, more confused, rambling in his speech, and difficult to manage at home. He also complained of headache and fever. After an unstable recovery on native methods of treatment, he was admitted to Bansang Hospital on June 20.

On admission he was in a state of acute maniacal excitement. His temperature was 99° F. (37.2° C.), pulse 80, and respirations 20. A general physical examination revealed nothing grossly abnormal in the vital systems. Laboratory investigations showed that malaria parasites were not present in the blood, and that trypanosomes were present in the cerebrospinal fluid and gland juice. His excitement was controlled by 1 g. of hexobarbitone, and a course of "antrypol" and tryparsamide injections was started.

Six days later his condition had greatly improved. After the first injection of 1 g. of antrypol he became sensible, co-operative, well orientated in place, took his food, became interested in his condition, and expressed his gratitude for the care that was taken in his case. This improvement continued for another nine days, until July 5. On the morning of this date he had his third injection (2 g. of tryparsamide). At about 1 a.m. next day he had an epileptic fit which continued for two hours with only a few seconds between the attacks. This status epilepticus was controlled by 1 g. of hexobarbitone intramuscularly. He became somnolent and continued in this state for 36 hours. On recovery he was garrulous, incoherent in his speech, restless, untidy in his habits, refused his food, and was a danger to himself. Another physical examination disclosed no abnormality. The plantar response was flexor.

The excitement continued until July 15. During that time he was agitated, aggressive, noisy, restless, difficult with his food, and cantankerous. He slept for long hours between attacks, which lasted on the average about 20 minutes. On July 18 laboratory investigation revealed that trypanosomes were present in the gland juice and cerebrospinal fluid.

He entered into an apparently lucid period on July 16 and continued fairly well behaved and co-operative till August 8, when he again became noisy and confused and exhibited grotesque behaviour. He was auditorily and visually hallucinated. He spoke to imaginary people around him and complained that they said they were going to kill him. During the relapse on August 8 he had another attack of status epilepticus, and this recurred the following day. The cerebrospinal fluid was again examined, but this time trypanosomes were not present. This relapse lasted only two days, after which he became normal with only an occasional outburst of shouting and delusional displays.

He maintained his improvement and on August 16 inquired whether the man in his place had been informed that he was "well" and would soon go home. He became preoccupied with his discharge from hospital and continually inquired when he would be allowed out. This unstable recovery he maintained until his discharge on September 16. He was facile, childish, mentally retarded, stereotyped in behaviour, but easy to manage. He was discharged to the care of his relatives.

Comment

Trypanosomiasis with epilepsy has already been reported. This case had an additional symptom complex—namely, that of status epilepticus. It is to be noted that these epileptic episodes had no relation to the presence or absence of trypanosomes in the cerebrospinal fluid. It is possible that the attacks were due to a structural damage to the brain itself.

Medical practice in the Tropics is prejudiced by the delay before hospital facilities are sought. This is sometimes due to ignorance and sometimes to fear. It is possible that cases of this nature may not be brought to hospital until an attack of status has begun, or during the post-epileptic somnolent stage, which in the above case lasted for thirty-six hours. In trypanosomiasis endemic areas all patients brought to hospital in epileptic fits or seemingly unconscious must be suspected of having trypanosomiasis in addition to the other more common causes—cerebrospinal meningitis, cerebral malaria, and hysteria.

I wish to thank the Acting Director of Medical Services, Dr. T. P. Eddy, for permission to publish this case, and Dresser-dispenser Wilson for his invaluable assistance in the compilation of the record and for translating the patient's Mandinka.

Edward F. B. Forster, M.D.,
Medical Officer in Charge, Bansang Hospital.

Case of Double-headed Monster

This is a case of twins united by the trunk (thoracopagus and dicephalus).

Case Report

A 3-para aged 25 was at full term. Her first delivery was a breech, the second a vertex, both children being alive and normal. At the antenatal examination the presentation was diagnosed as breech. An unsuccessful attempt at external version was made at 34 weeks, but no further efforts were made as the patient was a multipara and had had a previous successful breech delivery.

