On examination the girl had a temperature of 100° F. (37.8° C.) and on her back were four or five subacute boils which were not particularly tender to pressure. Apart from this there were no abnormal physical signs. The patient was kept in bed under observation for two or three days, during which time her temperature rose to 101.5° F. (38.6° C.) in the evenings, and subsided to 99.5° F. (37.5° C.) in the mornings. In view of the fact that the boils did not improve, penicillin therapy was commenced. The patient was given 20,000 units of penicillin intramuscularly every three hours. There was no change in the patient's condition for the next two or three days, and on the fourth day after treatment she complained of pain in both legs. At the time this was thought to be due to the injections. However, on the fifth day the patient discovered that she could not move her legs. On examination a flaccid paralysis was found to be present in both legs. A lumbar puncture was done, (this was typical of poliomyelitis), and the patient was transferred to an isolation hospital. I saw her again three months later and discovered that there was still a severe degree of residual paralysis in both legs.

About this time I read the article in the *British Medical Journal* (March 19, 1949, p. 465) which suggested that the degree of paralysis bore a relationship to the amount of exercise undertaken in the pre-paralytic stage. I observed to myself at the time that in the case of this particular girl, although she had been resting in bed for at least seven or eight days before the onset of paralysis, she had been left with a severe degree of paralysis in both legs after three months.

I thought no more of the case at the time.

During recent weeks on thinking back I realize that in the case of this girl we had been giving intramuscular injections in both thighs and nowhere else, and that in her case it was her two legs that had been affected, and nowhere else. In view of this and similar cases reported I think we should seriously consider whether it is trauma due to the needle passing through the muscular tissues which predisposes the limb to paralysis, this effect being independent of the contents of the syringe.—I am, etc.,

Newport, Mon. J. NEWCOMBE.

Vaccination Certificates

SIR,—It might be well to add to the useful information on vaccination and inoculation certificates in Sir Philip Manson-Bahr's letter (July 22, p. 215) the reminder to doctors advising migrants overseas that, although the official certificate form states, "This certificate is not valid for more than three years from date of issue," several quarantine authorities in the Far East, and possibly elsewhere, strictly limit the validity of certificates against smallpox for their area to 12 months from date of issue. One authority recently limited the validity to 60 days. These "parochial" regulations seem to be altered with very little notice and are apt to cause very considerable trouble on attempting to disembark.—I am, etc.,

London, E.C.2. O. MARRIOTT.

Folic Acid and Pernicious Anaemia

SIR,—We have read with interest the article by Dr. H. Fuld (July 15, p. 147) entitled "Effect of Vitamin B_{12} on Neuropathy in Pernicious Anaemia Treated with Folic Acid," in which the conclusion is drawn that since neurological lesions or symptoms developed during the course of such treatment there existed a causal factor in the folic acid.

It is, of course, highly desirable that clinical findings of this sort should be brought to the attention of the medical public, and equally desirable that whenever there are differing interpretations these should also be expressed, in order that scientific knowledge may progress through the interchange of critical observations until a truly accurate consensus of opinion is reached. With the desire to be helpful in the clarification of the proper role of folic acid in the treatment of anaemias we wish to cite a few comments and findings which were in all probability not available to Dr. Fuld at the time of the writing of his paper.

An editorial which appeared in the *New England Journal of Medicine* (March 23, 1950) takes the stand that while folic acid does not possess the power of protecting the nervous system against the development of disorders as concomitants of certain macrocytic anaemias, as does liver or vitamin B_{12}, and whereas it does not possess therapeutic properties in respect of these neural lesions, it nevertheless does not play a toxic, causal, or harmful role in this direction. If this is true, then there is every reason to avail ourselves of the benefits of this medication, which has proved its usefulness in eliciting reticulocyte and erythrocyte responses. A proper understanding of its action, however, would call for the addition of liver extract or vitamin B_{12} for the protection afforded the nervous system by these agents where such protective or therapeutic action is indicated.

The following are quotations from the editorial cited: "That folic acid does not offer neurologic protection to patients with pernicious anaemia is clear, but that it actually does harm to nervous system tissue directly appears to have been disproved. Folic acid may even be used safely in typical cases of pernicious anaemia, for maintenance, provided that liver extract is also used." The editorial goes on to point out the great usefulness of folic acid in the treatment of atypical, tropical, megaloblastic anaemias, and the megaloblastic macrocytic anaemias of infancy. We quote: "'Achrestic' anaemia and the 'refractory' megaloblastic anaemias described by Davidson seem to respond better to folic acid (referring to the effectiveness of liver extract and vitamin B_{12} in these cases). Thus, this chemical appears to have earned a definite place as a useful drug, although its exact relations, if any, to vitamin B_{12} require further elucidation."

In the same issue of the *New England Journal of Medicine* there appears an article from the Medical Clinic of the Peter Bent Brigham Hospital and the Department of Medicine, Harvard Medical School, by Harvey, Howard, and Murphy, who concur with the opinion of the editorial we have cited. These investigators treated 40 subjects with 20 mg. of folic acid daily for three to twelve months. They say, "None of the subjects demonstrated spinal cord or peripheral nerve damage during the period of treatment. This confirms other recent studies and supports the accumulating evidence that folic acid does not have a toxic effect on the central nervous system of persons without pernicious anaemia. In the February, 1950, issue of *Blood* Drs. Weissberg, McGavack, Vogel, and Kenigsberg of the Metropolitan Hospital Research Unit of the New York Medical College report that folic acid has no harmful effects on the central nervous system. These physicians investigated 26 persons who were normal or who had some form of neural changes not associated with anaemia. Each person was given 20 mg. of folic acid daily. The period of treatment was from six to twelve months, with the average at ten months.

From the observations cited above we would submit, then, the following conclusions: (1) Folic acid is a valuable medicament in the treatment of anaemias, being especially useful in refractory, achrestic, atypical macrocytic types of anaemia exemplified by the megaloblastic anaemia of infancy, tropical anaemias, the so-called "pernicious anaemia of infancy," and sprue; (2) that in many of these anaemias folic acid brings about a normal peripheral blood picture and favourable marrow responses in a way which is superior to the effect of liver extract or vitamin B_{12}; (3) that folic acid does not *per se* play any causal role in neurological damage, nor does it have a toxic action; but (4) that folic acid should not be used with the anticipation of correcting or preventing the neurological lesions associated with pernicious anaemia, but that liver extract or vitamin B_{12} should be used in addition to folic acid where this therapeutic action is needed. We respectfully submit the above observations in the hope that they will receive attention and that they will be useful in the clarification of the proper role to be played by folic acid in the treatment of disease.—I am, etc.,

RUTLEDGE W. HOWARD,
New York. Director of Professional Service, Lederle Laboratories Division, American Cyanamid Company.

Cancer of the Respiratory System

SIR,—There has been a steady and progressive increase in the number of deaths from cancer of the respiratory system in men and women in recent years. The Registrar-General's returns for England and Wales are as follows:

	Males	Females
1937	4,089	1,162
1942	5,596	1,525
1943	6,094	1,581
1947	8,603	2,019

In the annual returns of the Medical Officer of Health for Manchester for the years 1937 to 1946 inclusive, the increases were from 133 to 188 in males and 23 to 45 in females. In 1949 it affected 234 males and 49 females. Leading British insurance companies have been impressed by an increase of bronchial cancer in their death claims. These increases are probably due, to some extent, to more careful and accurate diagnosis of diseases of the lungs, but there are other probable reasons for them.

There has been a great increase in cigarette smoking since the 1914–18 war, and especially by women. The Board of Trade returns show that the total weight of all forms of imported tobacco in millions of pounds rose from 114 in 1910 to 356 in 1919. In succeeding years it varied in amount, especially during the second world war, and in 1946 it was 434 million pounds.

In American opinion the incidence of diagnosed cases of bronchial carcinoma is increasing at a rate which appears to be faster than that of other diagnosed tumours. Tobacco smoking as a cause has received particular attention there because of the great incidence of carcinoma of the lung in males as compared with females. It occurs chiefly in heavy smokers and especially from 40 to 70 years of age. In 330 post-mortem examinations 78% were of men and 21.9% women. The life tables prepared by Pearl in America have a bearing on this point; he gave these, from the age of 30, for 6,813 individuals—non-smokers, moderate, and heavy smokers—and found that only 30.4% of heavy smokers lived to 70.

There is much tar-containing soot in the Manchester atmosphere from domestic and commercial fires, and in recent years this has been added to, as elsewhere, by the black exhaust of Diesel-engine buses and other heavy vehicles. A sample of this was found to contain 3% of a tarry oil which produced epithelioma of the skin on laboratory mice. There was no evidence found at Manchester that inhalation of this exhaust tar can cause cancer of the lungs, as laboratory animals could not be exposed to it for long enough periods for more than bronchial irritation to be obtained.—I am, etc.,

Manchester. E. M. BROCKBANK.

Morphine in Bronchial Asthma

SIR,—Dr. A. G. Ogilvie does not quote me correctly in his letter (July 29, p. 300). I did not write that "the use of morphine in severe asthma is justified because sedation is urgent." I stated that morphine is justified if other means of sedation have failed, and then only if its depressant and—probably histaminic—broncho-constrictor actions are compensated by adrenaline. I do not agree with Dr. Ogilvie that the asthmatic who has had morphine will not respond to adrenaline. Naturally, an effective dose of adrenaline is necessary, and if the patient is tolerant to it (tolerant to *any* dose of it) morphine would be as dangerous as it is without adrenaline. I do not see why Dr. Ogilvie wants to exclude morphine from use in asthma without any exception: that its injudicious use is dangerous is no valid reason. All that is necessary is that the medical practitioner is aware of the danger and of his responsibility.—I am, etc.,

London, W.C.1. H. HERXHEIMER.

Deaths in Breech Deliveries

SIR,—Dr. T. Redman (April 8, p. 814) showed that in breech deliveries the combined foetal and neonatal death rate is irrespective of parity and type of breech. Some statistics from Sorrento Maternity Hospital, Birmingham, may be of interest in this connexion. From 1945–9 inclusive, out of a total of 9,225 deliveries—excluding twins, malformations, and babies weighing less than 5½ lb. (2.5 kg.)—there were only 178 breech deliveries. The results are summarized in the following tables:

TABLE I.—*With Legs Flexed*

	Number	Stillbirth, With Cause	Neonatal Deaths, With Cause	Combined Foetal and Neonatal Mortality Per cent
Primigravidae	13	0	0	0
Multiparae ..	23	3 (1 prolapsed cord 2 intracranial birth injury)	1 (intracranial birth injury)	17

TABLE II.—*With Legs Extended*

	Number	Stillbirth, With Cause	Neonatal Deaths, With Cause	Combined Foetal and Neonatal Mortality Per cent
Primigravidae	88	1 (cord tight round neck; died during 1st stage labour)	4 (1 atelectasis, 1 haemorrhagic diathesis, 2 intracranial birth injury)	6
Multiparae ..	54	2 (intracranial birth injury)	0	4

Owing to the infrequency of breech deliveries, it has become very difficult for midwives and general practitioners to be taught and to keep in practice. In addition, to minimize foetal and neonatal deaths an expert team is required for the delivery, as stressed by L. Cox.[1]

The diagnosis must obviously be made prior to term so as to ensure hospital delivery and also to enable the size of the pelvis to be carefully assessed, if necessary by *x*-ray pelvimetry. To avoid an excessively large baby, labour should be induced at term and, occasionally, shortly before. Frequently, surgical induction will be required, but by using the Drew Smythe catheter a bag of forewaters can be left with advantage. This method was used in 48 of the above cases.

At Sorrento Maternity Hospital better results have been obtained recently, shown by no foetal or neonatal deaths during the first six months of this year, and only one during 1949. This was a foetus with a flexed breech, the third pregnancy of a woman with a flat pelvic brim. The improvement is largely due to the routine use of pudendal block anaesthesia in all primigravidae, as well as an episiotomy when the foetal buttocks distend the perineum. The resultant pelvic floor relaxation facilitates delivery to a marked degree. The anaesthesia results in good co-operation of the patient, so that she is more likely to keep her buttocks well over the edge of the bed when in the lithotomy position, and so ensure that the baby's body can hang and aid flexion of the after-coming head. Any shoulder manipulation can be performed painlessly, without further anaesthesia, and the occiput rotated anteriorly if necessary, the Mauriceau–Smellie–Veit grip being preferred. Should there still be difficulty with the head—if disproportion is prevented this should be rare—forceps can usually be applied without further anaesthesia.

The prime object of this letter is to urge that the time has come for revision of the Central Midwives Board rules regarding breech deliveries. Every breech should be considered as an abnormality, medical aid sought, and hospital delivery ensured. In hospital, a delivery team is necessary. Pudendal block anaesthesia is a great advantage in primigravidae.—I am, etc.,

Birmingham, 13. JEAN L. HALLUM.

Myeloid Leukaemia and Pregnancy

SIR,—As Drs. L. M. Edwards and H. D. Freeth (July 22, p. 199) found that there are few records of pregnancy in myelogenous leukaemia, the following brief case notes may be of interest to them.

A woman, aged 36, was admitted to the Meath Hospital, Dublin, in August, 1947, with gross splenic enlargement, which was found to be due to myelogenous leukaemia. She had deep *x*-ray therapy to the spleen, ending on August 22, 1947. The white blood count began to rise in December, and by the end of February, 1948, she needed further deep *x*-ray treatment, which was completed on March 8. In July she was given a third course of deep *x*-ray therapy. At the end of October she was found to be pregnant, and her white-cell count was 62,200. She was given a further course of *x*-ray treatment in January, 1949, and a normal baby was born on May 1. The baby, now 14 months old, is a normal, well-grown, and healthy child. The mother had to have further *x*-ray treatment in October, 1949, and is still keeping quite reasonably well.

It is interesting to note that pregnancy occurred after three courses of deep *x*-ray therapy and that a course given during pregnancy had apparently no ill-effects on mother or baby.—I am, etc.,

Dublin. BRENDAN O BRIEN.

Diphyllobothrium Infestation

SIR,—The very full article by Drs. J. C. Harland, J. G. Humble, and P. G. Mann (July 22, p. 188) upon diphyllobothrium infestation in Great Britain encourages a brief report of a case met with in 1936.

The patient, a man at that time aged 43, had spent part of the first world war in Northern Europe and admitted later that he and his Army colleagues had often caught and eaten fish somewhat inadequately cooked. He had been diagnosed as having pernicious anaemia in 1923 and treated with liver for many years before he was seen in 1936. In that year he had a macrocytic hyperchromic anaemia: haemoglobin 112%, and r.b.c.s 3.8 million. The differential white cell count showed 4% eosinophils. He complained of a bad taste in his mouth, flatulence, occasional bouts of diarrhoea, and borborygmi. Treatment for his anaemia failed to produce a normal blood picture, and examination of his stools showed scanty ova of diphyllobothrium.

The worm was obtained, head and all, by the use of filix mas. Subsequently his red blood count rose to normal, but his eosinophilia actually increased and continued between 6% and 11% for eighteen months afterwards. The test meal showed that he was achlorhydric. Ova were never found again in this man's faeces and he appeared to be the host of only one worm.

—I am, etc.,

London, W.1. F. HARWOOD STEVENSON.

Obituary

E. CRANMER HUGHES, O.B.E., M.Chir., F.R.C.S.

Mr. E. C. Hughes, consulting surgeon to Guy's Hospital, died at Pembury, Kent, on July 28 aged 71.

Ernest Cranmer Hughes was educated at Marlborough and Clare College, Cambridge, and went to Guy's Hospital in 1901. He qualified in 1904, took the F.R.C.S. in 1906, and M.Chir. of the University of Cambridge in 1907. He was appointed assistant surgeon to Guy's Hospital in 1911, full surgeon in 1932, and consulting surgeon on his retirement in 1938. He served on the Court of Examiners of the College from 1930 to 1940, and also examined in the Universities of Cambridge and Birmingham. In the first world war he was a captain in the R.A.M.C., and was consultant surgeon to Queen Mary's Royal Naval Hospital at Southend-on-Sea. On the outbreak of the recent war he was appointed surgeon to the E.M.S. hospital at Pembury, near Tunbridge Wells, and when the medical school of Guy's was evacuated to Pembury he became once again the chief teacher in surgery of the undergraduates of his old school. Throughout the war, and up till 1947, he operated and taught at Pembury and at the same time conducted a weekly teaching round at Guy's.

As a young man Hughes came under the influence of two very great surgeons: he was house-surgeon to Arbuthnot Lane and assistant surgeon to F. J. Steward, and throughout life he carried on Lane's clean, careful technique and Steward's clinical wisdom. He wrote little, his publications being for the most part lectures on clinical subjects. He will, however, be remembered by all who came in contact with him for his personal charm, his sunny disposition, his complete inability to speak or think unkindly of anyone, and his wonderful gift of bedside teaching and of expounding the simplest things in telling phrases that fixed them permanently in the minds of his students. To many generations of Guy's men, and to those surgeons who worked with him or were examined by him during the years that he served on the Court of Examiners of the Conjoint Board, he was known affectionately as Joey Hughes. He was a wonderful teacher, a wonderful examiner, and a well-loved colleague. He is survived by his widow and a son and a daughter.—H. O.

E. T. JENSEN, M.B.

Dr. E. T. Jensen died suddenly in London on July 31 at the age of 76. He was co-founder of the Institute for the Scientific Treatment of Delinquency and chairman of its council until his death.

Ernest Thomas Jensen studied medicine at Guy's Hospital. He graduated M.B. in 1901. In his early days he held several posts. At one time he was civil surgeon to the Herbert Hospital, Woolwich. He served with the Field Force in the Boer War, and later he went as the medical officer to an expedition into unexplored parts of East Africa. Throughout his professional life he exhibited a catholic interest in many branches of medicine.

We are indebted to Dr. Edward Glover for the following appreciation: Dr. Jensen will be remembered not so much for his strictly medical services as for the part he played in founding and developing the Institute for the Scientific Treatment of Delinquency. The psychological study of criminal conduct is of comparatively recent growth, and even yet lags behind other branches of medico-psychological investigation. As is so often the case, much of the impetus to research came from without, in this case from persons whose primary interest was in social reform rather than in clinical and social psychology. When Dr. Jensen first interested himself in this field, little or no systematic work had been done on the subject. A happy association with Dr. Grace Pailthorpe, who in the early 'twenties had pursued a research on prison populations, led to the formation of an organizing committee under the chairmanship of Dr. Jensen. Soon the services of a number of medical psychologists were enlisted, and the Institute for the Scientific Treatment of Delinquency was formed. An embryo clinic, housed at first at Dr. Jensen's own residence and later given a roof by the West End Hospital for Nervous Diseases, soon acquired a regular organization and home of its own under the name of the Psychopathic Clinic. After 16 years of work, uninterrupted by war, this was taken over in 1948 by the National Health Service and now functions as the Portman Clinic: I.S.T.D.—a special out-patient centre dealing yearly with well over 400 cases of pathological crime. Throughout this period Dr. Jensen supported the organization with unflagging zeal and, once the clinic was taken over, devoted his attention to expanding the existing Institute for the Study and Treatment of Delinquency, which remains a private enterprise engaged in numerous teaching, publishing, and research projects.

Those who had the opportunity of working with Dr. Jensen were quick to recognize his personal qualities, a quiet courtesy and humour, fertility of resource in difficulty, and an almost boyish optimism which could not be shaken by any reverse. The breadth of his cultural interests—he was in private life an art connoisseur of note—could not be mistaken. He was a man of distinguished, almost ascetic, cast with a somewhat frail stooping figure. His memory will long remain with those colleagues who worked with him in what proved to be a pioneering experiment in social medicine and which in fact remains a lasting tribute to his unquenchable spirit.

Dr. Grace W. Pailthorpe writes: Although a lifelong friend, Dr. Jensen and I came together in our medical work in 1931, when I had completed a research for the Medical Research Council on the "Psychology of Criminals." Because my colleagues were impressed with my research findings, I was encouraged to feel that something should immediately be done. This led me to approach Dr. Jensen with the idea of founding a body to deal with delinquency both scientifically and clinically. In May, 1931, he and I founded the Institute for the Scientific Treatment of Delinquency. For the following six years his home at 56, Grosvenor Street housed the institute. As chairman from its inception till his death he gave his time and money freely, and to him as well as to myself came the satisfaction of seeing the work well rewarded by results. In 1937 the I.S.T.D. at last was able to house itself, and moved from Dr. Jensen's home to Portman Street. But unfortunately this change was not to last: during the war the Portman Street house was bombed, and Dr. Jensen again came forward with his assistance until the I.S.T.D. was finally accommodated in its present quarters at 8, Bourdon Place, Mayfair.

During the last war, old as he was, he was in London actively taking part in tending air-raid casualties. His publications were relatively few. His modesty accounted for this, for he would often prepare a paper for publication which his colleagues thought of value but which he could not feel had reached the point of perfection which he demanded of himself. This need for perfection was due to his highly developed aesthetic sense. To the day of his death

his vitality, his joy in his work, and his love of his fellows were among his outstanding features. His death brings sorrow and a void in the hearts of all those who knew him intimately, whether as patient, medical colleague, or friend.

HENRY FAITHFUL SMITH, who died on July 12, was born, in his own words, of South Saxon stock, the younger son of Dr. J. A. Smith, vicar of Swansea and later dean of St. David's. He was educated at Repton and Oxford, and after farming for a few years in Canada began to study medicine at Edinburgh University in 1904, when he was about 10 years older than most of his fellow students. He graduated M.B., Ch.B. in 1909, and after acting as house-physician to the late Sir Byron Bramwell he settled in partnership in a practice at Windermere, his old chief describing the terms as "not a deed of partnership but an agreement between gentlemen." He proceeded M.D. in 1913. In the first world war he served in the R.A.M.C. in Mesopotamia, where he won the reputation of always knowing his own mind and acting with promptitude and decision. He had a most strict sense of duty, and from his duty no power on earth could make him swerve. He could turn his hand to most things. He returned to his Windermere practice and remained there, a doctor much beloved. Dr. Smith's last professional work was done as chairman of the Kendal recruiting medical board during the last war. Then he retired to Gower, the place of his boyhood, and there, after a laryngotomy performed in London, he died. He had unusual physical toughness, and even in his seventies could tramp the fells all day and walk his juniors off their legs. He was a devoted golfer, and almost his only sedentary recreation was bridge. He was no intellectual, but he had an abounding common sense. He was a survival of the God-fearing Victorian Englishman and a gentleman in the tradition of Charles Kingsley, and he will be missed.—J. W.

Medico-Legal

A DOCTOR EXONERATED

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

A man who was demobilized from the Army in 1945 suffered from chronic rheumatism, for which his doctor treated him. The diagnosis was confirmed by various specialists. In January, 1948, he returned home from work feeling very ill, and late in the evening he collapsed. His wife telephoned to the doctor and asked him to come to the home, but the doctor did not do so, and prescribed sedatives. In the early morning she asked a policeman to call the doctor again, and at 4 a.m. he came and arranged for the patient to go into hospital, where he was operated upon for a perforated gastric ulcer. He died the following morning. His wife sued the doctor, Dr. John D. Hempseed, of Sheffield, at Yorkshire Assizes for negligence.[1] In defence the doctor gave evidence that at no time had the patient ever complained of stomach pain, but rather of pains of the shoulders, legs, arms, and lumbar region. He had understood the wife to say over the telephone that the husband was suffering from the "usual" pains; she had not mentioned the stomach. Her counsel then said that he was no longer prepared to submit that the doctor should have diagnosed a gastric ulcer, but maintained that he had been unskilful in not attending the patient when he was first summoned.

Mr. Justice Hilbery said in giving judgment that he was satisfied that there had never been any complaint of abdominal pain or sign of abdominal disturbance. It would, he added, be a shocking thing if in the circumstances the court were to hold that a medical man was guilty of negligence because he did not rush round immediately. He entered judgment for the doctor with costs.

Universities and Colleges

UNIVERSITY OF DURHAM

The following candidates have been approved at the examinations indicated:

M.D.—C. B. Henderson, C. Josephs, G. S. Michelson, W. Walker, J. E. Wilson, W. K. Yeates.

FINAL M.B., B.S.—J. Anderson (with second-class honours), A. King (with second-class honours), Jean Armstrong, J. S. Bearcroft, Dorothy G. Blackett-Ord, Mary A. Brennan, I. S. Brown, H. Byrne, R. Carr, Joan M. Cashman, A. Chesshire, D. B. Clough, Irene Colbert, Greta I. Drummond, Ola E. P. During, M. Graham, R. P. Graham, Mary E. S. Gray, K. Hardy, R. J. Harris, Anne H. Harrison, W. R. Heeler, J. G. Hindmarsh, K. W. Holt, G. Hurst, P. Hutchinson, Audrey Jennings, B. O. Kawala, Joyce L. Kemp, June M. Kirk, J. C. Knox, G. B. Lawrence, Hilda M. McCormick, J. A. McCraith, M. J. Morgan, Elizabeth Nicholson, J. D. Rickinson, C. Robertson, D. Russell, C. Shadforth, Monnica C. Stewart, K. A. Stone, N. Thompson, T. A. Trotter, D. M. Turnbull, K. E. Wardill, Joyce M. Watson, F. J. Wilkinson, B. Zimet.

D.P.H.—A. Forster, W. B. A. Smyth.

UNIVERSITY OF LONDON

Sir Archibald Gray has been appointed by His Majesty in Council as a member of the University Court from October 1 for the remainder of Sir Henry Dale's term of office—i.e., 1948-53.

Sir Alexander Fleming, F.R.S., will represent the University at the fifth International Congress of Microbiology to be held at Rio de Janeiro from August 17 to 24.

The following have been appointed, or nominated for appointment or reappointment, as representatives of the University on the governing bodies indicated in parentheses: Professor Dorothy Russell (Institute of Ophthalmology); Professor W. J. Hamilton (second representative, Royal Veterinary College); Major-General P. H. Mitchiner (Territorial and Auxiliary Forces Association of the County of London); Dr. A. Topping (University College Hospital).

The following have been recognized as teachers of the University in the subjects indicated in parentheses: *Middlesex Hospital Medical School:* Dr. A. C. Thackray (Pathology); Dr. F. C. Golding (Radiology); Mr. Rainsford Mowlem and Mr. T. Holmes Sellors (Surgery). *Westminster Medical School:* Dr. I. W. Magill and Dr. G. S. W. Organe (Anaesthetics); Dr. J. G. Humble and Dr. B. W. Lacey (Bacteriology); Dr. I. McA. Anderson (Children's Diseases); Dr. G. D. Lumb and Dr. A. D. Morgan (Pathology). *Royal Free Hospital School of Medicine:* Dr. Nuala F. T. Crowley (Bacteriology). *King's College:* Dr. J. P. Quilliam (Pharmacology). *Institute of Psychiatry:* Dr. K. Cameron (Mental Diseases). *Institute of Obstetrics and Gynaecology:* Dr. V. B. Green-Armytage (Obstetrics and Gynaecology). *Guy's Hospital Medical School:* Mr. R. O. Holland, M.R.C.S., L.R.C.P., L.D.S. (Dental Surgery). *St. Thomas's Hospital Medical School:* Dr. J. F. Ryan (Anaesthetics).

The South Middlesex Fever Hospital, Isleworth, has been added to the list of institutions at which students may take the course in fevers for the M.B., B.S. degrees.

The following candidates have been approved at the examinations indicated:

M.D.—*Branch I (Medicine):* Daphne S. A. Anderson, P. G. Arblaster, G. Beven, E. P. Bharucha, D. P. Bowler, P. D. Bryant, G. B. Carruthers, Betty L. Coles, J. B. Cook, J. N. C. Cooke, Rosemary Davies, D. M. Douglas, H.-J. B. Galbraith, R. F. Griffith-Evans, A. G. S. Grimble, D. B. Gunasekara, H. C. Hamilton, E. P. W. Helps, H. D. G. Hetherington, F. C. N. Holden, Mary C. Holt, O. A. N. Husain, S. L. O. Jackson, J. W. M. K. W. S. Jayewardene, I. D. MacDonald, W. Mackenzie, J. G. Millichap, J. C. Mitchell, Madeleine B. Morris, *W. O'Brien, Ethel A. Perrott, *F. I. Sophian. *Branch V (Hygiene):* L. R. L. Edwards, H. T. Phillips, Alison D. McDonald, G. H. Stuart, W. C. Turner. *Branch VI (Tropical Medicine):* S. Fernando.

*Mark of distinction.

No. 29

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended July 22.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1950 (a)	(b)	(c)	(d)	(e)	1949 (Corresponding Week) (a)	(b)	(c)	(d)	(e)

Deaths (0–1 year)	207	27	38	16	15	275	43	29	17	9
Deaths (excluding stillbirths)	4,092	611	550	146	108	4,228	678	496	146	91
Annual death rate (per 1,000 persons living)			11·0					9·9	9·0	
Live births	6,758	1142	913	443	235	7,608	1223	866	411	209
Annual rate per 1,000 persons living			18·3					17·4	25·5	
Stillbirths	181	29	22			182	20	19		
Rate per 1,000 total births (including stillborn)			24					21		

* Measles is not notifiable in Scotland, and the returns are therefore an approximation only.

† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

‖ Includes puerperal fever for England and Wales and Eire.

¶ Primary pneumonia no longer notifiable in Eire.

EPIDEMIOLOGICAL NOTES

Poliomyelitis

Notifications in the week ended July 29 were: paralytic, 197 (189); non-paralytic, 108 (71); total, 305 (260). The figures for the previous week are shown in parentheses. It is perhaps satisfactory that the main increase—37—occurred in the non-paralytic types and only 8 in the paralytic, and that the proportion of the former for the week under review increased to 35.4% of the total notifications.

The four counties London, Warwick, Lancaster, and Stafford contributed one-quarter of the total notifications for England and Wales, compared with 46% in the previous week.

The more important increases in the week under review were as follows:

	Paralytic	Non-paralytic
Warwick	12	1
Essex	(1 less)	7
Gloucester	(3 less)	8
Leicester	6	5
Middlesex	8	3
Isle of Wight	4	3
Total	26 net	27

Total 53 (reduced to 45 for England and Wales by excess of decreases over increases elsewhere).

Attention has been focused in the past week on a relatively serious outbreak in the village of Digby, near Sleaford, Lincs. In this village, with its population of some 400 people, there have been 15 confirmed cases since July 10, and on August 8 there were 4 suspects under observation. The main weight of the attack fell on a new housing estate of 32 houses and 130 inhabitants, in which 11 confirmed cases occurred, including 2 deaths. The situation was improving by August 8 in that there had been no cases on the estate since August 5, although two or three of these suspect cases had developed after August 5 elsewhere in the Digby village area.

A small defect in the drainage system suggested the possibility of contamination of the water supply on the estate, but further investigations appear to have eliminated this possibility, and the evidence points to the spread of the disease in the community by ordinary contact infection from the first case, the onset of which was on July 10. Detailed epidemiological inquiries are being carried out, but the results are not yet available.

Anthrax in Cattle

In the outbreak of anthrax in cattle at Holme Pastures, Sutton-on-Trent, Nottinghamshire, 13 cattle had died by August 5. By the previous week-end 9 had died. Bacteriological proof has been obtained in 5 cases. About 150 cattle are exposed to risk in the area, and measures to prevent spread of infection have been carried out.

Discussion of Table

In *England and Wales* there were decreases in the notifications of measles 541, whooping-cough 236, dysentery 56, scarlet fever 22; while the only increase of any size was 48 for acute poliomyelitis. The incidence of scarlet fever remained practically constant in every area of the country, the only exception being a decrease of 41 in Lancashire. The largest local changes in the incidence of measles were decreases in Lancashire 164 and Yorkshire West Riding 123. Notifications of diphtheria fell by 10 in Lancashire.

In contrast to the general trend the incidence of whooping-cough in London and the surrounding counties increased during the week, the largest increases being in London 47, Surrey 45, and Middlesex 32; the largest decreases were in Lancashire 83, Gloucestershire 51, and Norfolk 51. The largest returns of dysentery were Lancashire 61 (Preston C.B. 15, Oldham C.B. 14, Littleborough U.D. 8); Yorkshire West Riding 28 (Bradford C.B. 8); Derbyshire 12 (Belper U.D. 11).

The rise in cases of acute poliomyelitis continues, 1,195 cases having been notified during the past eight weeks, compared with 496 in 1949, 228 in 1948, and 599 in 1947 for the corresponding period. The largest increase during the week occurred in London, where the cases rose from 8 to 28. Twelve of the 28 boroughs reported a case, and the largest returns were

Lambeth 5 and Woolwich 5. In Northumberland the cases fell from 16 to 8. Other large returns were Warwickshire 43 (Birmingham C.B. 28, Sutton Coldfield M.B. 5); Lancashire 24 (Manchester C.B. 8, Liverpool C.B. 6); Staffordshire 24; these cases were notified from 11 administrative areas. Worcestershire 13 (Dudley C.B. 5); Essex 13 (West Ham C.B. 5); Yorkshire West Riding 12, involving 9 administrative areas; Gloucestershire 11 (Bristol C.B. 7).

In *Scotland* increased notifications were reported for dysentery 22, acute primary pneumonia 14; decreases were reported for measles 70, whooping-cough 35, and acute poliomyelitis 9. A small rise in the incidence of dysentery occurred in every area, the largest returns being Glasgow 58 (an increase of 26) and Edinburgh 12. Notifications of acute poliomyelitis in Glasgow rose from 15 to 25, and the next largest returns were Fife county 7 and Angus county 4.

In *Eire* there were decreases for measles 92 and scarlet fever 23, while the only rise was whooping-cough 24. A decrease of 28 for measles and an increase of 11 for whooping-cough were recorded in Dublin C.B.

In *Northern Ireland* notifications of measles decreased by 53. This was due to a fall of 44 in the number of cases in Down county and 19 in Belfast C.B., where 12 of the 18 cases of acute poliomyelitis were also notified.

Week Ending July 29

Notifications of infectious diseases in England and Wales during the week included scarlet fever 1,012, whooping-cough 3,714, diphtheria 42, measles 8,291, acute pneumonia 277, acute poliomyelitis 305, dysentery 166, paratyphoid fever 7, typhoid fever 10.

Medical News

Royal College of Surgeons

The Honorary Medal of the Royal College of Surgeons of England has been awarded to Lord Webb-Johnson, in recognition of his many generous acts and continued labours in the interest of the college throughout the eight years of his presidency.

Travelling Fellowship Offered

The American Association for Thoracic Surgery has created a travelling fellowship (value approximately $1,000) for the study of thoracic surgery or its related sciences in the U.S.A. or Canada. The fellowship will be an annual appointment, and the American Association has generously invited the Society of Thoracic Surgeons of Great Britain and Ireland to nominate the first holder. Anyone interested in this fellowship is advised to communicate with the honorary secretary of the Society of Thoracic Surgeons, Mr. O. S. Tubbs, 15, Upper Wimpole Street, London, W.1.

Raymond F. Longacre Award

The Raymond F. Longacre Award for 1949 has been presented to Sir Charles Symonds by the Aero Medical Association of America. The award is given annually by the association to the person who has contributed most to the advancement of neuropsychiatric aspects of aviation medicine, including the development of aptitude tests for flying. The first award was presented to Dr. Ross A. McFarland in 1947 and the award for 1948 was made to Dr. Detlev W. Bronk. The presentation was made in London by Group Captain Corbett, of the Royal Canadian Air Force.

Delinquency

The Institute for the Study and Treatment of Delinquency has begun publication of a new quarterly, the *British Journal of Delinquency*, the main purpose of which is to enable students of criminology to keep in touch with recent developments in the various branches of science concerned with the investigation, treatment, and prevention of delinquency. While clinical contributions will receive special consideration, it is intended also to publish articles on medical psychology, psychiatry, psycho-analysis, organic medicine, educational psychology, sociology, economics, anthropology, psycho-biology, and statistics. The journal is published by Baillière, Tindall and Cox, and the annual subscription is £1 7s. 6d.

Japanese Journal of Biochemistry

The *Journal of Biochemistry*, organ of the Japanese Biochemical Society, has restarted publication. Founded in 1922, the journal was discontinued in 1944. In the past it has published many important papers by Japanese biochemists. It will appear quarterly from the Institute of Biochemistry, Tokyo University.

COMING EVENTS

World Federation for Mental Health

The third annual meeting of the World Federation for Mental Health will be held at the Cité Universitaire in Paris from August 30 to September 7. The discussions have been designed to lead up to the work of the next International Congress on Mental Health, which will take place next year. They are concerned with mental health in education, in industry, and among transplanted and homeless persons. A further subject of discussion will be that of leadership and authority in local communities. It is understood that the Government of Mexico has invited the International Congress to hold its meeting there in December, 1951.

Conference on Venous Disorders

A conference on venous disorders will be held at Aix-en-Provence on September 15–17 under the presidency of Professor René Leriche. Particulars may be obtained from the Secrétariat, Journées Internationales de Phlébologie, 4, Cours Mirabeau, Aix-en-Provence, France.

American Public Health Association

The 78th annual meeting of the American Public Health Association, and meetings of 32 related organizations in the field of public health and preventive medicine, will be held in Kiel Auditorium, St. Louis, Missouri, on October 30–November 3. The programme will be published in the September issue of the *American Journal of Public Health*. Additional information may be obtained from Dr. Reginald M. Atwater, executive secretary, American Public Health Association, 1790, Broadway, New York 19, N.Y., U.S.A.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Tuesday

EDINBURGH POSTGRADUATE BOARD FOR MEDICINE.—At University New Buildings (Anatomy Lecture Theatre), Edinburgh, August 15, 4.30 p.m., "*The Anatomy of the Bile Ducts*," by Professor John Kirk.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Barber.—On July 25, 1950, at Johnstone House, Belfast, to Nan, wife of Dr. J. M. Barber, a son.

Holiman.—On July 31, 1950, at University College Hospital, London, W.C., to Catharine (formerly Large), wife of Dr. Arthur Holiman, a daughter—Catharine Margaret.

Ritch.—On July 27 1950, to Dr. Elsie (formerly Morison), wife of Dr. Donald R. S. Ritch, "Dunholme," Stamfordham, Newcastle-upon-Tyne, a son.

Scadding.—On July 27, 1950, to Mabel, wife of Dr. J. G. Scadding, F.R.C.P., a daughter.

Starey.—On July 30, 1950, at Churchill Hospital, Oxford, to Phyllis (formerly Horton), wife of Dr. C. J. H. Starey, of Stokenchurch, Bucks, a son.

Taylor.—On July 29, 1950, in East London, South Africa, to Andrée, wife of Dr. W. Norman Taylor, of Fort Hare, Cape Province, a son.

Thomson.—On July 31, 1950, in Ashleigh Nursing Home, Newcastle-upon-Tyne, to Elizabeth (formerly McCarn) and Dr. Donald Thomson, Glenroy, Stanhope, Co. Durham, a daughter.

White.—On July 25, 1950, at Mayday Hospital, Croydon, to Margaret White, M.B., D.Obst.R.C.O.G. (formerly Stather Hunt), and Thomas White, M.B., M.R.C.O.G., a daughter.

MARRIAGE

Eyles—Cassells.—On July 12, 1950, in Norfolk, Reginald Eric Eyles, L.D.S. R.C.S., to Nulece Cassells, M.B., Ch.B.

DEATHS

Audland.—On July 31, 1950, at Witherslack Nursing Home, Westmorland, William Edward Audland, M.B.E., M.R.C.S., L.R.C.P., aged 90.

Bankes.—On August 1, 1950, at The Royal Masonic Hospital, Ravenscourt Park, London, W., John Herbert Bankes, M.R.C.S., L.R.C.P., aged 71.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Prematurity and Intracranial Injury

Q.—*I was told during my training that in order to prevent cerebral haemorrhage in premature infants it was necessary to avoid delay in delivering the shoulders. To do this, as soon as the head is born one hand is put inside, the shoulders rotated, delivered immediately, and the baby extracted. The reason given for this was that while the baby's head remains in utero and inside the vagina an even pressure is exerted on the skull. When the head is born there is an alteration in the pressure due to the sudden release of the head, and if the shoulders are not delivered immediately blood is forced down into the baby's brain and the force is sufficient to tear a blood vessel and cause a cerebral haemorrhage. I have never seen this theory in print. Is there any evidence to support it or not?*

A.—Babies born prematurely are undoubtedly more liable to intracranial injury and haemorrhage, and it is generally believed that their tendency to suffer intranatal asphyxia is a predisposing factor, although this acting alone is not likely to cause more than petechial cerebral haemorrhages. The release from compression which accompanies delivery of the head may play a part in some cases, possibly because it allows a resurgence of blood to the brain and meninges, but mainly because it results in a sudden change in the shape of the skull and an alteration in the strains to which the intracranial ligaments are exposed. The release phenomenon occurs no matter whether the shoulders follow the head quickly or slowly, and the writer has never previously heard it suggested that during the interval between the birth of the head and of the shoulders the intracranial vessels can become so engorged as to rupture spontaneously. Certainly this has never been proved and it can only be regarded as a theoretical possibility which is open to dispute. The congestion of the superficial tissues which is sometimes seen pending delivery of the shoulders does not necessarily mean that there is a similar change in the intracranial vessels. Moreover, in the premature baby the girth of the shoulders and trunk is very much less than that of the head, so that they not only tend to slip out easily and quickly but in the meantime are subjected to minimum pressure from the lower birth canal already stretched by the head. The tendency for the head to become congested is therefore less than in the case of the mature infant. One of the facts established beyond reasonable doubt is that the premature baby is ill-fitted to withstand manipulation during labour, and it would appear that manual rotation of the shoulders and extraction or expression of the trunk is potentially more dangerous than allowing the very short delay necessary for the delivery to be completed spontaneously.

In most cases intracranial injury leading to haemorrhage occurs before the delivery of the head, and in premature babies may be caused merely by the resistance of the vagina and perineum. It is now fairly well established that episiotomy appreciably reduces this risk. It may be added that, if there is anything in the argument put forward, episiotomy also ensures rapid and easy delivery of the shoulders without recourse to manipulations.

Coroners

Q.—*What system governs appointments to the office of coroner? By whom are such appointments made? Are they advertised, or is it customary to appoint the deputy already in office? How are coroners nominated, and what are the limits of income available from their office? Is any preference shown to an applicant with a legal qualification over one who is medically qualified? Are any such appointments given only to applicants possessing both medical and legal qualifications?*

A.—A county coroner is appointed by the county council, a borough coroner by the borough council (Coroners (Amendment) Act, 1926, s. 2). If the district of a county coroner is wholly within a county borough the appointment is made by the council of that borough (Coroners Act, 1887, s. 33; Municipal Corporations Act, 1882, s. 34 (4)). An appointing authority is not obliged by law to advertise a vacant coronership, but it is customary to advertise the more important appointments in the legal and medical journals and in the "Public Appointments" columns of the leading daily newspapers. It sometimes happens—but by no means invariably—that a deputy-coroner already in office is appointed to the vacant coronership. In such a case his experience and general suitability rather than the fact that he happened to be the deputy would be the deciding factor. Experience as a deputy, however, carries great weight—this is especially the case where the more important appointments are concerned.

It must be remembered that there are about 270 coroners in England and Wales, and that their coronerships vary very greatly in size and importance. At one end of the scale are the small country appointments where the remuneration amounts to not much more than a honorarium, and at the other extreme are the busy posts requiring the services of men who give their whole time to the duties of the office. Of recent years there has been a tendency for paying authorities to make a distinction between a coroner's basic salary and the amounts it allows him for the expenses incurred in carrying out his work. These allowances for expenses in some instances reach high figures. Thus the two whole-time coroners for the County of Middlesex are paid a salary of £1,500 and receive £1.000 for their expenses. In London the basic salary for a whole-time coroner is £1,600 and he receives £350 for defraying his costs. It must be understood that these sums are paid to the coroner for his personal expenses and have nothing to do with the reimbursements he receives for money paid out in connexion with his administrative or judicial duties. Between these two extremes coroners' salaries vary very widely and the variation does not always bear a constant relation to the amount of work done or the time involved in doing it. The pay of a deputy, or assistant deputy, is a matter of arrangement between himself and the coroner.

Since out of approximately 270 coroners the great majority are lawyers it would be reasonable to infer that a legal qualification is held to be more important than a medical qualification so far as fitness for the office is concerned. In London, and a few of the more important centres, the electing authority endeavours to limit the candidature to persons who possess both legal and medical qualifications. No coroner has been appointed in the county of London for the past thirty years who has not had the dual qualification. There are 13 whole-time coroners in England and Wales, of whom 10 are qualified in both law and medicine. These 13 coroners between them dispose of about one-third of all the cases reported in England and Wales during the year. Of the remaining 257 coroners, 16 have a medical (but no legal) qualification; and 241 are barristers or solicitors with no medical qualification.

Ps. pyocyanea Infection of Middle Ear

Q.—*A man had a chronic discharge from the middle ear. The organism cultured was Ps. pyocyanea. Is there any antibiotic which is active against this organism? Would C.T.A.B. applications be likely to help? What local treatment is indicated?*

A.—*Ps. pyocyanea* is remarkably resistant to both antiseptics and chemotherapeutic agents. Among the former none can be recommended for use in such a case as this. C.T.A.B. (cetavlon) has less action on this organism than on any other commonly concerned in sepsis. Penicillin is useless, and the newer antibiotics aureomycin and chloramphenicol are also generally powerless in the concentrations which can be attained at the site of infection. Streptomycin is the exception; the susceptibility of *Ps. pyocyanea* to this antibiotic varies, but it is usually such that the concentrations attainable by local application are effective. A solution of 5 mg. per ml. should be instilled into the ear several times a day: the drug may also be given intramuscularly, particularly during any surgical treatment which may be indicated. Authors reporting favourably on local streptomycin treatment for otitis media, some of whose

patients were infected with this organism, are Pulaski and Matthews (*Arch. Otolaryng.*, 1947, **45**, 503) and Harris and Finland (*North Carolina Med. J.*, 1947, **8**, 276).

Local treatment would consist in keeping the meatus as clean as possible, and in ensuring that the discharge was allowed a free exit from the middle ear. The first object is attained either by syringing with warm water, followed by dry mopping, or by dry mopping alone, twice daily; the second by removal of granulations with chromic acid, of polypi by a snare, and of debris by syringe or scoop.

Indications for P.A.S. in Pulmonary Tuberculosis

Q.—*What are the indications for the use of para-aminosalicylic acid? I have a patient, aged 22, with advanced pulmonary tuberculosis. She has persistently refused sanatorium treatment, still refuses it, and is beginning to go downhill now. Is it worth while prescribing P.A.S.?*

A.—The indications for this drug in the treatment of pulmonary tuberculosis may be briefly stated as (*a*) recent disease, and (*b*) in combination with streptomycin to prevent or delay the loss of sensitivity of the tubercle bacillus to the antibiotic. P.A.S. is effective only in those lesions in which there is an absence of fibrosis; it is therefore suitable in cases where there is evidence of recent spread of the disease. In chronic fibroid phthisis it has the temporary effect of creating a feeling of well-being, and some improvement radiologically may occur from the clearing up of recent foci of activity, but a state is soon reached beyond which no further improvement can be expected. In combination with antibiotics it is useful in the prevention of drug-fastness. There is also evidence that with the combined administration of streptomycin and P.A.S. patients improve more rapidly than when treated with streptomycin alone.

The treatment of the patient in question with P.A.S. depends very greatly on the character and chronicity of her lesion. However, it is probable that benefit would be derived from P.A.S. but the permanency of any good effects will depend on the clinical state of the patient.

Sensitization to Calf Lymph

Q.—*On February 17 I vaccinated a European baby of 20 months not previously vaccinated against smallpox. No immediate change was observed in the temperature, pulse rate, or respiration, though the same batch of calf lymph was found to be potent when used on control cases. Eight days later a series of papules appeared on the vaccinated leg; within 24 hours they changed first to vesicles and finally to pustules. During the next five weeks the same type of eruption was observed on the other leg and both arms. Very few were seen on the face and trunk. The child at no time ran a temperature and, apart from a slight inclination to scratch individual lesions, showed no signs of constitutional disturbance. This child, now in Nyasaland, will continue to reside in tropical areas in which smallpox is endemic, and it is important that a correct diagnosis should be established. If this was a case of generalized vaccinia, then I must issue a certificate to that effect to ensure that she is not vaccinated again. What is the likely diagnosis, and is revaccination advisable or not?*

A.—Although the information is not explicitly given it is assumed that the papules, vesicles, and pustules which appeared at the site of attempted vaccination were typical and were followed by the usual foveated scars and represented a successful vaccination. It is then necessary to go over the complications of vaccination so far as the skin is concerned in an endeavour to ascertain as accurately as possible the nature of the condition. (i) *Contact vaccination.*—This can be ruled out. Such transference could occur only in the susceptible phase, so that all the lesions (primary vaccination and those transferred) should progress more or less together and not more than a week apart. (ii) *Generalized vaccinia.*—No mention is made of an eczematous condition of the skin, so Kaposi's dermatosis may be excluded. Ordinary dissemination is possible as an explanation, but seems unlikely in view of the absence of constitutional upset. (iii) *Sensitization to calf lymph.*—Rashes —erythematous, papular, urticarial, and vesicular—may be encountered after vaccination and are akin to the "serum rashes" seen after the administration of antitoxins. These usually fade within seven to ten days of their appearance, but a longer duration is possible. Five weeks, however, does seem a rather excessive period. (iv) *Impetigo.*—It is assumed that a vesicular form of impetigo can be excluded.

It seems therefore most likely that a sensitization rash is the best explanation. The following observations are relevant. First, in the absence of an atopic eczema there is no reason to believe that subsequent vaccination would necessarily again be followed by dissemination of virus. Secondly, if sensitization is the cause one would expect further manifestations of sensitization to appear, and these should be looked for. If it was considered practicable a patch or scratch test with heated calf lymph (to destroy the virus) might be tried. Certainly it would be worth while carrying out this simple procedure before any subsequent vaccination.

Penicillin in Chronic Sinusitis

Q.—*Has any work been done on the treatment of chronic sinus infections by antibiotics, particularly those infections which cannot be treated by irrigation?*

A.—A great deal of work has been done on this problem, especially with penicillin. Boyd, in an article in the *Laryngoscope* (July, 1947), gives an excellent summary of the literature, and describes his own results in a small series of cases. He concludes that penicillin undoubtedly has a useful place in treatment. But here, as in all chronic infections of this type, the difficulty is to bring the antibiotic into contact with the organisms in adequate concentrations. For this reason the results of treatment are usually disappointing, even when the antibiotic is administered locally and parenterally over long periods.

NOTES AND COMMENTS

Cracked and Painful Fingertips.—Dr. H. Maitland Moir (Midlothian) writes: Your pessimistic answer (July 15, p. 178) is surely unwarranted. "Circulatory, metabolic, or hormonal dysfunction, xeroderma, psoriasis, lichen simplex, constitutional background factors"—I have none of these, though I do have occasional "hacks," as we call them in Scotland. They are quickly curable and instantly relievable. I pass on Dr. Grant Peterkin's advice to me, which I have proved to be excellent. Dry the hack, open it up, and insert a piece of cobbler's wax about the size of a large pinhead. Hold the finger near the fire or radiator: the wax quickly softens, and is then pressed firmly into the hack. A small piece of adhesive tape may be used to cover up the black spot. A pennyworth of wax is enough to cure all the hacks in Europe.

Corrections

In a leading article entitled "Public Health Dispute" (August 5, p. 336), the Conditions of Employment and National Arbitration Order, 1940, of the Defence (General) Regulations, 1939, was incorrectly described as the National Arbitration Tribunal (Defence) Regulations, 1940.

We regret that Professor R. D. Passey's name was wrongly spelt in the article entitled "Diphyllobothrium Infestation and Anaemia in Great Britain" (July 22, p. 188), and also in the list of references (p. 192).

CLINICAL TRIALS OF ANTIHISTAMINIC DRUGS IN THE PREVENTION AND TREATMENT OF THE COMMON COLD

REPORT BY A SPECIAL COMMITTEE OF THE MEDICAL RESEARCH COUNCIL*

The investigations of Brewster (1947, 1949), Gordon (1948), Murray (1949), Arminio and Sweet (1949), Phillips and Fishbein (1949, 1950), and Tebrock (1950) suggested that antihistaminic drugs had beneficial effects in the prophylaxis and treatment of the common cold. On the other hand, these observations could not be confirmed by Paton, Fulton, and Andrewes (1949), Hoagland, Deitz, Myers, and Cosand (1950), Feller, Badger, Hodges, Jordan, Rammelkamp, and Dingle (1950), and Cowan and Diehl (1950). A critical review by the Council on Pharmacy and Chemistry of the American Medical Association (1950) cast serious doubt on the validity of the conclusions and the interpretation of the results of some of the earlier investigations, referred to above, which had seemingly shown favourable effects.

In view of the great practical importance of the favourable findings, if confirmed, the Medical Research Council undertook, at the request of the Ministry of Health, to investigate in this country the value of the treatment. A special committee was appointed early in 1950, and the results of the tests arranged by the committee are reported here.

The trials have been of two kinds: (1) small-scale tests of two powerful antihistaminic drugs—promethazine hydrochloride ("phenergan," May & Baker, Ltd.) and chlorocyclizine hydrochloride ("histantin," Burroughs Wellcome & Co.)—in the prevention of inoculated colds in volunteers at the Common Cold Research Unit, Harvard Hospital, Salisbury; and (2) large-scale trials of the much weaker antihistaminic thonzylamine (also known in America as "neohetramine" or "anahist") for the treatment of colds occurring naturally among volunteers drawn from the general adult population—workers in the Civil Service, industrial establishments, universities, and the like (see Appendix).

I. THE PROPHYLACTIC EXPERIMENT AT SALISBURY†

The object of this experiment was to see whether antihistaminics given before, and for a few days after, nasal instillation of common-cold washings to human volunteers would prevent the development of a cold. Histantin and phenergan were selected as the drugs for test, as the antihistaminic activity of both was known to be high. The volunteers were isolated in pairs throughout the trial—in the same way as has previously been described by Andrewes (1949). Half the subjects received the drug under test, the other half received dummies indistinguishable from it and containing ¼ gr. (16 mg.) of phenobarbitone. It was felt that the latter would, in the dosage employed, have a mild sedative effect and so be acceptable as a control medication against which the efficacy of the antihistamine could be measured. Tablets were given at approximately 10 a.m. and 7 p.m., swallowing being supervised by the matron. Two members of a pair were given the same substance. Whether they were to be given the drug or the dummy was decided randomly, and neither the patient nor the clinical observer knew which any particular patient had received.

Trial 1: Histantin (January 18–28, 1950)

A 50-mg. tablet of histantin (or of the dummy) was given twice daily, beginning 48 hours before the cold inoculation and continuing until 72 hours after it. The virus inoculum was a 1 in 3 dilution of an unfiltered washing from patient G., who had developed a cold after receiving passage material from one of the Common Cold Research Unit's "pedigree" strains, Harrow. The results are shown in Table I. The incidence of colds is seen to be the same in the treated and control groups; there was no clinical difference from the usual course of experimental colds. One spontaneous cold developed in a subject who had been taking histantin for 24 hours; a similar case occurred in the control group.

Table I.—*Results of Trial 1*

Drug Administered	Cold	No Cold
Histantin	4*	4
Control tablet	4*	4
Total	8	8

* Includes one spontaneous cold developing during quarantine period before inoculation.

Trial 2: Phenergan (February 1–11, 1950)

A 20-mg. dose of phenergan (or of the dummy) was given twice daily, beginning 60 hours before virus inoculation and continuing for 72 hours after. Two test viruses were used —unfiltered G diluted 1 in 3, as in Trial 1, and a filtrate

*The membership of the committee was as follows: Dr. F. H. K. Green (chairman), Dr. C. H. Andrewes, Professor W. A. Bain, Professor A. Bradford Hill, Dr. W. C. Cockburn, Dr. P. D'Arcy Hart, Dr. J. Faulkner, Dr. N. L. Lloyd, Group Captain T. C. MacDonald, Dr. L. G. Norman, Dr. J. P. Sparkes, Dr. T. Sommerville, and Dr. J. A. Harrington (who was appointed secretary and co-ordinated the trials).

†Members of the staff concerned with this investigation were C. H. Andrewes, T. Sommerville, K. R. Dumbell, and J. S. Porterfield.

TABLE II.—*Results of Trial 2**

Drug Administered	Cold Washing	Cold	No Cold
Phenergan	G	5	0
	Pool 82	2	2
Control	G	3	4
	Pool 82	1	3

* In the phenergan experiment two volunteers of opposite sex were unpaired; these were treated as singletons, one getting the drug and one not. In addition one volunteer and her partner inoculated with the G virus have been excluded since she developed influenza in the course of the experiment.

of pool 82 (also virus of Harrow passage series). Table II shows the results. As in Trial 1 there is no evidence of prevention with the antihistaminic drug.

Side-effects

Subjects were not warned that some side-effects of the drugs might be apparent, but may well have read of this possibility in the lay press. In the first trial, of the eight persons taking the drug only one complained of "fuzziness in the head" half an hour after her fourth dose of histantin; it lasted ten minutes. In the second trial four patients complained of drowsiness; two were in the phenergan and two in the control group. In assessing the significance of this low incidence of side-effects it must be remembered that the volunteers in this trial were leading a very leisurely existence and were under no kind of strain.

Discussion

Some claims to a beneficial effect of antihistaminics in curing colds have emphasized the need for beginning treatment within a few hours of onset. It is thus particularly noteworthy that the results at Salisbury with experimental colds showed no effect even when the drugs were given for two to three days *before* infection. Clinical observation of the volunteers revealed no difference in the nature and duration of experimental colds in those who received antihistaminic treatment and those who did not. The results with the two antihistaminics tested were clear cut, and there seemed to be no good reason for repeating the experiment with other drugs of a similar kind.

II. LARGE-SCALE THERAPEUTIC FIELD TRIAL

Plan of Investigation

To assess the value of antihistaminic drugs in the treatment of the common cold it was necessary to compare the experience of treated individuals with that of a similar group not treated; for this purpose it was decided to plan the inquiry on similar lines to those adopted by a committee of the Council in investigating the value of patulin for the same purpose during the war (*Lancet*, 1944, 2, 373).

Choice of an Antihistaminic for Test.—The antihistaminic drugs vary considerably in their properties, potency, and toxicity, but it clearly was impracticable to carry out field tests of more than one product if sufficiently large groups for statistical analysis were to be obtained within a reasonable period. The available evidence indicated that thonzylamine would be the most appropriate choice in the first instance, as it was generally accepted as having a low toxicity (Friedlaender and Friedlaender, 1948; Criep and Aaron, 1948; Schwartz, 1949) and had been claimed as very effective against the common cold by Arminio and Sweet (1949) and Tebrock (1950).

Organization of Trials at Individual Centres.—The supervision and conduct of the investigation at the individual centres were carried out by medical officers who had been visited by the secretary of the committee and instructed in the standard procedure proposed; at some centres the conduct of the test was delegated to a trained industrial nurse working under the supervision of a medical officer. The existence of the trial was brought to the notice of potential volunteers by means of posters, notices, etc., the details of publicizing the scheme being left to the medical officer in charge. Volunteers were told of the experimental nature of the inquiry and the desirability of attending for treatment as soon as possible after the onset of symptoms of a cold.

Selection of Cases.—Admission to the trial was limited to volunteers over the age of 15 years in whom there was good evidence of the presence of the common cold. As it was important to obtain uniformity in different areas, the following definition of a common cold was given as a guide to the observers: "A catarrhal inflammation of the upper respiratory passages usually without pyrexia but with a watery or mucous discharge from the nose and associated with sneezing, fullness in the head and nose, and sometimes with cough, headache, sore throat, hoarseness, and running eyes." Reliance was placed mainly on the subjective diagnosis, and cases were accepted on the basis of the patient's description of his symptoms; clinical examination, other than the recording of temperatures, was carried out only to exclude other conditions. All volunteers whose conditions fell into any of the following categories were excluded: chronic catarrh or sinusitis; acute tonsillitis; suspected influenza; any person whose temperature was found to exceed 100° F. (37.8° C.); those who, on inquiry, seemed likely to have taken an antihistaminic drug for any purpose within the previous week; those with a *present attack* of hay-fever or allergic rhinitis. Persons with a *previous history* of allergic states were included, but a note to this effect was made in the appropriate column of the record sheet.

Design of Trial

To ensure that no bias could enter into the assessment of results it was essential that neither the patient nor the investigator should be aware whether antihistaminic tablets or control tablets had been given in a particular case. For this purpose, those who were to be treated and those who were to be "controls" were prearranged in random order by the use of random sampling numbers, with the one restriction that each batch of 50 volunteers should include 25 treated (T) and 25 controls (C) (a restriction not known at the centres).

These lists were numbered consecutively, so that, for example, a series might run as follows: 1T, 2T, 3C, 4T, 5C, 6C, and so on, randomly. Such lists were constructed, in the Council's Statistical Research Unit, for each centre. Record sheets and cartons containing the appropriate tablets were then marked (in the Statistical Research Unit) with the serial number—namely, 1, 2, 3, 4, 5, 6, etc., but with no reference to (T) or (C)—and sent to the local centres; thus at the local centre one carton and one record sheet, *the serial numbers of which corresponded*, were used for each patient. They were used in strict order of serial number; thus if the last patient on one day was recorded on record sheet "15" and received tablets from carton "15," the first patient on the next day was recorded on record sheet "16" and received tablets from carton "16." The key to the identity of the serial numbers was kept centrally and secret until the end of the investigation.

This somewhat novel method was adopted in place of the more usual one of merely labelling one product X and the other Y and giving them in random order, in view of the side-effects to be expected with the antihistaminic drug. If decisive side-effects were observed with even one patient then the nature of X (and Y) would ever after be known (or suspected). With the method chosen the identity of one carton might well be suspected in the patient with

side-effects, but no evidence would thereby be given regarding the treatment of any other patient.

Course of Treatment

At the first attendance the medical officer, having satisfied himself that the patient was suffering from a common cold and was not within one of the excluded categories previously defined, completed Part A of the record sheet (reproduced here) and then proceeded to dispense the tablets.

Each patient, it was laid down, should receive one tablet *three times a day for three days*—that is, a total of nine tablets. The individual and numbered carton for each patient held three envelopes, each containing three tablets: one envelope was issued each day—that is, on reporting, on the next day, and on the day following that. Antihistaminic tablets contained 50 mg. of thonzylamine; control tablets contained 5 mg. of quinine sulphate in a lactose base. All tablets were sugar-coated, and those which contained the antihistaminic were indistinguishable in appearance from those which did not. Volunteers were told to swallow the tablets whole, to remove the possibility of detection by taste if they were bitten or chewed. Each patient was given an instruction leaflet (explaining the details of the treatment and follow-up) and a note to hand to his family doctor if the latter was consulted during the period of the test.

Follow-up and Assessment of Progress

Patients were instructed to report progress at the end of 24 hours, 48 hours, and after a week. At these attendances the volunteers were requested to state quite frankly whether they thought the treatment given had been effective; assessments of progress were recorded by ringing the words "cured," "improved," "unchanged," "worse," or "recurred" as appropriate. The definitions of these categories had been laid down as follows:

"*Cured.*"—Only those persons who, after questioning, are found to be *completely* free from symptoms and who, on examination, are found to be without objective signs.

"*Improved.*"—Persons who, on questioning and examination, are found to be improved but not cured since the previous examination.

"*Unchanged.*"—Persons in whom, on questioning, the symptoms and signs are found to be unchanged since the previous examination. (*All cases in which there was doubt regarding progress were included in this category.*)

"*Worse.*"—Persons in whom, on questioning and examination, the symptoms and signs are found to have increased since the previous examination.

"*Recurred.*"—Patients, previously classified as "cured," and who report with another cold within 14 days of recovery from the previous one.

Assessment of Side-effects.—Direct questions about side-effects were avoided during treatment lest the investigator

(*Please do not ask* DIRECT QUESTIONS *about specific side-effects as this may give misleading results*)

1. Has the treatment agreed with the patient? Yes No
2. If "No," what symptoms does the patient attribute to the tablets? (*State nature and severity as "mild," "moderate," or "severe"; and date of occurrence*)

Off work* from..... to..... Reason:
* (*Delete if not off work during trial*)

ANY FURTHER COMMENTS

might surmise from the answers whether the patients were on the antihistaminic or the control treatment. Where, however, side-effects were spontaneously complained of, details were noted, including the nature, date of onset, and severity. In all cases the patient was asked at his *last* attendance, and after the assessment of progress, whether the tablets had affected him adversely in any way; if the answer was in the affirmative the symptoms attributed by the patient to the tablets were noted.

Results

These therapeutic trials were set up at 19 widely distributed centres with a total population of approximately 58,000. They were carried out in each area between the middle of March and the middle of May, 1950, though not invariably over the whole of that period.

In total, 1,550 volunteers at the various centres were treated in the investigation—775 with the drug and an equal number with the control tablets. However, 394 record sheets had subsequently to be rejected from the analysis for such reasons as failure to complete the treatment or to report progress on the required days. These rejects came about equally from the treated and control groups (196 and 198 respectively), and thus show no differential bias. Deducting the rejects, 1,156 record sheets were available for analysis—579 for patients who received antihistaminic treatment and 577 for patients who had the alternative treatment. Since analysis of the results from each centre revealed no significant difference between them, only the combined results from all centres need be given here. It may also be noted that a special analysis was made according to the number of records that had to be rejected. The centres were grouped in three categories: under 10% of records rejected, 10–19% rejected, 20% or more rejected. No differences in results were revealed, showing again that the lapses did not bias the inquiry.

Feeling ill	44	7·6	46	8·0

The comparable nature in regard to initial symptoms of the volunteers who received antihistaminic treatment and those who did not is shown in Tables III and IV. It will be seen that the method of random allocation used resulted in two groups which were closely alike in relevant respects.

The results at the end of the first day, second day, and one week for different durations of colds before treatment are given in Table V. None of the differences is individually statistically significant for each duration of cold before treatment, and indeed the similarity in response of the two groups seems more remarkable than any dissimilarity. For instance, of those who came for treatment within the first day of their onset of symptoms, 13.4 and 13.9% of the treated and controls, respectively, reported a cure on the second day; 48.8 and 46.8% were cured at the end of the week. It may, however, be noted that the treated group had consistently a slightly higher proportion of cured and improved on the first day of treatment than had the controls.

By combining all results, irrespective of duration of cold before treatment, 48.0% of the treated and 42.1% of the control group were found to be improved (including nine treated and five control cases who were cured) at the end of the first day's treatment. The difference, 5.9±2.9, is just significant in a technical sense, but even if it be real it is so small that it clearly has no practical importance. Also, this small difference, it will be seen, vanished on the second day, when, taking all the group together, the proportions of cured and improved were respectively 8.8% and 53.0% in the treated and 8.5% and 51.3% in the control group. Possibly the apparent small difference at the end of the first day's treatment can be accounted for by a slight sedative effect in some few subjects who received thonzylamine or by the unwitting inclusion of some individuals who were suffering from hay-fever or an allergic rhinitis and not from the common cold.

It has been mentioned that volunteers with a present attack of hay-fever or allergic rhinitis were, so far as possible, excluded, but persons with a previous history of allergic conditions were included provided they were believed to be suffering from a cold. From Table VI it will be seen that a previous history of hay-fever, allergic

Gastro-intestinal	13	12
Combined gastro-intestinal and nervous symptoms	8	7
Miscellaneous	16	16
Total	121	111

of side-effects attributed to the alternative treatment can have been due to the small doses of quinine given in the control tablets. It seems much more probable that many of the symptoms described as side-effects were, in fact, symptoms of the cold itself. On the other hand, when, as here, efforts were made to avoid direct questions about specific side-effects, prior knowledge of the possibility of reactions may have led to a spurious increase in their incidence through psychogenic factors.

CONCLUSIONS

In a small but carefully controlled experiment two antihistaminic drugs—promethazine hydrochloride and chlorocyclizine hydrochloride—showed no evidence of having any value in the prevention of experimentally induced colds.

A large-scale clinical trial of thonzylamine in widely separated areas in Great Britain and Northern Ireland, carried out between the middle of March and the middle of May, 1950, showed that, in the dosage employed, this antihistaminic drug had little if any value in the treatment of the common cold.

The committee is greatly indebted to Dr. W. J. Martin, of the Medical Research Council's Statistical Research Unit, for carrying out the statistical analysis of the results, and to the managements, medical staffs, and volunteers in the industrial and Civil Service establishments, universities, and elsewhere for their co-operation and assistance in carrying out the trials. Thanks are also due to Dr. W. E. Chiesman, Treasury Medical Adviser, for much help, and to the Director-General of Medical Services, Royal Air Force, for permitting the inclusion of R.A.F. personnel in the trial. The antihistaminic drugs and control tablets for the experiment at Salisbury were kindly supplied by May & Baker Ltd., and Burroughs Wellcome & Co., and the supplies of thonzylamine used in the therapeutic field trials were specially made for the purpose by May & Baker Ltd., who also kindly provided the control tablets.

TRIAL OF ANTISTIN IN THE COMMON COLD

BY

GERARD LORRIMAN, M.B.E., M.D., M.R.C.P.
Medical Adviser to Ciba Laboratories, Ltd., Horsham

AND

W. J. MARTIN, D.Sc., Ph.D.
(From the Medical Research Council's Statistical Research Unit, London School of Hygiene and Tropical Medicine)

Following American reports of the suppression of symptoms of the common cold by the prompt administration of antihistaminics, it was felt necessary to make a large-scale trial in the United Kingdom, adopting such controls as were practicable, in an endeavour to remove doubt concerning the efficacy or otherwise of the suggested treatment. "Antistin" (2-phenyl-benzyl-aminomethyl-imidazoline hydrochloride), synthesized by Miescher, Urech, and Klaren, of Ciba, was selected as suitable for such a trial because it is an antihistaminic of which favourable reports have been published in the treatment of allergic conditions such as urticaria, angioneurotic oedema, and hay-fever, and it has a comparatively low incidence of side-effects (Meier and Bucher, 1946; Britton, 1947; Overton, 1948).

The plan of the trial was based on that of the Medical Research Council's trial of patulin in the treatment of the common cold. Their report (1944) emphasized the following points in connexion with such a trial:

1. Since there is no reason to believe that the common cold is always or even usually due to the same agent either in sporadic cases or in different epidemics, it is necessary to include a large number of patients at several widely separated places, over a period long enough to exclude the possibility that a single prevalent epidemic is being studied.

2. Since the duration of colds is not constant but varies not only between different epidemics but also between different patients in the same epidemic, there must be a satisfactory series of control cases. This can be done only by ensuring that alternate cases at each centre receive a spurious treatment which to the recipient is indistinguishable from the genuine treatment.

3. The objective signs associated with the common cold are too variable to suffice as criteria of its presence or progress. A cold manifests itself mainly by subjective symptoms, and consequently diagnosis rests mainly upon the statements of the untrained patient.

Method

The trial was carried out in eight factories and one public school. These centres, comprising a total population of over 50,000, were widely scattered throughout the country. Antistin tablets (0.1 g.) and dummy tablets of identical appearance and practically identical taste were used, the latter having the following composition: lactose, 0.085 g.; quinine sulphate, 0.005 g.; starch, 0.031 g.; talc, 0.015 g.; and gelatin, 0.004 g. (The *British Pharmacopoeia* gives the effective dose of quinine sulphate as 0.3 to 0.6 g.)

It was arranged that none of the medical staff at any of the trial centres should be informed which tablets were active and which dummy. In order further to reduce the likelihood of identification, four letters were used instead of two (Q and S being dummy, and R and T antistin). The tablets were packed in cellophane containers, each container of nine tablets bearing one of the above four letters and instructions for taking the tablets.

It was originally intended that each patient should be seen by a doctor, but in three of the smaller trial centres there was none, and in some of the remainder it was impossible for the doctor to see all patients himself. Therefore many of the case record cards were completed by nurses or medical orderlies. Since the record was in the main simply the patient's own account of his symptoms there seemed to be no serious objection to this procedure.

So far as possible the investigation was confined to patients reporting within 24 hours of the onset of a cold. At the first examination, after recording the patient's name, occupation, etc., on a case record card, the relevant items among the following were ringed:

Duration of cold before first examination: 6, 12, 24 hours.
Nasal: Sneezing Discharge (clear, purulent) Obstruction.
Throat: Soreness Irritation Hoarseness Cough.
Head: Fullness Stuffiness Headache Lacrimation.
General: Malaise Pains Feverish.

At one centre, where all cases were seen by the doctor, the presence or absence of the following physical signs was regularly recorded: pharyngitis, laryngitis, tonsillitis, and sinusitis. The above scheme is by no means free from criticism, but it appeared to serve its purpose.

Successive patients received containers of tablets marked Q, R, S, and T, and the appropriate letter was noted on the case record card. Instructions were given to take two tablets at once, and thereafter one tablet every four hours except during the night. The patient was asked to report again after 24 hours, 48 hours, and one week, and at each interview the patient's own opinion whether the cold was cured, improved, or unaffected was recorded. The number of tablets taken was also noted. Not altogether surprisingly, the request to report three times during treatment met with only very partial success. The trial ran from November, 1949, until April, 1950.

Results

Therapeutic trials were carried out in nine centres, and the records of 1,744 patients were received from these centres. The numbers were 866 in the treated group and 877 in the control group, while for one person the group was not recorded. Of the treated group 379 and of the control group 366 reported after 24 hours, 48 hours, and seven days. Records for the remaining patients who reported once or more were completed for the first day after treatment for 318 in the treated group and 344 in the control group, for the second day after treatment for 245 treated and 249 controls, but only 23 treated and 21 controls reported on the seventh day.

The method of alternative allocation to the treated and control groups gave two groups which were comparable with regard to initial symptoms. Table I shows that the distributions of symptoms at the first examination were very similar for the two groups.

TABLE I.—*Symptoms at First Examination*

	Treated		Controls	
	No.	%	No.	%
Nasal:				
Sneezing	528	61·0	553	63·1
Clear discharge	478	55·2	469	53·5
Purulent discharge	83	9·6	87	9·9
Obstruction	184	21·2	201	22·9
Throat:				
Soreness	283	32·7	233	26·6
Irritation	198	22·9	198	22·6
Hoarseness	155	17·9	139	15·8
Cough	329	38·0	293	33·4
Head:				
Fullness	152	17·6	158	18·0
Stuffiness	358	41·3	370	42·2
Headache	299	34·5	287	32·7
Lacrimation	98	11·3	104	11·9
General:				
Malaise	146	16·9	105	12·0
Pains	79	9·1	91	10·4
Feverish	85	9·8	87	9·9
Physical signs*:				
Pharyngitis	106	12·2	119	13·6
Laryngitis	13	1·5	9	1·0
Tonsillitis	19	2·2	15	1·7
Sinusitis	38	4·4	30	3·4

* Recorded in one factory only.

The results for the patients who reported on each of the three days are shown in Table II. On each day the proportion recovering was slightly smaller in the treated than in the control series, but none of the differences is statistically significant.

TABLE II.—*Results for Patients who Reported on Each of Days 1, 2, and 7*

	Day 1		Day 2		Day 7	
	Treated	Controls	Treated	Controls	Treated	Controls
Cured	6	9	56	68	168	163
Improved	208	215	213	203	121	120
No effect	165	142	110	95	90	83
Total	379	366	379	366	379	366
% cured:						
Treated	1·6		14·8		44·3	
Controls	2·5		18·6		44·5	
Difference	−0·9		−3·8±2·7		−0·2±3·6	
% cured and improved:						
Treated	56·5		71·0		76·3	
Controls	61·2		74·0		77·3	
Difference	−4·7±3·6		−3·0±3·3		−1·0±3·1	

The experience of the patients with incomplete records is shown in Table III. In this group the controls also showed a statistically insignificant advantage over the treated.

TABLE III.—*Results for Patients with Incomplete Records*

	Day 1		Day 2	
	Treated	Controls	Treated	Controls
Cured	8	9	31	39
Improved	169	191	127	142
No effect	141	144	87	68
Total	318	344	245	249
% cured:				
Treated	2·5		12·7	
Controls	2·6		15·7	
Difference	−0·1		−3·0±3·1	
% cured and improved:				
Treated	55·7		64·5	
Controls	58·1		72·7	
Difference	−2·4±3·9		−8·2±4·2	

No direct or indirect questions were asked concerning possible side-effects. The number of patients who had conditions which they attributed to the treatment was too small for detailed analysis, for only 14 in the treated group and 13 in the control group complained that the tablets had any adverse effects. Most of the symptoms described could in fact have been symptoms of the cold.

Conclusion

A large-scale trial of antistin failed to show that this drug had any effect on the course of the common cold.

We are greatly indebted to the managements and medical staffs of the centres where the trials were carried out, and we should like to thank the following people in particular for their co-operation and assistance: Dr. G. G. Crisp; Mr. L. Ellis, of Messrs. James Townsend and Son, Ltd., Exeter; Dr. T. England, of Messrs. Currans, Ltd., Cardiff; Dr. J. V. Manning, of Messrs. Pilkington Brothers, Ltd., St. Helens; Mr. J. E. Olsen, of the Ministry of Supply, Military Engineering Experimental Establishment, Christchurch; Dr. M. W. Robinson, of Metropolitan Vickers Electrical Co., Ltd., Manchester; Dr. Philip Ross, of the Morgan Crucible Co., Ltd., London, S.W.11; Miss Kathleen Stott, of Messrs. Beatson, Clark and Co., Ltd., Rotherham; and Dr. J. Magill Young, of the Brush Electrical Co., Ltd., Loughborough.

EARLY CLINICAL MANIFESTATIONS OF DISSEMINATED SCLEROSIS

BY

DOUGLAS K. ADAMS, M.D., F.R.C.P.

JOHN M. SUTHERLAND, M.D.
(From the Western Infirmary, Glasgow)

AND

W. 'BELL FLETCHER, F.S.S.
(From the Nuffield Bureau of Health and Sickness Records, Glasgow)

The object of this investigation was to determine which clinical features of disseminated sclerosis are of most diagnostic value, with special reference to the paramount importance of early recognition. The report is based on an analysis of 389 cases of disseminated sclerosis, 79 of which were investigated in a medical ward in the Western Infirmary, Glasgow.

Although not directly concerned in this report with the aetiology of disseminated sclerosis, we would suggest, as does McAlpine (1946), that the evidence in favour of the infective nature of the disease is increasing. Such a contention is strengthened by the recent work of Steiner (1941) and of Margulis and his associates (1946). Campbell and his colleagues (1947) and Campbell (1947) re-emphasize the possible relationship between disseminated sclerosis and agricultural exposure, previously referred to by Morawitz (1904), Steiner (1918), Dreyfus (1921), Adams (1923, 1927), and Wilson (1927).

The diagnosis of disseminated sclerosis at an early stage is important from the point of view of treatment. If therapeutic measures are to be of benefit they must be employed before irreparable damage has been inflicted on the central nervous system. This will be equally true if and when the causal agent is known and specific treatment is available for its eradication. As stressed by one of us in 1923, the ideal hope for the future lies in prevention of infection of the individual by detecting the mode of transmission. Ferraro (1944) has suggested that, once the initial aetiological basis is established, additional factors, such as the development of antigens from the white or grey matter, may play a part in the progress of the disease or in its exacerbations. Bailey and Gardner (1940) have shown that antigenic substances can be derived from myelin sheaths. If such an allergic reaction should indeed occur the importance of early diagnosis and treatment is obvious. The most satisfactory standard of diagnosis will entail recognition of the disease at a monosymptomatic stage.

This standard cannot be achieved, however, until disseminated sclerosis is made known to the general public. It is surprising how infrequently the patient communicates the first symptom to a doctor. Unless the lay public are taught to appreciate the potential significance of such symptoms as temporary weakness in a limb, transient dimness of vision, and diplopia the latter part of Buzzard's (1897) criticism, "the full-grown disease is frequently not recognized, the infant disease practically never," must remain justified.