Labour started at 4.30 a.m. and she was admitted at 5.30 a.m., when the cervix was near full dilatation. The membranes were intact and both feet could be felt. Labour was allowed to proceed normally. The membranes ruptured at 6.40 a.m. and the first foot was delivered in five minutes, followed by the second with the next pain. The descent of the foetus was slow, but nothing was suspected until a third foot presented at the vulva. On examination another foot was felt and a second pelvis. The patient was fully anaesthetized and a hand was inserted to push up the posterior foetus in order to deliver the anterior twin. This was found to be impossible, and the correct diagnosis was made only after thorough palpation with the whole hand inserted.

As the two pelves were causing obstruction, one was amputated at the level of the superior crest of the ilium. Traction even then failed to effect any progress owing to the size of the trunk, and the second pelvis was also amputated at the same level. This allowed for the compression of the body, and all the four hands were brought down one after the other. The next problem was the delivery of the two heads. I decided to cut off one of them with a hook, and in order to reach it asked my assistant to exert steady traction on the trunk upwards towards the mother's abdomen while I inserted my hand from behind to reach the posterior neck to insert the hook round it.

This manœuvre resulted in an unexpected delivery of both heads one after the other. The convexity of the anterior head fitted in the concavity of the posterior neck, and the posterior head was first delivered over the perineum followed rapidly by the anterior head, thus making the amputation of one of the heads unnecessary.

The third stage was quite normal: the placenta was delivered complete after 10 minutes at 8.10 a.m. There was only one umbilical cord. The perineum was not torn, though there was a good deal of bruising. Penicillin and sulphonamides were given as a prophylactic measure, and the patient made an uneventful recovery.

The Foetus.—Permission to preserve the specimen and for further post-mortem examination was refused. The combined trunk was very big, and the line of fusion of the two trunks is oblique and can be seen clearly in the accompanying photograph. The umbilical cord was inserted between the two pelves. The left anterior hand and the right posterior hand belonged to one of the twins and vice versa owing to the oblique plane in which the two trunks had joined. Both foetuses were female and completely separate from the neck upwards and from the pelvis downwards. The parts were fairly well developed, the total weight being 11 lb. (5 kg.). The heads were also of normal size, and I was surprised at their normal delivery, though the mother's pelvis was roomy.

WEIR MITCHELL

S. Weir Mitchell: Novelist and Physician. By Ernest Earnest. (Pp. 279. £1 8s.) London: Geoffrey Cumberlege. 1950.

We have waited a long time for an adequate biography of Silas Weir Mitchell, America's foremost and first neurologist. Born in Philadelphia in 1829, four years after Charcot, six years before Hughlings Jackson, and sixteen years before Gowers, Weir Mitchell was blessed with robust health and vitality despite the handicap of an essential tremor of his upper limbs. His vigour thus enabled him to endure a long life and a full one, glorying in his achievements as a pioneer in medicine, a novelist, a poet, and a *bon viveur*. Perusal of his life story teaches us that, albeit difficult, it is possible for a neurologist to be a man of culture and sensitivity; that he can live to the advanced age of 84 continuing in a busy consulting practice, and, what is more, continue to be a valuable hospital physician.

The biographer is not himself a medical man, and perhaps the purely technical aspects of Weir Mitchell's career are subordinated so as not to dismay a general reader. We are left in ignorance of many things we should like to know. The first year of postgraduate study was in Paris, but we are not told where. His work abroad must have been a powerful stimulus, for Weir Mitchell was one of the early few who introduced into American medicine the European conception of research. A most competent physician with an overpowering presence, he made a considerable impression, especially upon his large circle of adoring female patients. He was not a good teacher; for his faulty memory compelled him to relearn his material, and he consequently disliked lecturing. His mind was original, suggestive, fertile—"yeasty," as his friend L. Keen put it. He was unlucky in his successive application for professorships in Philadelphia, but no doubt mankind benefited therefrom, for, as Oliver Wendell Holmes said of him, "Perhaps it is hardly desirable that an active man of science should obtain a chair too early, for I have noticed . . . that the wood of which academic fauteuils are made has a narcotic quality which occasionally renders its occupant somnolent, lethargic, or even comatose!"

Although Weir Mitchell was a close friend of Osler, he seems to have been no great admirer of England. Perhaps it is the biographer who is responsible for the acidulated remarks on British weather, which we cannot help, on British cooking, which is fair enough, on the British attitude towards the American Civil War, which is understandable, and on the huge feet of British women, which is absurd.