Early diagnosis depends on proper appreciation of the disease process. We would like to stress the concept that in its early stages disseminated sclerosis is a functional nervous disorder. It was emphasized by Head (1920) that "all disease of the nervous system manifests itself

in loss of function." "Functional" is not the antithesis of "organic," and is not a euphemism for "hysterical." Experience has shown that certain signs depend, commonly, on the destruction of particular parts of the nervous system. It must be appreciated, however, that these are, *per se*, signs of deranged function. In the early stages of disseminated sclerosis they may not be proof of irreversible changes in the central nervous system. Since it is perhaps only at this stage that complete cure can be hoped for, the disastrous policy of waiting for multiple signs and symptoms to become apparent is at once obvious. This paper is mainly concerned with emphasizing those symptoms and signs which appeared first in our series, with a view to the earliest possible recognition of the disease.

Diathesis of the Patient

An important aspect of the clinical recognition of disseminated sclerosis is an appreciation of the type of individual most often attacked by the disease. In the past there has been a tendency to study disseminated sclerosis from the point of view of the "seed" to the exclusion of the "soil." The causal agent of what is almost certainly an infective process may be extensively distributed in nature. The occurrence of the disease in a clinically recognizable form would then be conditioned by personal susceptibility, predisposing factors, or exposure to an overwhelming infection. Such a hypothesis presupposes the existence of subclinical forms of disseminated sclerosis. This possibility has been referred to by Schaltenbrand, and quoted by McAlpine (1946). As in neurosyphilis, there can be little doubt that disseminated sclerosis may exist in an asymptomatic form.

In one case in our experience a paretic curve to colloidal gold was noted in a pensioner suffering from hysteria and showing no clinical evidence suggestive of an organic basis. Four years later loss of the abdominal reflexes was noted. Six years after the colloidal-gold observation had been recorded the patient was admitted to hospital suffering from unmistakable disseminated sclerosis.

With regard to personal susceptibility, disseminated sclerosis occurs most commonly in the sympatheticotonic type of individual. This view has been expressed by Adams, Blacklock, Dunlop, and Scott (1924) and by Adams and Sutherland (1948). As pointed out by Purves-Stewart (1945) in another connexion, sympatheticotonia may be localized. McAlpine (1946) suggests that sympathetic stimulation, by causing a vascular disturbance in the central nervous system, may in some instances be responsible for the appearance of clinical signs. It is not unreasonable to suppose that the effects of such stimulation will be most marked in sympatheticotonic individuals. The occurrence of the disease in patients with a frankly vagotonic diathesis is rare in our experience.

In this series the occurrence of the disease in more than one member of a family has been exceptional. This was also the experience of Risien Russell (1910), Bramwell (1917), Adams (1923), and Wilson (1940). On the other hand, Curtius (1933) found more than one case of disseminated sclerosis in 6 out of 56 families investigated. McAlpine (1946) found a familial incidence in 5% of 143 cases, and Brain (1947) considers that some 5–10% of cases of disseminated sclerosis have a near relative similarly affected. In one case in our series, from a mixed farm in Ayrshire, the patient's father and uncle had died from disseminated sclerosis, whilst his cousin living on an adjacent farm was probably similarly affected. This series of four cases shows common familial and occupational factors.

Predisposing Factors

In 127 cases (32.6%) one or other of four factors preceded the first symptoms of disseminated sclerosis by a short period of time. In no instance did this exceed six months. By so doing, they might reasonably be regarded as predisposing to the illness. These factors were febrile illness (14.4%), trauma (10.5%), pregnancy (4.5%), and emotional upset (2.8%). The association of one of them together with a symptom such as weakness in a limb or diplopia should suggest the possibility of disseminated sclerosis.

Infection

A relationship between disseminated sclerosis and infection has been noted by many workers. Head (1920) observed that disseminated sclerosis not unusually begins with short attacks of what is called "influenza." Bramwell (1917) found this relationship in 28 of his 200 cases (14%). Wilson (1940) and McAlpine (1946) suggest 5% as the possible figure. As a transitory febrile illness may be readily forgotten by the patient, the value of statistical evidence on this point is difficult to assess. Brain (1947) grants that such an illness may be reasonably regarded as a predisposing factor, but considers the cause of the pyrexial reaction to be unknown. Collier and Adie (1933) emphasized the possibility that in some cases this reaction may be a febrile phase of disseminated sclerosis itself.

By analogy with syphilis it was thought that a febrile onset might be associated with a long latency of infection subsequent to the initial manifestation. Thus, Mattauschek and Pilcz (1913) and Browning and Mackenzie (1924) have observed that the course of syphilitic infection may be modified by an intercurrent infection. This possibility was investigated by relating the mode of onset to the duration of the period before the patient presented for treatment. The results obtained suggest that a febrile onset does not materially influence the subsequent course of the disease with regard to latency of infection or progression of the disease process. Of the 56 cases which gave a history of febrile onset, 13 (23.2%) presented for treatment within one year of the first recognizable manifestation of the disease, and 35 (62.5%) within five years. In the 293 cases in which no history of febrile illness was obtained the corresponding figures were 56 (19.1%) and 173 (59%).

Trauma

In 41 (10.5%) of the 389 cases there was a history of either accidental or surgical trauma occurring shortly before the first manifestation of disseminated sclerosis. In a further considerable number of cases a history of trauma preceding an exacerbation was obtained.

This relationship is noted, amongst others, by Marie (1895) and by Adams, Blacklock, Dunlop, and Scott (1924). It appears to exist in 5–10% of cases of disseminated sclerosis (Brain, 1930, 1947). Thus Bramwell (1917) noted the influence of trauma in 17 (8.5%) of 200 cases, von Hoesslin (1934) in 59 (11.4%) of 516 cases, and McAlpine (1946) in 8 (5.6%) of 142 cases.

The mode of action of peripheral trauma as a predisposing factor is not known and the various theories will not be discussed. It is worthy of mention, however, that Browning and Mackenzie (1924), observing that the existence of latent periods in disease is not peculiar to syphilis, consider that trauma may give rise to disturbed relations between the patient and organisms which have already been present for some time without causing an active lesion. In disseminated sclerosis it is possible that trauma may act by adversely influencing the antigen-antibody balance

mechanism in the central nervous system. Klauder (1947), investigating the relationship of trauma and herpes zoster, has afforded some evidence that trauma may light up a latent virus infection.

Pregnancy

The first symptoms of disseminated sclerosis occurred after childbirth in 19 (8.8%) of the 216 female cases. Many authors have referred to the deleterious effect pregnancy and parturition have on this illness. Mention of this is made by Gowers (1893). Risien Russell (1910) observed that pregnancy or parturition may be responsible for relapses or more rapid progress of the disease, and stated that the first symptoms of the malady are not infrequently observed in these instances.

The National Multiple Sclerosis Society (1947) considers that the onset of the disease or a relapse is precipitated in about 40% of female patients who become pregnant. Walshe (1947) refers to the possible ill effects of pregnancy on disseminated sclerosis, but considers that it is not uniformly deleterious, while Wilson (1940) emphasizes the difficulty of establishing a causal nexus between the two. We would suggest that pregnancy in disseminated sclerosis should be regarded as avoidable trauma, and that the occurrence after parturition of a symptom referable to dysfunction of the central nervous system calls for the closest clinical examination.

Emotional Upset

An emotional upset such as grief, worry, or fright preceded the onset of disseminated sclerosis by a short period in 11 cases (2.8%). This relationship has been referred to by Risien Russell (1911), Bramwell (1917), McAlpine (1946), the National Multiple Sclerosis Society (1947), and Adams and Sutherland (1948). Emotional upset may act by "accentuating or evoking phenomena previously existing" (Risien Russell, 1910) or by "reducing resistance" (Wilson, 1940). Emotional reaction may produce stimulation of the sympathetic nervous system, resulting in localized vascular phenomena. It is important to note that in this series patients were not questioned specifically about the occurrence of an emotional upset. The 11 cases concerned volunteered the information, and a note to this effect was made in the case record.

Age and Sex Incidence

Only the age incidence can be regarded as being of diagnostic significance. As will be seen from Table I, 271

Table I.—*Age Incidence at Onset of Disease in 389 Cases of Disseminated Sclerosis*

Age at Onset in Years	Private Series		Hospital Series		All Cases	
	No.	%	No.	%	No.	%
Under 20	22	7·1	5	6·3	27	6·9
20–24	48	15·5	10	12·6	58	14·9
25–29	56	18·0	19	24·1	75	19·3
30–34	61	19·7	19	24·1	80	20·6
35–39	46	14·8	12	15·2	58	14·9
40–44	33	10·7	11	13·9	44	11·3
45–49	14	4·6	1	1·3	15	3·9
50	11	3·5	2	2·5	13	3·3
Not stated	19	6·1	—	—	19	4·9
Total	310	100	79	100	389	100

(69.7%) cases were in the third and fourth decades of life. It is relatively infrequent for the first symptom of disseminated sclerosis to occur in a patient under 20 or over 45 years of age.

In this country female cases slightly predominate. Our figures of 216 (55.5%) female cases and 173 (44.5%) male cases are in accordance with results previously reported by Bramwell (1917), Adie (1937), Wilson (1940), and Brain (1947). Neither the age nor the sex of the patient was found to influence materially the initial symptomatology, with the exception that retrobulbar neuritis predominated in the younger age groups and motor weakness in the older. Thus in the 20–29 years age group of 133 patients, 28 (21%) suffered from transient loss or dimness of vision as a first symptom. In comparison, the 40–49 age group of 59 cases had four cases (6.8%) so affected. Similarly, paresis of one or more limbs was the initial manifestation of the disease in 61 (45.9%) cases in the 20–29 years age group, and in 37 cases (62.7%) of the 40–49 years age group.

Symptomatology

As emphasized by Adie (1932), the onset of disseminated sclerosis is sudden, if by "onset" the appearance of the earliest symptom is referred to. The first symptom is generally attributable to a single lesion in the white matter of the central nervous system. In most cases the initial symptom, after persisting for a variable time, disappears. This is followed by a more or less complete remission, during which time the patient feels in normal health.

An appreciation of those symptoms which suggest the onset of disseminated sclerosis is of fundamental importance. The earliest manifestations in 389 cases are recorded in Table II. It is apparent that the common early symptoms

Table II.—*Initial Symptoms in 389 Cases of Disseminated Sclerosis*

Symptoms	No.	%
Weakness in one lower limb	90	23·1
Weakness in both lower limbs	73	18·8
Temporary dimness or loss of vision in one eye	54	13·9
Diplopia	50	12·9
Paraesthesiae	34	8·7
Weakness in one upper limb	19	4·9
Weakness in one lower and one upper limb	16	4·1
Vertigo	15	3·8
Upset of micturition	11	2·8
General debility; exhaustion; weakness	4	1·0
Mental confusion; inability to concentrate	3	0·8
Pain in leg(s)	3	0·8
Pain in back	3	0·8
Weakness in all four limbs	2	0·5
Epileptiform attacks	2	0·5
Dysarthria	2	0·5
Unilateral facial paralysis	2	0·5
Loss of sensation over side of face; weakness of mastication	2	0·5
Staggering gait	2	0·5
Vomiting	1	0·3
Nervousness	1	0·3

are weakness in one or more limbs (51.4%), visual upset (26.8%), paraesthesiae (8.7%), vertigo (3.8%), and upset of micturition (2.8%). One or other of these symptoms was the earliest manifestation of disseminated sclerosis in 93.5% of cases. The figures obtained differ in no significant manner from those previously recorded by Wilson (1940), who reviewed the initial symptomatology in 539 cases from four series.

We should like to make further reference to the occurrence of acute retrobulbar neuritis in disseminated sclerosis. Owing to the long remission which may follow transient dimness or loss of vision in one eye, the accuracy of statistical evidence on the subsequent development of disseminated sclerosis after retrobulbar neuritis is difficult to assess. Gunn (1904) found that of 233 cases of primary retrobulbar neuritis 51 (21.9%) were due to disseminated sclerosis. Marburg (1920) reported that 14 (58.3%) out of 24 cases of retrobulbar neuritis subsequently developed disseminated sclerosis. Weill (1923) investigated 22 cases of retrobulbar neuritis; 12 were found to be suffering from disseminated sclerosis, and a further five subsequently developed the disease.

Adie (1932) examined 70 cases of retrobulbar neuritis within one or two weeks of onset. He found 31.3% of

these cases to be suffering from disseminated sclerosis, and in a further 41.8% the diagnosis was probably disseminated sclerosis. Thus in only some 26.8% was there no other suspicious symptom and no definite sign of organic nervous disease. Adie (1929) emphasized that "there is only one known, proved, common cause of this condition, and that is disseminated sclerosis." This fact was previously stressed by Adams (1927). We would suggest that as the primary chancre or secondary rash of syphilis need not portend neurosyphilis, so retrobulbar neuritis need not progress to widespread involvement of the central nervous system. It is nevertheless probable that almost every case of otherwise idiopathic retrobulbar neuritis is due to the causal agent of disseminated sclerosis.

Emphasis has rightly been placed on those initial symptoms which occur most commonly, and, by so doing, to some extent suggest the diagnosis. We would stress, however, that in some 5% of cases the first symptom may not in itself be suggestive of the onset of disseminated sclerosis. Thus we have encountered, as the first manifestation of the disease, mental confusion, pain in the back, pain in legs (each three cases, 0.8%), epileptiform attacks, facial paralysis, loss of sensation over side of face, dysarthria, and staggering gait (each two cases, 0.5%).

Potential Relationship Between Occupation and Initial Symptoms.—This aspect was investigated, but with the exception of brain workers difficulty was experienced in classifying the occupation of the 389 patients into clear-cut divisions. It is interesting, however, that the clearly defined group of brain workers showed the highest incidence of retrobulbar neuritis. It is known that in tabes dorsalis occupational overstrain of the eyes predisposes to optic atrophy.

Potential Relationship Between Initial Symptoms and Latency of the Disease.—Adie (1932) observed that very long remissions "up to 20 years or more" are not uncommon where retrobulbar neuritis is the first symptom. He considers, however, that similar remissions are not common after other modes of onset. This question was investigated by relating initial manifestations to the duration of the period before the patient reported for treatment. In some instances this period will refer to the rate of progress of the disease rather than to absolute latency of infection. Despite this, it seemed to constitute a reasonable basis for investigation.

A latent period of 15 years or more followed the initial symptoms in 31 cases (7.9%). The only initial symptoms to be followed by a latent period of such duration were dimness or loss of vision in one eye in 8 cases (14.8%), paresis in 19 (9.5%), and diplopia in 1 (2%). It would therefore be reasonable to suppose that, since these symptoms may be followed by such a long latent period in some instances, they may be the sole manifestation of disseminated sclerosis in a lifetime. As Adie (1929) suggested in connexion with retrobulbar neuritis, "If a remission should last for 24 years, why not 54?" It should therefore be stressed that a prolonged remission following the initial symptom does not in any way invalidate the diagnosis of disseminated sclerosis. A further manifestation may occur at any time, or the remission may last for a lifetime.

Later Symptomatology.—Table III lists the main symptoms in 389 cases on presenting for treatment. Most of these patients were suffering from multiple symptoms; in a few instances the disease was fully established. A noticeable feature is the frequency with which upset of micturition occurs in the later stages of the disease. As an initial symptom bladder control was defective in only 11 cases (2.8%). In comparison, on presenting for treatment 173 patients (44.5%) complained of some defect of micturition. In view of the nature of this paper further discussion on late symptomatology is unnecessary.

TABLE III.—*Main Symptoms in 389 Cases of Disseminated Sclerosis on Presenting for Treatment*

Symptoms	No.	Patients Affected %
Paresis of limb(s)	368	94·6
Upsets of micturition	173	44·5
Paraesthesiae	135	34·7
Diplopia	84	21·6
Dimness or loss of vision	57	14·7
Vertigo	32	8·2
Facial paralysis	12	3·1
Pain in legs	11	2·8
Pain in back	10	2·6
General debility	10	2·6
Headache	8	2·1
Disorder of speech	6	1·5
Loss of sensation over one side of face	4	1·0
Vomiting	3	0·8
Deafness	3	0·8
Epileptiform attacks	2	0·5
Difficulty in swallowing	2	0·5
Mental confusion	1	0·3

Examination of the Patient

It would be reasonable to suppose that, in the early phases of disseminated sclerosis, signs which by custom we speak of as being "organic" are minimal. As previously emphasized, however, these signs are in reality evidence of disturbed function and not of structural change. Thus even in the earliest stages of disseminated sclerosis signs occur which are of fundamental importance in differentiating the disease from hysteria. This difficulty in distinguishing early disseminated sclerosis from hysteria was stressed by Buzzard (1897) in the following words: "In its infancy . . . the name given to disseminated sclerosis is hysteria." Further, it must be remembered that in all the phases of disseminated sclerosis hysterical manifestations complicate the clinical picture. Brain (1930) has observed that hysterical symptoms occur more often with disseminated sclerosis than with other organic diseases of the nervous system.

The physical findings which will be referred to are largely based on the result of examination of cases in the hospital series. The majority of these patients were in the oligosymptomatic stage of disseminated sclerosis. We are of the opinion that these signs occur and are of equal significance in the earlier phase of the disease.

1. Mental State of the Patient

The frequent hysterical overlay in cases of disseminated sclerosis has already been mentioned. Cottrell and Wilson (1926) stressed as being of diagnostic importance the triad of change in prevailing emotional disposition, change in emotional expression and control, and change in sense of physical well-being. Since available records were inadequate, no statistical analysis of this aspect was undertaken. Our impressions, however, are in accordance with the conclusions of these authors.

2. Neurovascular Phenomena

Vasomotor symptoms are common in patients with disseminated sclerosis. Thus cold hands and feet, acroparaesthesiae, and chilblains are often encountered. Erythromelalgia occurred in one case. Purves-Stewart (1945) observes that this condition may be one of the earliest signs of organic spinal cord disease such as disseminated sclerosis.

We have been impressed by the fact that weakness in a limb is often associated with a lowered skin temperature in that limb. It is possible that cutaneous angioneurosis may be an expression of "the soil" which predisposed to the development of disseminated sclerosis. Vasomotor instability of the extremities in disseminated sclerosis has also been referred to by Langworthy (1948).

3. The Eyes

We have found that three ocular signs have an important diagnostic value in disseminated sclerosis. This triad consists of imbalance of the ocular muscles, mydriasis, and hippus.

The ocular imbalance does not amount to strabismus, which in our experience is infrequent; it rather suggests a somewhat dissociated action of the extrinsic muscles of the eyes.

The pupils are generally larger than the average. In only five cases (6.3%) of the hospital series were the pupils myotic. Associated with this is the fact that the pupils are unduly mobile. The reaction to light is generally brisk. In only two cases (2.5%) was the light reflex absent. Similarly, the reaction of the pupil to near vision was found to be brisk in 74 cases (93.7%). The occasional occurrence of paralysis of accommodation has been referred to by Kinnier Wilson (1940), and was observed in three cases (3.8%) of the hospital series. In no instance were the requirements of the Argyll Robertson pupil fulfilled.

In a considerable number of cases the phenomenon of hippus was observed. Lagrange and Marquezy (1924) have referred to the occurrence of hippus in disseminated sclerosis, but it is felt that its presence is not accorded enough importance in textbooks or in teaching.

Gowers emphasized the difficulty in distinguishing between cases of disseminated sclerosis and neurosyphilis. We would suggest that the association of ocular imbalance, mydriasis, and hippus in disseminated sclerosis is of considerable importance in the differential diagnosis of these two conditions. With regard to other ocular manifestations, the pupils are not infrequently unequal and sometimes irregular. Nystagmus occurred alone or in combination with other components of Charcot's triad in 38 (47.9%) of the 79 hospital cases. The "characteristic" ophthalmoscopic picture is that of pathological pallor of the temporal half of the optic-nerve head. Such was found in only 13 (16.5%) of the hospital series. This figure is very low compared with that of "over 50%" suggested by Brain (1947). It closely approximates, however, to the incidence of symptoms referable to retrobulbar neuritis which occurred in 13.9% of the total series as a first symptom. Further, it is our experience, as it was of Adie (1932), that retrobulbar neuritis occurs relatively infrequently after the disease is established. In our series pathological temporal pallor of the optic disk was not present in a high proportion of cases; the absence of this feature should in no way cast doubt on this diagnosis.

4. Knee-jerks

Of the various tendon reflexes, particular diagnostic importance attaches to the knee-jerks. These were regarded as normal in only 7 (8.9%) of the 79 hospital cases. The knee-jerks were unequal in 36 patients (45.5%). In no patient in this series were these reflexes abolished.

5. Abdominal Skin Reflexes

In the diagnosis of disseminated sclerosis the importance of the abdominal skin reflexes is evident from the fact that they were abnormal in 77 patients (97.4%) in the hospital series. They were present normally in only two instances. In 69 cases (87.3%) there was bilateral loss of the reflex; in three (3.8%) unilateral loss was reported, and in five (6.3%) the abdominal reflexes were regarded as being readily exhausted.

The importance of the absent abdominal reflex was noted by Risien Russell (1910). Strümpell is quoted by him as finding them absent in 67% of 24 cases of disseminated sclerosis, compared with 13.5% in 185 persons with normal nervous systems. In Probst's series, quoted by Russell, the abdominal reflex was absent in 73% of cases. "The almost constant absence" of this reflex was emphasized by Adams (1921). Kinnier Wilson (1940) considered that suspicion of disseminated sclerosis should be attached to a case in which the abdominal reflex can be tired. Similarly, Purves-Stewart (1945) stresses the significance of absence or diminution of the reflex on one or both sides. Further, we would suggest that disseminated sclerosis should be suspected in a young patient whose abdominal reflexes do not share in the overactivity of the knee-jerks, should this latter abnormality be present.

Böhmig (1922), analysing 155 cases, considered that the addition of any single nervous physical sign to the combination of spastic phenomena in the lower limbs and the loss of the abdominal reflexes justifies the diagnosis of disseminated sclerosis, syphilis being excluded. This view is undoubtedly correct. It is emphasized, however, that spastic phenomena in the legs are not essential to the diagnosis. In a young adult the presence of a sign or symptom referable to a lesion in the white matter, associated with any of the abnormalities of the abdominal skin reflex mentioned above, should arouse suspicion of disseminated sclerosis. Wartenberg (1944) considers that the abdominal muscle reflex was of value in detecting a pyramidal-tract lesion "much earlier, better, and more surely" than the loss of the abdominal skin reflex. Such a view may be acceptable if significance be restricted to the loss of the skin reflex. If, however, the importance of the other abnormalities of the skin reflex be appreciated, it is felt that in disseminated sclerosis, at any rate, this reflex is at least of equal value in the early recognition of disturbed pyramidal-tract function.

The abdominal skin reflex was abnormal in several instances in which the plantar response was either equivocal or flexor. On the other hand, in no instance was an extensor plantar response associated with normal abdominal skin reflexes. An extensor plantar response (Babinski phenomenon) occurred in 66 cases (83.5%), in 8 (10.1%) it was equivocal, and in 5 (6.3%) it was flexor. In several instances Chaddock's sign has furnished evidence of pyramidal-tract dysfunction at a stage in which the plantar response was flexor or equivocal.

6. Adductor Spasm

We have found hypertonus of the adductor muscles of the legs to be the earliest manifestation of spastic phenomena in the lower limbs. As such, by constituting one of Böhmig's criteria, it is of value in the diagnosis of disseminated sclerosis.

7. Sensory Phenomena

The presence of signs referable to dysfunction of the posterior columns occurred in 37 cases (46.8%) of the hospital series. In this connexion, impairment of vibration sensibility was found to be the earliest manifestation of dorsal cord involvement. Loss of spinothalamic-tract function was unusual, and was found in only three patients (3.8%).

Summary

The symptoms and signs of 389 cases of disseminated sclerosis are discussed.

Weakness in one or more limbs was the first symptom in more than half the cases examined, while visual upset was the earliest manifestation in a further 26% of the patients.

The onset of the disease was found generally to occur in the age group 20–45 years, and when disseminated sclerosis is suspected in patients outside these limits other aetiological factors should be carefully considered.

For the development of disseminated sclerosis personal susceptibility is of importance, and in our experience the incidence of the disease is greatest in those with a sympatheticotonic diathesis.

Reference is made to those clinical signs which are of importance in distinguishing disseminated sclerosis from the manifestations of hysteria. In this connexion significance should be attached to the association of overactive knee-jerks and sluggish or readily exhausted abdominal skin reflexes. Other signs of diagnostic value are the mental state of the patient, the presence of neurovascular phenomena, and the triad of ocular imbalance, mydriasis, and hippus.

Stress is laid on the need for recognition of the disease before permanent damage has been inflicted on the central nervous system. Whatever advances in treatment the future may hold, the degree of recovery will depend on the stage at which a diagnosis is first established.

AFTER-HISTORY OF SUCCESSFULLY TREATED CASES OF SUBACUTE BACTERIAL ENDOCARDITIS

BY

HENRY MATTHEW, M.B., Ch.B., F.R.C.P.Ed.
Senior Registrar, Royal Infirmary, Edinburgh

The outstanding achievement of penicillin in overcoming infection in subacute bacterial endocarditis and in procuring a 65% cure (Christie, 1948) has presented new problems in prognosis. The immediate prognosis has received much attention, and an evaluation of the facts on which it may be based has often been presented (Jones *et al.*, 1947; Christie, 1946, 1948, 1949). The long-term influence of the infective process on the heart has naturally not received equal attention owing to the relatively short time since successful treatment of the infection was initiated. As penicillin has now been available for the treatment of subacute bacterial endocarditis since 1944 in America and since 1945 in this country, sufficient cases have been followed over a period of years for a tentative expression of remote prognosis to be offered.

Prognosis in rheumatic heart disease itself is always difficult owing to the tendency to additional damage due to relapse or reinfection, *ouvert* or subclinical. When it is appreciated, as Matthew and Gilchrist (1949) and MacIlwaine (1947) have shown, that the bacterial infection is frequently engrafted on a heart the seat of concomitant active rheumatic carditis, the difficulties of the assessment of the prognosis in subacute bacterial endocarditis will be seen to be further increased. Therefore prognostication of the after-effects of a bacterial infection engrafted on such a background cannot be easy, nor is it likely to be accurate. Deterioration will be difficult to ascribe either to the natural trend of the original rheumatic infection (DeGraff and Lingg, 1935) or the occurrence of rheumatic relapse, or to the after-effects of successful penicillin therapy for the superimposed bacterial infection. Despite such difficulties, it is important to know the fate of survivors from a disease which up to six years ago carried a 96% mortality (Lichtman, 1943).

Of a total of over 40 patients treated for subacute bacterial endocarditis, 20 have been cured for 27 months or longer. These 20 unselected patients provide the information on which assessment of remote prognosis is based. These patients have been closely followed up for periods varying from 2¼ to 5¼ years. Since discharge from hospital no survivor has relapsed or become reinfected, although at least one has had a further attack of rheumatic fever. The absence of relapse or reinfection is noteworthy, as Christie (1949) has indicated that the incidence of delayed relapse is of the order of 2% per annum.

A severe infection of the endocardium and myocardium, often of six months' duration before being arrested, is likely to lead to further cardiac damage. Apportioning of the degree of damage by the bacterial infection, in a heart already the seat of rheumatic or congenital pathology, is difficult for the reasons already advanced. Deterioration, if noted, cannot invariably be ascribed to the healing of the bacterial infection, as the relentless progress of the underlying rheumatic lesion will, especially in the elderly patient, contribute to a greater or less extent.

The cardiac efficiency of successfully treated cases can best be assessed by a study of three factors: (1) a comparison of the patient's capacity for effort before infection and after recovery; (2) changes in the heart size as noted radiologically; (3) the detection of physical signs indicative of new valvular lesions or an increase in the severity of established lesions.

Exercise Tolerance

Table I shows the comparison of cardiac grade (New York Heart Association, 1939) before and 2¼ to 5¼ years after treatment. The preponderance of cases with good

Table I.—*The Cardiac Grade Before and After Treatment*

Cardiac Grade	Before Infection	After Infection	Died
1	11*	11†	—
2a	7	7*	1
2b	2†	0	—
3	0	1	—

* One deterioration. † One improvement (congenital heart).

exercise tolerance before acquiring infection is in accordance with the findings of Libman and Friedberg (1948) that subacute bacterial endocarditis rarely occurs in the presence of advanced rheumatic heart disease. The information in Table I is revealing. Of 11 cases in Grade 1 (symptom-free before treatment) only one has shown deterioration in capacity for exertion, and that only to a slight extent. In seven patients classified as Grade 2a before the bacterial infection was acquired no deterioration was observed with the passage of the years.

One patient with congenital pulmonary stenosis was convinced that his exercise tolerance had improved considerably subsequent to the infection. In one patient, aged 34, classified as Grade 2b, further deterioration has become manifest by advancement into Grade 3 (congestive heart failure).

There has thus been a remarkable maintenance of capacity for effort in the survivors. All but two patients have resumed their former occupations or are now undertaking employment as strenuous as that prior to the onset of the infection. Of the two patients not working, one developed a right-sided hemiplegia during treatment and, although employable, has not yet been suitably placed; the other, in Grade 3, is naturally unfit for work. The occupations of the survivors range from busy housewife to general labourer, farm-worker, electrician and shop-assistant.

Four female patients have married since their illness, two have borne children without difficulty, and one is healthy at the sixth month of pregnancy at the time of review.

The degree to which subjective evidence of increased myocardial damage is absent is remarkable. Investigation of the second factor of assessment—x-ray examination for alteration in heart size—tends to substantiate the subjective evidence of lack of permanent damage from the infective process.

Heart Size

X-ray records were available of the size of the heart in two instances shortly before the onset of infection. In the remaining cases the heart size was assessed in the postero-anterior and both oblique views, if possible during the first week in hospital. This latter time of examination naturally varied with the duration of infection before admission. The variation, however, does not appear to confuse the deductions that can be made.

All patients had radiographs taken at the time of their follow-up, and the heart size was compared with that before or early in the infection (Table II).

The grades of heart size employed are: normal; slight enlargement, for a heart having one or more chambers just outside the limits of normal; one "plus" for a heart definitely enlarged in one or more chambers; and two "plusses" for a grossly enlarged heart. In only four instances did the heart enlarge during or after subsidence of the infection. No heart which was normal in size before treatment subsequently enlarged; increase, if it did occur, took place in a heart already enlarged to some degree.

Table II.—*Change in Size of Heart Found at Follow-up. In Only Four Instances has the Heart Enlarged*

Heart Size	Before or Early in Infection	At Follow-up			
		Normal	Slight	+	++
Normal	5	5			
Slight enlargement ..	10		8	1	1
+	5			3	2

Investigation of the four cases with evidence of change in heart size shows that the enlargement has not been slowly progressive over the years since cure. It occurred to its greatest extent during the weeks of penicillin treatment, and thereafter the size has remained almost stationary. It may be noted in passing that in no instances did the heart enlarge during treatment, only to regress during convalescence—a finding contrary to that of Jones *et al.* (1947), who report three cases showing enlargement which subsequently lessened, although only to a very slight extent. It is therefore assumed that, should the heart enlarge during treatment, it is likely to remain enlarged. That cardiac enlargement during the process of eradication of infection is the result of the bacterial infection cannot be certain. A concomitant rheumatic infection might as readily produce such a change in size.

Further investigation of the four cases with an increase in size shows no constant feature such as age, rhythm, valvular lesions, length of time prior to treatment, past or present rheumatic history, or electrocardiographic evidence of myocardial damage sustained during the bacterial infection, any of which might be responsible for the increase in size. Nor does the increase in heart size correlate with any deterioration in exercise tolerance except in one of the four cases—the patient formerly in Grade 2b and now in Grade 3 has considerable enlargement of the left ventricle and auricle. Jones *et al.* (1947) found that cardiac enlargement occurring at the time of, or subsequent to, treatment was usually associated with decreasing capacity for effort. There is therefore no doubt that heart size on termination of treatment is an important observation in assessment of remote prognosis. Although deterioration may not be evident, it is to be expected that the larger heart will fail earlier.

Fresh Valvular Damage

The finding of fresh evidence of valvular lesions in a heart the seat of rheumatic pathology cannot be ascribed solely to the bacterial infection and the healing process. However, Rosenblatt and Loewe (1945) and, Bloomfield *et al.* (1945) have demonstrated cases in which the mutilation of the valves immediately after penicillin therapy has been such as to constitute a grave mechanical handicap and to contribute materially to heart failure. In a series of fatal cases (Matthew and Gilchrist, 1949) no such destruction was evident at necropsy in 13 instances, except that in one case an aortic cusp had perforated as the result of the infection.

A comparison of the auscultatory findings at the outset of treatment and at the time of follow-up is presented in

TABLE III.—*Valvular Lesion Before and After Treatment. The Term "Mitral" is Employed to Cover Mitral Stenosis and Mitral Damage*

Valvular Lesion	Before Treatment	After Treatment
Mitral	9	8
Aortic incompetence and mitral ..	7	8
Aortic stenosis	1	Died
Congenital	3	3

Table III. In only one instance is there now evidence of additional valvular damage, aortic incompetence having appeared where previously mitral stenosis was the sole lesion. In three other patients the heart murmurs have permanently altered in character. This finding suggests that in these four instances it is probable that the healing of the infective process had some effect on the structure of the valve cusps.

Arrhythmias

Once again it must be emphasized that an alteration in rhythm cannot be attributed with any degree of certainty to the effects of the bacterial infection. However, three patients now suffer from occasional attacks of palpitation which have been shown by electrocardiogram to be due to paroxysmal auricular fibrillation. One additional patient has developed frequent ventricular extrasystoles. These arrhythmias do not disturb the patients unduly, but in one instance the cardiac grade has deteriorated to Grade 2a.

One Death

One patient died 29 months after treatment. He was 49 years old and was the only case of pure aortic stenosis in the series. He gave no rheumatic history, nor was there an aortic diastolic murmur or evidence of rheumatic heart disease, thus suggesting that he comes into the category of pure aortic stenosis (Kiloh, 1950). Death occurred from congestive heart failure of rapid onset and increasing in severity over the course of two months. There was no suspicion of reinfection or relapse of the bacterial infection, nor was there subjective evidence of active rheumatism. Details of his last illness when correlated with a history of effort pain for two years prior to acquiring the bacterial infection indicated death from congestive heart failure subsequent to ischaemic myocardial damage. As death occurred in the patient's home in the north of Scotland a post-mortem examination was not made.

Discussion

The significant prognostic features affecting the immediate outcome of a case of subacute bacterial endocarditis have been clearly enunciated (Jones *et al.*, 1947; Christie, 1948; Bramwell, 1948; Matthew and Gilchrist, 1949). Sufficient time has now elapsed since the availability of penicillin to suggest features of significance pertinent to the remote prognosis of this disease. The period since treatment does not permit of dogmatic statement, but points are now evident which, observed at the time of cure of the initial infection and subsequently, allow a tentative opinion to be expressed.

This disease, carrying in 1943 a 96% mortality rate (Lichtman, 1943), has had the immediate mortality rate reduced to around 30% (Wagner, 1948). Penicillin can unstintingly be credited with this remarkable improvement. As 25% of cases sustain myocardial damage of some magnitude during the infection (Seabury, 1947), it might be assumed that antibiotic therapy, in overcoming the infection, would leave the patient a cardiac cripple. That this does not pertain is amply demonstrated by a study of this series of 20 cases followed for 27 to 63 months. Apart from one death, deterioration in capacity for effort has been restricted to two instances; ten patients remain in cardiac Grade 1 before and after infection and six maintain a grading of 2a despite the infection.

Other investigators have had less encouraging results in the subsequent progress of their cases and have endeavoured to explain on various grounds the deterioration and, on occasion, death of their patients long after eradication of the infection. Kaplan *et al.* (1949), in a study of 18 cases followed up from 25 to 61 months after the infection was cured, found that in 12 instances the infection had behaved as an intercurrent process, the healing in no way aggravating the pre-existing heart disease. Of the remaining six cases, three had a greatly reduced exercise tolerance and three died of congestive heart failure. The severity of the underlying rheumatic infection might have brought about such developments; however, no information is given regarding the age, cardiac grade, or rhythm which might assist in determining this point. One factor common to these six cases and not noted in any survivor is that all had a high pulse pressure on termination of treatment or shortly afterwards. In five this was due to a severe degree of aortic incompetence and in the sixth to a patent ductus arteriosus.

Kaplan postulates that the healing of the infected valve under the influence of penicillin may induce a severer degree of aortic incompetence than would occur in the natural process of the rheumatic endocarditis. Rosenblatt and Loewe (1945) were early aware of this possibility. Kaplan emphasizes that the degree of aortic leak must be sufficient to cause a "dynamic" burden on the heart mechanism. In the series under consideration the one patient who died suffered from aortic stenosis and had no aortic regurgitation. He did, however, suffer from myocardial ischaemia.

Seven cases in this series had aortic regurgitation (Table III). In three the diastolic pressure shortly after the completion of penicillin therapy was below 60 mm. Hg and has since remained below that level. This could be considered as imposing a "dynamic" burden on the myocardium. None of these seven cases shows any deterioration in exercise tolerance. One patient, who had only an organic mitral systolic murmur at the end of treatment, now also has aortic regurgitation with a blood pressure of 134/60. Her cardiac grade has deteriorated from Grade 1 to Grade 2a. She also suffers from paroxysmal auricular fibrillation. Rapoport and Ellis (1948) report 11 cases studied two years after successful penicillin treatment. No deterioration occurred in the four cases of their series showing aortic valve involvement. The degree of valvular damage is not, however, stated. In fact, all 11 of their cases were "at least as well and as active, and some could do more," as compared with their condition before the bacterial infection.

Bramwell (1948) is inclined to vest the healing process under the influence of penicillin, at least in the instance of the mitral valve, with diagrammatically opposite powers to those of erosion and destruction. On the evidence of one patient who originally had aortic incompetence at the time of infection and who two years later developed mitral stenosis, and on the fact that in two other patients the electrocardiograph showed an increased tendency to right axis deviation, it was postulated that, in the process of healing, a stenotic lesion may develop or increase in severity at the mitral valve. The three cases mentioned were the only instances in which deterioration in exercise tolerance occurred in the 18 patients reported on two years after eradication of infection.

In my series no patient developed a stenotic valvular lesion, nor did stenosis once present tend to increase, although the patient dying of aortic stenosis may have been in this category. The alteration in the pitch of the mitral systolic murmur observed in three patients is not necessarily indicative of incipient stenosis. The development of right axis deviation can be attributed to the natural progress of rheumatic heart disease without evoking the healing process of the bacterial infection even as a contributory factor. Based on the slender evidence of one case in this series and another in which the infection has not been eradicated long enough, the effect of the healing process, at least on the pulmonary valve, seems to be the opposite of a stenosing tendency.

A boy aged 14 suffering from congenital pulmonary stenosis with superimposed subacute bacterial endocarditis was unable to trot the length of a football pitch before infection. Now, four years after infection, he can partake energetically in a game of football without undue breathlessness. This improvement cannot be the result of the natural evolution of pure pulmonary stenosis, the tendency in such cases being relentless deterioration (Allanby and Campbell, 1949). It would appear that the infection had freed the stenosis after the nature of a Brock (1948) operation. The other patient with infection eradicated from a stenosed pulmonary valve or infundibulum possesses a capacity for effort greater than she has enjoyed for years. Neither patient has a pulmonary diastolic murmur, only a systolic thrill and murmur at the base of the heart with conclusive *x*-ray and electrocardiographic evidence of the diagnosis. This evidence that healing of the infected process possesses destructive rather than fibrotic powers in the instance of the pulmonary valve has been noted by Pollack *et al.* (1948). As has already been shown, at least in this series, a similar development has fortunately not occurred in healing aortic valves.

Conclusions

In the vast majority of cases of subacute bacterial endocarditis it would appear that, provided the infection is overcome and congestive heart failure avoided at the time of treatment and shortly afterwards, the disease can be regarded as an incident which leaves little or no evidence of additional permanent damage in a heart the seat of congenital or rheumatic disease. In the few cases in which deterioration occurs, it may be anticipated if attention be paid to the following facts: the cardiac grade of the patient when the infection is acquired; the detection of a severe degree of aortic regurgitation after elimination of infection; and the heart size, radiologically, during and immediately after eradication of infection.