Weir Mitchell's hospital clinic for nervous disorders was founded in 1861, and hence was the oldest in the States and one of the oldest in the world. His career as a novelist did not begin until he was 51, and he wrote until the time of his death at the brink of 85. His fiction was always of a psychological genre, and he has been compared to Henry James and to O. W Holmes. Though his novels are often problem-studies in human affairs, they are marked by a certain primness—an attitude which the biographer sums up by emphasizing that he was a Philadelphian. His verse, we are told, was undistinguished. Weir Mitchell is associated with the successful treatment of certain neurotic states, a success which is probably due as much to his domineering personality as to his methods. Freud shocked him. After reading a library book on psycho-analytic beliefs Mitchell threw it in the fire, with the protest, "Where did this filthy thing come from?" Weir Mitchell was always a clubman, a socialite, and an assiduous attendant at boards of management. The last-named chore became more and more irksome to him, and eventually he expostulated to his wife that she should engrave upon his tombstone: "Committee'd to Death." This is a warning which modern physicians and surgeons might well take to heart.

THE BREAST

The Breast. Structure: Function: Disease. Edited by F. D. Saner, M.B., Ch.B.(Camb.), F.R.C.S. (Pp. 316; 193 illustrations. £2 5s.) Bristol: John Wright and Sons. 1950.

Many books, large and small, have been written on diseases of the breast, but this symposium seems to strike a happy medium between bare sufficiency and such prolixity as is suitable only for the extreme specialist. Here within the compass of some 300 pages we find all the essentials of the subject attractively discussed in a manner which is well balanced despite the multiple authorship. Indeed, it may be described as a very competent book of really useful size.

There is a good section on pathology, illustrated by excellent photomicrographs which do not appear to have lost much detail in reproduction. A particularly interesting chapter is that on the importance of spread of carcinoma along the internal mammary lymphatic chain. The author of it recommends that in early cases without extensive axillary involvement an intercostal biopsy should be performed at an early stage of the operation; if the immediate section report is negative a radical operation is carried out, but if the result is positive a simple mastectomy is done, the treatment of the secondary deposits being by radiotherapy.

The whole question of the relationship of surgery to radiotherapy is fully discussed and the final opinion is thus expressed: "The extent and timing of the respective use of surgery and radiotherapy is dependent on the state of the disease and will be subject to adjustment as experience increases, but the merit of a combination of the two methods is undoubted." There is a very useful appendix giving a summary of the statistical data relating to certain aspects of incidence, diagnosis, and outcome of treatment.

The only small criticism which we have to make is that the coloured illustrations, except the colour photographs, should have been omitted. They fail to give a recognizable impression of the conditions they set out to illustrate and in this way are misleading. No doubt they are good art, but a scientific subject like surgery does not allow of any artistic licence.

Norman C. Lake.

VENEREAL DISEASES

A Textbook of Venereal Diseases. By R. R. Willcox. (Pp. 439; 154 figures. £1 12s. 6d.) London: William Heinemann Medical Books. 1950.

The list of appointments, past and present, held by the author of this book is a guarantee that he knows what he is writing about; few, if any, venereologists can have studied venereal diseases in so many parts of the world. The book is admirably put together and the illustrations are excellent, showing what they are meant to show; the coloured plates are exceptionally clear. It will appeal to

venereologists all over the world and can be strongly recommended both for its sound teaching and for its wise advice.

The author ranges over the whole subject and includes accounts of those diseases of the Tropics and subtropics which closely resemble syphilis. He discusses also a number of para-venereal conditions seen commonly in V.D. clinics. The risks and nursing attention required when pyrexia is produced by T.A.B. given intravenously might with advantage have been set out more fully, for the reaction caused may on occasion be alarming to patient, doctor, and nurse. Unfortunately the literary standard of the book falls short of the technical, and more than a hundred errors, many of a minor nature, were noted; for some of these the proof reader must be held responsible.

DEFECTIVE CHILDREN

Children with Mental and Physical Handicaps. By J. E. Wallace Wallin, Ph.D. (Pp. 549; illustrated. £2 2s.) London and New York: Staples Press. 1950.

This book is intended to supply professional workers in the fields of special education with a modern reference book descriptive of mental and physical disease in children. The author has been for nearly forty years a specialist in the United States in the education of handicapped children, and if he had written only of matters within his special field he might have produced a first-class book.

The first part of the book is concerned with a description of mentally defective children—their types, classification, degrees of educability, and so on. So far as I can judge, these chapters constitute an admirable review, informed by special knowledge and wide experience.

It is impossible to write favourably of the part of the book on physical handicaps. It is composed without expert knowledge, it is peppered with references from old and modern authors indiscriminately selected and to whose papers the author in his preface ingenuously explains that he has not always had personal access, and he is equally undiscriminating in his selection of relevant subjects. For example, he describes such rare diseases as Wilson's disease, gargoylism, the Hand–Schüller–Christian syndrome, epiloia, Tay–Sachs disease, pituitary dwarfism, pubertas praecox, and so on, and yet he does not mention rheumatic heart disease or congenital cardiac disorders. In writing of mongolism the author devotes three pages to some fourteen described causes of mongolism, nearly all of them entirely speculative. In short, any worker who is concerned with handicapped children and who wants information about physical disease in children is advised to consult a standard textbook of paediatrics, whether English or American, rather than rely on the information provided in this book.

D. V. Hubble.

The Medical Annual, 1950 (John Wright and Sons, Ltd., 25s.), is the 68th of the series, and once again the many contributors, under the experienced editorship of Sir Henry Tidy and Mr. A. Rendle Short, have surveyed recent progress in medical science. The aim of the *Medical Annual* is to help the practitioner, and emphasis is of course on the practical aspects of recent developments; but even so this volume is remarkably comprehensive. Cortisone and the new antibiotic drugs are obvious subjects, but space has also been found for, among other things, a full description of the Pulheems system of medical classification and for a brief discussion of the discovery of oestrogen-like substances in clover and grasses. The usefulness of this volume is enhanced by excellent plates (some in colour), a comprehensive index, and a classified list of new books published in Britain and America.

BOOKS RECEIVED

Review is not precluded by notice here of books recently received

The Child and the Magistrate. By J. A. F. Watson. (Pp. 367. 12s. 6d.) Revised edition. London: Jonathan Cape. 1950.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY OCTOBER 28 1950

ANTICOAGULANT THERAPY OF ACUTE MYOCARDIAL INFARCTION

In assessing the value of any form of treatment for acute myocardial infarction it is essential to be closely familiar with all the details of the natural course of the disease. Failing this, the treated series must be compared with a like series of untreated controls. This platitude will be forgiven by those who realize the great difficulty in obtaining so simple a thing as the natural mortality rate for acute myocardial infarction and the many uncertainties that surround controls. Mortality figures given in the literature are mostly based on hospital experience, and vary from 8% for first attacks treated by means of rest and a low-calorie diet[1] to 78% in young adults.[2] Unless details are known, crude mortality figures mean little. For example, the largest series quoted by Drs. J. A. Tulloch and A. Rae Gilchrist in their article at page 965 is that reported by Yater and his colleagues,[3] in which the crude mortality rate was 50% of 866 cases. These patients were all under 40 years of age and all men. They were collected by the U.S. Army Institute of Pathology and the Veterans Administration. In 450 cases the diagnosis was established by necropsy; of these, 223 died abruptly or within 15 minutes, and another 45 died between 16 minutes and 2 hours. Thus more than half of the fatal cases would have been reported to the coroner in civil life. If all the immediate survivors had been sent to hospital, the mortality rate calculated by the hospital staff could not have exceeded 30%. Then, of the total of 866 patients, only 75 (8.6%) died after the first 24 hours. Again, while most fatal cases must have been included in the series, owing to the manner in which the material was collected "cases of many living patients were excluded because of inadequate data." The details of this large series therefore indicate that in American soldiers under 40 years of age acute myocardial infarction causes instant death in 16%, almost immediate death (within 15 minutes) in an additional 10%, and death within two hours in a further 5%. Of the remaining 598 patients who would have had a chance of reaching hospital and obtaining treatment, 107 or 18% died within 24 hours and 12.5% died afterwards of the acute illness. This gives a very different impression from the 50% mortality figure originally quoted. Similar data are needed about older men and women in civil life.