Summary

Twenty cases of healed subacute bacterial endocarditis have been followed for periods of between 27 and 63 months. No case relapsed or became reinfected after successful treatment of the bacterial infection. One death occurred.

The effect of the bacterial infection in two cases of congenital pulmonary stenosis is described.

The exercise tolerance, radiological heart-size, and auscultatory features at the time of treatment and after the lapse of years are compared and the significant points identified.

The patients providing the information for this paper were all under the care of Dr. A. Rae Gilchrist, to whom I am grateful for help and criticism.

CONGENITAL MALARIA

REPORT OF THREE CASES

BY

B. S. JONES, M.D., F.R.C.S.Ed.

Surgical Specialist, Colonial Medical Service

A considerable divergence of opinion persists regarding the frequency with which congenital malaria may occur. That it is occasionally encountered there can remain no doubt. Jones and Brown (1924) reported two authentic cases in London, while cases have also been recorded by Beekel (1910), who describes 12 instances of undoubted placental transmission, by Tanner and Hewlett (1935), and by Van Nitsen (1932), who demonstrated malarial schizonts in the spleens of six infants, either born dead or dying soon after birth. Chen *et al.* (1944) have summarized 39 cases of congenital malaria from the world literature, while Wickramasuriya (1935) believes that transplacental foetal infection occurs more often than is normally conceded and records six proved cases of *Plasmodium falciparum* infection.

Most British and American authors, however, while recognizing the possibility of congenitally transmitted malaria, regard its occurrence as a rarity. Thus English (1946), who was in charge of a large maternity hospital in Singapore for 20 years, encountered only one case of congenital malaria amongst the 5,551 deliveries during 1938—a European infant aged 6 days.

During and since the recent war many European women have elected to produce their babies in Nigerian hospitals, and the possibility of congenital malaria has become a significant consideration. Since congenital transmission is still generally regarded as a remote contingency, a pyrexial illness in the first few days of life is more likely to raise suspicions of neonatal infection, while a convulsive seizure will more probably suggest an intracranial birth injury. Even less likely is the possibility of congenital malaria to be entertained in the cases of such women who return to the United Kingdom to have their babies. Therefore three cases personally encountered are recorded.

Most non-African labours in Lagos are conducted at the Creek Hospital, the patients being mainly Europeans, Syrians, or Lebanese of varying duration of residence in the country, though almost all may be assumed to have been subject to subtertian malaria at one time or another.

The occurrence of three confirmed cases of congenital malaria during February, 1949, suggested the possibility that certain of the neonatal deaths in earlier years might have been similarly caused. An investigation of the records, however, showed that of the four deaths occurring within the first 12 days of life in the course of the 143 deliveries conducted during 1947 and 1948 only one could possibly be attributed to congenital malaria. From January 1 to June 30, 1949, the period under consideration, there were 37 accouchements.

Case 1

An Englishwoman aged 29 had been resident in East Africa for some years, and was subject to periodic malarial attacks. She had arrived in Nigeria about one year previously, had taken suppressive quinine somewhat irregularly, but since arrival had had no overt attack of malaria. Her husband was English. She had two children, aged 6 and 4 years, her first labour having been prolonged and followed by subinvolution, the second being easy and normal. Throughout the present pregnancy she had been well, with the exception of one attack of cystitis. Her expected date was February 1, and she was admitted at 4.30 a.m. on February 11 with good pains, os dilated two fingerbreadths, a persistent occipito-posterior presentation, and premature rupture of the membranes. At 7.30 a.m. she was easily delivered of a healthy female infant. The maternal blood on admission showed no malaria parasites.

The infant remained quite well till February 13, when it was observed to be fretful and to be vomiting after feeds. At 2 p.m. that day the rectal temperature was 102.6° F. (39.2° C.); the mouth was healthy, the cord was clean, and the chest, cardiovascular system, and abdomen showed no abnormality, but the vulva appeared slightly inflamed, with a scanty thin purulent discharge. A blood smear was taken, and 5,000 units of penicillin intramuscularly three-hourly and 0.125 g. of sulphathiazole six-hourly were prescribed.

At 10 a.m. next day the blood smear was reported to contain scanty subtertian rings, and 2 gr. (0.13 g.) of quinine was given intramuscularly, and 1 gr. (65 mg.) of quinine orally three times a day was prescribed. At 4.30 p.m. the infant was very ill, with a poor slaty colour. At 6.30 p.m. there was a slight improvement; the spleen was found to be palpable and a further 2 gr. of quinine was given intramuscularly. At 9 p.m there were continuous convulsions and the condition was very poor. The infant, whose temperature was now 105° F. (40.6° C.), was sponged with tepid water, and 3 min. (0.18 ml.) of syrup of chloral was given, this being repeated at 9.30 p.m. At 11 p.m. convulsions had ceased, but diffuse moist rales were heard in the lungs: atropine, 1/600 gr. (0.11 mg.), was given and oxygen administered by oral catheter.

At 12.30 a.m. on February 15 the infant was asleep; the respirations were, however, irregular, and there appeared to be a one-in-three heart-block. At 8.30 a.m. she was quiet, the pulse and respirations were regular, but the temperature, which had been sustained, was 104.4° F. (40.2° C.), and 2 gr. of quinine was given intramuscularly. At 9 a.m. there was renewed respiratory and circulatory depression with cyanosis and occasional twitching of the upper limbs, and death occurred half an hour later. Necropsy was not performed.

Case 2

The mother, aged 37, and her husband were Europeans of French nationality. She had been resident in Nigeria for many years, and had had numerous bouts of malaria, though none recently, but took suppressive proguanil, 100 mg. daily. She had three children, the youngest aged 2½ years, and had had no miscarriages. All previous labours had occurred two or three weeks before the expected date, and all had been easy and rapid. She had been well throughout the present pregnancy and the expected date was March 4. Pains started at 5 a.m. on February 20. She was admitted at 6.30 a.m., and an easy rapid vertex delivery was completed by 7 a.m. The maternal blood showed no malaria parasites.

The infant, a healthy female, was bottle-fed from birth. The cord-blood smear, taken at birth, contained scanty subtertian rings, and ¼ gr. (32 mg.) of quinine orally three times a day was prescribed from birth.

At 2 p.m. on February 23 the baby appeared unwell and was vomiting. The rectal temperature was 101° F. (38.3° C.). At 11.15 p.m. 2 gr. of quinine was given intramuscularly. At midnight the vomiting was more severe; it was accompanied by hiccup, a slaty cyanosis, and some twitching of the arms and eyes.

At 1.15 a.m. the next day 3 min. of syrup of chloral was given. At 8.30 a.m. the condition had somewhat improved. The cord was separated cleanly, the chest and cardiovascular system showed no abnormality, but the liver edge was palpable and there was slight icterus. Quinine, 1½ gr. (0.1 g.), was given intramuscularly. At 3.45 p.m. the temperature was 102.8° F. (39.3° C.), the jaundice was deeper, the liver was enlarged to one fingerbreadth below the costal margin, and there were diffuse bilateral moist rales. Penicillin, 5,000 units intramuscularly three-hourly, was prescribed, but death occurred at 5 p.m. Permission for a full necropsy was not obtained, but a post-mortem hepatic puncture smear showed scanty malaria parasites.

Case 3

A Scotswoman aged 29, the wife of an African, had been resident in Nigeria for one year only and took daily suppressive quinine. She had two children, aged 3 years and 1 year 8 months, both labours having been easy, and had had no miscarriage. She had been well throughout the present pregnancy apart from an attack of malaria three weeks before delivery, when she was treated with 0.1 g. of mepacrine orally thrice daily for one week. Her expected date was March 4. She was admitted at 11.15 p.m. on February 25, and an easy vertex labour was completed one hour later. Her blood on admission showed no parasites, but from February 27 to March 1 she had slight pyrexia (99 to 99.8° F.—37.2 to 37.7° C.) accompanied by headache, which responded to a further course of oral mepacrine.

The infant was a healthy half-caste male, and the cord blood at birth contained scanty subtertian rings. On the day of birth, February 26, 3 gr. (0.2 g.) of quinine was given intramuscularly, and ¼ gr. thrice daily by mouth and proguanil, 25 mg. twice daily, were prescribed. Next day a further 3 gr. of quinine was given intramuscularly. On the 28th there was slight pyrexia, but the infant seemed to be well and was taking his feeds. The chest, abdomen, and cardiovascular system were normal, and the blood showed no malaria parasites. There was slight swelling of the left buttock, probably post-injection. Another 3 gr. of quinine was given intramuscularly. At 4.30 p.m. the baby was unwell, with slaty colour and vomiting, and 2 gr. of quinine was given intramuscularly. On March 1 there was rapid deterioration, with coffee-ground vomits, and death occurred at 5.30 a.m. Necropsy was not carried out.

Subsequent to Case 1 every expectant mother was prescribed, in addition to her customary daily suppressive, 400 mg. of proguanil daily, beginning 10 days before the expected date and continuing until admission in labour; a cord-blood smear was also taken at every birth and examined for malaria parasites. Of the 37 deliveries, the first six were not cord-tested: the 31 which occurred after Case 1 were all cord-tested at birth, and only Cases 2 and 3 showed positive smears. Placental smears were not examined as a routine, as it was felt that the universal daily suppressive habit would certainly invalidate the results.

Since my departure from the Creek Hospital there have been a further 23 deliveries during July and August, 1949, all infants being cord-tested at birth. Of these only one showed parasites in the cord blood: a febrile illness developed within a few days of birth, but responded to treatment. A second infant, despite a negative cord blood, developed high pyrexia 26 hours after birth, and was tentatively diagnosed on clinical grounds and therapeutic response as a case of malaria.

Discussion and Conclusions

Since the initial case of congenital malaria, three cord bloods in the course of the next 54 deliveries showed subtertian rings, and all three infants subsequently developed symptoms compatible with a diagnosis of malaria. Of the 51 infants whose cord blood smears were negative, only one developed suggestive symptoms. It is concluded that among non-indigenous European women of relatively low immunity, infected with the Lagos strain of *P. falciparum*, congenital transmission of malaria is by no means rare.

As regards predisposing causes, only one of the three mothers admitted to any recent malarial attack, so that placental transmission may occur in the absence of any overt maternal malarial bout during pregnancy. In all three cases the placenta was macroscopically healthy and intact, an observation which does not support Manson-Bahr's (1940) hypothesis that transmission to the foetus can occur only through a placental breach or defect.

There seem to be few effective precautionary or preventive measures. Thus regular suppressive procedures throughout pregnancy, here almost universal, did not seem to give reliable protection; nor, indeed, did a therapeutic course of proguanil, and in one case mepacrine, before delivery. It is, however, strongly urged that in the case of West Coast wives, whether delivered there or in the United Kingdom, the cord blood should be examined at birth as a routine.

Among the salient clinical features in these three cases was the fact that all three mothers were multiparous and past their first youth, being aged 29–37 years. Two had been long resident in the Tropics and previously subject to malaria, though admitting of no recent attack; while the third, a more recent arrival, had suffered an attack of clinical malaria three weeks before delivery. All labours were easy and rapid.

The intervals between birth, when the infants appeared healthy, and the onset of symptoms were 54, 77, and 60 hours, suggesting the possibility of a short-lived passive protection due to maternal antibodies. The earliest manifestations were pyrexia, vomiting of feeds, and a poor colour—a slaty pallor. Convulsions supervened later, and finally pulmonary oedema. One case exhibited hepatomegaly and jaundice, and one splenomegaly.

Quinine, intramuscularly and orally, in one instance combined with oral proguanil, proved quite ineffective. Subsequent experience of two cases of cerebral malaria in European infants under 6 weeks old suggests that intramuscular mepacrine is the treatment of choice and may be dramatically effective. In each case an intramuscular injection of 0.1 g. of mepacrine precipitated an alarming convulsive seizure within 15 to 20 minutes, followed by complete recovery. To avoid this very real danger the dosage should be sufficiently small and divided—0.03 g. daily being suggested as adequate—and preferably begun immediately on discovery of a positive cord blood.

The notable contrast between hyperimmune indigenous populations, among whom placental infection is exceedingly common but congenital malaria very exceptional, and non-indigenous individuals of low immunity, among whom placental infection is very rare but congenital malaria relatively less so, cannot be passed without comment. In Sierra Leone, Blacklock and Gordon (1925) found placental infection in 38% of indigenous deliveries, but consistently failed to demonstrate parasites in foetal cord or peripheral blood, though Walton (1947), in Freetown, found 0.32% of 2,154 newborn infants to be congenitally infected. Bruce-Chwatt (1949—personal communication), in Lagos, reports a 26% placental infection rate in 450 African women but no single case of congenital malaria. Peel and Van Hoof (1948), from the Congo, record that of 400 African mothers 60% showed malarial infection; infection of the placenta was found in 53.9%, and yet no case of congenital malaria was encountered among the 393 newborn infants. In marked contrast, Clark (1915), in Panama, while finding a significant proportion of infected placentas in the West Indian negroes, found none among the European women.

It is suggested that with the increasing degree of immunity to malaria the frequency of infection of the placenta rises, while coincidentally the efficiency of the placenta as a barrier to foetal transmission increases and the incidence of congenital malaria falls.

It is a pleasure to acknowledge my thanks to Dr. G. B. Walker, Director of Medical Services for Nigeria, for permission to publish this paper; to Dr. L. J. Bruce-Chwatt, Government malariologist, for much helpful information and advice; and to Dr. I. G. MacGregor, senior specialist, for information concerning cord-blood results subsequent to my departure from the Creek Hospital.

FATAL CASE OF POISONING DUE TO INHALATION OF METHYL BROMIDE

BY

A. C. MacDONALD, M.A., M.B., Ch.B.

I. C. MONRO, M.D., D.P.H.

AND

G. I. SCOTT, F.R.C.S.Ed.

Methyl bromide has been widely used of recent years in fire extinguishers for ships and aircraft, and in refrigeration plants. The dangers of exposure to this compound should therefore be better known than they are. For that reason we are reporting a fatal case with which we were concerned, and which arose from the scrapping of fire-extinguishers from aircraft engines.

Case Report

A man aged 21 was admitted to the Joint County (Fever) Hospital, Elgin, on December 2, 1947, at approximately 5 p.m. with a provisional diagnosis of meningitis. The history then available was that he had felt unwell at his work in the afternoon, had come home, had complained of headache, and quite suddenly at about 3.45 p.m. had had a convulsion, rapidly followed by others and by loss of consciousness. Subsequently it was learnt that the patient had been engaged on emptying and "cleaning" aircraft fire-extinguishers. The method employed was to perforate the lower end of the copper "bottle"—shaped like a vacuum flask—with a fireman's hatchet, and to let the vapour and fluid escape. Thereafter

the brass top was sawn off the bottle. Normally all this was done in the open air, but on the day in question there was severe frost, and the empty bottles were stacked in a shed and later cleaned there under cover. In the course of the morning's work, probably about noon, he had splashed a quantity of liquid methyl bromide over his clothes, a little of it reaching his face.

On examination the patient was having recurring convulsive seizures at the rate of about 10 a minute. These affected the jaw, back, both arms, and both legs, and were in the nature of clonic spasms. He was unconscious. An alcoholic odour in the breath was most pronounced. Attempts were made to control the spasms. Thiopentone was given, and, by adjusting the dose, control was effected for a few minutes at a time. During the first interval of freedom from spasm a further rapid examination was made, but there were no additional positive findings except that moist sounds were heard on auscultation of the chest. Samples of blood, urine, C.S.F., and stomach content were secured. The urine was blood-stained. A further dose of thiopentone at a later hour had the same effect. Between 10.30 and 11 p.m., after the intramuscular administration of paraldehyde had proved fruitless, 2 ml. of this drug was given intravenously, with 1/50 gr. (1.3 mg.) of atropine. This combination immediately controlled the seizures. In the course of the next few hours the general condition steadily deteriorated. Nikethamide was injected intravenously to combat respiratory depression, but large amounts counteracted the sedative action of the paraldehyde, leading to recurrence of the clonic spasms. The patient died at 5.15 a.m. on December 3.

At the necropsy on December 5 the stomach showed submucous haemorrhages at the distal end. The duodenum also showed submucous haemorrhages. The remainder of the bowel was normal. The liver, pancreas, and spleen showed no obvious changes. The chest cavity was normal in size; the pericardium was healthy; there was no evidence of valvular disease of the heart, and the heart muscle appeared healthy. The kidneys were very congested. The capsule stripped off easily; there was no evidence of inflammation of any duration, and the appearance of the cortex was in keeping with the condition of haematuria which developed on the night of the onset of illness. The brain showed no evidence of meningitis; the ventricles were normal; the surface of the brain was considerably congested and there were numerous small haemorrhages.

The appearances of the organs accorded with the absorption of an acute irritant poison which had caused submucous haemorrhages of the stomach and duodenum and had acted as a convulsant, causing congestion and haemorrhage of the cerebral cortex and acute congestion of the kidneys in the process of elimination.

Biochemical Findings.—Urine: a slight degree of albuminuria was found on direct examination; there were no other abnormal constituents. Blood: 30 mg. of NaBr per 100 ml. C.S.F.: No NaBr. Stomach contents: 30 mg. of NaBr per 100 ml. These findings suggest that a derivative of bromine was not the cause of death.

Discussion

Methyl bromide (CH_3Br) is a gas at normal temperatures, the boiling-point of the liquid being 4.5° C. (40.1° F.). It is a heavy gas, its weight being aproximately six and a half times that of air. Like chloroform, ethyl chloride, and carbon tetrachloride it is not inflammable. Its use as an agent for extinguishing fires depends on its weight, which leads to a blanketing effect and the exclusion of oxygen, or on its non-inflammability, which is utilized in aircraft engines, where it is played on the carburettor, thus lowering the flash-point of the petrol.

Poisoning by its agency was first noted in 1901, and up to 1940 a total of 42 cases had been reported in the literature. Of these, 12 were fatal, 23 recovered, and in the remaining 7 information was incomplete. From 1939 to 1944 an additional 22 cases were reported in the Royal Navy, with fatalities (Clarke *et al.*, 1945). Cases may have occurred among Air Force personnel, but under conditions of national emergency they would not be disclosed. Inquiry of R.A.F. medical personnel in the neighbourhood suggested that little was known of methyl bromide as a toxic agent.

Its mode of action depends largely on the concentration. If this is of the order of 10,000 parts per million the gas acts as a lung irritant. The victim seeks to escape, and if he does so the duration of exposure is unlikely to be sufficient to produce the chain of events described below. If he fails to escape, the signs, including post-mortem signs, are those of lung irritation, with haemorrhage and oedema of the lung and pleural effusion. Oxygen may be effective in treating this class of case.

If the concentration is in the neighbourhood of 1,000 parts per million the sequence described by Leschke (1934) is typical. After inhalation of the poison there are slight non-characteristic symptoms, such as headache, giddiness, fatigue, vomiting, and double vision. There is then a free interval of hours or even days, followed by the sudden onset of twitching, lockjaw, cramps, double vision, delirium, and raving madness. Leschke thinks that these symptoms are due to some intermediate metatoxic process, and not to the methyl bromide as such. In support of this view is the fact that methyl bromide has never been recovered from man or experimental animals. When death occurs in this class of case there has usually been some degree of pulmonary oedema and pleural effusion. Necrosis of the renal cortex is also a fairly constant sign. In only one other instance have we ascertained that haemorrhages into the cerebral cortex have occurred. This was one of a group of boys from an approved school who were living in a disused naval launch.

No curative treatment is known when convulsions have begun; indeed, in only one instance have we found a report of recovery after the onset of convulsions. Exposure to minimal concentrations of the order of 200–400 p.p.m. results in loss of appetite, nausea, headache, and muscular pains, the symptoms rapidly disappearing on cessation of exposure. Prolonged application of methyl bromide to the skin may lead to burning. It is clear, however, that this does not always happen, as workmen have used it to remove grease from their hands without ill effect. There is, in fact, a strong suggestion of idiosyncrasy.

One feature common to all the reported cases we have studied is its occurrence in an enclosed space, such as a ship, covered railway wagon, or workshop. In our case the actual opening was carried out in the open air, but the "cleaning" was done in a shed, and on a cold day. In our opinion this combination of circumstances led to imperfect emptying of the fire-extinguishers in the open air, with a consequent rise in the methyl bromide content of the shed to dangerous levels.

We wish to acknowledge our indebtedness to Dr. W. Fyffe Dorward, police surgeon, Dundee, for particulars of the cases from the approved school; to Dr. F. S. Fiddes, of the Department of Forensic Medicine, University of Edinburgh; to Dr. Hendry, of the Clinical Laboratory, Royal Infirmary, Edinburgh, for reports on the body fluids and other information; and to Professor S. Alstead, of Glasgow University, for help in the treatment of the case and advice in the preparation of this paper.

THE INTERNAL SPERMATIC FASCIA

WITH REFERENCE TO REPAIR OF INDIRECT INGUINAL HERNIA

BY

C. BRUN, F.R.C.S.

Chief Surgical Assistant, Salford Royal Hospital

The object of this communication is to stress the importance of a thorough exposure of the defect at the internal inguinal ring during the course of operation for repair of indirect inguinal hernia in adults. This step, which is usually dismissed all too briefly in descriptions of the operation, is an essential prerequisite to the performance of an accurate repair. A defect is always present in these cases but requires careful dissection to be clearly displayed, and it is obvious that unless this is done the repair can be only approximate and the risks of recurrence are thereby increased.

Hughes and Fathi (1948), in a short but clear and precise paper, have drawn attention to the same subject, but the manœuvre they advocate (see below) is not, in my experience, quite so easy as it sounds.

The operation referred to above is the one described, with slight modifications, by Ogilvie (1937), Edwards (1943), Lytle (1945), and others. On anatomical and pathological grounds it seems clearly to be the operation of choice. Its essential feature is the direct repair of the stretched internal ring after excision of the sac, without altering in any way the normal anatomy and mechanism of the inguinal canal.

But the difficulty is that the stretched ring is not immediately apparent; its margins are very indefinite and the transversalis fascia itself is not at all easy to identify. It is hoped to show that this difficulty can be overcome by the simple procedure to be described. At least I have found it extremely helpful in the course of some 200 operations.

Anatomy

It is necessary first to refer briefly to the anatomy of the internal inguinal ring. The ring is simply an opening in the transversalis fascia for the passage of the spermatic cord from the abdominal cavity into the inguinal canal. Lytle (1945) has shown that it is strengthened by an obliquely placed U-shaped fibrous sling over which the cord bends; but this is not really relevant to the present argument except to show that the normal ring has three well-defined margins—namely, superior, medial, and inferior—while the fourth one—that is, lateral or more precisely supero-lateral to the cord—is indefinite.

From the margins of the ring a tube of fascia—the internal spermatic fascia—is prolonged on to the cord, to which it closely adheres. In fact the cord does not pierce the transversalis fascia at all, but merely evaginates it at the internal ring (Fig. 1). The continuity of the internal spermatic fascia with the transversalis fascia makes it extremely difficult to decide what are the limits of the ring when viewed from the external aspect—that is, as seen at operation. Gray's *Anatomy* (1946) actually states: "This opening [the internal inguinal ring] is not visible externally since the transversalis fascia is prolonged on these structures [spermatic cord or round ligament] as the internal spermatic fascia." This observation can be easily verified on any normal subject in the post-mortem room and at every operation for inguinal hernia.

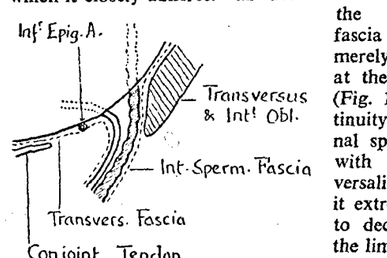

FIG. 1.—Diagrammatic horizontal section through the internal inguinal ring.

The Operation

When an indirect sac is present it is found to lie lateral and superficial to the cord, and always within the internal spermatic fascia. After the cord has been lifted out of its bed the fascial tube must be deliberately incised, and the sac may then be picked up with forceps and freed up to its neck by blunt dissection. It is excised as usual and the stump allowed to retract.

If the cord is now lifted up with slight traction and the conjoint tendon retracted outwards, the appearance will be more or less as shown diagrammatically in Fig. 2. The internal spermatic fascia will be seen to spread out funnel-wise as it approaches the internal ring, which at this stage is not visible. A rent is apparent in the fascia through which the sac was dissected, and is often reduced to a mere slit as the cord is lifted up. The stump of the sac will have disappeared within this rent. It is remarkable how this fascial tube, in spite of the rough treatment which it often receives during the dissection of the sac, becomes more or less accurately re-formed after the excision of the sac and maintains its attachments to the margins of the ring. Furthermore, the extent of the defect at the ring can be neither seen nor felt unless the finger is actually slipped through the rent just mentioned.

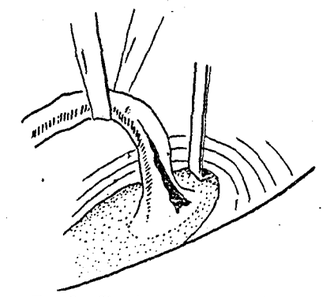

FIG. 2.—Showing appearance after the cord is lifted up with slight traction and the conjoint tendon is retracted outwards. The cremaster is omitted for the sake of clarity.

To expose the defect clearly and to display the margins of the ring, it is now necessary to divide the internal spermatic fascia all round the cord. It should be deliberately picked up with forceps and cut with scissors while gentle traction is exerted on the cord.

Slight difficulty may sometimes be experienced on the medial side of the cord, which is here tethered to the margin of the ring. The small cremasteric vessels are blamed for this by Hughes and Fathi. They stress the importance of these vessels, and state: "After the cremasteric vessels covered by their fascia have been exposed they are divided between silk ligatures. With the division of this 'ligament' the cord can be displaced laterally." However, I have never been able to expose them to my satisfaction, nor am I convinced that it is necessary to do so, because once the fascia has been divided the cord can be retracted laterally, and probably carries the vessels with it.

The stretched internal ring is now clearly displayed (Fig. 3), and usually admits the index finger easily. The cord is retracted laterally and the margins of the defect are approximated by interrupted sutures or a continuous suture medial to the cord. The newly reconstructed ring can in

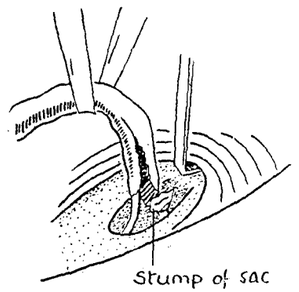

FIG. 3.—Showing the stretched internal ring.

fact be made as small as desired and should fit snugly round the cord.

In some cases the ring has been so stretched that its lower fascial margin is practically non-existent. In such cases the sutures may be anchored to Poupart's ligament inferiorly as described by Edwards, but even then it is usually possible with care to pick up with the needle a strand of tissue that will hold the stitches quite well just above Poupart's ligament and deep to the lower leaf of the cremaster.

Summary

The anatomy of the internal inguinal ring is reviewed.

The importance of a complete exposure of the stretched ring in operations for indirect inguinal hernia is stressed, and a simple method for ensuring this is described.

Medical Memoranda

Parathion Poisoning

The increasing use of organic phosphorus insecticides has created a new occupational hazard to agricultural workers. Hunter (1950) has drawn attention to this group of compounds, which includes "parathion" (*para*-nitrophenyl-diethyl-thiophosphate), and has described casualties which have occurred elsewhere, although he noted that no cases of poisoning had been reported in Great Britain. Detailed information concerning organic phosphorus insecticides has been recorded by Goldblatt (1950), together with a description of the signs and symptoms of their toxic effects and the specific antidotal action of atropine. The case of parathion poisoning here recorded should serve to emphasize the nature of the risk, the importance of its prompt recognition, and the value of treatment with atropine.

CASE REPORT

A man aged 46 had been engaged for three weeks in preparing an insecticide spray for hops, using a commercial preparation containing 20% of parathion. The preparation was clearly labelled as to its poisonous nature, and workers were instructed to wear protective clothing.

On June 20, 1950, while preparing a lorry tankful of spray solution (24 oz. (680 g.) of the 20% preparation to 500 gallons (2,270 litres) of water), a drop of the 20% preparation splashed on to his forearm, covering an area about the size of a sixpenny piece. He washed it off with water within 30 seconds; this was at 4 p.m. Within a few minutes a raised weal appeared, but no further local injury. During the evening he remained well, took food, and smoked some cigarettes.

At 9.45 p.m. he experienced a sudden severe pain at the back of his head, spreading forward to the forehead. A few minutes later he vomited violently and developed persistent abdominal pain. This was soon followed by a feeling of weakness in the legs, after which he remembered nothing until the next morning in hospital.

He was admitted to Worcester Royal Infirmary at 11.25 p.m. Atropine, 1/60 gr. (1.1 mg.), had already been administered as a first aid, so that the pupils were dilated but reacting. The patient was very drowsy, sweating profusely, and appeared to have violent headache and abdominal pain; his pulse rate was 60 and of good volume; his blood pressure was 110/90; speech was slightly slurred; there was occasional muscular twitching in the upper and lower limbs; respirations were shallow but not distressed.

Dr. V. Keane (then house-physician) continued treatment with atropine sulphate, 1/75 gr. (0.87 mg.) intravenously; then 1/100 gr. (0.65 mg.) hourly for three doses; then two-hourly for two doses; then hypodermically hourly for three doses. In the morning the patient was rational and in the afternoon clinical examination showed him to be normal. He was discharged well on the fifth day after admission.

COMMENT

The patient's history, condition, and recovery on treatment with atropine are indicative of parathion poisoning. His statement indicates that he was aware of only trivial contact with the toxic material, but as parathion is a cumulative poison it seems likely that he had already absorbed and retained a harmful amount before the final intoxication, which was then further aggravated by smoking and by taking food.

The toxic action of parathion and related organic phosphorus insecticides is due to their inhibiting effect on the activity of choline esterase. Atropine is the specific antidote, but the order of dosage required may be much more than the usual therapeutic quantities. In this case a total of 11/100 gr. (7.1 mg.) of atropine sulphate was administered.

Auricular Fibrillation After Electric Convulsion Therapy

Transient cardiac irregularities are a recognized complication of the various forms of shock therapy employed in the treatment of the psychoses. The following case is of interest because of the prolonged duration of the arrhythmia.

CASE REPORT

A man aged 54 was admitted to hospital in October, 1949, suffering from an agitated depressive state of approximately 12 months' duration. His main complaints were insomnia, inability to concentrate, depression, delusions of guilt and unworthiness, and a feeling which recurred often, and for no reason that he knew, of being urged to strike out at those around him. His blood pressure varied between 230/130 and 150/100, for which fluctuation emotional factors seemed to be largely responsible. No cardiac irregularity or enlargement, tachycardia, or other abnormal physical signs were present clinically.

Electric convulsion therapy was given on alternate days, and was terminated after eight shocks, there being considerable improvement in his mental condition. However, after the last convulsion he complained of palpitation, and on examination

the pulse was irregular, the rate being 110 and the blood pressure 150/90. Electrocardiography confirmed the presence of auricular fibrillation and also showed a minor degree of left axis deviation. This condition persisted for four weeks, with little apparent discomfort to the patient, and then reverted to normal rhythm after quinidine sulphate, 5 gr. (0.32 g.) four-hourly, had been given for four days.

One week later feelings of depression and mental tension had returned. The blood-pressure readings varied between the extremes noted above. Radiological examination of the chest failed to show any definite cardiac enlargement. The electrocardiogram was normal apart from slight left axis deviation. The blood urea was 24 mg. per 100 ml. and the renal clearance (van Slyke) was within normal limits.

In consequence of the mental deterioration, two further convulsions were given at an interval of a week, being preceded on the first occasion by 7½ gr. (0.5 g.) of sodium amytal intravenously, which resulted in a fall of blood pressure from 230/130 to 150/100. For two minutes immediately following the clonic phase in this fit the pulse became irregular, a condition due apparently to premature beats, though electrocardiography was not available to confirm this. The blood pressure, after a transient rise to 180/100, remained within 2 or 3 mm. of 130/85 for 30 minutes afterwards. Oxygen was administered orally throughout.

In the second instance curarization was employed, 22 mg. of D-tubocurarine chloride preceded by 7½ gr. of sodium amytal being given intravenously. A similar fall in blood pressure was noted, but no irregularity. An electrocardiogram taken one minute after the clonic phase showed the left axis deviation and also nodal rhythm for two beats. Other changes were of the type described by Kauntze and Parsons Smith (1948), among others, and consisted of an increase in the height of P_2 and T_2 and depression of the S-T segment in Lead II.

Further convulsive treatment has not been given owing to the improved mental state of the patient.

We wish to thank Dr. E. U. H. Pentreath, medical superintendent of the Pastures Hospital, Derby, for permission to report this case.

Survival of a 16-oz. Baby

Only a few cases are on record of the survival of babies weighing less than 2 lb. (0.9 kg.) at birth. In a survey of the available literature I have been able to trace only six such cases.

De Lee and Greenhill (1943) recorded the delivery of a viable child 182 days after conception, and Ronaldson (1943) one after 189 days. Hoffman, Greenhill, and Lundeen (1938) reported the survival of a baby weighing 26 oz. (0.74 kg.) at birth. Bush (1947) reported the survival of a female infant born at the 27th week and weighing 24 oz. (0.68 kg.) at birth. Browne (1942) quotes the combined weights of the Dionne quintuplets, who were all girls, as 13 lb. 6 oz. (6 kg.), thus giving the average weight of each child as just under 2 lb. 11 oz. (1.2 kg.).

CASE REPORT

A healthy woman aged 31 had her last regular period on June 20, 1948, and there was a slight loss towards the end of July, 1948. She attended the antenatal clinic of the Civil Hospital when four months pregnant. She was well built and nothing abnormal was detected. She was instructed to return to the clinic in a month's time, but failed to do so.

On January 29, 1949, she returned and complained of swelling of the feet and hands which had been present for three weeks. There was no anaemia, albumin was not detected in the urine, and the blood pressure was 130/80 mm. Hg. Palpation of the uterus revealed the presence of three small nodular fibroids, and the fundus was higher than one would expect for the stage of the pregnancy. The woman was admitted to the maternity ward of the Civil Hospital for rest and treatment. She was then 26 weeks pregnant by her date. The day after admission she began to have labour pains, and a female child presenting by the vertex was delivered normally at 7 p.m. on January 30. The third stage was normal and the placenta showed no abnormality. The puerperium was uneventful, and the patient was discharged home on the eleventh day after delivery.

THE CHILD

At birth the infant was very feeble and did not cry. The air passages were cleared with the mucus catheter, and after injecting 1 ml. of nikethamide into the vein of the umbilical cord respirations became well established. The child weighed 1 lb. (0.45 kg.).

As an incubator was not available on the island, the child was wrapped up in cotton-wool and placed in an ordinary cot lined with blankets. The cot was kept warm with hot-water bottles. During the first four days she was fed by pipette with 2 dr. (7 ml.) of glucose water hourly and she took her feeds well. On the third day her weight was still 1 lb. On the fifth to the tenth days she was fed every hour with 2 dr. of expressed breast milk, diluted with its own volume of glucose water. The supply of breast milk then ceased. On the 16th day she weighed 1 lb. 10 oz. (0.74 kg.) and began to give feeble cries.

Since the infant would not tolerate breast milk from other sources, she was given artificial milk. From the 15th to the 38th days the baby was fed two-hourly with 2 dr. of condensed milk diluted with an equal volume of water. She then weighed 2 lb. 12 oz. (1.25 kg.). She was put on dried milk, and has been kept on it since.

The child has progressed satisfactorily, and her weight five and a half months after birth was 6 lb. 12 oz. (3.06 kg.). She was then receiving 4 oz. (114 ml.) of reconstituted dried milk three-hourly, and only six feeds are given in 24 hours.

In addition to her feeds, from birth she was given thyroid. sic., 1/10 gr. (6.5 mg.) daily for 45 days, and dienoestrol, 0.5 mg. daily for 69 days.

The measurements of the infant when only a few days old were:

Distance from crown to heel	13 in. (33 cm.)
Circumference of head	11 in. (27.9 cm.)
Circumference of shoulders	7½ in. (19 cm.)
Distance from umbilicus to pubes	¾ in. (1.9 cm.)
Distance from xiphisternum to umbilicus	1¾ in. (4.4 cm.)

X-ray examination of the foot on the 18th day after birth showed the presence of the ossification centres of the calcaneus and astragalus. The centres for the lower epiphysis of the femur and the upper epiphysis of the tibia had not appeared at that time. The femur was *x*-rayed again two months later (on the 81st day after birth) and the centre for the lower epiphysis was present.

I have not found any record of the survival of a child weighing less than 16 oz. at birth.

I wish to thank Dr. A. Rankine, Director of Medical Services, Mauritius, for permission to report this case, and Dr. Y. Cantin, medical superintendent, Civil Hospital, Mauritius, for his advice. Credit is due to Miss G. Davies, matron, Civil Hospital, for her tireless care and supervision and to the nurses of the Civil Hospital for their co-operation in the management of the infant. I would like to thank Mr. L. N. A. Planel, of Glaxo Laboratories Ltd., for supplying the milk powder and the vitamins.

Reviews

RARITIES

Further Rare Diseases and Debatable Subjects. Edited by F. Parkes Weber. (Pp. 236; illustrated. £1 5s.) London and New York: Staples Press.

This is a companion volume to the one by Dr. Parkes Weber published in 1946, which was welcomed as "a mine of interesting information which may well cause us to think." A further 39 rare diseases or syndromes are described here, and the book closes with a short article on zest in old age.

This is a stimulating volume, valuable to the collector of medical curiosities. Dr. Parkes Weber is well known not only for his abstruse medical knowledge but for his interest in diagnostic problems. The conditions described include such unfamiliar subjects as Sjögren's disease and illuminating accounts are given of more familiar occurrences, such as death while bathing. Those interested in the disturbances of lipoid metabolism will welcome the article on xanthomatosis and arterial atheroma. If "rarity enhances pleasures," many will delight to read this book.

G. E. BEAUMONT.

PSYCHOLOGICAL POLEMICS

Freud or Jung. By Edward Glover. (Pp. 207. 15s.) London: George Allen and Unwin. 1950.

The bewildered doctor who has heard a good deal about Freud and Jung, but has never been able to follow the technical jargon in which their teachings are expressed, may very likely approach this book with the hope that here at last is something which will clear up his ideas and give him new aids in understanding his patients. He will be disappointed, for he will have to be almost as profound a scholar as Dr. Glover himself to understand from this exposition what it is all about. Jung, he will learn, for instance, says that there is only one form of mental energy, which may in its widest sense correspond with *élan vital.* Freud says there are two forms, involved respectively in sexual appetites and instincts towards death and destruction. According to Dr. Glover the first view is false and the second correct, but it would puzzle the reader to understand the argument why.

In his sustained polemic Dr. Glover exposes the nebulosity, vagueness, and self-contradictoriness of the Jungian system, in which psychological, philosophical, and metaphysical elements are all combined. The reader will also be made aware that the Freudian system is much more concrete, closely knit, and logical. It is for that very reason that the Freudian feels that Jung is a threat. Individual Jungian conceptions can be disproved or shown to be meaningless, and other parts of his contribution to psychology may yet stand. If it were once accepted, however, that mental energy is unitary, the whole Freudian house of cards would be in danger of falling to the ground.

One of the faults of Dr. Glover's discussion is that he can find no defect in Freudian doctrine, no good whatever in that of Jung. In his final chapter he issues a serious warning to the eclectic—to the psychiatrist, doctor, or layman who wishes to choose for himself the "best" out of any or all schools. The Freudian system, it is laid down, must be accepted in whole or not at all. This is not the way in which science has progressed, nor is it necessary in the present case. It is perfectly possible to build new theories from fragments taken from Freud and Jung, and any such theory will prove itself less by its internal consistency than by its capacity for making predictions which prove true when subjected to the test of experience. "Who is not with me is against me" is the worst of mottoes for the scientist.

ELIOT SLATER.

TECHNIQUE OF HINGE GRAFTING

The Hinge Graft or Ginglymus Implant. By Arnold K. Henry, M.B.Dubl., M.Ch.(Hon.)Cairo, F.R.C.S.I. (Pp. 64; illustrated. 15s.) Edinburgh: E. and S. Livingstone. 1950.

This small book is about a method of stabilizing certain joints without having resort to arthrodesis. The technique consists essentially in placing a thin narrow strip of cortical bone, with its attached periosteum, longitudinally across each side of the joint to be stabilized. Rigid immobilization is avoided, and progressive movements in the desired plane are encouraged. The bony elements of the grafts break at or near the axis of movement, and a hinged osseofibrous "ligament" is formed along each side of the joint. It is claimed that these ensure lateral stability while permitting free flexion-extension movement. The method has been applied to the treatment of such conditions as instability or deformity of the foot after poliomyelitis, genu recurvatum, and flat-foot. Other possible applications are suggested. No attempt is made to draw definite conclusions from the small number of cases recorded: the author's object has been simply to present the idea and to leave the reader to judge for himself whether or not it is worth pursuing.

Clearly the book's appeal will be mainly to the orthopaedic surgeon. Remembering Professor Henry's masterly work, *Extensile Exposure Applied to Limb Surgery,* most readers will inevitably approach this new book with high expectations. Many will be disappointed. Some, indeed, may wonder whether the hinge graft is really worthy of a book to itself, or whether the author's purpose would not have been served as well by a succinct account of the technique published in an orthopaedic journal. The quality of some of the radiographs falls short of the standard that one has come to expect from this publishing house.

J. C. ADAMS.

FORENSIC MEDICINE

Medical Jurisprudence and Toxicology. By John Glaister, J.P., D.Sc., M.D., F.R.S.Ed. Ninth edition. (Pp. 755; 234 illustrations, 88 in colour. £1 15s.) Edinburgh: E. and S. Livingstone. 1950.

With indefatigable industry the author has kept the ninth edition of this well-known standard textbook thoroughly up to date. It has grown steadily to become a comprehensive source of reference rather than a medical students' handbook, for no student could be asked to measure the subject by this exhaustive standard. The text will nevertheless provide the graduate, specialist, or criminal bar with a sound and authoritative text which incorporates a remarkable amount of detail and reflects current writing over a vast field.

Glaister's painstaking revision includes much new statutory law—the National Health Service and National Insurance (Industrial Injuries) Acts, reviews of Pharmacy and Poisons Law, reference to the liability of hospitals and nursing-homes, to the legality of necropsy, and to artificial insemination. New writing on fingerprints, the coroner, Rh subtypes, blast and blunt head injury, D.D.T., beryllium, and radioactive substances, among innumerable new case histories and references to current literature, reflects Glaister's determination to keep abreast of forensic advances.

There is a danger that this desire for comprehensiveness will lead to a dichotomy of this valuable textbook—into sections on forensic medicine and toxicology—and this would be a serious disadvantage to the study of what is, after all, one subject. Something must be done to limit its growth: *R. v. Ruxton* could be usefully shortened from its 10 pages; many less pointed illustrative cases might be eliminated and arguments long disposed of be relinquished. The less common subjects such as thallium, copper, borax and cadmium, phosphorus, and fluorine might yield space to the more common. Arsenic can no longer lay claim to 14 pages when carbon monoxide achieves only six (and CO_2, D.N.O.C., or the methyl compounds only a paragraph). This is not a criticism of substance but a plea for a general contraction of what is a most valuable single volume lest it grow unmanageably bulky. "Glaister" remains a fine textbook, maintaining the deep-rooted Scottish traditions in the subject.

KEITH SIMPSON.

PROBLEMS OF PUBLIC HEALTH

Ecology of Health. The New York Academy of Medicine Institute on Public Health, 1947. Edited by E. H. L. Corwin, Ph.D. (Pp. 196. £1.) New York: The Commonwealth Fund. London: Geoffrey Cumberlege.

In 1947 the New York Academy of Medicine held, as part of its Centennial Celebration, an Institute on Public Health, and a number of papers dealing with a large variety of problems were presented. These, together with the discussions of the papers and with some other contributions, have been incorporated in this book to present a survey of modern knowledge and practice in such fields as genetics, maternal nutrition, animal and insect transmission of disease, climate and geography, preventive psychiatry, and public health services. Thus the volume covers a number of fundamental aspects of human oecology, and is concerned with the status of social medicine to-day and with the implications for much-needed research in the future.

The sections into which the material is divided vary considerably both in their comprehensiveness and in their attitudes to public health. In the first section is given a very full and interesting discussion on mutation, and many useful suggestions are made not only on the relation of mutation to mortality but on the effect on morbidity and on the application of genetic theory to public health. The chapter on animal and insect reservoirs of disease will interest workers in the field of public health as much as zoologists and bacteriologists; and the section on maternal nutrition gives a very thorough account of the importance of work being done.

There are necessarily many gaps in this book, not only in respect of the branches of public health which are omitted but in many of the sections given. Much could have been said on the relation of climate and geography to disease, and many useful lines of research could have been indicated. The chapter which discusses the preparation of professional workers is extremely brief, as are also other chapters towards the end of the book.

The accounts given of State and local health services will be of particular interest to many readers in Britain in view of the recent changes in health services in this country. In general, this volume contains such a variety of material and covers so much ground that there will be few readers who will not find in it matters of interest to them.

ANTIHISTAMINIC DRUGS AND THE COMMON COLD

The common cold has again come unscathed through an ineffective therapeutic attack. The hopes that were initially raised by reports of the value of antihistaminic drugs in the prevention and treatment of colds have received no further support. On the contrary, two reports in this issue of the *Journal* provide convincing evidence that these drugs have little or no effect on the course of a cold. It is not the first time that claims for new cures have proved to be groundless, but in this instance emotions have been aroused unnecessarily and tragedies have occurred which should have been avoided. The first report that antihistaminic drugs appeared to cut short the course of the common cold was that of Brewster[1] in 1947. Since then favourable results have been reported by Brewster in another series,[2] Gordon,[3] Murray,[4] and, notably, Arminio and Sweet.[5] All this work was done in the U.S.A., where, as in England, it was received with a certain amount of scepticism by the profession. Several drug manufacturers, on the other hand, accepted it, and the American public was urged to buy drugs in advertisements which featured such statements as "Sensational new discovery kills colds in hours." The public interest was so great that the Council on Pharmacy and Chemistry of the A.M.A. thought it advisable to review the evidence and issue a report.[6] Two of the papers reviewed were based on clinical impressions without the use of untreated controls, and in Brewster's investigations—which contributed more than half of the total patients studied—the statistics were open to important criticisms. For example, in one much-quoted experiment 20% of the treated cases were given drugs within the first two hours of the onset of symptoms, while only 9% of the controls were observed in this period. The council concluded that further experiment was required, preferably of the sort in which volunteers were inoculated with virus, and that "until a scientifically acceptable study is performed, the true effectiveness of the antihistaminic drugs in the control of the common cold cannot be evaluated." This conclusion created a mild sensation, and the council and the *Journal of the American Medical Association*—which had commented editorially on the council's findings—were berated for expressing their beliefs. It was, in fact, hinted that the medical profession was trying to belittle a cure which patients could buy across the counter without having to consult their physicians.

In the case against the treatment of colds with antihistaminic drugs evidence has since been provided by Cowan and Diehl,[8] who, in a carefully controlled study of students at Minnesota University, obtained the same results in the treatment of colds with a placebo containing citric acid as with phenindamine tartrate, tripelennamine hydrochloride, or ascorbic acid. It is just as well that studies should also have been undertaken in this country, though there has been less public interest in this medical nine-day wonder. To-day we publish the report of a committee of the Medical Research Council on two complementary types of experiment, a small-scale laboratory investigation and a large-scale field trial. In the former, conducted at the Common Cold Research Unit, Salisbury, volunteers were inoculated intranasally with cold virus. Half of the subjects, selected at random, were given chlorocyclizine hydrochloride ("histantin") or promethazine hydrochloride ("phenergan") before and after the inoculations and the other half were given dummy tablets containing a small dose of phenobarbitone. Neither the patients nor the clinical observer knew what any particular patient had received. The results were clear cut; full doses of powerful antihistaminic drugs neither prevented colds nor had an effect on the nature of the cold when once it was established. However, the number of volunteers who took part in this trial was small, and the result of the field trial was, in its way, more impressive. For although the diagnoses could not be determined with absolute confidence, and were in fact with certain limitations dependent on the subjective feelings of the patients, there was the compensatory advantage that the drug was given an opportunity of showing whether it had any effect on any group of what may have been a heterogeneous mixture of diseases. The drug used in this experiment was thonzylamine, and it was given in the same dosage as was reported on so favourably by Arminio and Sweet. Medical officers at nineteen centres took part in the investigation, and 1,550 volunteers with colds were treated. They reported to the medical officer concerned or to his assistant as soon as possible after the first symptoms began, when they were given an envelope containing three tablets with instructions how to take them. They saw the doctor again on the two following days, when they were given further supplies

of tablets, and finally one week after their first visit. Half the patients received antihistaminic drugs and half received dummy tablets containing a trace of quinine, but neither the patients nor the medical workers knew what sort of tablets any particular patient received.

To ensure that neither patients nor doctors can identify drugs in trials of this kind it has usually been considered sufficient to give the two sets of tablets a code sign and to choose alternate patients for each type of treatment. This method, however, has the disadvantage that if one of the types of tablets comes to be recognized the investigation ceases to be blind and the possibility of bias arises. In the M.R.C. trial, the reported side-effects of the antihistaminic drugs might conceivably have given a clue to the nature of the tablets, and another method was therefore adopted. The tablets were made up centrally into sets and each set was numbered at random. Since the key was kept centrally until the investigation was finished it was impossible for anyone to know what any individual had received while his progress was being assessed, and even if a correct guess could be made in one instance no light was thrown on any of the others. The results showed that thonzylamine "had little if any value in the treatment of the common cold." The only element of doubt was introduced by the observation of just significant differences (in the technical sense) between the treated and control groups at the end of the first day's treatment, a difference which, however, had disappeared by the end of the second day. This may be interpreted as indicating that a small number of patients with allergic rhinitis (rather than with true colds) were inadvertently included in the series and that these patients had responded to treatment. In any case the difference is so slight that, even if real, it is of little practical importance.

Also published in this issue is a paper by Drs. G. Lorriman and W. J. Martin describing another carefully planned and well-controlled clinical experiment. The drug used was "antistin," and the results were essentially the same as those obtained by the M.R.C. committee: the only difference was that no trace of an effect was obtained on any day of treatment. It is remarkable that side-effects were as common with the placebo as with the drug, despite the full doses given—a feature which was also noted by the M.R.C. workers. Cowan and Diehl's comment on human suggestibility is apposite:

> "We have received many enthusiastic reports . . . from the subjects of the cold study. However, some of the most glowing testimonials came from members of the control group. The first request we received this fall concerning information on the availability of our cold pills came from a student who had been in the study series. . . . He made a special trip from the northern part of the State to get the drug, whereupon it became necessary for us to look up his record. He had been in the placebo group."

In this country we have been fortunate that there has been a spirit of co-operation which has prevented over-enthusiasm on the part of the manufacturers—and here it should be emphasized that there are no doubts whatsoever about the value of the antihistaminic drugs in their right place. There have, however, been individual tragedies. The pressure of public opinion, which is sensitive to news from afar, resulted in the open sale of antihistaminic drugs and their storage In many domestic cupboards. In some instances children have found the tablets, sampled them, and died. Such events are always tragic, but are the more so when the drug would not have been of any use for the condition for which it was bought.

EMOTIONS AND THE COLON

It is common knowledge that disorders in alimentary function which often resemble those resulting from organic disease can be caused by emotional stress. Recent work sheds light on the mechanisms concerned. In experiments on 39 healthy volunteers Almy and his colleagues[1] investigated the functional state of the sigmoid colon by proctoscopic examination or by pressure-recording with inlying balloons. The stimuli applied were cold pain, produced by immersion of the hand for five minutes in ice-cold water; head compression with a headscrew; insulin-induced hypoglycaemia; or discussion of real or imagined disturbing events in the subject's life. In about half of the subjects such stimuli caused stronger contractions of the colon, with hyperaemia and increased mucus secretion. In all who reacted thus there were associated emotional reactions and bodily changes such as sweating, pallor, and a rise in blood pressure. Of those whose sigmoid colon remained functionally unchanged, only two showed general signs of stress, and usually there was close correspondence between the degree of colonic change and the intensity of the general reaction. With all four experimental stimuli the colonic response appeared to be related, not simply to the stimulus itself, but to the subject's attitude towards it—the response occurring only when the subject believed his personal security to be threatened.

In a further investigation[2] the same technique was used in studying patients with spastic constipation which became worse during periods of emotional strain. Comparable results were obtained, but the authors found that the colon responded most vigorously when the patients were upset by discussion of emotional problems and difficult life situations. Strong wave-like colonic contractions were often recorded, but these were

[1] *Gastroenterology*, 1949, **12**, 425.
[2] Ibid., 1949, **12**, 437.

[6] *J. Amer. med. Ass.*, 1950, **142**, 1044.

non-propulsive because they occurred simultaneously in more than one place, an observation in accord with the finding of Adler and his colleagues[3] that the majority of colonic waves are non-propulsive for this reason. Thus the response of the colon to emotional strain in both normal individuals and those with spastic constipation is the same, though symptoms occur only in the latter, probably because of the greater intensity and duration of their reactions. Occasionally the source of strain may lie in some disturbing emotional situation, but more commonly tension arises because of the patient's neurotic traits which make him see danger where none exists. Sufferers from colonic spasm are generally sensitive and immature, adapting with difficulty to environmental stress, exacerbations of symptoms often being related to feelings of anxiety, resentment, or guilt. Thus the seat of the trouble lies not in the bowel but in the patient's conflict with his environment. His is a normal bowel reaction to abnormal stress. In a detailed study of the personalities of twenty patients with ulcerative colitis Mahoney and his colleagues[4] found that they presented an abundance of neurotic traits. Such terms as "autonomic imbalance" and "neuromuscular dysfunction" are therefore misleading, and treatment should be along psychiatric lines.

Lysozyme, a mucolytic and bacteriolytic enzyme, is normally present in human tears, nasal mucus, and gastro-intestinal secretions. When fed to dogs it causes acute ulceration of the upper intestinal tract. Grace and his colleagues[5] have recently shown that anxiety, apprehension, anger, hostility, and resentment are associated with variations in faecal lysozyme, particularly when these emotions are repressed. Moderate transient increase occurred in normal individuals in such moods. In sufferers from ulcerative colitis, however, marked and sustained rise in lysozyme production followed emotional upheaval, and the symptoms became worse as the faecal-lysozyme concentration increased. When the disease was in remission lysozyme concentration was low. Normal amounts of the enzyme were found in patients with carcinoma of the colon and mucous colitis. In a patient with a permanent colostomy small circumscribed areas of oedema and inflammation were observed after human tears containing lysozyme had been applied with cotton-wool pledgets for 24 hours. The authors therefore suggest that because of its mucolytic action excessive lysozyme may play an important part in causing colonic ulceration, and, further, that lysozyme production fluctuates with the emotional state of the individual. Grace, Wolf, and Wolff[6] have confirmed and amplified these findings in a particularly well-planned study of four subjects with colostomy. They found that unexpressed anger and resentment were associated with colonic hyperfunction, which was shown by hyperaemia, engorgement, hypermotility, and increased secretion of both mucus and lysozyme. In this state, which resembled that caused by the administration of methacholine chloride, the fragility of the colonic mucosa was much greater than normal. Sustained feelings of anger and resentment leading to continued colonic hyperfunction resulted in submucosal petechial haemorrhage and ulceration. This demonstration of the resemblance between gastric and colonic function under emotional stress helps to a better understanding of the importance of the psyche in the genesis and aggravation of ulcerative colitis, and it confirms Maudsley's dictum that "the sorrow which has no vent in tears may make other organs weep."

HEALED BACTERIAL ENDOCARDITIS

It is now five years since penicillin has been available in this country for the treatment of subacute bacterial endocarditis, and it is therefore possible to consider what the outlook for successfully treated patients is likely to be. In a paper published elsewhere in this issue Dr. H. Matthew makes such an assessment on the basis of cases treated in Edinburgh. It has hitherto been believed that, despite eradication of the infection, a patient's expectation of life may be short owing to the severe damage caused to the affected valves: as a result of inevitable fibrosis and contracture a valve may conceivably be more incompetent when the disease is over than it was when the infective process was active. The two cases of aortic valve disease described by Rosenblatt and Loewe[1] in a paper quoted by Matthew were striking examples of this change: cusps were reduced to mere stumps, the valve being consequently almost functionless. For this reason the final prognosis has been regarded as most favourable in patients with endocarditis not involving a valve, particularly in those whose underlying abnormality is a patent interventricular septum.

Matthew's follow-up study of the Edinburgh series will serve as a corrective to any undue pessimism in this matter. There were 20 patients out of a total of 40 treated who survived for periods varying from 2¼ to 5¼ years. Only one of these patients has died, the cause of death being heart failure and the lesion aortic stenosis. Of the remainder, none has relapsed or become reinfected. A study of their exercise tolerance shows impairment in only two, and an increase in the size of the heart has been observed in only four: all but two are engaged in the same occupation as before their illness or another no less strenuous. Two, whose lesion was pulmonary stenosis, have actually benefited, their capacity for exercise being greater than before the onset of the disease. It appears that the practical effect of the infection has been to reduce the degree of stenosis. In short, the majority of these patients are as well as they were before their disease developed. If an opportunity eventually occurs of examining their heart valves doubtless the sort of fibrosis and calcification will

[1] *Arch. intern. Med.*, 1945, **76**, 1.

be present which is occasionally seen in patients who are not known to have had bacterial endocarditis—a finding which is the chief support of a belief that spontaneous cure of this disease can sometimes occur.

These are very encouraging findings, but it is important to understand that they are based on a study of patients who had already survived for 2¼ years. The fate of 20 other patients in the Edinburgh series who did not survive for this length of time is not discussed in this paper. In fact congestive heart failure, due mainly to gross valvular damage, is most liable to develop actually during the course of treatment or, as Matthew says, "shortly afterwards." It is of some interest to know how long a period is covered by this term. Contracture following reparative changes should be well advanced within two to three months, and it would therefore be expected that heart failure consequent on it should show itself within that time if a gross degree of valvular incompetence were the result. In Rosenblatt and Loewe's two patients, already referred to, death occurred five and six months after treatment had begun. Evidently some such period as this should elapse before it can safely be concluded that the final prognosis is favourable.

CONGENITAL MALARIA

Malaria in the foetus infected by its mother before or during parturition has long been recognized. Plasmodia have often been detected in the peripheral blood of infants at birth, or at any time up to the shortest recorded "incubation" period for the species of parasite concerned. In other cases parasites have been demonstrated in the brain, liver, spleen, or heart's blood of the foetus. As long ago as 1866[1] deposits of malarial pigment were found in an infant at a necropsy performed three hours after birth. More than 100 papers have been published on this subject, but the only extensive series of observations are on the native populations of hyperendemic areas, where the predominant malarial parasite is *P. falciparum*, and where, though there is a high incidence of heavy placental infections, congenital malaria is for the most part extremely rare. Thus Clark[2] in Panama recorded one case in 400 births, Blacklock and Gordon[3] in Sierra Leone none in 173, Garnham[4] in Kenya none in 404, Walton[5] in Sierra Leone 7 in 2,154, and Peel and Van Hoof[6] none in 403.

These findings have created an impression that congenital malaria is everywhere a very rare event, but records for foreign (non-immune) residents in malarious areas show that in them the disease may be less uncommon than has generally been supposed. Dr. B. S. Jones puts forward evidence to support this view in a paper published elsewhere in this issue: three cases of congenital malaria were found among 37 infants born to European women in February, 1949, at a hospital in Lagos. Most of the published reports are of isolated cases, and there are no data available from which the incidence of malaria among non-immune individuals can be accurately calculated. The three cases recorded from Lagos were all due to infection with *P. falciparum*, but a number of infections with *P. vivax* and a few with *P. malariae* have been described.

The mechanism of transmission of congenital malaria is still not fully understood, but it has been generally assumed that the parasites pass from the maternal to the foetal circulation as the result either of mechanical damage to the placenta or of pathological changes in it induced by malarial infection. The reason why congenital malaria is so very rare among natives of hyperendemic areas though relatively common in non-immune subjects has been the subject of much speculation. Schwetz[7] suggested that the greater frequency in non-immune individuals is due to the greater friability and permeability of the placenta caused by febrile malaria. In the cases recorded by Jones, however, only one of the three mothers admitted to any recent malarial attack. Peel and Van Hoof suggested that the enormous numbers of phagocytes observed in the placentae of natives might be an obstacle to the transplacental passage of the parasite. This is in harmony with the view put forward by Jones that with increasing immunity the efficiency of the placenta as a barrier to foetal transmission increases, and the incidence of congenital malaria therefore falls.

EARLY DIAGNOSIS OF DISSEMINATED SCLEROSIS

The diagnosis of disseminated sclerosis is relatively easy when multiple lesions are found in the central nervous system and when the history indicates that they appeared at varying intervals of time. But in the early stages, and particularly when only one symptom is complained of, the diagnosis may be very difficult, and at times can be only presumptive. The diagnosis remains essentially a clinical one, based on the findings at examination and, more particularly, on the study of the way in which the disorder has progressed. A carefully compiled case history is essential. No pathological or radiological test is of value except in so far as these may help in excluding other types of neurological disease. In a few cases the finding of a completely normal cerebrospinal fluid except for a first-zone or "paretic" Lange gold curve may provide some confirmation of the clinical diagnosis if the Wassermann reactions in the blood and C.S.F. are negative. In a paper published elsewhere in this issue Drs. D. K. Adams and J. M. Sutherland and Mr. W. B. Fletcher have analysed the presenting symptoms in 389 cases of disseminated sclerosis, and they agree with previous authors that the most common early symptoms are weakness of one or more limbs, visual disturbances, paraesthesiae, vertigo, and disorders of micturition. The incidence of retrobulbar neuritis as an initial symptom was 13.9%, which is lower than the 20% recorded by Müller[1] in his remarkable recent study of 810 patients in Sweden. They suggest that the disease occurs most frequently in sympatheticotonic individuals and

[1] *Acta med. scand., Suppl.* 222, 1949, **133**.
[2] *Brit. J. Ophthal.*, 1944, **28**, 40.

that vasomotor disturbances, such as coldness of the hands and feet, and chilblains, are common in the early stages. Frequent early signs which they found in the eyes were imbalance of the ocular muscles, enlarged pupils, and hippus. The first of these, as demonstrated by the two eyes moving at different rates when the patient looks to one side, is a valuable sign of disturbed function of the posterior longitudinal bundle, and when ataxic nystagmus is also present the sign is almost diagnostic of disseminated sclerosis, as Harris[2] has noted. Mydriasis and hippus are quite commonly found in apparently normal people, while the latter is often noted in patients with Sydenham's chorea: it would therefore seem to be unwise to give prominence to these findings in the diagnosis of disseminated sclerosis. Temporal pallor of the optic disks was recorded in only 16.5% of the 79 cases investigated in hospital—a figure corresponding fairly well with the incidence of retrobulbar neuritis in the whole series—and many neurologists will agree that too much is made of this physical sign in some textbooks, especially since it is difficult to assess slight degrees of temporal pallor. Adams and his colleagues rightly emphasize the importance of impairment or absence of the superficial abdominal reflexes when the abdominal musculature is good, even when the plantar responses are flexor. In disseminated sclerosis these reflexes disappear in the early stages of a pyramidal lesion, while in some other neurological disorders, in particular amyotrophic lateral sclerosis, the abdominal reflexes may remain unaffected even when there is spasticity of the legs with ankle clonus and extensor plantar responses.

It is obviously desirable to diagnose disseminated sclerosis in the earliest stage of the disease, when the lesions are potentially reversible. But at the present time, when there is no specific treatment and indeed no therapy which can for certain modify the pathological process or the natural history of the disease in any way, there is a definite danger in attaching the diagnostic label of disseminated sclerosis to a patient on inadequate clinical grounds. Too frequently, when this diagnosis has been made, little further thought is given to the possibility of the diagnosis being wrong, and patients with more readily treated conditions, such as subacute combined degeneration of the cord, myasthenia gravis, and spinal cord tumours, are left untreated.

DOCTORS' HANDBOOK

The new edition of the B.M.A. *Medical Practitioners' Handbook*[1] is an invaluable compendium for the medical practitioner, whatever branch of medicine he practises. Though it is described as not a complete work of reference, it will answer most questions about medical practice, and indicate the sources to consult for the rest. The last edition was published 15 years ago, and many new special sections have been added to cover the changes that have taken place in recent years. The simple, though still fundamental, guidance given in the Hippocratic Oath appears in its opening pages, and the great complexity of medical practice to-day is reflected in the subsequent advice given on such topics as ethical conduct, the administration of the Health Service, business agreements between practitioners, and the legal obligations of doctors to the State. Since hardly any of this information is taught to medical students, newly qualified doctors will find the *Handbook* an indispensable companion to their medical textbooks—and incidentally be thankful that they were not examined on its contents in their Finals, so intricate has the legal and administrative side of medical practice become. The more experienced doctor will find many useful addresses, and the solutions to problems that perhaps crop up only once in a lifetime, while for the postgraduate student details are given of special courses and diplomas. The *Handbook* is well bound and printed, and will stand up to the hard use it is sure to receive.

[1] *The Medical Practitioners' Handbook* British Medical Association, 1950.

ON COUGHING UP CALCIUM

Erosion of calcified glands into the bronchi is known to be one of the rarer causes of haemoptysis, but it is surprising to read that Schmidt[1] and his colleagues consider that broncholithiasis has been of great interest to the medical profession for centuries. To justify this statement they have collected from the Mayo Clinic 41 cases in which calcified material was either coughed up or discovered during endoscopic or surgical procedures. Most of the patients were over the age of 40, and the presenting symptoms were usually cough and haemoptysis. Haemoptysis, the first symptom in nine patients, was severe enough in six to require treatment by blood transfusion. Other distressing symptoms were severe retrosternal pain, thought to be caused by bronchial colic, and intractable asthma. The most characteristic radiological finding was a focus of calcification in association with an area of segmental pulmonary collapse, penetrating radiographs often being necessary to demonstrate the calcium. In other cases there were merely single or scattered areas of calcification.

The term broncholithiasis is perhaps unfortunate, since stones are not formed within the lumen of the bronchus. Bronchial stones are always produced by the ulceration of peribronchial calcified material through the bronchial walls. Schmidt and his colleagues confirm the popular belief that much the commonest source of such material is calcified tuberculous lymph nodes; they give, as rarer causes, coccidioidomycosis and histoplasmosis, neither of which is of great importance in this country. The authors also suggest that the calcified bronchial cartilages so often seen in old age may sometimes separate off into the bronchi, but they do not make it clear that such a process was found in any of their cases.

The importance of stones in the respiratory passages is that the resulting symptoms and signs are apt to be confused with those of other pulmonary disorders, especially bronchial carcinoma. Indeed, the differentiation may at times be exceedingly difficult, since radiography is not conclusive, and bronchoscopy often reveals fleshy granulomatous tissue round the calcified mass. Thoracotomy and exploration may be necessary when doubt exists, though needless operation might be prevented by careful questioning. Almost half of Schmidt's patients gave a history of coughing up stones; one patient claimed to have performed this unusual feat no fewer than 103 times.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

CHEMOTHERAPY—I. ADMINISTRATION OF PENICILLIN

BY

LAWRENCE P. GARROD, M.D., F.R.C.P.

Bacteriologist, St. Bartholomew's Hospital; Professor of Bacteriology, University of London

In describing the therapeutic use of penicillin it is convenient to deal first with its administration and secondly with indications for it: these will be the subject of a succeeding article.

Therapeutic Action

Two theoretical aspects must be considered briefly: one of these is the nature of the action of penicillin. This is exerted exclusively on the bacteria causing the infection, and varies in nature and degree with the concentration to which they are exposed. Low concentrations do little more than inhibit bacterial growth, but one only 5 or 10 times greater than this is actively, though not very rapidly, bactericidal: 99% or more of a fully exposed bacterial population may be killed within a few hours. If the concentration is increased beyond this point no further acceleration of bacterial death occurs, and with certain organisms the rate may even be substantially decreased. Penicillin is unique in this behaviour. It has an optimum concentration for antibacterial effect beyond which an increase will certainly be useless and may be positively detrimental, whereas with other bactericidal substances increased concentration accelerates effect indefinitely. The optimum concentration for a sensitive organism is quite low—for a staphylococcus about 0.1 unit per ml., and for a haemolytic streptococcus even less. It might appear from this that the object of treatment should be to maintain this concentration in the tissues until the infection is eliminated. In the first place this is impossible except by the use of a continuous drip. It further overlooks the fact that penicillin has to diffuse into infected areas, where the concentration is likely to be lower than that attained in the blood. The view is widely held that the intermittent production of relatively very high blood levels is useful in promoting this diffusion into undrained abscesses, areas of necrosis, cardiac vegetations, etc.

How long should this action be maintained, and should it be continuous or intermittent? There are grounds for believing that the necessary duration of treatment depends on two principal factors. One is the sensitivity of the organism: the gonococcus, the most sensitive of all, can usually be eliminated in a few hours. The other is the total number of bacteria to be disposed of, which is tantamount to saying the stage or extent of the infection. At a very early stage the dose required may be only a small fraction of that necessary later. The relative merits of continuous and intermittent effect have been much debated and are still unsettled. Penicillin acts only on multiplying bacteria, and since any given dose leaves a number of semi-dormant bacterial cells alive (Bigger's "persisters") it is argued that these should be allowed to begin multiplying before another is given. It would obviously be dangerous to carry this policy too far. It is known that bacteria exposed to but not killed by penicillin resume growth in a period averaging three to four hours, and it seems reasonable not to allow the concentration in the blood between doses to fall below an effective level for much longer than this. Recent extensive therapeutic tests in animals support this view.

Absorption and Excretion

The ordinary salts of penicillin (the sodium salt being that commonly used) are freely soluble and highly diffusible. Injected in watery solution into the tissues, penicillin is quickly absorbed, reaching maximum concentration in the blood within less than 15 minutes if the dose is not very large. This rise to a high level is followed by a fall at first almost as steep, due to rapid renal elimination. Penicillin leaves the body as fast as it reaches the kidneys, and the enormous quantities which have to be given are due to the fact that on the average each molecule spends only a few minutes in the circulation between absorption from the injection site and excretion by the kidney. Comparatively few ever reach and still fewer remain at the site of a local infection. That the doses given are enormous will be conceded when it is remembered that in a patient of average weight with total anuria the dose required to produce an adequate concentration in the blood for treating a fully sensitive infection would be only 350 units. It is advisable to bear in mind that patients with impaired renal function require smaller doses at longer intervals.

The rate of fall in the blood level, although steep at first, progressively diminishes. During the latter part of this phase traces are probably still being absorbed from the site of injection, and some which has passed into the tissues is returning to the circulation via the lymph. The relation of duration of effect to dose, and means of obtaining more prolonged effect, are discussed later.

Treatment by Intramuscular Injection

Penicillin may be given either by continuous infusion—now an uncommon practice, and feasible only in a hospital—or by spaced single injections. It is usual to make these intramuscularly, but this route was originally adopted because the crude penicillin of early days was more painful given subcutaneously. This objection to the subcutaneous route no longer holds, and it has some slight advantage in being followed by rather slower absorption. The site of injection is theoretically indifferent, and practically so in a well-nourished patient requiring few injections. In an emaciated patient having a long course, rotation of the main sites is essential. In either, skill and a really sharp needle affect his reaction considerably.

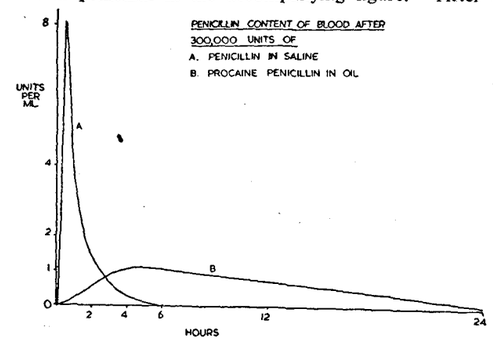
It was originally the practice to give small doses at intervals of three or at the most four hours in order to maintain the effect. With the free availability of penicillin the practice has grown up of giving large doses at long intervals, and this has been carried to greater lengths in this country than in any other. It is important to know how far this is justified, and in considering this it must be remembered that duration of effect is by no means directly proportional to the dose given. The larger this is, the greater the rate of elimination, and doubling the dose actually prolongs effect by only about one-third. The following are the approximate times during which a detectable and thus—for a sensitive infection—therapeutically useful concentration persists in the blood.

After	25,000	units	2½ hours
,,	50,000	,,	3 ,,
,,	100,000	,,	4 ,,
,,	250,000	,,	5 ,,
,,	500,000	,,	7½ ,,

These figures are only approximate, because the rate of elimination varies inexplicably in different apparently normal subjects. They conflict in the higher range with other published figures, but the last of them is based on recent observations by a colleague and myself made by an accurate technique in a series of 31 individuals, and we have no hesitation in asserting that for a dose of 500,000 units to produce a detectable blood level after the eighth hour is exceptional.

It has already been mentioned that bacteria are known to take some hours to recover from exposure to penicillin and to resume growth, the length of this period varying with species, length of exposure, and concentration. Allowing for this factor, the following intervals are appropriate between different doses for patients in whom it is necessary that the drug should exert a full and uninterrupted effect.

Dose			Interval
25,000	units		3 hours
50,000	,,		4 ,,
100,000	,,		6 ,,
250,000	,,		8 ,,
500,000	,,		12 ,,



In less serious cases; and when frequent administration is impracticable, these intervals may be lengthened, probably with some retardation of the therapeutic effect, but it seems inadvisable in any circumstances to give penicillin in this form only once daily: the interval for bacterial recovery is then too long. It is true that penicillin persists in exudates after it has disappeared from the blood, and this may add a few hours to the period of efficacy of each dose, but it is not known how far this persistence depends on the nature of the lesion and the rate of exudation into it, and there are some conditions, notably bacterial endocarditis, in which this factor is not operative at all.

Slowly Absorbed Preparations

The effect of a single dose can be prolonged either by delaying absorption or by blocking excretion. Various substances have been used which interfere with the renal excretion of penicillin. Of these the most useful is caronamide, since it can be given by the mouth. The dose required is large, and apt to cause nausea and other disturbances. This method should be used only under hospital conditions for sustaining very high blood levels in unusually resistant infections.

Delayed absorption was first secured by suspending calcium penicillin in an oil base also containing beeswax. Beeswax is essential for the full delaying effect, and it is this ingredient which causes local reactions, sometimes going on to suppuration. These preparations are now almost entirely superseded by oily suspensions (containing no beeswax) or powders, suspended in water before injection, containing procaine penicillin. This compound of the two substances has a low solubility to which its slow absorption is mainly due, and an antibacterial action equivalent to that of penicillin itself. The rate of absorption—and, it may be added, the facility with which the material will pass through a small needle—depend on the size and shape of the procaine penicillin crystals: it is possible, although not all manufacturers have yet succeeded in doing this, to produce crystals large enough (50 μ in diameter) to dissolve slowly, but so compact as not to cause needle blockage.

The rate of absorption of a good preparation of this kind is contrasted with that of an ordinary solution of sodium penicillin in the accompanying figure. After a

dose of 250,000 units or thereabouts the blood level rises to a maximum of about 1 unit per ml. in four hours, then diminishing very slowly so that an effective or at least detectable amount is still present after 24 hours. If the preparation also contains aluminium stearate, a water-repellent substance which delays absorption further, this shallow curve is even more flattened, and penicillin may be detected in the blood after two days or even considerably longer if a large dose (one million units or more) is given. Some of these preparations also contain sodium penicillin, which will also give a high initial level lasting only a short time.

The object of these preparations is to secure a continuous effect from a single daily dose, from doses given at intervals of two or more days, or even to cure an infection by a single dose which need not be repeated. They provide much the simplest means of treating patients efficiently in their own homes, where only infrequent injections are feasible. They may be used in a patient under nursing care either because a continuous fairly low blood level is thought desirable, or simply in order to obviate frequent injections. What they will not do is to produce a high blood level. If the infection is a relatively resistant one, or if for any other reason it is thought desirable to achieve a blood level of much over 1 unit per ml., then large doses of sodium penicillin should be given.

Oral Administration

Penicillin is destroyed by acid in the stomach and by bacterial enzymic action in the lower bowel. There is also some loss, not wholly explained, in the upper part of the intestine, since, even in patients with total achlorhydria or given penicillin through a duodenal tube, only a fraction of the dose is absorbed. It is therefore necessary to give from 5 to 10 times the intramuscular dose in order to achieve the same effect; even so the effect is not altogether dependable, since the proportion absorbed varies inexplicably in different subjects, and even in the same subject at different times. Absorption is better when the stomach is empty: oral penicillin should therefore be given before meals. Antacids and various capsules designed to overcome the acid gastric barrier have not been found helpful. Absorption is rather more constant in infants, and penicillin may be added to feeds. Here there is the double advantage of avoiding injections in patients to whom they are most disturbing, and of reasonable economy, since the dose required is comparatively small on a body-weight basis.

It is difficult to say what place this form of treatment should have, but even its more enthusiastic advocates are reluctant to employ it in serious cases owing to the uncertainty of its effects.

Local Administration

There are many ways in which penicillin may usefully be applied to the actual site of infection. Besides being a chemotherapeutic agent, it has all the properties of the ideal antiseptic, killing or preventing the growth of susceptible bacteria without doing the slightest harm to tissue. Local application may be indicated for its simplicity and economy, because the area concerned can be reached in no other way, or in order to attain a high concentration there which will persist for some time. The following are the more important examples.

Intrathecal Injection.—Only traces of penicillin reach the cerebrospinal fluid from the blood unless enormous doses are given intramuscularly. Meningitis should therefore be treated by intrathecal injection as well as intramuscular. Pure ("white") sodium penicillin should be used, and the solution should be prepared freshly with the strictest aseptic precautions and with no preservative such as phenol. A dose of 10,000 units will maintain an adequate level for 24 hours. Unless there is a block, remarkably uniform diffusion occurs throughout the central nervous system from an injection given by the lumbar route.

Serous Sacs, Joints, and Abscesses.—Penicillin solution may with advantage be injected into an empyema cavity, a joint affected by suppurative arthritis, or abscess cavities elsewhere, the dose depending on the size of the cavity: as much as 100,000 units may be indicated for a large empyema. Absorption from such an area is slow, and penetration into it from the blood equally or more so; this is therefore not only a convenient but the only way of keeping up a high concentration in such a collection of fluid for a whole day or more. If the dose is large, slow absorption will also maintain a systemic effect, to some extent taking the place of intramuscular injections. This is not the place (nor am I the person) to discuss the surgical treatment of these conditions further than to say that penicillin does not necessarily remove the need for it.

Carbuncle can be treated very successfully by injecting penicillin into and around it. Even though the solution also contains procaine, this is a painful proceeding, but may be well worth while to accelerate resolution.

Wounds.—One way of preventing infection in a recent wound is to dust it with a powder containing penicillin. The usual diluent is a sulphonamide (preferably sulphathiazole), and the procedure has been objected to on account of the risk of causing sensitization. Established sepsis in superficial wounds and burns, if due to a demonstrably sensitive organism, may be treated similarly, or by the spraying of a solution or the application of a cream. These last two methods are applicable, under the same condition, to the treatment of infections of the skin. Among other superficial infections, conjunctivitis may be treated by drops frequently applied or by lamellae.

Upper Air Passages.—Infections of the main nasal cavity (it being remembered that the sinuses are generally inaccessible to such measures) can be treated either with a spray or, probably better, by the frequent use of a snuff containing 5,000 units of calcium penicillin per gramme of sulphathiazole. This has been particularly successful in clearing up nasal carrier conditions; and, owing to the backward flow of mucus in the nose, it has also an effect on the nasopharynx and even the throat.