Anticoagulant therapy for acute myocardial infarction is now widely practised, and since it is an expensive and troublesome form of treatment there should be general agreement about its value. Tulloch and Gilchrist describe the treatment of 70 patients and compare the results obtained with the behaviour of the disease in 84 control subjects. Their claim that anticoagulant drugs reduce the mortality rate of acute myocardial infarction by one-half, and the incidence of thrombo-embolic complications also by one-half, must receive very close attention. Their conclusions are based on careful and well-presented work, and their controls appear to fulfil all requirements. Moreover, the same conclusions may be drawn from data which they have collected from the literature. Yet there may still be some who are not quite satisfied, or who feel that anticoagulants should be reserved for particular cases rather than used routinely. By far the largest treated series in the literature is that collected and reported by a special committee set up by the American Heart Association.[4] This series comprised 432 cases, and results were compared with those obtained in 368 controls. The mortality rate was 24% in the controls and 15% in the treated group. The difference was attributed chiefly to a reduction in thrombo-embolic deaths—3% in the treated patients and 10% in the controls. The incidence of thrombo-embolic manifestations was 25% in the control group and 11% in the treated group. Comparisons between the two series for each week of the disease were equally impressive up to the end of one month. An important finding was that the mortality rate was reduced by anticoagulants only in patients over 60 years of age. But thrombo-embolic complications were greatly reduced in all patients.

These results look impressive, and the controls seem strictly comparable; moreover, it is just the kind of result that would be expected. Yet there are one or two disturbing features. Independent studies do not put the death rate from pulmonary embolism as high as these figures suggest. Eppinger and Kennedy,[5] for instance, found it was 6.5% in 200 fatal cases of acute myocardial infarction, and Hellerstein and Martin[6] 12% in their series of 160 necropsies. If the total mortality rate was around 25%, then pulmonary embolism could have caused death in only 2–3% of all cases encountered.

---

1 Master, A. M., *Amer. Heart J.*, 1936, **12**, 549.
2 Newman, M., *Lancet*, 1946, **2**, 409.
3 *Amer. Heart J.*, 1948, **36**, 334.
4 Wright, I. S., *et al.*, ibid., 1948, **36**, 801.
5 *Amer. J. med. Sci.*, 1938, **195**, 104.
6 *Amer. Heart J.*, 1947, **33**, 443.
7 *Amer. J. med. Sci.*, 1948, **216**, 172.

This does not tally with the 10% incidence quoted above. Again, Hellerstein and Martin found clinically detectable thrombo-embolic lesions in 11.5% of 1,605 cases of acute myocardial infarction collected from the literature. This makes an interesting comparison with the incidence of 11% found in Irving Wright's series treated with anticoagulants.

Tulloch and Gilchrist calculated the crude mortality rate in their control patients to be 40%. In the series reported by Wright and his colleagues it was as high as this only in persons over 70 years old, being 30% in those between 60 and 70 and only 10% in those under 60. The mortality rate was nearly 50% in Tulloch and Gilchrist's 53 controls over 60 years old, and 28% in their 32 controls under 60. The difference between the two series is probably explained by the large number of admissions within the first 24 hours in the Edinburgh group (33%). Immediate admission to hospital was almost certainly uncommon in the American series; otherwise the mortality rate in the first week would have been appreciably higher than that in the second, whereas they were practically the same. One of the most impressive features of the Edinburgh series is the close similarity of the treated and untreated groups in duration of the illness prior to admission. The chief difficulty about accepting Tulloch and Gilchrist's conclusions arises from a study of the causes of death in their series. It will be seen that 20% of the controls and 21% of the treated patients died suddenly or from heart failure. This is the expected incidence, and it must be generally agreed that these are the chief causes of death in acute myocardial infarction among those not dying from shock, and that anticoagulants would not prevent the last. The higher mortality among the controls was caused by three deaths from persistent shock or coma, five from a recurrence of myocardial infarction, and six who died in the first 24 hours. Could these have been prevented by anticoagulant therapy? Clearly dicoumarol could not have prevented the six immediate deaths, but heparin might have done. A detailed analysis of the early mortality rate in those treated with heparin and in matched controls is required. Could dicoumarol have prevented "recurrent myocardial infarction"? According to Selzer[7] only 2% or 3% of patients with acute myocardial infarction die from secondary coronary thrombosis.