Local treatment of the throat and mouth is best carried out with gelatin pastilles, one of which should be kept in the buccal sulcus throughout the day. Solution is slow, and replacement necessary at intervals of not less than an hour. The official trochiscus penicillinae of the *B.P.*, a tablet with a lactose base, is less satisfactory. The choice of this product was dictated by the greater stability of penicillin in a dry form, but gelatin pastilles are now obtainable which retain the greater part of their activity for months; alternatively, they can easily be made fresh by a pharmacist. Penicillin chewing-gums are also suitable for this type of use if the patient will persist with them.

Infections of the bronchi and lungs may be treated by inhalation, a small volume of concentrated solution containing, say, 100,000 units being administered by a Collison or other inhaler several times a day. There is some absorption by this route: thus a large enough dose will also exert a systemic effect. The inhalation of a fine powder of penicillin, recently advocated in the U.S.A., has not apparently been adopted in this country, and seems likely to be more disagreeable to the patient than a liquid spray.

PHARMACY AND POISONS ACT, 1933

The Poisons List Order, 1950 (S.I. 1950, No. 1213) and the Poisons Rules, 1950 (S.I. 1950, No. 1214), which were made by the Secretary of State on July 21, come into operation on September 1. These Statutory Instruments make the following changes in the Poisons List and the Poisons Rules, 1949, hereafter called the Principal Rules.

Part I of the Poisons List and the First Schedule to the Principal Rules.—The following substances are added: Alphaprodine; its salts. The following antihistamine substances and their salts: antazoline, diphenhydramine, 3-di-*n*-butylaminomethyl-4:5:6-trihydroxyphthalide, phenindamine, substances being tetra-substituted N derivatives of ethylenediamine or propylenediamine. Betaprodine; its salts. Di-isopropyl fluorophosphonate. Hydroxypethidine; its salts. Isoamidone; its salts. Ketobemidone; its salts. Methadol; its salts. Methadyl acetate; its salts. Polymethylenebistrimethylammonium salts. The following items are amended: Amidone (DL-2-dimethylamino-4:4-diphenylheptane-5-one); its salts. The chemical description is omitted and the entry now reads: "Amidone; its salts." The item "6-morpholino-4:4-diphenylheptane-3-one; its salts," which describes the poison now known as phenadoxone is omitted, and after the item "Pethidine; its salts;" there is inserted "Phenadoxone; its salts."

The Third Schedule to the Principal Rules.—Antihistamine substances and their salts are added to Group II of this Schedule and are thereby exempted from the requirements of the Pharmacy and Poisons Act and the Principal Rules when in the form of "preparations intended for external application only."

The Fourth Schedule to the Principal Rules.—Antihistamine substances and their salts, other than the preparations exempted by inclusion in Group II of the Third Schedule, and polymethylenebistrimethylammonium salts are added to this Schedule. The item "6-morpholino-4:4-diphenylheptane-3-one; its salts" is deleted from this Schedule. This poison (under the name phenadoxone) is now subject to control under the Dangerous Drugs law.

The Seventh Schedule to the Principal Rules.—At the end of this Schedule the following paragraph is added: To be labelled with the words "Caution. This preparation should be administered only under medical supervision. The vapour is dangerous": Medicines made up ready for the internal or external treatment of human ailments and containing di-isopropyl fluorophosphonate.

Rules 7 and 12 of the Principal Rules.—These Rules are amended to provide that when a poison is supplied in ampoules the "signed order" or prescription may state either the total amount to be supplied (as at present) or the total amount intended for administration or injection.

Rule 16 and the Thirteenth Schedule to the Principal Rules.—In paragraph (*e*) of the proviso to this Rule and in the Schedule the description "executive officer" is replaced by the description "county agricultural officer or assistant county agricultural officer."

Copies of the Poisons List Order and of the Poisons Rules may be obtained from H.M. Stationery Office or through any bookseller.

INFANT-FEEDING IN NORTH-EAST AFRICA*

BY

LESLIE HOUSDEN, O.B.E., M.D.

Nearly all infants are breast-fed, especially in the southern half of the Sudan. In the northern half western influence and customs have already begun to give native mothers western views. A woman will occasionally come to hospital with her baby already off the breast, saying that her milk was no good. In Somaliland the fathers sometimes demand that their babies shall be given undiluted cows' milk, believing that it makes them "more lively." These fathers also have a way of sending their wives into the interior to look after the stock, leaving the young infants to the care of the grandmothers.

Deprived of breast milk in the early months of life—as through the death of the mother—infants rarely survive. Alternative food is difficult to find, especially in the milkless tsetse-fly country, and is usually unsuitable both in quantity and kind. Overfeeding and malnutrition go hand in hand. Sometimes the young infant is fed on porridge made from sweet potatoes or groundnuts, with additions of mango juice during the mango season, which may last from April until

FIG. 1.—Mother comforting her child.

July. In countries where cows' or camels' milk is obtainable, it is usually very dirty, and gastro-enteritis is a common cause of death. Tea, ghee (clarified butter), rice, and chewed fat are other forms of infant food.

*Notes based on experience in the Anglo-Egyptian Sudan and British Somaliland.

FIG. 2.—Baby shielded by half-gourd on mother's back.

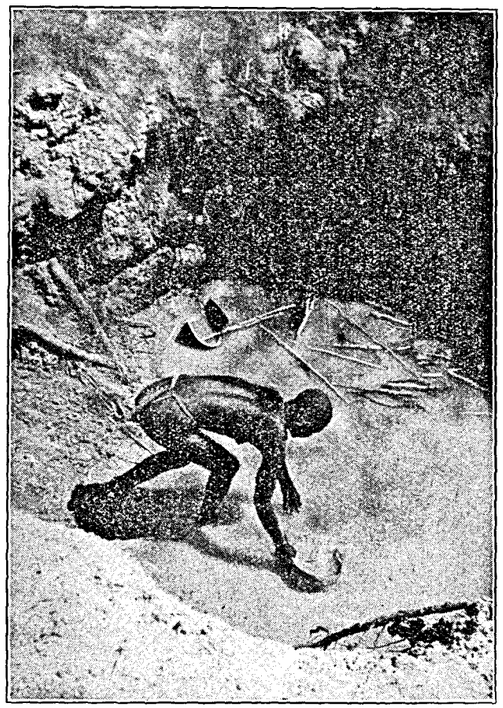
Breast-fed Too Long

The chief fault of native nursing is that it is continued too long. Two years is a very usual time, and often the child is breast-fed up to the age of 3 or 4. Early progress is usually good, especially if the mother is herself reasonably well nourished, but after the age of 8 or 9 months the baby ceases to do well and later still loses ground. Often the mother is undernourished and ill, especially in Somaliland, where the standard of nutrition is low and infants of 18 months have been found in an emaciated condition, starving on 6 or 8 oz. of breast milk a day.

There are several reasons for this prolonged nursing. First there is the difficulty of alternative feeding in lands where milk is scarce or unknown and where adult food is unsuitable for infants and often insufficient for the adults themselves. Then there is the physical contact with their mothers in which infants spend so much of the first two years of their lives. They live attached to their mothers. They use neither cot nor cradle. By day they are carried slung to the mother's back or side, at night they lie against her as she sleeps. Whenever a baby cries he is fed. One of the objections to the use of a cradle is that the mother thinks her baby should not leave her. A third reason is that in some tribes husbands do not engage in sexual intercourse with a wife who is nursing a baby. Prolonged breast-feeding therefore acts as a method of birth control.

It is not the prolonged breast-feeding that harms the native infant but breast starvation. After a grossly inadequate intake of breast milk over many months the infant is marasmic and anaemic and ready to succumb to the diarrhoea set up by unsuitable foods at weaning. If additional foods were given the breast milk would be a boon. In some tribes additional foods are given. Zande mothers, for instance, sometimes give scraped banana, with or without water, from the seventh day. They also chew sugarcane and spit it into the baby's mouth. From one month, dura (millet) porridge and chewed sweet potato and cassava may be given. Other Zande mothers, however, give nothing until they add porridge at the ninth month. During these nine months the mothers themselves take nothing but gruel and simsin (a vegetable oil). Among the Shilluks a mother may not drink milk for the first six months of pregnancy lest the cow from which the milk came goes dry.

Hazardous Gardening



Complementary foods, such as oranges and lemons, sweet potato, banana, millet, and local fruits such as pawpaw, are either obtainable or could be produced if fathers had the will and energy to grow them, but even when they are available the mothers are often unwilling to give them. They say that their babies will not eat them, and continue

to underfeed them on the breast. In some parts there is a further difficulty in persuading the fathers to provide the needed foods, the popular belief being that if anyone produces a garden better than all the others he will die the same year.

Native babies spend the greater part of their first two years in close contact with their mothers' bodies. When the baby cries or when the mother has nothing else to do, her infant is fed. There are no regular feed-times; the breast is available at all times of the day and night. This close maternal contact is maintained as long as the mother has the baby's welfare uppermost in her mind. During the rains, when she may join the rest of the tribe in cultivating the land, she will leave her baby all day with no food at all, to be carried about on the back of an elder brother or sister, crying for food until she returns. The elder brother or sister provides the physical contact usually supplied by the mother but cannot produce the food.

The only other time when the breast is unavailable to the baby is when the mother is drunk. This is a common occurrence in some areas.

The age of weaning varies according to the tribe, the time of year (i.e., the state of cultivation), and chance, but the most usual food at all times is porridge made from

FIG. 3.—Woman drawing water by means of half-gourd from waterhole.

dura (millet). This requires hours of grinding by hand between two stones if a fine flour is to be produced, but mothers are often unwilling to spend so long over its preparation. They use it for their infants in an incomplete and gritty form. It causes diarrhoea, which is lethal to marasmic and anaemic infants.

Infant Death Rate

In North-east Africa there are few vital statistics—and they are unreliable. There are, however, well-founded impressions. One of these is that in some parts the death rate of infants during the first two years of life is between 50% and 60%. Some natives forget very quickly that they had any children who died, but some figures of value can be produced. In February, 1949, fourteen chiefs of the Torit area had had 186 children, of whom 87 were still living. This was an infant- or child-mortality rate of 53.2%. One Somali interpreter had had by his eight wives 42 children, of whom 18, that is 43%, had died "from some kind of sickness." The eight wives of another interpreter had presented him with 35 children, of whom 22 had died, a mortality rate of 63%. A Somali medical assistant had lost seven out of nine children with "diarrhoea and abdominal pain." Very little is thought of these high death rates. As a Sudanese medical assistant said, "When ill-nourished, anaemic babies get any intercurrent disease, they die. No one ever thinks of natural death."

Infant Welfare

In many parts of the world where black-skinned people dwell there are too many people; in some there are too few. Torit in Equatoria (Anglo-Egyptian Sudan) is one of these, and on May 7 the Save the Children Fund sent a team of one doctor and two nurses to spend the next few years in teaching the local tribes how to keep their babies alive. Although in principle the saving of these infants will be simple, in practice there will be difficulties.

The logic of infant welfare will appeal only to those who have logical minds. It is good to make certain simple preparations for the reception of a baby, but many native mothers believe that if any preparations at all are made for an unborn baby it will surely die. A father should grow food for his children, but, besides his likely death the same year if his garden excels those of his neighbours, he must guard his crops day and night as they reach maturity or they will be stolen. Western ideas of dealing with native problems must be modified by the native outlook. The study and research of the Save the Children Fund team should produce information of interest and value.

A circular from the Ministry of Health states that hospital boards sometimes acquire property with moneys from their endowment fund with the intention of selling or renting the property to the Minister when it is required for hospital purposes, but the Minister warns boards that he cannot acquire a property for which a price has been paid in excess of that appropriate to a compulsory purchase. Nor can he purchase any property for which such an excess price has been paid, even though the board offers to resell to him at the compulsory-purchase price, the loss being taken by the endowment fund, and he cannot rent, lease, or accept a gift of such a property. The Minister is bound to carry out the intentions of Parliament as expressed in Part V of the Town and Country Planning Act, 1947, and he could not take part in a transaction which would undermine the provisions of that Act. This should be remembered whenever a board is buying from the endowment fund property which might be suitable for hospital purposes; and if the board is likely one day to wish to sell, lease, rent, or give such property to the Minister it should consider whether it is advisable to pay a price in excess of the district valuer's valuation of the property. Boards do not at present know what the district valuer's price would be, as his services are available only where purchase by a Government Department is in view. The Minister has therefore arranged that any board may ask him to request the chief valuer to make the services of the district valuer available to the board.

Reports of Societies

ASSOCIATION OF CLINICAL PATHOLOGISTS

Scientific Meeting at Leeds

The 44th Scientific Meeting was held at Leeds on July 20, 21, and 22 under the presidency of Dr. NORAH SCHUSTER. The inaugural session was devoted to a consideration of allergic diseases of blood vessels. Dr. G. DISCOMBE (London) reviewed 16 proved and 6 suspected cases of polyarteritis nodosa. Laboratory investigations did not always help in the diagnosis, for biopsy was sometimes negative. Lesions might heal, and, if in the kidney, could produce an essential hypertension the changes of which might almost completely obliterate those of polyarteritis nodosa. Eosinophilia, although common and usually demonstrable by direct counts during the active phase, was not an essential part of the syndrome. Dr. W. PAGEL (London) discussed some unusual aspects of histology and the question of aetiology. Subendothelial swelling due to permeation of fluid seemed to be followed by exudation of fibrinogen with subsequent necrosis, mostly eccentric, of the vessel wall, a breach in which became plugged with fibrin. Fibrin was deposited, too, both inside and outside the necrotic wall. He preferred to reserve the term "fibrinoid" for changes which failed to show the staining affinities of fibrin, and which sometimes occurred in positions which did not always favour the assumption that one was dealing with fibrin which had lost its staining affinities. In his opinion the differences between polyarteritis nodosa and the "pararheumatic" diseases, including lupus erythematosus disseminatus, dermatomyositis, and temporal arteritis, were more in the natural history of the disease and the preferential site and distribution of the basic change rather than in the basic histology, which appeared to be identical. In polyarteritis nodosa extramural foci involved the collagen fibres and were indistinguishable from the acute infiltrative changes in rheumatic fever, lupus erythematosus disseminatus, and dermatomyositis. In some instances healed polyarteritis nodosa appeared to be the basis of an eosinophil-celled alveolitis (Loeffler's syndrome) associated with exfoliative dermatitis and asthma (in one case terminated by cerebral haemorrhage). Intradermal injection of heat-killed streptococci in healthy persons and in rheumatic and other patients who had volunteered had established the significance of bacterial antigens in the reproduction of the changes characteristic of polyarteritis nodosa. Both the histological and experimental evidence supported the view that polyarteritis nodosa and the related diseases were an expression of the hyperergic response to any aetiological factor, including bacterial (notably streptococcal) antigen.

Dr. I. RANNIE (Newcastle-upon-Tyne) described the value of biopsy. A positive result was obtained in 8 out of 12 cases, the four unsuccessful biopsies being explained by either the unsuitability or the insufficiency of the material submitted. In 5 of the 8 positive instances biopsy was carried out for confirmation of diagnosis; 4 were taken from the muscle, and 1 from a skin nodule. The diagnosis of polyarteritis nodosa was established as a chance biopsy finding in the remaining 3 cases, the organs submitted being respectively appendix, liver, and cervix uteri and ovaries. Muscle was the material of choice; a tender area should be chosen for excision, and a negative report should not be issued until serial sections had been studied.

Professor T. CRAWFORD (London), discussing the experimental production of polyarteritis nodosa, said that there were two main types of procedure which had led to the production of lesions in animals closely resembling those of polyarteritis in man. The first, introduced by German pathologists about 1930 and used extensively by Rich and Gregory in the U.S.A., consisted in the administration of foreign protein to a suitable animal such as the rabbit. The second, described in this country by Wilson and Byron, depended upon the production of hypertension by some procedure such as the clipping of a renal artery in rats. The interpretation of these experiments which the speaker favoured was that the first procedure led to a tissue antigen-antibody reaction characterized by necrosis and fibrin deposition in the vessel walls and a cellular reaction around the injured area; whereas with the second procedure sudden elevation of blood pressure caused damage to the less well supported arteries, and this again led to necrosis and fibrin deposition in the vessel wall, with a secondary cellular response as in the former lesion. When considered in conjunction with knowledge gained from clinical sources, the first of these experimental procedures seemed to constitute a closer parallel to the conditions of the human disease than did the latter. Study of these lesions might well lead to better understanding of the human disease and of the effects of various agents upon it.

The sessions which followed provided a varied programme. Short papers were read by Dr. G. B. S. ROBERTS (Glasgow), Dr. I. FRIEDMANN (London), Dr. T. B. MAGATH (Rochester, Minnesota), Drs. R. AIDIN and G. H. TOVEY (*Bristol*), Dr. R. W. FAIRBROTHER (Manchester), and Air Vice-marshal T. C. St.C. MORTON (Wendover).

Dr. SCHUSTER, whose presidential address was entitled "Nec silet mors," told of the increasing demands which advances in medicine and surgery made on pathologists who undertook necropsies; to-day they must needs pay attention to parts of anatomy which 25 years ago they could safely ignore. As a profession doctors were always willing to learn, but it was comforting to know that at the age of 80 Leonardo da Vinci was to be seen passing through the streets of Milan on his way to the medical school to refresh his memory on points of anatomy. A full medical and occupational history was essential for the pathologist at the time of the necropsy, otherwise there might be great wastage of material.

Non-pulmonary Tuberculosis

Dr. G. S. WILSON (London) gave an account of the survey that was carried out in England and Wales during 1943–5 into the distribution and frequency of non-pulmonary tuberculosis caused by the bovine type of bacillus. The survey was an excellent example of what could be achieved by co-operation between different laboratories making use of ordinary routine material, and Dr. Wilson took the opportunity of thanking the 149 pathologists who had gone to the trouble of collecting specimens for examination by the bacteriologists. In England strains from 994 patients had been examined; of these, 26.3% belonged to the bovine type. The percentage distribution according to site of disease was: meninges 27.1; cervical glands 46.5; bones and joints 10.8; genito-urinary system 12.8; miscellaneous 10.6. The proportion of bovine-type strains was highest in the second quinquennium of life, and higher among females than males. It was calculated that in England and Wales during 1944 about 24% of all cases of non-pulmonary tuberculosis were of bovine origin and that 1,300 to 1,400 persons died of milk-borne tuberculosis. In conclusion Dr. Wilson drew attention to the high proportion of mistaken diagnoses in cervical adenitis, and suggested that further work was required to distinguish the tuberculous from other forms of the disease. Dr. G. STEWART SMITH (*Exeter*) spoke on the problem of non-pulmonary tuberculosis as seen in an urban and rural community in the south-west.

Dr. A. J. RHODES (Toronto) gave an account of the epidemiology of the Coxsackie virus and of a recent epidemic in Dufferin county in which both the viruses of poliomyelitis and of the Coxsackie infection appeared to take part. Dr. F. O. MACCALLUM (Colindale) described briefly the results of recent investigations made on material sent in to the Virus Reference Laboratory, and the problems of diagnosis which faced us to-day. Other papers on a variety of subjects were read by Dr. J. B. FOOTE (London), Dr. P. G. WALKER and Mr. R. D. WILKINS (London), Professor C. H. GRAY (London), Drs. E. M. DARMADY, J. HARKNESS, and A. RICHARDSON JONES (Portsmouth), Dr. C. J. YOUNG (Bradford), Dr. OSCAR B. HUNTER, *jun.* (Washington, D.C.), Dr. C. MERSKEY (Oxford), and Dr. J. V. DACIE (London). Speakers at the dinner of the association, which was held on July 21, included Professor MATTHEW STEWART and Dr. ROBERT A. MOORE, professor of pathology at the Washington University, St. Louis, Missouri, and secretary of the American Board of Pathology.

Correspondence

Haemorrhage from Peptic Ulcer

SIR,—Your readers must be tired of the bandying about of statistics on the results of the treatment of haemorrhage from peptic ulcer, but I should like to raise the question whether these haemorrhages need really occur. If every peptic ulcer, once definitely established as chronic, was operated upon "in the cold" there would be few or no bleedings or perforations, the total mortality from the disease would probably be less, and patients would be saved those years of semi-invalidism which the so-called medical treatment of peptic ulcer involves. Such at least is my belief.—I am, etc.,

Streatley, Berks. ROBERT HUTCHISON.

SIR,—In neither of the two articles on haematemesis in the *Journal* (July 15, p. 138) is any mention made of aspirin as a cause of acute peptic ulcer and haemorrhage. There is no doubt that aspirin tablets swallowed whole can have this effect and that cases are now occurring. Arthur Hurst may have over-estimated its frequency, but since his death this factor seems to have been forgotten. Unless the possibility of aspirin tablets having been taken in this manner is specially inquired for, it is most unlikely that it will be mentioned by the patient. It should be borne in mind by those studying the aetiology of peptic ulcer and compiling statistics on haematemesis.—I am, etc.,

London, W.1. HENRY TIDY.

Reflections on Criminal Conduct

SIR,—Sir David K. Henderson's paper "Reflections on Criminal Conduct and Its Treatment" (August 5, p. 311) is a miracle of clarity and good sense such as one might have expected from its source. I am sure that sooner or later his conclusions will become universally adopted. For example, his view that a man medically insane should be regarded as legally insane is a case in point. One certifies a man because he is dangerous to himself or others, yet if he kills someone when confined in a mental hospital he is liable for trial! Was there ever such an illogical position? To my mind a person suspected of insanity who is accused of a crime should be examined before the trial and certified if he is insane. The certificate should be checked by the Board of Control, and if necessary by further independent specialists. If the prisoner is insane he should be regarded as unfit to plead, and sent to a mental hospital. This would prevent the recurring argument over the M'Naghten rules, which, as Sir David points out, are anomalous and antiquated. Juries in my experience are absolutely unable to give a reliable opinion on a prisoner's sanity. I have given evidence in the case of a man whose mental age was eight years, who had confirmed epilepsy, and who did a senseless crime in either an epileptic rage or in a state of automatism. The jury found him guilty. I wrote to the Home Secretary and pointed out that under the Lunacy Acts he must have the prisoner re-examined on the information submitted. He did so, and the man was found impossible to hang humanely because he had a wooden leg! Recently in the face of three doctors' evidence, which included the prison doctor, that he was schizophrenic, a man called Rivett was twice found guilty of murder, his appeal was disallowed, and Lord Justice Goddard praised the jury system—presumably for disregarding medical evidence.

The treatment of sexual offences in court is most extraordinary. I have seen men discharged with a caution by a magistrate for exactly the same offence as received a heavy sentence from a judge. Psychotherapy, which is often very successful in these cases, is allowed grudgingly, if at all. Yet I have treated five cases of exhibitionism during the past two years and not one offended during that time; and everyone who treats sexual cases knows that many respond well to proper therapy.

It is to be hoped that Sir David's valuable paper will be perused by the legal profession, particularly magistrates and judges who have the ultimate disposal of prisoners, so that they have some idea at least of the trend of medical thought since the formulation of the M'Naghten rules 107 years ago.—I am, etc.,

London, W.1. CLIFFORD ALLEN.

SIR,—I yield to no one in my admiration for Sir David K. Henderson's article, but venture on the strength of almost fifty years in practice—for twenty of which I held a prison appointment—to make the following remarks. The clash between lawyer and doctor in these cases is due to each looking at it from his own narrow or specialized viewpoint. All agree that society must be protected: the lawyer says "by incarceration in prison and/or death"; the psychiatrist says "by incarceration in hospital and/or castration"; but these measures are only justifiable, surely, if decreed by a society that is itself blameless. My experience in the years I served in prison as a medical officer was that the more intelligent the prisoner the more emphatic he was that his only extra sin was that of being found out. He confessed readily to hard luck and even to stupidity in allowing himself to be caught, but he remained convinced that in a competitive society where one man's weakness was the other man's opportunity—jungle law, in fact—he was no worse than the judge, jury, lawyer, and doctor who had sent him to jail. In all honesty, Mr. Editor, was he far wrong?

I regret that I cannot agree that the psychiatrist and/or his unit, which Sir David advocates, would yield any result sufficient to justify its inevitable expense. I may have been unfortunate in my experience, but I have seldom or never known of any case being cured by these agencies. I find that attendants and attended, if long enough together, gradually approximate to each other mentally till in time they find a common level. How can it be otherwise?—I am, etc.,

Glasgow, E.1. JAMES COOK.

SIR,—The masterly memorandum by Sir David K. Henderson and your leading article on the causes of delinquency are of great general interest. But to study the problem should we really insist, as might be thought from your article, on classification by types of reaction rather than by types of person? If we consider the equation which expresses type of reaction as the product of environmental stress on a particular type of person, surely it is equally necessary to make adequate records of the other two variables—namely, the person and his burdens.

I would have welcomed some reference in your article to William H. Sheldon's recent book[1] giving detailed biographies of 200 delinquent youths side by side with their somatotype photographs. Sheldon claims that the confusion in psychiatric nomenclature can be reduced by reference to morphology, and the subject made thereby intelligible. His system of somatotyping is governed by objective standards. Types of reaction are found to be closely linked in precise and numerical terms with type of physique. Moreover, he points out that where psychiatrists have repeatedly disagreed about the diagnosis of a particular case the patient's physique lies half-way between the two body types associated with the conflicting diagnoses of types of reaction. These claims are big, but well enough substantiated in his book to warrant at least investigation by other workers.

Stott argues that we ought to begin with the study of the normal before we turn to the delinquent, and it is this which leads me, as general physician in charge of an undergraduate health service, to take the cue. After somatotyping more than 300 undergraduates and completing a short scale-index of temperament, together with a record of the signs of neurosis, it is clear to me that the main substance of Sheldon's work showing the closeness of association between physical type and temperament and the prevalence of signs of neurosis is sound. I should recommend that the use of somatotyping or similar photogrammetric methods be included in any comprehensive scheme for future research into the causes of delinquency. It might, for example, help in time to resolve the perennial argument about the efficacy or suitability of corporal punishment,

and do this by distinguishing those for whom it is unsuited from those whose physique and temperament will stand up to corporal punishment or will even benefit from it. Although somatotyping will provide information about only one aspect of this very complex problem, yet I must emphasize that in studying the delinquent, just as in studying the normal, a positive and objective record of what the subject is himself is likely to be as essential as recording the stress of his environment or the type of his reaction.—I am, etc.,

Oxford. R. W. PARNELL.

Typing of Bact. coli

SIR,—Your annotation (July 22, p. 205) draws attention to the present confusion in nomenclature of the two serological types of *Bact. coli* found during recent years in association with infantile diarrhoea and vomiting. These types are commonly known as *Bact. coli* alpha (or as *Bact. coli neapolitanum, Bact. coli* D 433, etc.) and *Bact. coli* beta. Your annotator suggests that Kauffmann's notation could be adopted with advantage, and, on the basis of the identification of the somatic (O) antigen, gives the two types the more definitive names of *Bact. coli* O group 111 and *Bact. coli* O group 55 respectively. He does not discuss, however, the criteria upon which these designations should depend. Clarity on this point would seem essential if accurate and comparable results are to be obtained.

To some bacteriologists absorption tests would appear necessary, at this stage of our knowledge, for the confirmation-of the O group. These procedures, however, are not practicable in the identification of the large numbers of strains sometimes obtained in clinical and epidemiological studies. Direct tube agglutination titrations present certain difficulties with regard to absolute and relative end-points (see Wramby, 1948), and may involve a consideration of partial antigenic components and overlapping reactions. Further, it may be recalled, certain "paracolon-like non-lactose-fermenters" have been agglutinated to titre by a *Bact. coli neapolitanum* serum (Bray, 1945). In any case, tube titration tests, in addition to biochemical tests, would prove too time-consuming for many laboratories.

Slide agglutination with impure K sera (prepared with living organisms and therefore of a complex nature) is the method usually employed to-day for the detection of *Bact. coli* alpha and beta colonies on primary culture plates. One fears that, unless the distinction is understood, "detection" may come to be regarded as the equivalent of "identification." The further risk then exists that strains detected by slide agglutination may be assigned, without further investigation, to a *Bact. coli* O group. Drs. A. M. M. Payne and G. T. Cook (July 22, p. 192) record that the first isolations of *Bact. coli* D 433 from 15 infants in a residential home were subjected to biochemical test and were agglutinated to titre by *Bact. coli* D 433 K and O sera; in subsequent isolations from the same infants, however, "the identification of *Bact. coli* D 433 was made by slide agglutination only." In all, 25 (or 62%) of the 40 strains recorded by them as *Bact. coli* D 433 would appear to have been subjected to this test alone. The nature of the serum used for the slide agglutination test is not stated, but it was presumably a K serum. It is not clear how many of these strains have been classed in your annotation as *Bact. coli* O group 111.

The same authors state that a study of the literature reveals that strains of *Bact. coli* α-type isolated by several groups of workers during recent years are, in fact, antigenically identical, and that they are the same as that described in their own paper. Establishment of antigenic identity among these organisms requires consideration of the O, B (see Smith, 1949), and H (see below) antigens, and, so far as I am aware, complete antigenic determinations have not as yet been made in this country. In order that present and future workers may follow clearly the developments of work in this field, I would suggest that, when "serological identity" is reported, accompanying reference should be made to the nature of the antigens determined and the methods used for their determination.

At the present time I am making an investigation of the H antigen(s) of a number of *Bact. coli* alpha strains isolated in the course of a clinical and bacteriological study undertaken in collaboration with Dr. A. T. Roden. Thirty-one of the 144 infants admitted to one gastro-enteritis ward in 1949 yielded *Bact. coli* alpha strains from rectal swabs taken in the admission room. The 31 infants were all suffering from diarrhoea and vomiting. The 31 strains all produced, within 24 hours, acid and gas in glucose, lactose, maltose, and mannite, and, within a few days, acid and gas, or acid only, in sucrose, salicin, and dulcite; all were indol +, M.R. +, V.P. −, citrate −, and urease −; and all were agglutinated to titre by *Bact. coli* alpha O and K sera. All 31 strains were motile, most of them highly so, when subcultured in Craigie tubes of soft nutrient digest agar. An H serum, prepared with a formolized suspension of one highly motile strain, gave "large-flake" agglutination and had a titre of 1/12,800 with the homologous strain and with certain of the other strains but not with all of them. It has not been possible to draw conclusions from these results, since as yet the observations are few and the techniques far from refined.

Four other infants, in the same series and also suffering from diarrhoea and vomiting, yielded atypical *Bact. coli* alpha strains from rectal swabs taken in the admission room. These four strains failed to conform to the characteristic biochemical pattern of the typical strains in two, three, four, and five particulars respectively. They were all agglutinated to titre by *Bact. coli* alpha O and K sera. Three of them were actively motile in peptone water, but did not show significant agglutination with the *Bact. coli* alpha H serum. In contrast to the typical *Bact. coli* alpha strains which were "*O-inagglutinable*" (i.e., not agglutinated in the living state by homologous O serum), the four atypical strains were, in varying degree "O-agglutinable" (i.e., agglutinated in the living state by homologous O serum). Attempts are being made to produce a *Bact. coli* B serum by the employment of one of these "O-agglutinable" strains for absorption.

Among the *Bact. coli* beta strains isolated during the course of the investigation the three following patterns of fermentative activity have been observed: (*a*) rapid acid and gas in sucrose; slow acid and gas, or acid only, in maltose; (*b*) rapid acid and gas in maltose; slow acid and gas, or acid only, in sucrose; (*c*) acid only in seven commonly used "sugars."

The variants and sub-types of *Bact. coli* alpha and beta would seem to merit further attention, since it is possible that in time they might be found to have some clinical or epidemiological significance. The number of atypical strains may prove to be not inconsiderable. Based on comparatively few tests, 11% of the *Bact. coli* alpha strains, isolated from infants on admission to one gastro-enteritis ward during one year, were found to show variation from the type strains and from one another.

There are two lines of approach to the existing and coming problems in the investigation of *Bact. coli* types associated with infantile diarrhoea and vomiting. The first is the advancement of knowledge by fundamental research regarding their antigenic components, their biochemical reactions and other properties, their variants, and their sub-types. The second is the development of simplified techniques designed to meet the needs of the many bacteriologists who are showing an interest in the work and who are anxious to bring the typing of *Bact. coli* strains within the scope of their laboratories. It is particularly in connexion with antibiotics trials and cross-infection studies that this need is being felt. Between the simple but insufficient slide agglutination test and the time-consuming full agglutination and biochemical tests it may be possible to devise a standardized typing technique applicable to everyday use. An inclusion of the determination of the somatic antigen would be of value, because then the O group, as your annotator suggests, could be made the main antigenic component, to which other factors could be added as knowledge grows.—I am, etc.,

Tottenham, N.15. JOYCE WRIGHT.

Value of Tuberculin-jelly Tests

SIR,—Dr. W. Pointon Dick's article on this subject (*Journal*, July 15, p. 141) has escaped my previous notice owing to absence on holiday. I would like to take this opportunity of confirming his findings, first as to the value of an abrasive technique before applying the jelly, and secondly of the superiority of an old tuberculin (O.T.) jelly over one whose active constituent is purified protein derivative (P.P.D.).

Since I originally published the method of skin abrasion (*sand-papering*) in 1946, I have carried out many series of jelly tests on known Mantoux-positive reactors, and have found fairly consistently that the technique of skin abrasion increases the number of positive reactions about 20% over the technique in which abrasion is not used, and yields results comparable to the 1:1,000 Mantoux using O.T.

As regards Dr. Dick's second point, I too have found that a jelly made up of O.T. gives superior results to one containing P.P.D., even using the latter in double strength (i.e., 4 mg./g.), and would recommend that all tuberculin jellies used for skin testing should have old tuberculin as their active constituent.—I am, etc.,

Appley Bridge, near Wigan. E. H. W. DEANE.

Infection by Syringe

SIR,—Some fourteen years ago I was initiated by Dr. Bousfield into the technique of diphtheria immunization and Schick-testing, and since then have been regularly employed in immunizing and testing children from 9 months to 15 years. His letter (August 5, p. 365) was therefore of special interest, for, quite independently, I have during the last few weeks been employing just the technique he suggests—i.e., taking up into the syringe a small overdose and pumping out the excess before refilling the syringe. There is, however, yet another safeguard which for years past has invariably been employed in this area—namely, rapidly passing the needle two or three times through the flame of a spirit-lamp before taking up fresh antigen. We have had no mishaps so far over the years, and the mild local reactions that occasionally follow injection are promptly controlled with a cold saline compress.—I am, etc.,

Haywards Heath. H. L. DUKE.

Obstetrical Anaesthesia

SIR,—While welcoming Dr. J. G. Warnock's support (July 22, p. 218) for my contention (July 1, p. 47) that in domiciliary midwifery the left lateral position is far safer than the lithotomy position for forceps delivery, I would at the same time very readily respond to his invitation to suggest a simple technique which could, I think with advantage, replace chloroform in midwifery, though the method I practise is not original, and may be even disappointing in its simplicity.

First, however, perhaps I may be allowed a few words of comment on his letter. His successful record, on which he is to be congratulated, of freedom from the calamity of primary cardiac failure in his whole series does not mean of course that light chloroform anaesthesia is free from that risk in operative procedures, even in obstetrics. I well remember seeing a sudden death from primary cardiac failure while chloroform was being administered by an expert during a simple stretching of the sphincter ani.

It is not so long ago since a case was recorded in this *Journal* of a woman of 25 whose heart stopped just as the child had been delivered by forceps under chloroform anaesthesia. In this instance the doctor performed cardiac massage by Nicolson's method in circumstances which allowed only the use of an unsterilized scalpel and unwashed hands, and the patient recovered. The case was recorded, very naturally, as a triumph for cardiac massage, though it might well have been published as a warning in respect of the chloroform which unquestionably was the cause of the disaster.

The technique which I use is simply the substitution of ether for chloroform, either by the open method or in a Clover's apparatus, and I have had no mishaps during the whole of thirty years of general practice involving a good deal of midwifery. I do not believe that an open fire in the room need deter one from using ether, but, of course, its potentialities must always be borne in mind and certain common-sense precautions must be observed. These include: (1) adequate ventilation; (2) the site of anaesthesia must be remote from the fire, and this may involve moving the bed; (3) the fire should be rendered "dead"—actual flames are the real danger; (4) in rare instances it may be necessary to have the fire removed in a bucket—if, for example, the room is very small; (5) a gas fire should be turned out during the anaesthetic. I make no apology for detailing these precautions, as they are of crucial importance.

In low-forceps delivery the degree of anaesthesia can be diminished once forceps have been applied, for light ether anaesthesia has no inherent dangers, whereas deep ether anaesthesia, if prolonged, and still more deep and prolonged chloroform anaesthesia carry the risk of post-partum inertia and haemorrhage.

In support of ether I should like to quote Dr. John Elam, whose contribution to anaesthesia as a general-practitioner anaesthetist is unique. He writes:

"Ether is unquestionably the safest and best anaesthetic for the general practitioner to administer for a forceps delivery, the repair of the perineum, or the removal of an adherent placenta. Ether can be safely left in the hands of a midwife once the induction has been accomplished."[1]

With this I am in entire agreement, though I would add to his last paragraph the words "provided the patient is lying in the left lateral position."

The objection that is sometimes raised that ether is unpleasant to take is met by the fact that all anaesthetics are well tolerated during labour, and in actual practice one finds that when, during delay in the second stage, the indications for forceps are fulfilled the patient cares little what anaesthetic is used so long as it is efficient in relieving the pain.—I am, etc.,

London, N.W.7. A. H. MORLEY.

Mongolism in One of Twins

SIR,—The following report may be of interest in adding another case of mongolism in one of twins to the scanty literature on this subject.

I attended the mother on May 19, 1938, when she had her first pregnancy. A healthy male child was born, and this child has developed normally. On March 17, 1943, I was in attendance for her second confinement, when she was delivered of twins. She was then 38½ years of age. There have been no miscarriages. The pregnancy was uniovular, with separate amniotic sacs, and the sex was female in each. There was no obstetric difficulty and the delivery was at full time. The mongolism in the one twin is of a very severe degree, and although now 7 years old her weight is only 19 lb. (8.6 kg.). She is unable to walk, stand, or crawl, and sits all day in a leaning-forward position. She is still bottle-fed, and as yet there is no evidence of any permanent teeth. The circulation in the hands and feet is very poor, but there is no congenital heart defect. The other twin has developed normally and is of a good average intelligence, likes arithmetic, reading, and music, but does not show outstanding ability in any particular subject.

—I am, etc.,

Middleton-in-Teesdale, Co. Durham. ROBERT DAWSON.

Crisis in Tuberculosis

SIR,—We treat live patients, not dead ones. To calculate bed requirements on the basis of mortality rates (see *Journal*, July 29, p. 295) is to presume a constant ratio between those developing tuberculosis and those dying from it. In fact, the evidence suggests that this ratio grows steadily larger; on the one hand more cases are diagnosed, and on the other a smaller proportion end fatally and those that do take longer to do so. Probably there are wide regional variations.

Sanatorium waiting-lists offer only a minimal figure. The waiting period is now so long that at many chest clinics the names of patients are just not put on these lists. Domiciliary

treatment is employed as an alternative, often with very good results, but often with the production of further cases by infection in the home, the statistical effects of which will no doubt become apparent in due course. Meanwhile sanatorium physicians, trying to help the general situation by accelerating their turnover, discharge their patients earlier than they would wish, with results less good than we might hope.

Our true aim therefore should be to provide institutional treatment for all cases of active tuberculosis and for cases where activity is suspected for periods long enough reasonably to ensure stability of the lesion. I suggest that, whereas two and a half beds per annual death may serve as an immediate objective, the proper figure may lie, as Bogen (*American Review of Tuberculosis*, 1949, **59**, 707) indicates, somewhere between 5 and 10.—I am, etc.,

Slough, Bucks. BRIAN THOMPSON.

Multiple Primary Carcinoma

SIR,—In view of the recent correspondence (July 29, p. 297) on double synchronous carcinomata we would like to record the following case.

A married woman of 34 was seen in the out-patient department complaining of bilateral mastitic swellings of six months' duration and intermittent abdominal distension. On examination the patient was emaciated and anaemic (Hb 30%). There was a firm swelling 3 in. by 2 in. (5 cm. by 7.6 cm.) occupying nearly the whole of the right breast, not attached to skin or the pectoral fascia. A swelling 1 in. by 1 in. (2.54 cm.) presenting the same physical signs was present in the left breast. There were glands palpable in the right axilla.

The abdomen was distended and a fluid thrill was elicited. Paracentesis withdrew eight pints (4.5 litres) of straw-coloured fluid, and following this a mobile rounded swelling was palpable in the left iliac fossa. She died ten days after admission.

The necropsy revealed a colloid carcinoma of the stomach. The ovaries were replaced by two mobile swellings which proved to be Krukenberg tumours on microscopical section. The right breast on section showed a spheroidal-cell carcinoma, with colloid degeneration in parts of the specimen.

On going into the family history, further interest was added to the case when it was found that the patient's paternal grandfather died of carcinoma of the stomach at the age of 52; her mother died of carcinoma of the stomach at the age of 54; and her father died of a perforated gastric ulcer (pathology unknown) at the age of 51.

This case shows two primary neoplasms and secondaries, with a strong family history of carcinoma of the stomach. The early onset of malignancy in the patient is noteworthy.

We wish to thank Mr. F. P. Forrest for permission to publish this case, and Dr. W. McNaughtan for the pathological reports.

—We are, etc.,

Poole, Dorset. AUSTIN BROWN.
ALEXANDER Z. ELKES.

Genius and Crank

SIR,—Dr. Eliot Slater (July 29, p. 255) overrates the influence which Fliess exerted on Freud. Fliess, whom I knew intimately, never claimed that his own teachings had made a mark on psycho-analysis. Freud's interest in sex was primarily psychologically determined. Breuer and Charcot were his mentors, not Fliess, who was a physiologist trained under Du Bois-Reymond, though he did not share his belief in "Ignorabimus" and was interested in sex from the genetic point of view. Apart from the insight that a homosexual trend is a general tendency in all neurotics, concluded from the Fliessian concept of the *permanent bisexuality* of all living organisms, there is little evidence of Fliess's influence to be found in Freud's writings. This is all the more remarkable as his interest in, and regard for, Fliess, as Dr. Slater rightly states, was very great indeed. When in 1912 I had published a case of hysteria in which the intervals between states of anxiety as well as between appearance and disappearance of conversion symptoms showed the pattern of Fliess's 28-day and 23-day rhythm, and concluded that a periodically recurrent physiological factor precipitates neurotic states, or may even be responsible for psychological mechanisms to be put into action, Freud wrote to me that he would welcome the introduction of this line of investigation into psycho-analytical work. But this was all, and among his disciples no one showed interest in Fliess except Stekel, who, however, no longer belonged to the Freudian school.

It is true that Fliess made it difficult for anyone who did not share Dr. Slater's view that he was a "crank of the first water" to support him. Some of his concepts are and always were untenable. Nevertheless, if one had to prove that he was cranky, one would have to do it on the lines of Dr. Russell Brain's memorable article on "Authors and Psychopaths," and could certainly not mention in evidence teachings which are based on sound observation—e.g., the "bizarre hypothesis of two types of rhythm." This is not a hypothesis. These types exist, as anyone can see who studies one of his books or, for that matter, one of my publications on the subject. The hypothesis which Fliess has built round his observations may be right or wrong or bizarre. But there can be little doubt that they reveal genius. And this fact alone, and not the "emphasis on sexuality," explains Freud's interest in, and high regard for, Fliess. If this were not so, Freud's infatuation (what else could it have been?) would have to be interpreted in psycho-analytical terms.—I am, etc.,

London, N.W.11. B. C. SAALER.

Do Weed-killers Poison Food?

SIR,—Dr. Alan Maberly does a service in his letter published in your issue of July 29 (p. 299) in questioning the assumption that the differential weed-killers and latest insecticides when absorbed into the sap of plants leave no trace in the fruit or seed. The members of these two classes of agricultural and horticultural aids have rendered possible the growth of heavier crops on land already in use and have made it possible to cultivate hitherto unused tracts of tropical countries. However, disturbances in the local oecology are inevitable following their use, and some of these may be undesirable—e.g., the killing of bees, leading to less efficient pollination. (Another trend of modern times is the mechanization of agriculture, leading to the present scarceness of farmyard manure and the consequent increase in the use of artificial manures.) The effect on human teeth of minute amounts of fluorine in water is now well recognized. The use of nitrogen trichloride in the treatment of flour ("agene" process) is to be replaced by the use of chlorine dioxide on the recommendation of the Medical Research Council, not because any effects in humans have been traced to its use but because dogs fed on such treated flour have developed canine hysteria. Is it not possible that such poisonous substances as dinitro-ortho-cresol mentioned by Dr. Maberly may be equally undesirable? O.M.P.A. (octamethyl pyrophosphoramide), which acts by inhibiting cholinesterase and thus affects parasympathetic activity, circulates in the sap of a plant for weeks.

I suggest that the effect on food of such potent substances used in agriculture and horticulture could with advantage be studied and reported on by some such body as the Medical Research Council. Such authoritative pronouncements would aid those entrusted with, or advising on, the formulation of a national food policy.—I am, etc.,

Rochester. J. H. WHITTLES.

A Clarification

SIR,—It has been pointed out to me that there is a misleading remark contained in the table of my article "*Bact. coli* D 433 in Cases of Diarrhoea in Adults" (July 22, p. 195). The remark in question is in connexion with Case 3, where the words "(nor with other cases of this series)" appear in the column headed "Contact with Children." This was intended to make clear that this was the only patient who developed diarrhoea *in hospital*, and so far as could be ascertained this patient could not have been infected by the others of the series. The cases of the series occurred in two separate hospitals in widely separated wards, but it is proposed to make this the subject of a future epidemiological study.—I am, etc.,

Glasgow, N. JOHN S. STEVENSON.

A School for Doctors' Children

SIR,—On p. 89 of the *Supplement* to the *British Medical Journal* of August 12 Dr. J. B. Wrathall Rowe pleads for the erection—inferentially at a cost of £120,000 or thereabouts—of a school for medical war orphans and "other children of doctors, particularly doctors serving overseas." On p. 414 of the same issue the 97th annual meeting of the governors of Epsom College is reported, including a statement that the council intends to make an appeal for funds required to make lasting improvements to the buildings. Is it possible that Dr. Rowe has not heard of Epsom College, and of its Foundation which pays for free board and education at Epsom of medical orphan boys and defrays scholarships elsewhere for girl orphans? Does he know that education is provided there strictly at cost price for the sons of all doctors, and that the buildings have an insured value of £250,000? Does he know of the numerous leaving exhibitions for boys intending to enter the medical profession? In a word, would not his ideals—with which I have a lot of sympathy—be best realized by expanding the resources of Epsom College as the most practical method of achieving what he has at heart? The B.M.A. has already a permanent representation on the council of the College, at present by Mr. N. E. Waterfield, F.R.C.S.—I am, etc.,

Tunbridge Wells. HENRY ROBINSON,
Deputy Hon. Treasurer,
Royal Medical Foundation of Epsom College.

Nervous Yet Unafraid

SIR,—Vast as is the English vocabulary it would, I think, be improved by the invention of a word which would do away with an unfortunate anomaly. The word nervous on the one hand is used for the great miscellany of neurotic illness and on the other for the timid and fearful. But they have nothing in common. The neurotic may be and in fact often is fearless, almost contemptuous of personal danger, and yet the word lumps him together with the craven-hearted. The new word should be quite new, with no associations with the many unsatisfactory synonyms which have tried vainly to deal with the dilemma. A meaningless word with no ethical significance for the neurotic type of nervousness I suggest is *crobly*, adjective or adverb, and *crobliness*, where a substantive is needed. No such word exists in the *O.E.D.*—I am, etc.,

London, S.W.1. E. GALLOP.

POINTS FROM LETTERS

Psoriasis

Dr. C. F. PATTERSON (St. Neots, Hunts) writes: I have found that the strain of responsibility and the "adrenal flood" of anger are the principal precipitating factors, and this is why retirement to bed is of value, but there is really more frictional trauma in bed, particularly to the forearms, than anywhere else. As for Father William, cited by Dr. R. M. B. McKenna in his Refresher Course article (July 22, p. 207), the patient does not need to stand on his head to obtain a scalp like a contour map. He can do this quite simply and absentmindedly by scratching or picking at his head while reading his book in bed (or in an armchair), and the more so if his book is exciting or his newspaper alarming. Repeated baths are not advisable, as they clear the skin of its natural oils—including all its vitamin D. No, for the G.P. the answer remains as follows: to limit the patient to one bath a week, followed by a rub with ung. picis carb. co., and to give him a single dose of 150,000 units of vitamin D (i.e., three tablets of calciferol. fort. *N.F.*) in the *summer*, and to advise him not to live in large smoky towns or misty valley bottoms, and either to take regular phenobarbitone or to avoid anger and responsibility. Bed, or phenobarbitone, or both, should help more in the case of fear and anger than cortisone (when it comes), but how the sympathetic nervous system enters into the problem of psoriasis, as it undoubtedly does, still remains a mystery. At present, I suppose, we are forced back to Selye's target organ theory, but have no real idea as yet how this works.

Smallpox in the Unvaccinated

Dr. H. TUDOR EDMUNDS (Slough, Bucks) writes: I should like to reply to Dr. J. S. Gemmill's letter (July 8, p. 107) and to point out that, while it is impossible to prevent atypical cases of smallpox that may occur in the unvaccinated, it is possible to prevent those cases which are brought about by vaccination. . . .

Obituary

BERNARD J. WARD, F.R.C.S.

Mr. Bernard Ward, formerly the senior surgeon of the Queen Elizabeth Hospital, Birmingham, died at his home in Shelsley Beauchamp on July 30. He was 71 years of age, and his health had been failing for some time.

Bernard Joseph Ward was the son of the late Dr. Joseph Ward, who practised for many years in Birmingham. He received his medical education at Birmingham medical school and the London Hospital. Qualifying in 1902, he obtained his F.R.C.S. in 1905. He held resident posts at the Queen's Hospital, Birmingham, and in London at St. Peter's Hospital for Stone. He became assistant surgeon to the Queen's Hospital in 1907, and an honorary surgeon in 1917. In the first world war he served as a captain in the R.A.M.C. He was later appointed consultant surgeon to the Children's Hospital and to the Birmingham City Police. He served the medical school as lecturer and examiner in surgery. He achieved his greatest reputation in urology and in this field became one of the foremost surgeons in the country. He held office as president of the Section of Urology of the Royal Society of Medicine and was vice-president of the British Association of Urological Surgeons. This last office is commemorated by the Ward Medal, which he presented as an award to mark outstanding work in the field of urology. His own great skill in this field earned for him the confidence of the profession and of the public alike. He was a member of the British Medical Association for forty years. He leaves a widow, a daughter, and two sons: to them his many friends offer their sincere sympathy.

L. T. C. writes: For twenty-five years I had the honour to be Bernard Ward's anaesthetist. In that time and in those circumstances I had the unique opportunity of knowing the man, his strength, his weakness, his virtues, and his faults, and now at the end I can say with a full heart, "He was a great man, a powerful friend, and an outstanding surgeon." In this last capacity he was widely known, and such was the quality of his work that we who worked with him were glad to satisfy his demands—and for his patients he demanded the maximum. I recall that as a very young man about to anaesthetize one of our colleagues I sought his opinion, hoping to give "that little more." His reply I have never forgotten. "That little more, my lad! If that is possible, why do you deny it to my other patients? Doctor A is your patient—that is all you need to remember." The quality of a man may be judged by the stories and legends connected with him. In our teaching school, "Beeje," as we called him, figured in so many and, happily, so humorously. The whole man was known to the comparatively few, and that happy few gave him their complete devotion. How many of his furtive kindnesses to patients and friends do I recall—kindnesses which he would deny with the blustering innocence of a schoolboy caught in the larder. At heart "Beeje" was a countryman; horse, hound, and the trout stream for him spelt happiness. He was a man of impressive physique, essentially a man's man. It is pleasant to recall that on his retirement as senior surgeon his old house-surgeons practising in Birmingham gave him a complimentary dinner.

P. L. DANIEL, F.R.C.S.

Mr. P. L. Daniel, consulting surgeon to Charing Cross Hospital, died suddenly on July 28 at Checkendon, aged 79.

Peter Lewis Daniel was born in Carmarthen in 1871. He studied medicine at Charing Cross Hospital and was associated with that hospital for the whole of his professional life, except for a short period of work in Vienna. He qualified in 1898, and took the F.R.C.S. a year later. The list of the posts he held at Charing Cross is a large one, for in his time specialization was not carried to the lengths it is to-day. In addition to several surgical appointments he was also at one time or another house-physician, assistant demonstrator of anatomy, assistant in the electrical department, pathologist, and curator of the museum. He was also on the staff of the Gordon Hospital for Diseases of the Rectum, of the Metropolitan Hospital, Willesden, and of several smaller hospitals near London. He was medical referee to the Cremation Society. He retired from the staff of Charing Cross Hospital in 1931, but he continued to work at the Gordon Hospital until 1948. During the war he was able to help his old hospital, returning as a surgeon to the evacuated hospital at Ashridge.

Daniel was a man of great good sense and a very sound surgeon. He specialized in rectal and abdominal disorders, but quite early in his career he interested himself in the effects of oral sepsis and was the author of a book, published in 1910, entitled *Arthritis: A Study of the Inflammatory Diseases of Joints*. Old Charing Cross students will remember him as a man of fine character and an excellent practical teacher. He is survived by his wife and son, Dr. P. M. Daniel.

Dr. DOROTHEA JANE MANN died at her home in Nottingham on June 29. The elder daughter of the late Rev. Alexander Mann, she was a student at the University of Edinburgh, where she graduated M.B., Ch.B. in 1921, proceeding M.D. in 1926. She held the posts of assistant medical officer to the V.D. clinic and of medical officer in charge of the mental deficiency department at Nottingham.

G. G. D. writes: Some thirty years ago, when we left Nottingham, our house was taken by a young woman who had just graduated in medicine. She told me she was going to set up in practice for herself. We thought it a brave thing to do and wished her well. On our return some years later we found Dorothea Mann still in the same house, fully established, and one of the best-known and most-esteemed practitioners in the city, with a large general practice, built up by hard work and medical skill. She was just the right person to be a doctor, kindly, generous-minded, full of charm and personality. Her patients adored her, for, beside giving of her best for their ailments, she was interested in them as persons and could advise in their ordinary lives in a wonderfully far-seeing way. A few years ago she had a serious illness which we thought had yielded to treatment, and about which she made light, going on with her work as selflessly as usual. Early this year, however, she realized she was a very sick woman and was persuaded to retire. Within six months the end came. Her loss is irreparable, and it will be a long time before we see her like again.

ELIZABETH HONOR BONE died at her home in Hampshire on July 9 at the age of 75. Owing to ill-health she had led a quiet life since her retirement from general practice in 1935. She was the second of three daughters of William John Bone, manager of the Tyne Iron Shipbuilding Company; the girls were brought up on Tyneside and eventually sent to school in Edinburgh. Later she studied medicine at the Royal Free Hospital and London School of Medicine for Women. She graduated M.B., B.S. in 1898, and proceeded M.D. in 1905. While a student she met the late Dr. Christine Murrell, and together they planned to equip themselves to start general practice in the West End of London in a professional and well-to-do district. Graduates from the school were already established in many varieties of consultant practice, but women general practitioners had usually settled in industrial and working-class districts, so that the plan was something of an innovation for women at the turn of the century. Dr. Bone went to Vienna and Berlin after qualifying, and then took an appointment as medical officer to the Women's Settlement in Liverpool. Here, while practising in the dock areas, she worked with Sir Robert Jones. This contact influenced her outlook in practice very greatly. The partnership planned by Dr. Bone and Dr. Murrell began in 1903 in Bayswater (the first year's takings amounting to £87). The practice grew rapidly and was well established by the beginning of the first world war. Third, fourth, and fifth partners were taken on. Dr. Bone was an ideal family physician. She was a very small person with the quiet gravity which is always reassuring to children. She paid meticulous attention to detail both in diagnosis and treatment, and many of her old patients recall the good years when she ruled the health of their growing families. She had perfected the use of her senses in eliciting physical signs to an unusual extent and had a great gift for training her assistants. She was a part-time school medical officer under the L.C.C. for some years and was one of the original medical officers at the North Kensington Baby Clinic before infant-welfare centres were established. Here she had full opportunity for the constructive paediatric work that was dearest to her. Her small stature and her wish for a quiet life with no public appearance of any sort were in striking contrast to the imposing figure and full public activity of her partner, Christine Murrell, but the association of these two doctors in practice for 30 years had the happiness which so often results from wide dissimilarities.—A. G.

Dr. EDWARD MOIR, who had been senior anaesthetist to the Manchester Royal Infirmary for many years, died suddenly at his home in Combs, Chapel-en-le-Frith, on July 25 at the age of 72. The son of the late Dr. Douglas Moir, he qualified in 1907 and obtained his D.A. at Manchester in 1939. In addition to his appointment as anaesthetist to the Manchester Royal Infirmary, he was on the staff of the Manchester Ear Hospital and the Macclesfield Infirmary. F. G. W. writes: Edward Moir was for many years one of Manchester's foremost anaesthetists. His proficiency in his specialty was well recognized among his surgical colleagues, and his services were in great demand, particularly with ear-nose-and-throat surgeons. He could give a difficult anaesthetic for a bronchoscopy or an oesophagoscopy as well as anybody, and a great deal better than most. He was one of the old school to whom chloroform was the ideal anaesthetic, and in his hands it certainly proved a very safe and effective drug. Moir was always kind to his patients, especially to children, with whom he would carry on a conversation during the induction period; this was of course before the days of premedication. To his colleagues he was courteous and most obliging in every way. The regularity of his attendance in his hospital work was exemplary, and he would never think twice about going to hospital for urgent work at any time of the day or night. Dr. Moir's other sphere was that of athletics. In his student days he first played "soccer" for the university, but soon transferred his affection to "rugger." He remained faithful to the latter game for the rest of his life, both as a player and later in an advisory capacity. He was vice-president of the Manchester University R.C. and president in 1911, and again from 1922 to 1926. He was life president of the University Athletic Club, and president of the Athletic Union in 1919 and 1920. Moir was an official starter at the University Athletic Ground, and his capacity was recognized by his appointment as starter to the Olympic Games at Paris in 1924 and at Amsterdam in 1928. He served as a representative on the Lancashire and English Rugby Unions, where his experience and knowledge were of great value. His loss will be felt not only in the medical world but also in the field of athletics, where he was a well-known and popular figure.

Dr. ERNEST SOLLY, of Harrogate, died on July 26 at the age of 87. He was educated at Rugby School and studied medicine at St. Thomas's Hospital. He qualified in 1886, graduated M.B. in 1887, and took the F.R.C.S. a year later. After a period as a resident at the Royal Free Hospital, he came to Harrogate in 1893, taking over the practice of the late Dr. Russell. He began as a general practitioner and spa physician. Later he specialized in surgery and was appointed surgeon to the Harrogate Hospital in 1905, a post which he held up to 1932, when he retired to the consulting staff. He was also honorary surgeon to the Yorkshire Home for Incurables and Chronic Diseases. As a surgeon he was deft with his fingers, meticulous in procedure, and of sound judgment. He took an early interest in municipal affairs, serving on the town council for nine years, and becoming mayor in 1898. His work during these years as liaison officer between the corporation and the medical profession was invaluable, for he took an active part in the development of the spa. He served in France during the 1914–18 war in the R.A.M.C., attaining the rank of major. Mr. Solly had been a member of the British Medical Association for 50 years. He was a vice-president of the Section of Dermatology in 1906 (when the Association met at Toronto); a member of the Central Ethical Committee from 1932 to 1939; and represented his constituency at the Annual Representative Meetings in 1905, 1926, 1928, 1929, 1930, and 1932–9. Apart from his profession he had wide interests. Philately was his chief hobby; he had a large and valuable collection of stamps. At carpentry he was an adept. In his earlier years he was a keen cricketer, and he took an active part in the development of the Boy Scout organization. He was a founder member of the Harrogate Rotary Club. A man of many parts, he was well read and had a good memory. His general knowledge was great. When called upon he could deliver an interesting address on almost any subject desired. Of late years he led a retired life owing to failing health. His wife died in 1932. He is survived by one son and three daughters; another daughter died in 1946. He will be greatly missed by all his contemporaries and friends.

Dr. JOHN HERBERT BANKES, of Lindfield, Sussex, died on August 1 in London, aged 71. He was related to the well-known family of lawyers and judges of that name. He was a student at St. George's Hospital, and he qualified in 1904. Afterwards he practised in South Kensington. He served in the R.A.M.C. during the 1914–18 war, and on demobilization did not resume general practice but took an appointment with the Ministry of Pensions. In this he was so energetic and successful that in 1929 his name was put forward for appointment as deputy lieutenant for the County of London, and he was duly chosen. Throughout his career Dr. Bankes was a keen Mason. He was Provincial Grand Master for the Province of Middlesex, and he was on the boards of management of both the masonic educational charities. He had lived in (professional) retirement for several years, but always came to London for meetings of the lieutenancy and for his masonic duties.—H. R.

The Services

Surgeon Captain G. F. Abercrombie, V.R.D., R.N.V.R., has been appointed an Honorary Physician to the King in succession to Surgeon Captain C. C. Elliott, D.S.C., V.R.D., R.N.V.R.

A *Supplement* to the *London Gazette* has announced the following awards:

"1st Clasp" to the Territorial Efficiency Decoration.—Lieutenant-Colonel S. W. Barber, M.B.E., T.D., R.A.M.C.

Territorial Efficiency Decoration and "1st Clasp."—Major (Honorary Lieutenant-Colonel) C. L. Heanley and Majors J. E. Elliott and P. H. Jobson, R.A.M.C.

Territorial Efficiency Decoration.—Majors S. Curwen and R. F. Ward (died by enemy action), Captains (Honorary Majors) F. D. Hindmarsh, A. D. Kelly, M.B.E., A. J. G. Newton, and J. M. Sturrock, Captains C. F. Fairlie and S. Howe, R.A.M.C., and Captain E. Saunsbury, T.A.R.O., R.A.M.C.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

Frank Howarth, M.D., has been appointed a University Lecturer in Pharmacology with tenure for three years from October 1.

Nigel Dean Compston, M.D., has been elected to the E. G. Fearnsides Scholarship.

UNIVERSITY OF EDINBURGH

At a graduation ceremonial on July 19 the following degrees and diplomas were conferred:

M.D.—[3] [5]D. M. Blair, [3]H. M. Brown, [2]J. H. F. Brotherton, [5]J. Collins, Mary A. J. T. Douglas, Frances M. Earle, Audrey L. Ferguson, [2]D. C. Haig, S. P. Hall-Smith, Morag L. Insley (née Henderson), [2]Mary E. Lothian (née McLaren), [1]I. F. Sommerville, [2]T. Sommerville, [2]J. A. Tulloch, [2]J. Wallace, [1]G. M. Wilson.

D.Sc.—*In the Department of Pure Science:* R. F. Ogilvie, M.D.

PH.D.—*In the Faculty of Medicine:* F. H. Sims, M.Sc., M.B., Ch.B.

M.B., CH.B.—J. G. Abercrombie, W. T. C. Adamson, A. A. Akiwumi, D. S. Alexander, Jean M. Arkieson, Natalie H. F. Armstrong, J. D. Arthur, T. A. Ballingall, Rosemary A. Begg (née Kemp), Sheila M. Black, Jennifer P. Bland, R. Bliss, D. W. Bookless, Elizabeth S. Brown (née Bennett), J. R. Brown, L. S. Brown, Janet C. Bryce, Patricia M. Burke, I. D. Campbell, J. C. Cape, R. A. Caulfield, J. Chalmers, I. MacD. Clark, I. L. Clark, Agnes A. Cochrane, J. F. J. Collins, I. A. Colville, N. M. J. Cowan, F. J. Darby, A. H. Darling, A. S. Dawson, R. McN. Dean, I. Dial, G. M. Dobbie, C. G. B. Downie, R. W. Downie, J. J. Drever, Catherine W. Drysdale, R. Edmond, A. E. Elliott, D. J. Erskine, G. S. Fiddler, J. W. Fisk, J. I. McL. Forsyth, G. D. Forwell, Margaret C. Galloway, W. A. S. Georgé, J. M. C. Gibson, Deidre M. M. Gillies, Elsie M. Glennie, T. M. Goodall, A. B. Goorney, J. G. Gray, G. J. Green, D. C. Greig, S. C. C. Grieve, R. E. Gristwood, A. A. Gunn, G. K. M. Hall, A. M. Hall-Gardiner, W. A. Hanna, J. Harkness, Joan Harper-Ball, D. M. Hastings, R. E. Haworth, Daphne E. A. Healey, Ethna E. R. Henderson, Jean M. Higgins, J. Hill, G. F. A. Howie, R. Hutchinson, Margaret Jackson, F. D. Johnston, W. T. Jones, Victoria K. Kelly, D. S. S. Ker, C. O. R. King, [4]M. R. King, J. R. Kirkpatrick, A. W. Laing, [4]Anne T. Lambie, I. H. Lawrence, Barbara Leach, F. H. Lockwood, J. R. A. Luckas, R. McAdam, J. S. McP. Macaskill, R. H. McClure, P. W. McCormick, F. I. MacDonald, J. D. McDonald, J. S. Macdonald, Jill MacDonald (née Russell), Annie McL. McDougall, J. B. Macfarlane, P. S. MacGibbon, A. D. McIntyre, Patricia C. Mackay, G. L. MacLeod, D. C. McNutt, A. I. MacPhail, Margery A. Macpherson, Frances E. A. McVey, D. H. McVie, W. L. Marshall, J. A. McL. Martin, M. C. Maw, A. W. Maxwell, D. Maxwell, N. Mendick, G. L. Minter, Jean S. H. Mitchell, L. Mitchell, Pamela A. Moncrieff, B. McL. More, Donalda M. Morgan, J. A. L. Morrell, Hilary L. Morss, Mary W. Moss, J. R. Munro, Danuta Oktawiec, L. L. Ostrowski, I. V. E. Owen, J. C. Paterson, Joan Pears, D. Penman, W. A. Penman, N. B. Peterkin, A. F. Phillips, J. T. Rabie, B. A. Rapier, I. D. Reid, L. R. Roberts, J. G. Robertson, Elizabeth Rose, W. R. Ross, [4]G. F. M. Russell, I. A. Ruthven-Stuart, J. D. St. Clair, T. F. Sandeman, P. J. Scally, D. G. Scott, G. A. Scott, R. G. Scott, Kathleen J. C. Shaw, W. C. Shepherd, F. O. Simpson, W. T. Simpson, [4]A. W. McI. Smith, S. McC. Smith, Yvonne R. Sneddon, J. Spence, J. F. Stephen, W. I. Stuart, Pamela M. Sutherland, Elizabeth M. Sweet, Margaret E. Taylor, W. Taylor, B. Teelock, A. Thomson, W. G. Thomson, Priscilla E. Turnbull, D. H. Vaughan, Margaret A. Walker, W. C. Walker, W. G. Walker, J. J. Wallace, A. S. Watson, Alison A. P. Watson, A. St. J. Wilding, A. K. Wilson, G. C. Wilson, Pauline I. M. Winn, H. J. Woodliff, D. G. Wray, A. C. Wright, M. J. Wright, Sheena M. Yule.

B.Sc.—*In the Department of Pure Science:* P. N. Edmunds, M.B., Ch.B. (with first-class honours in bacteriology).

D.P.H.—M. D. B. Ahmad, A. McD. Allan, Doris M. Beaton, G. Dison, G. A. F. R. Gibson, R. Lwin, Phyllis E. Lyne, Joan M. McWilliam, J. McE. Neilson, C. A. Phillips, I. C. Wilson.

D.T.M.&H.—W. L. Barton, A. R. Duff, A. B. G. Laing, G. S. C. Nzegwu, W. T. Thom, A. V. Wells.

D.M.R.D.—R. J. Bruce, M. A. Caldwell-Nichols, R. Cuthbert, J. G. Duncan, G. Goodhall-Copestake.

D.M.R.T.—V. R. Naidu.

DIPLOMA IN PSYCHIATRY.—Helen C. S. MacLean.

The Cameron Prize in Practical Therapeutics has been awarded to Rudolph Albert Peters, M.D., F.R.S., Whitley Professor of Biochemistry in the University of Oxford and Fellow of Trinity College, Oxford, in recognition of his discovery of British anti-lewisite (B.A.L.) and the application of this drug in practical therapeutics.

The following scholarships, bursaries, prizes, etc., were also awarded in the Faculty of Medicine. *Ettles Scholarship and Leslie Medal, Scottish Association for Medical Education of Women Prize, Dorothy Gilfillan Memorial Prize,* and *Lawson Gifford Prize in Obstetrics and Gynaecology,* Anne T. Lambie. *Buchanan Scholarship in Obstetrics and Gynaecology,* A. W. McI. Smith. *James Scott Scholarship in Obstetrics and Gynaecology,* J. D. St. Clair. *Mouat Scholarship in the Practice of Physic,* G. F. M. Russell. *Beaney Prize in Anatomy and Surgery, Annandale Medal in Clinical Surgery,* and *Keith Memorial Prize in Systematic Surgery,* M. R. King. *Murdoch Brown Medal in Clinical Medicine,* F. O. Simpson. *Royal Victoria Hospital Tuberculosis Trust Medal,* Kathleen J. C. Shaw. *Wightman Prize in Clinical Medicine,* G. F. A. Howie. *Sir Robert Jones Prize in Orthopaedic Surgery,* I. A. Ruthven-Stuart. *Vans Dunlop Scholarship in Materia Medica and Medicine,* C. W. M. Wilson. *Gunning Victoria Jubilee Prize in the Practice of Physic,* Constance C. Forsyth. *Gunning Victoria Jubilee Prize in Chemistry,* A. B. Roy. *Thomson Memorial Medel in Child Life and Health,* Margaret J. Poole. *Stirton Bursary* and *Colonel Thomas Biggam Memorial Medal and Prize in Pathology,* S. H. Davies. *Maclagan Prize in Forensic Medicine,* K. Wood. *Wellcome Medal and Prize in the History of Medicine,* H. P. Tait. *Junior John Aitken Carlyle Bursary in Anatomy and Chemistry,* P. H. Jaques. *Whiteside Bruce Bursary,* J. C. J. Ll. Bath. *Mackenzie Bursaries,* H. A. Crispin, Mary G. Dunlop, Dorothy L. Grieve, C. M. Taylor. *Robert Wilson Memorial Prize in Chemistry,* W. C. Hartley. *Vans Dunlop Prize in Physics and Chemistry,* J. C. J. Ll. Bath and W. C. Hartley (equal). *Vans Dunlop Prize in Botany and Zoology,* Elizabeth M. Connell and Elizabeth L. Handasyde (equal). *MacGillivray Prize in Zoology,* Elizabeth M. Connell.

[1]Awarded medal for thesis. [2]Highly commended for thesis. [3]Commended for thesis. [4]With honours. [5]In absentia.

UNIVERSITY OF LONDON

Frederick Murgatroyd, M.D., F.R.C.P., has been appointed to the Wellcome Chair of Clinical Tropical Medicine, tenable at the London School of Hygiene and Tropical Medicine, from October 1.

Stephen Dyonis Elek, M.D., Ph.D., has been appointed to the University Readership in Bacteriology, tenable at St. George's Hospital Medical School, from October 1.

Bernhard Katz, M.D., Ph.D., D.Sc., has been appointed to the University Readership in Physiology, tenable at University College, as from October 1.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

The following candidates were duly admitted Licentiates in Medicine and Midwifery on July 7, having passed the final examination in Medicine, Surgery, and Midwifery of the Conjoint Board of Ireland: J. C. C. Ryan, Louise Burleigh, Bridget Conlon, Norma A. C. Coogan, J. O. MacC. Craig, Margaret J. E. Dickinson, B. M. Gray, A. D. Kelly, J. A. Lagan, Eileen P. Leahy, E. W. A. Malone, Nora J. Murphy, Eibhlin M. MacCollum, D. F. McFeely, L. E. McLoughlin, Fiona M. O'Brien, R. V. Power, A. I. Roith, J. B. Sheils, Nualla P. Summerville, O. G. Tolkin, Maura V. Toner, F. P. Treacy, J. H. Walsh, A. E. O. Williams, P. J. Yoffe.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

At a meeting of the Council of the Royal College of Obstetricians and Gynaecologists, held in the College House on July 22, with the President, Professor Hilda Lloyd, in the chair, the following officers were re-elected: *President,* Professor Hilda Nora Lloyd; *Vice-presidents,* Mr. John Eric Stacey and Dr. V. B. Green-Armytage; *Honorary Treasurer,* Mr. Arthur A. Gemmell; *Honorary Secretary,* Mr. Humphrey G. E. Arthure; *Honorary Librarian,* Mr. Frederick W. Roques; *Honorary Curator of the Museum,* Mr. Aleck W. Bourne.

The following candidates were elected to the Membership of the College: G. T. Altimas, J. D. Andrew, P. R. Blahey, G. T. Carson, C. J. Champi, F. L. Clark, T. R. Clarke, W. W. Coppinger, B. M. Corkill, E. D. Crichton, C. N. Degaris, W. Donovan, H. P. Dunn, Isabel L. Dyke, M. W. Elliott, B. Fatima, C. J. Farr, W. R. Foote, M. B. Fox, H. H. Francis, A. C. G. Frost, W. D. Giffen, C. A. Haxton, H. A. Henderson, H. F. Hills, R. Hodkinson, R. H. Horner, D. R. Hughes, T. G. Ingram, D. J. McI. Irvine, H. A. Kelsey, D. Kutty, J. F. Leaver, J. L. MacArthur, D. C. McEwen, K. T. MacFarlane, Ishbel M. Macrae, C. M. Mair, W. D. Marshall, G. B. Maughan, A. C. Naylor, Helen M. Noble, R. H. O'Hanlon, D. C. P. Paranjothy, M. G. Pearson, E. Quehl, G. J. Quigley, P. D. Rajaratnam, I. Ramamurthi, D. H. Rea, K. E. E. Read, H. A. Rowley, A. M. Rutherford, D. R. Sheumack, J. M. Slattery, E. M. Southern, D. W. Sparling, S. K. S. Roy, L. G. R. Van Dongen, D. B. B. Whitehouse, J. Wilbush, E. A. Williams, M. H. V. Young.

No. 30

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended July 29.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each Infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1950 (a)	(b)	(c)	(d)	(e)	1949 (Corresponding Week) (a)	(b)	(c)	(d)	(e)
Meningococcal infections	28	2	14	1	3	28	1	10	—	2
Deaths		—	—				2	—		
Diphtheria	42	2	6	4	2	76	12	24	8	1
Deaths	—	—	—	—	—	—	—	1	—	—
Dysentery	166	7	83	—	—	90	6	54	1	—
Deaths		—			—				—	—
Encephalitis, acute	6	—	—		—	3	—	1	1	—
Deaths		—		—			—			
Erysipelas			16	2	1			17	10	4
Deaths							—			
Infective enteritis or diarrhoea under 2 years				35					53	
Deaths	6		3	—	—	31	4	3	4	3
Measles*	8,291	580	158	151	92	5,052	379	92	140	64

* Measles is not notifiable in Scotland, and the returns are therefore an approximation only.

† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

‖ Includes puerperal fever for England and Wales and Eire.

¶ Primary pneumonia no longer notifiable in Eire.

EPIDEMIOLOGICAL NOTES

Poliomyelitis

Notifications of poliomyelitis in the week ending August 5 were: paralytic 262 (197); non-paralytic 105 (108); total 367 305). The figures for the previous week are shown in parentheses. The following county areas, with notifications as given, contributed some 69% of the total notifications for England and Wales in the week under review:

	Paralytic	Non-paralytic
London	16	12
Essex	14	3
Gloucester	6	5
Lancaster	15	7
Middlesex	8	3
Northumberland	8	6
Southampton	8	3
Stafford	21	12
Surrey	10	2
Warwick	24	14
Worcester	21	5
Yorks (West Riding)	18	6

The total increase for the week of 62 compared with the previous week was due to increases in notifications in a number of counties, of which the more important were Hertford, Kent, Lancaster, Lincoln (Holland, Kesteven, and Lindsey), Northumberland, Stafford, Surrey, Worcester, Yorkshire (West Riding). Notifications of non-paralytic cases dropped to 29% of the total compared with 35.4% in the preceding week.

Cases notified in the Isle of Wight in the week ended August 5 were paralytic 4, non-paralytic 3. Numbers have increased since that to a total of 28 confirmed cases (including 26 paralytic) by August 12. The medical officer of health has advised that visitors with children should not visit Freshwater and Newport for the time being.

According to the *Weekly Epidemiological Record* of August 2 of the World Health Organization, the following is a summary of the situation in countries other than Britain where a relatively high incidence of poliomyelitis is reported for 1950:

Australia.—Epidemic outbreaks occurred in 1949, and the incidence is still high in 1950. The number of cases has been decreasing since the week ending June 17, when 207 cases were reported. The figure fell to 116 during the week ending July 8. Corresponding figures for 1949 are 66 and 60.

United States.—The incidence is high, but not so high as last year at the same time. For the week ending July 15, 665 cases were reported, as against 1,014 in 1949. Total cases registered in the U.S.A. since January 1 number 4,328, against 4,883 for the corresponding period of 1949.

Germany.—There has been an increase of cases during recent weeks in the German Federal Republic. Whereas 41 cases had been reported during the week ending June 17, the number rose to 51 during the week ending July 8. The incidence in the corresponding weeks of 1949 had been 10 and 16 respectively.

Belgian Congo.—Poliomyelitis notifications in the Belgian Congo, which until 1947 had never been more than 53 per year (in 1936), rose to 111 in 1948 and 207 in 1949. This year 38 cases were reported for the week ending July 8, against 9 for the corresponding period of 1949 and 0 for the same week in 1948.

France.—The number of cases recorded from January 1 to July 15 is higher than that of the corresponding period during the years 1942–9: 519 in 1950 against 296 in 1949. Last year's incidence (1,957 cases) was the greatest for two decades.

Mexico.—During the period May 21–June 17, 53 cases were reported in the Federal District. In 1949 the May and June incidence in all Mexico was 18 and 32 respectively.

Philippines.—The number of cases of poliomyelitis reported at Manila is considerably higher in 1950 than during the preceding years. Up to July 8, 117 cases were reported, whereas the annual incidence in the years since 1939 never exceeded 63. For the week ending July 8, 32 cases were reported, against 0 for the corresponding period in 1949.

Discussion of Table

In *England and Wales* there were decreases in the notifications of measles 463, whooping-cough 167, and scarlet fever 141. The number of notifications of dysentery was the same, 166. The number of notifications of acute poliomyelitis (305) was 45 more than in the previous week.

In *Scotland* there was a decrease in the notifications of dysentery 26, while there were increases in the notifications of whooping-cough 92 and scarlet fever 16. There was a decrease in the number of notifications of acute poliomyelitis from 58 in the previous week to 52.

In *Eire* there were decreases in the notifications of measles 78 and whooping-cough 23. The notifications of scarlet fever increased by 8 to 61.

In *Northern Ireland* there were increases in the notifications of measles 17, whooping-cough 11, and scarlet fever 7. There were 15 cases of acute poliomyelitis notified, three fewer than the previous week.

Week Ending August 5

The notifications of infectious diseases in England and Wales during the week included scarlet fever 956, whooping-cough 3,687, diphtheria 45, measles 7,973, acute pneumonia 273, acute poliomyelitis 367, dysentery 179, paratyphoid 5, typhoid fever 8.

Medical News

Birth of a Princess

The following bulletin was issued from Clarence House on Tuesday, August 15: "Her Royal Highness Princess Elizabeth, Duchess of Edinburgh, was safely delivered of a princess at 11.50 a.m. to-day. Her Royal Highness and her daughter are both doing well." The bulletin was signed by Sir William Gilliatt, Mr. John H. Peel, Dr. V. F. Hall, and Sir John Weir.

Harveian Society at Papworth

The summer meeting of the Harveian Society of London was held in the Papworth Village Settlement on July 19. Members and their guests were entertained to lunch, after which Dr. R. R. Trail, the president of the Society and medical director of the Settlement, explained the principles on which Papworth worked. The three main principles were active treatment, rehabilitation, and resettlement. During the 32 years of its existence no child born at Papworth had developed pulmonary tuberculosis, and even those men from Papworth who were prisoners of war in Japanese hands in the recent war had not developed pulmonary tuberculosis as the result of their captivity. A visit was paid to the *x*-ray department, where demonstrations of cases were given. The industries were subsequently visited, and patients were seen at work making leather goods, furniture, and motor-car bodies, or engaged in printing and bookbinding. Dr. Hope Gosse proposed a vote of thanks to the committee of management for extending the invitation and to Dr. Trail and Miss Robinson, the matron.

Records of the Fallen

The R.A.M.C. War Memorial Fund has now issued a booklet entitled "The Book of Remembrance," which gives the roll of honour of the 437 officers and 2,026 N.C.O.s and men of the Corps who gave their lives in the 1939–45 war. In addition, it records the ceremony on June 27 in Westminster Abbey last year, when the original of the roll was placed beside the Golden Book which gives the names of the 743 officers and 6,130 other ranks who died in 1914–18. Both books are now housed in the Pyx Chamber of the Abbey.

History of Science

The *British Journal for the Philosophy of Science,* which began publication in May, is sponsored by the Philosophy of Science Group of the British Society for the History of Science. Its aim is to direct attention to the philosophical basis of the sciences, and it will deal among other things with problems of logic and methodology and the interrelation between the sciences. The journal will be published quarterly by Thomas Nelson and Sons at an annual subscription of 30s.

Health Services for Children

A committee convened by the World Health Organization has met to recommend measures designed to improve health services for children of the school-age group. Dr. Fraser C. Brockington, medical officer of health of Yorkshire West Riding, was elected chairman, and Professor Jacob de Haas, from The Hague, was elected vice-chairman. Among the problems discussed were the nutritional aspects of school health, preventive mental-health education, and medical supervision in schools.

Editor of Tuberculosis Journal

Dr. Philip Ellman is succeeding Dr. Clifford Hoyle in the editorship of the *British Journal of Tuberculosis and Diseases of the Chest*. He will be assisted by an editorial board which comprises Dr. Clifford Hoyle, Mr. T. Holmes Sellors, Dr. A. Brian Taylor, and Professor Cameron. Dr. Clifford Hoyle succeeded the late Dr. L. S. T. Burrell in 1938 and has edited the journal for 12 years.

New Members of M.R.C.

Professor W. E. le Gros Clark, F.R.S., professor of anatomy in the University of Oxford, and Professor F. G. Young, F.R.S., professor of biochemistry in the University of Cambridge, have been appointed members of the Medical Research Council from October 1.

Wills

Professor John Alfred Ryle, professor of social medicine in the University of Oxford, and formerly regius professor of physic at Cambridge, left £27,608. Dr. Bertram Henzell Pidcock, of Winchester, left £18,517; Dr. Harry Bowen Williams, of Goring by Sea, £11,922, bequeathing £500 to the Royal Medical Benevolent Fund.

COMING EVENTS

London Nursing Exhibition

The London Nursing Exhibition will be held at Seymour Hall, Seymour Place, London, W.1, on October 23–27 concurrently with the Professional Nurses and Midwives Conference. Information may be obtained from the organizer at the *Nursing Mirror*, Dorset House, Stamford Street, London, S.E.1.

International Society of Medical Hydrology

A meeting of the International Society of Medical Hydrology will be held in Florence, Italy, from October 3 to 7. The subjects under discussion will be "Sweat," on October 4, and "Gout," on October 5. Members of the medical profession who wish to attend the meeting should communicate with Dr. Donald Wilson, "Cranbourne," Southdown Road, Bognor Regis, Sussex.

Bengué Memorial Award Lecture

Dr. Nadia du Bouchet, head of the Anaesthetic Centre and chief instructor of the Teaching Centre, Broussais Hospital, Paris, will deliver the Bengué Memorial Award Lecture on "Modern Anaesthesia in France and its Developments related to Cardiac Surgery" at the Royal Institute of Public Health and Hygiene, 28, Portland Place, London, W., on Wednesday, September 20, at 3 p.m. Admission to the lecture is free, without ticket, but applications for seat reservations may be made to the secretary of the institute.

London County Medical Society

The next clinical meeting of the London County Medical Society will be held at St. Stephen's Hospital, Fulham Road, Chelsea, S.W., on Thursday, September 14, at 3 p.m. All inquiries and communications should be made to Mr. J. Gabe, F.R.C.S., St. Alfege's Hospital, Greenwich, S.E.10 (Tel.: Greenwich 2655, Ext. 48).

British Postgraduate Medical Federation

The British Postgraduate Medical Federation has arranged a course of lectures on "The Scientific Basis of Medicine" to be given at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C., on Tuesdays and Thursdays, at 5.30 p.m., from October 10 to March 20, 1951. The lectures are designed especially for research workers and specialists in training, and admission is free without ticket. Details will be published in the diary column week by week.

Malcolm Morris Memorial Lecture

Professor J. Earle Moore, M.D., of Johns Hopkins University, Baltimore, U.S.A., will deliver the Malcolm Morris Memorial Lecture under the auspices of the Chadwick Trust at St. Mary's Hospital Medical School, Norfolk Place, Praed Street, Paddington, London, W., on Thursday, September 21, at 4.30 p.m. His subject is "The Public Health Aspects of Venereal Disease Control." Admission to the lecture is free and no tickets are required.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Wednesday

EDINBURGH POSTGRADUATE BOARD FOR MEDICINE.—At University New Buildings (Anatomy Lecture Theatre), Edinburgh, August 23, 3.30 p.m., "*Endocrine Control of Carbohydrate Metabolism*," by Professor F. G. Young, F.R.S.

APPOINTMENTS

Dr. Edward John Bury has been appointed an Appointed Member of the Executive Council of the Gambia.

AFFLECK, IAN, O.B.E., M.R.C.S., L.R.C.P., Factory Doctor for Farnworth, Lancs.

BREARLEY, BRIAN F., M.B., B.Chir., M.R.C.P., Consultant General Physician, Preston and Chorley Hospitals.

EAST ANGLIAN REGIONAL HOSPITAL BOARD.—*Senior Registrar in Radiology at White Lodge Hospital, Newmarket*, K. E. Barlow, M.R.C.S., L.R.C.P., D.M.R. *Consultant Psychiatrist at St. Andrew's Hospital, Thorpe, Norwich*, J. D. Fraser, M.D., D.P.M.

HUTCHISON, ALEXANDER, M.D., Ph.D., F.R.F.P.S., D.P.H., D.P.A., Medical Officer of Health and School Medical Officer, Bolton.

JONES, M. T. ISLWYN, M.D., D.P.H., County Medical Officer of Health and School Medical Officer, Denbighshire.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Baker.—On August 9, 1950, at Wednesbury, Staffs, to Hazel Baker, M.B., B.S. (formerly Hill), wife of Mr. T. A. C. Baker, M.A., a son—Robert Frederick.

Smillie.—On July 25, 1950, to Pamela (formerly Stevens), wife of Dr. T. G. Smillie, 195, Greenhill Avenue, Sheffield, 8, a son.

MARRIAGE

Forbes—Burbery.—On August 5, 1950, at Newton Abbot, John Ronald Forbes, M.D., to Pamela Stone Burbery, S.R.N.

DEATHS

Brand.—On August 7, 1950, at St. Andrews, William Gillon Brand, M.B., Ch.B., of 3, Elms Avenue, Lytham St. Annes, Lancs, formerly of Adlington, near Chorley.

Brims.—On July 31, 1950, Donald James Brims, M.R.C.S., L.R.C.P., of 8, Devonshire Place, London, W.

Craig.—On August 8, 1950, in Scotland, Douglas Craig, M.D., of Stanford-le-Hope, Essex.

Ferguson.—On August 3, 1950, at Hillcrest, Bodorgan Road, Bournemouth, James Henry Ferguson, M.R.C.S., L.R.C.P.

Hunter.—On July 29, 1950, at Nairobi, Ernest Villiers Hunter, L.M.S., of the C.M.S., Uganda, aged 73.

Jensen.—On July 30, 1950, at 25, Berkeley Square, London, W., Ernest Thomas Jensen, M.B., aged 76.

Lornie.—On August 8, 1950, at 7, Barossa Place, Perth, Peter Lornie, O.B.E., M.D., aged 68.

Morris.—On August 3, 1950, at Lew Down, Devon, Henry Gibbins Morris, M.R.C.S., L.R.C.P.

Oxley.—On July 30, 1950, Frederick John Oxley, O.B.E., T.D., M.R.C.S., L.R.C.P., of 66, Palmerston Road, Buckhurst Hill, Essex, aged 83.

Steele.—On August 9, 1950, in a nursing-home, William Frederick Steele, M.B., B.S., of 32, Severas Avenue, Acomb, Yorks, late of Tockwith and Darwin, Lancs.

West.—On July 29, 1950, at Hazelcombe, Dulverton, Somerset, Waldemar Shipley West, M.D., formerly of Aylesbury, aged 84.

Young.—On August 12, 1950, at 8, Ampton Road, Edgbaston, Birmingham, James Carruthers Young, M.C., M.D., M.S.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Intravenous Procaine in Asthma

Q.—*I understand that in the U.S.A. intravenous procaine ½% has been used in the treatment of asthma. I have tried it on two occasions—giving 5 ml. intravenously—in status asthmaticus which had not responded to any familiar treatment. In both cases complete relief of the bronchial spasm resulted within half an hour. Is there any literature on this treatment, particularly on dosage, side-effects, dangers, contra-indications, etc.?*

A.—Intravenous procaine is recognized as a method of treating status asthmaticus both in America and in this country. Intravenous procaine has chiefly been used by the anaesthetists, and many of the references concerning its use are in the journals devoted to this specialty. A review by W. W. Mushin and L. Rendell-Baker on the uses of intravenous procaine (*Lancet*, April 9, p. 619) refers to its effect on allergic conditions, and a number of references are given. The following references may also be useful: Woolmer, *Progrès méd.*, 1945, **73**, 407; Gordon, R. A., *Canad. med. Ass. J.*, 1943, **49**, 478; Dirceu, H., Clerq, F., and Duprez, A., *Acta clin. belg.*, 1946, **1**, 150. Although its effect in status asthmaticus is sometimes dramatic, like that of other drugs which are useful in this condition, intravenous procaine is, however, no panacea. It has been suggested that its effect in allergic conditions is due to its antihistamine-like action, but there is no proof that this is the correct explanation.

The usual dosage in asthma is 4 ml. of 1% procaine given slowly intravenously, or 0.1% procaine in saline given as a drip up to a maximum of 500 ml. in 30 minutes.

Primary Carcinoma of the Other Breast

Q.—*Is there a higher incidence of primary carcinoma in the remaining breast in those women who have already undergone one successful operation for cancer of the breast, as compared with a control group? If the incidence is approximately equal in both groups, can this be taken as evidence in favour of an intracellular (genetic) origin for breast cancer, as opposed to any extracellular carcinogenetic influence? If the second carcinoma arises purely fortuitously, would not the incidence of cancer in those with only one breast be approximately half that of those who still possess two?*

A.—There does not seem to be on record any specific statistical study of the incidence of primary carcinoma in the remaining breast after successful radical mastectomy for carcinoma of the opposite breast. Clinical experience does not lead to the assumption that this is likely. If there is no greater incidence than in a control group it would be difficult to say what this means; it is generally considered that some ovarian hormonal influence is at work in the genesis of breast cancer. The disease starts in the ducts of the breast, but some extra-mammary influence is believed to be at work. There must also be borne in mind the question of "immunity" and resistance developing in a patient who has been treated successfully for cancer; if this happens it would presumably affect the possibility of malignancy supervening in the remaining breast.

Homologous Serum Jaundice

Q.—*Were cases of serum jaundice reported as a result of inoculating many recruits with the same syringe? At a training centre I used to inoculate several hundred recruits in an hour or two. A fresh needle was employed for each injection, but the same syringe was used for dozens of cases.*

A.—Homologous serum jaundice was reported in British and American troops after inoculation with a yellow-fever vaccine which contained small amounts of human serum. An outbreak occurred among troops after the injection of convalescent mumps serum, and several groups of workers reported a high incidence of jaundice in the Service V.D. clinics; this was controlled when care was taken to sterilize syringes and needles between injections (Salaman *et al.*, *Lancet*, 1944, **2**, 7). The transfer of the causative agent of serum jaundice has not apparently been reported after injections of T.A.B. vaccine and the like, but an unduly high incidence has been noted in a diabetic clinic. Usually it has been presumed that only the needle is contaminated after subcutaneous or intramuscular injections, but the recent report by Evans and Spooner (*Journal*, July 22, 1950, p. 185) indicates that the syringe itself may be contaminated by back suction when the needle is being removed. The risk of transferring infection by the "separate needle, common syringe" technique is obviously small in this country except possibly for the risk of conveying homologous serum jaundice. Until other means of overcoming this are devised, it may be advisable to sterilize both syringe and needle before each injection. For a fuller discussion of this point an annotation in the same issue of the *Journal* should be consulted (p. 204) and a letter from Sir Alexander Fleming, F.R.S., in the *Journal* of August 5 (p. 365).

Intravenous Iron

Q.—*Please outline the latest information on therapeutic intravenous iron with reference to the indications, contraindications, dosage, and the technique of administration.*

A.—A number of satisfactory proprietary preparations of saccharated iron oxide suitable for intravenous injection are now available in this country. Provided that excessive doses are avoided, there are no contraindications to this form of treatment, which is as well tolerated by children as by adults. Intravenous iron is indicated for those cases of hypochromic anaemia which do not respond to adequate doses of iron by mouth, either through failure of absorption, as in coeliac disease and idiopathic steatorrhoea, or because orally administered iron provokes severe gastro-intestinal symptoms. It has also been shown that the anaemia accompanying certain chronic toxic or infective states, such as rheumatoid arthritis, which is usually refractory to iron given by mouth, may be corrected by parenteral therapy. The dose for an adult is 200 mg. daily or every other day. However, it is advisable to start with a dose of 50 mg.; 100 mg. is given on the second day, and the full dose thereafter. The technique of administration is simple, the aim being to avoid any deposition of iron outside the wall of the vein, where it produces intense irritation. As the solution is very dark in colour it is difficult to detect a small quantity of blood in the barrel of the syringe on withdrawing the plunger; 3–5 ml. of blood should therefore be withdrawn before the injection is made. The subject was discussed fully in an annotation in the *Journal* of May 13 (p. 1127).

Inhibition of Micturition

Q.—*Some male patients complain that they are unable to begin the act of micturition unless they are in more or less complete privacy. They are incommoded when the only opportunity for emptying the bladder is in a crowded lavatory. There is no organic lesion to account for this difficulty. It is a psychological trouble, not uncommon among shy, sensitive males, micturition presenting no difficulty to them at home or in relative privacy. Has modern psychotherapy any assistance to offer?*

A.—Such a condition must be regarded in the nature of a conditioned reflex, and is found to be due to some experience of shame or threats connected with the genital organs in childhood, usually concerning micturition, masturbation, or exhibitionism. The forms of treatment are: (*a*) Reconditioning by gradually and stage and by stage getting accustomed to the presence of other people. The effectiveness of this is doubtful. Some men got over it spontaneously under Army conditions, others did not. (*b*) Suggestion, under hypnosis or otherwise, in an attempt to break the vicious circle, is often more effective. (*c*) Discovery of the "traumatic" cause and release of the pent-up emotion by analysis is certainly the most effective and

permanent method, but it takes more time. It is, however, well worth while if such treatment can be obtained in view of the distress suffered by many of these patients—distress far beyond the mere inconvenience, for the situation arouses to some extent the original feeling of shame.

Domiciliary Treatment of Tuberculosis

Q.—*Is there any antibiotic treatment which is worth trying in general practice for a case of chronic fibrocaseous pulmonary tuberculosis? The patient I have in mind is a man of 55 with chronic cavities and a positive sputum; he has been treated with P.A.S. for a long time. Could streptomycin be given while he is at home, or would "aureomycin" or "chloromycetin" or any other antibiotic be worth a trial?*

A.—Streptomycin is the only antibiotic that might benefit the patient, but this should not be given at home unless there are facilities for determining the streptomycin sensitivity of the tubercle bacilli in the patient's sputum. An exception to this general rule is the use of the drug as a palliative measure in cases of painful tuberculous laryngitis. From the description of the case it is unlikely that any permanent benefit will result from the use of streptomycin.

Treatment of Defective Fat Absorption

Q.—*Is "sorethitan mono-oleate" of proved value in the treatment of deficient fat absorption? Is it safe to take over long periods at the dose recommended—6 g. daily? My particular interest is in cases of subtotal gastrectomy with failure to gain weight.*

A.—Sorbitan polyoxyethylene mono-oleate (Tween 80) appears to be effective in improving fat absorption in certain cases, including the post-gastrectomy syndrome (C. M. Jones, P. J. Culver, G. D. Drummey, and A. E. Ryan (1948), *Ann. int. Med.*, **29**, 1), although it seems unlikely that the effect is due to any change in emulsification, since this is commonly normal in such cases. Extensive studies on the toxicity of this substance have also been carried out by P. J. Culver in Boston and by L. Emmett Holt, jun., in New York. In human subjects 4.5–6.0 g. per person per day have been administered for periods of up to two years and no ill effects could be demonstrated. Similar investigations were carried out in children; 50 mg. of "Tween 80" per gramme of fat ingested caused no demonstrable ill effects in premature infants. Care should be taken to see that unspecified impurities are not present with the sorbitan polyoxyethylene mono-oleate, since these may be toxic.

Artificial Parthenogenesis

Q.—*I should be interested to know whether any experiments on artificial parthenogenesis have been, or are being, carried out in this country.*

A.—It is not clear whether the questioner is referring to experiments on artificial parthenogenesis in mammals or in invertebrates. Very little work has been done anywhere on artificial parthenogenesis in mammals, but a great deal has been done on artificial parthenogenesis in invertebrates such as the sea-urchin. A useful and comprehensive review of this work was published in the British journal, *Biological Reviews* (1941, **16**, 291), by Dr. Albert Tyler.

Dioxyamidopyrine in Asthma

Q.—*A new proprietary for the relief of asthma is said to contain dioxyamidopyrine. Is this drug likely to lead in some cases to agranulocytosis? What is the action of the drug, and have any clinical trials been reported?*

A.—The proprietary preparation which this correspondent probably has in mind is made up of a large number of ingredients, and no clinical trials with it have been reported in the literature. Some of these ingredients are of known value in relaxing bronchial spasm, while others are valueless in this respect. This type of polypharmacy is to be deprecated. Reliance should be placed on official preparations of adrenaline, ephedrine, isoprenaline, or theophylline and ethylenediamine, each of which will be found to be just as effective as—and usually cheaper than—proprietary preparations containing many ingredients. One of the constituents of this particular preparation is a small dose of dioxyamidopyrine. It is true that amidopyrine has been found on occasion to produce agranulocytosis, and has in consequence acquired an unenviable reputation. However, the danger of using amidopyrine is probably considerably exaggerated. At one time almost all patent headache powders, which were consumed by thousands of people daily, contained a little amidopyrine, and yet agranulocytosis remained uncommon. Still, there is no point in including amidopyrine in prescriptions when other analgesics will do equally well without incurring this objection.

Thrush and Myasthenia Gravis

Q.—*Can you suggest any treatment for a thick white deposit on the hard palate and tongue of a woman aged 60 suffering from myasthenia gravis? Her symptoms are well controlled by prostigmin, but the condition of the oral mucous membrane has been present for about four years, and does not react to any ordinary local treatment.*

A.—It is difficult to recommend treatment for this condition in the absence of a precise diagnosis. The description suggests extensive thrush, which occurs in debilitated states, and which may here be related to the dysphagia. In some elderly patients this infection may clothe the entire buccal mucosa with a thick white deposit which is most resistant to treatment. Swabbing the mouth gently but thoroughly with a 5% solution of sodium metabisulphite and afterwards with borax, soda, and glycerol is usually effective. The possibility of leukoplakia must be considered; and, if lichen planus seems likely, a trial of arsenic is worth while.

NOTES AND COMMENTS

Prophylaxis Against Syphilis.—Dr. Arthur S. Wigfield (Worcester) writes: In your answer under this heading ("Any Questions?" July 22, p. 231) it is stated that "even 200,000 units to 300,000 units (of penicillin) taken by mouth within a few hours has been reported as preventing infection." If this report relates to clinical experiment it seems pertinent to ask by what method these "protected" patients were shown to be incubating syphilis. While not wishing to dispute the veracity of such an assertion, I would nevertheless like to express my doubts of the wisdom of making it under the heading of "Any Questions?" The answers to "Any Questions?" are primarily of general interest. Your brief dissertation on the prophylaxis against syphilis is presumably designed not for competent venereologists but for general practitioners. How many general practitioners will now administer 300,000 units of penicillin by mouth in order to allay the fears of apprehensive patients? If none, why mention this dangerous practice without due warning? The danger of such a procedure would seem to be not so much the possibility of masking syphilis as the creation of a fool's paradise in which further transmission of the disease might occur. In mentioning the "best" prophylaxis against syphilis the total dose of four million units of penicillin should be coupled with a reasonable duration of its administration—i.e., seven to fourteen days. It is difficult to escape the conviction that such "protected" patients should be regarded as sero-negative primary cases and followed up for two years. Is it not wiser to persuade these patients to refrain from coitus for three months and ask them to report for examination then?

Corrections

Dr. J. W. Dundee (Walton, Liverpool) has written to point out that in the Medical Memorandum "Acquired Sensitivity to Thiopentone" (August 5, p. 332) the dose of thiopentone given at the first operation was 0.3 g., not 0.3 mg.

In the report (August 5, p. 358) of a discussion at the Section of Tropical Medicine during the Annual Meeting of the B.M.A. in Liverpool we wrongly attributed Colonel E. H. Vere-Hodge's remarks to Dr. R. F. Vere-Hodge. Colonel Vere-Hodge has written to point out that his statement that santonin was non-toxic was qualified by the words "in therapeutic doses."

BRITISH MEDICAL JOURNAL

LONDON SATURDAY AUGUST 26 1950

METHODS OF EDUCATION

BY

J. A. LAUWERYS, D.Sc., F.R.I.C.

Professor of Comparative Education in the University of London, Institute of Education

Last year's educational number of the *British Medical Journal* contained an introductory article on reform in medical education by Professor Melville Arnott, and thereafter a number of distinguished contributors considered, from the standpoint of their own special knowledge, problems which arise in the teaching of physiology, anatomy, biology, chemistry, and physics. Their papers displayed remarkable, indeed surprising, agreement regarding not only general aims and objectives but even regarding methods that deserve adoption. My own experience of teaching in school and university lies outside the field of medicine, and it would be unforgivably presumptuous on my part to criticize medical education or to offer suggestions for its improvement. I am encouraged, however, by Flexner's remark that "medical education presents a problem not of medicine but of education" to compare what is being said about the teaching of medicine with general trends of educational reform.

Those who are concerned with the professional preparation of young people who intend to become physicians or surgeons are faced, like all other teachers, by the effects of rapid social and political change. They face problems which arise through the adoption by statesmen and Parliament of policies the roots of which lie elsewhere than in the sciences. They are expected to deal with vast and growing numbers of students many of whom are insufficiently prepared for advanced or professional work and who come from social strata which a generation or two ago supplied few university entrants. They are puzzled, as we all are, by the rate at which scientific knowledge grows and theories change. They note, often with dismay, that new specialized fields of study constantly crystallize out, while on the other hand the need for an integration of studies becomes ever more apparent.

As for our colleagues in secondary schools, they too meet problems which, at their own level, are homologous with those which we face in higher institutions. They too have to deal with large numbers of pupils coming from homes materially and culturally poorer than those which sent their children to grammar schools thirty years ago—homes, moreover, where there is no tradition of independent reading and usually no trace of a professional outlook. The courses of study pursued in secondary schools have been much broadened by the introduction of new subjects in the curriculum: more modern languages, more art and music, social studies. Thirty years ago, boys usually learnt in science only physics and chemistry, girls only botany; now both sexes learn a little about each of the three, plus a little zoology and sometimes some astronomy and geology. The total time allotted to science, however, is no more than it was. Inevitably, standards of attainment suffer: those who now enter the university are not as well grounded in the basic sciences as the previous generation. Furthermore, all young people nowadays are to an ever greater extent distracted from serious study by the pervasive radio, the call of the cinema, the football pools, and the multitude of mechanized amusements which seduce the adolescent mind from pursuits of more permanent value.

The Student at the University

In framing proposals for the improvement of university education it is well to begin by considering as clearly and vividly as we can the conditions in which our students live and the nature of the attractions with which we have to compete. Many, if not most, of the young people who attend the first- and second-year courses have come from middle-class or working-class homes, and they are anxious to establish themselves in the world and thereby to live up to their parents' expectations. Our examinations are to them primarily a way of obtaining guaranteed social status, together with the appropriate income, rather than tests of scientific or professional competence. Many of these young people are living away from home for the first time and, in addition, they are forced to be very economical. Apart from the relatively small proportion who have rooms in hostels or college, they occupy modest and cramped rooms in what are often noisy houses. For the most part they cannot afford to buy books, while a visit to theatre or concert is a rare luxury. Under such conditions, and in such a frame of mind, wide and leisurely reading is not to be expected: it will be replaced very largely by the "swotting up" of condensed and potted lecture-notes that are thought to be the essence of the course on which the all-important examination will be based.

These young people are often deeply impressed by the surroundings of a university and by the supposed eminence and omniscience of their professors. Of course, very often they hide their embarrassment and lack of assurance behind a deceptive façade of bravura and nonchalance. But it shows itself by their hesitation in asking for help when they need it, by their attempts to hide their ignorance when

it would be better to expose it so that it might be removed, and by the inadequate support they give to general university functions and activities.

These beginners, who have never acquired the habit of reading or of individual self-directed study and have learned to rely overmuch upon the help and direction of devoted secondary-school teachers who coach with care their promising pupils, are suddenly flung into lecture-room or ward. Occasionally unable to hear what is being said or to see what is being shown, untrained in the art of picking out essential principles from a mass of material, they tend to scribble down unimportant details, often mentioned by the lecturer only by way of illustration.

Of course, the above picture has been painted quite deliberately in rather sombre hues, but it is not, I think, altogether false. Nor need we feel unduly gloomy, nor bemoan the fact that things would be better if they were different. After all, our students are perfectly prepared to work hard and to exert effort if they are shown the way and wisely directed. They are not less intelligent and are probably as devoted as preceding generations. We have at our disposal teaching methods, as well as instruments of communication or exposition, and a general equipment of laboratories and buildings superior to those available to our predecessors. Further, we have the satisfaction of knowing that our methods of selecting university students enable us to get intelligent people from all ranks of society. We shall meet with success if we learn to mobilize and to employ effectively the resources at hand.

Activity Methods

In the effort at adapting traditional university methods of instruction to changed conditions, it may be helpful to study what is happening in the schools and to take account of the views of educational reformers. Not, of course, that this implies that university teachers should copy what is done elsewhere. At most, they must take account of the practices of those who specialize in the process of instruction in order to see whether there are here methods that might be adapted to meet other needs.

Incidentally, it is noteworthy that many of the ideas defended by so-called "progressive educators" and recommended by them for adoption in teaching young adolescents resemble in large measure the practices of the best and wisest university teachers. For instance, "progressives" have long condemned didactic methods—that is, the simple dogmatic exposition of knowledge, by a method involving mainly chalk and talk, to a whole class who listen passively and attempt to memorize, sponge-like, verbal formulations. It is said that this involves enormous waste. First, because human beings learn imperfectly by listening. Their minds have to be activated and sensitized, which happens most easily when they are forced to face and to deal with problem situations. Secondly, because different human beings think and learn at different rates, so that class instruction is too slow in tempo for the more intelligent and too fast for the less bright.

It is evident that such criticism resembles that frequently urged against the lecturing to large numbers of students which is the central feature of most modern universities, and not only in Great Britain. It reminds one, too, of the attacks of Professor H. E. Armstrong, some half-century ago, against the methods of teaching chemistry then current in school and university.

Reformers have urged that the success of a teacher anywhere is to be measured, not by the number of words or verbal formulations which his pupils learn, but by the degree of purposive mental activity which he arouses in them. And in order to arouse this activity they have recommended the adoption of a number of methods and devices, partly intended directly to stimulate purposeful thinking about practical problems and partly intended to individualize instruction—these two being always connected.

The "Project"

Possibly chief among these activity methods is what is called the "project," a scheme of teaching analogous to what the French call the "*centre d'intérêt*." In its most extreme form a project method implies the abandonment of subject teaching; that is, children should no longer be taught mathematics, science, history, etc., but instead they should study and attempt to deal with a number of comprehensive problems. For example, as a result of joint discussion between teacher and pupils, the class (note: the class, not the teacher) might decide to spend a few weeks or months considering how the public water supply is obtained, purified, distributed, and got rid of; or how their city is governed and the public services paid for and administered. They would divide themselves into groups, to each of which a set task would be allocated or a definite problem assigned for study, again after joint discussion. During the course of the work the pupils would, so to say incidentally, be forced to learn some mathematics, science, history, etc. At the end, when the project is accomplished, the results would be displayed, shared, made public in a series of papers, an exhibition, perhaps a play.

Some years ago many schools, especially in the U.S.A., organized the whole of their curriculum in such a manner. Experience has shown quite clearly, however, that this is going too far. The result is inevitably that the young people do not, when they leave school, possess any worthwhile equipment of knowledge and skill organized in such a way as to make it generally usable. It is now accepted that it is wise to retain subject instruction but that the latter gains in value when the curriculum is enriched by a number of project activities.

Incidentally, projects nowadays are nearly always proposed and adopted in the form of problems which lead, when analysed, to subsidiary problems. Thus teachers go some way to meet the wishes of H. E. Armstrong, who, it will be remembered, urged that all science everywhere be taught by a heuristic method, modelled on the research work of investigators who attempt to find answers to problems. They go some way, too, to adopt the advice of modern psychologists, chiefly of the Dewey school, who have pointed out that active thinking takes place most easily when a human being faces a real problem of importance to him.

There are, I think, one or two things which can be learned from this experience, remembering that the university analogue to didactic teaching is the lecture. For example, one might suggest that an effort be made to provide for groups of students, even in their first or second year, as part of their general course, some project or other which they could investigate. And, further, one wonders whether the practical work which they are asked to do might not, in a great many cases, be set as the practical investigation of a problem, an attempt to find the answers to questions by methods of experiment, rather than as a simple manual exercise involving no more than the careful following of detailed instructions.

The second tendency, mentioned above, arises from the clear realization that the ability of pupils and students varies between very wide limits and that they work and learn at very different rates. There is, of course, no doubt that private tutorials—one pupil, one teacher—form the most effective of all methods. The way in which slow learners sometimes manage to pass, after a few months' coaching by a crammer, examinations which they had failed more than once illustrates the point. Again, it is clear that quick learners waste much time listening to lessons or lectures the speed of which is adjusted to the average. However, the cost of a full tutorial system of instruction would be much too heavy, in money and in personnel, to be borne at a time when universities have everywhere doubled in size.

The Dalton Plan

The Dalton plan—the name refers to a town, not to a person—worked out in the U.S.A. some thirty years ago, was an attempt to adapt methods of instruction to the requirement of individualization and to offer pupils the advantage of private attention without having to provide an excessively numerous staff. In essence, the plan consists in the careful preparation of detailed assignments telling the pupils what to read, which experiments to try, which problems to solve. These assignments are worked out together by teacher and pupil, and they provide a plan of activities intended to last for a month or six weeks. The pupil works at his own rate, distributes his time as he wishes among the different subjects, and consults his tutor whenever he meets a real and insurmountable difficulty.

Two points deserve mention. First, that many schools adopted the whole plan in the nineteen-twenties and thirties. Most have now gone back to a modified form of class teaching, devoting, say, only the afternoons to individual work on assignments. The chief reason was that the full "plan" overloaded the staff, even though the weaker pupils still failed to get sufficient attention. It seems that the scheme does not work well if the pupil:staff ratio is greater than about 8:1.

There is here, too, I think, a lesson to be learnt. The old "Oxbridge" tutorial system involved regular meetings between tutor and student, at which the latter read essays and had them thoroughly criticized. It is a system which admirably develops verbal facility and a happy command of language as well as a general interest in a rather vague and woolly philosophy. It is not particularly well adapted to the requirements of science-teaching. Tutors would probably find it well to spend most of the time available in planning courses of reading and laboratory work, taking care that these plans are duly noted down in a diary. American universities are certainly moving in this direction—indeed, many of us tend to think that they have already gone too far in supervising the work of their students, setting them tasks and problems, planning every minute of their day. However, we in Britain certainly have not gone too far and we usually leave our students too much to their own resources.

Social Aspects of Science

In all proposals put forward for the reform of school curricula and for changes in the content of instruction, there is one common factor. It is always urged that the material be selected and taught in such a way as to make evident its social importance. Some, indeed, go so far as to say that subjects or topics which have no social importance should not be taught at all. Now, in part, this tendency arises from the changed standpoint of the psychologists. The old faculty psychology is no longer defended by anyone. Nobody now thinks of the mind as a collection of mental muscles (called attention, memory, criticism, etc.) which are capable of being developed and trained by special exercises. Therefore one can no longer justify formal modes of teaching by urging that they develop powers of memory, observation, criticism, and so on. The justification has to make clear the social or individual value or utility of what is being done. In part, too, the new emphasis on social significance is the result of increased knowledge in the fields of sociology and of the history of science. But probably the true reason lies elsewhere: in the pervasive climate of thought, in the widespread realization that western civilization has to adapt itself to a changed technology and that it has to accommodate itself both to the challenge of Russian Communism and to the new conditions created by the emergence on to the world stage of the Asian nations.

However this may be, the point remains that our students are very receptive to lectures and talks on elementary sociology and on the social aspects of science. It seems that they learn more easily, are more receptive and attentive, when their teachers include references to such aspects in their courses. It would be a mistake to ignore or reject them as futile: their inclusion helps to activate the rest of the material by making it more evidently meaningful. In any case, one should not forget two facts. First, that one becomes a good doctor not simply by learning certain facts and skills, but also by acquiring certain attitudes and habits. Initiation into a great profession, with age-long traditions, is no easy matter. Secondly, as was pointed out earlier, most of to-day's university students come from homes where there is no professional tradition of any kind and where there has been no real contact with professional men and women. Thus, concentrating completely on pure subject-matter, and hoping quite simply that the professional attitude is sufficiently contagious to be caught across lecture desk or demonstration table, may not suffice. More direct methods may be called for.

The Process of Teaching

New inventions, of use in exposition, have always modified the business of teaching: one need think only of the invention of printing—or of the blackboard. The last fifty years have been particularly fertile in such—cheap linotype printing, new processes of colour reproduction, the episcope, the film strip, the moving film, the polygraph which allows easy reproduction of typed documents or even of diagrams and photographs. All these have found their way into class-room and lecture-room, but we have not yet discovered how to use them to best advantage. Potentially, the film is probably the most powerful of all these new media for the communication of ideas and of factual information. But it is also probably the most complicated and, because of its superficial attractiveness, the most prone to misuse. For instance, it is a mistake to use a film for showing the development of an animal from fertilized cell to adult. The whole point of the study is to show how one part develops into another. This study is most easily done on twenty or thirty still photographs, allowing detailed study. With a film each succeeding photograph wipes out the previous impression and the study becomes more complicated, the total idea more confused. Yet many of us would feel tempted to use a film in such cases—and would be disappointed by the result.

There is no room here to discuss the pedagogical problems arising from the use of such visual presentations. It must suffice to remark that their wider adoption, their more successful utilization, will depend upon our finding new ways of teaching. Our traditional methods have relied upon the spoken and the written word, and are adapted to

them. The new ways stem from the oldest of all methods of recording and transmitting knowledge—the drawing, the painting, the hieroglyph. But all of us, through the process of our own education, have been insulated from such direct modes, and many of us find it more difficult to interpret a visualization than a written page—except, for example, those skilled in reading radiographs.

One point arises directly and bears upon the much-discussed lecture-method of teaching. I have already indicated that educators and teachers, in general, continue to believe that the method has value, even though less than was thought. The tradition of university lecturing was established at a time when books were scarce and expensive. They are now cheap and numerous; and they contain all the facts that are needed. The lecture never was an instrument of great efficiency as regards teaching facts: its value was chiefly in inspiring zeal, in developing a liking and gift for criticism and analysis, in permitting some contact, albeit rather slight, with persons of distinction. The example quoted by Professor Pickering of a brilliant lecture by Sir Joseph Barcroft on the kidney shows that it can do all this. But would it not be wise to distribute duplicated notes, diagrams, photographs to the students wherever possible, thus leaving the lecturer free to concentrate on his proper business and taking little account of whether he is mentioning enough facts? The students must learn to get their facts elsewhere and in other ways than by scribbling quickly during lectures.

The Training of Teachers

I have left till last one of the most puzzling and difficult questions of all: whether university teachers need and would profit from special training in methods of teaching and in education. On the one hand, it is clear that the lack of teaching skill, and indeed common sense, of many brilliant research workers involves great waste of time. I remember listening to the lectures of a mathematician, whom I admired and still admire as a man of remarkable genius. I feel convinced I would have learned more had I been able to hear what he said: unfortunately he usually talked to the blackboard and not to his class. Again, I would have liked to copy down what he wrote on the blackboard: unfortunately he always stood in front of what he wrote and wiped it off immediately. I have often wished that someone had given him a few words of advice at the beginning of his lecturing career.

On the other hand, young university teachers know very well that their future career depends mainly on their research work and has very little to do with their teaching prowess. Many tend to regret, as an interruption to their serious scientific work, the need to teach young beginners. To suggest that they should set aside a year or six months would be felt by them to be quite intolerable, and in any case futile. Again, there is involved here—albeit in a very limited way—the principle of academic freedom. No university teacher will consent to have the content of his courses discussed or considered by others—except in the most general way.

Now, what in fact would it be well for the beginner in teaching to know? I suggest that he would be helped by knowing about the instruments (episcope, film projector, and so on) used in visual education and about the educational techniques involved in their use; that he would profit from advice about good methods of lecturing and of demonstration and that he needs criticism of his own methods so that he may remove his defects; that he would find it helpful to learn something about the psychology of the adolescent and young adult as well as about the process of learning; that he would enjoy the opportunity of discussing with men of experience the problems which he meets in his teaching work.

I venture to suggest, therefore, as a modest start: (*a*) that to every young beginner there be offered the opportunity of having an experienced teacher attend his lectures for a term or for a year. This experienced person would then discuss with him the method of arranging his lectures and his actual teaching: suggesting how best to introduce his topic, how to frame and word the problems, what aids to use, how best to demonstrate experiments, questions of voice production, and so on. It would be best if this adviser or critic were not himself an expert in the branch or subject being taught, for it would then be quite plain that there was no question of finding fault or of spotting mistakes. Possibly one might use for this purpose university teachers beyond the age of retirement: many would be glad to undertake so useful a job. (*b*) It would also be, I believe, highly advantageous if heads of departments made a point of calling together their staffs regularly to discuss various educational and pedagogical problems. Knowing how pressed for time all university teachers are everywhere, and realizing only too well how many committee meetings professors are expected to attend, one hesitates to suggest yet one more weekly or fortnightly meeting. Yet the advantages would be great, and it is not impossible that in the end time might well be saved. (*c*) Lastly, it is not inconceivable that week-end meetings of staff, say in one of the many conference homes now available, would be appreciated by all. At such meetings it would be possible occasionally to invite a psychologist or an educationist who might expound current views on some educational problem or tendency or on some new technique of teaching.

In my view, it would not be either wise or practical to attempt to go further than this at the moment. Indeed, some may find it slightly ludicrous to suggest forms of training for university teachers, remembering how many brilliant teachers there have been who have never had any training and who lacked all systematic psychological knowledge. One notes, however, that fifty years ago secondary teachers were never trained and had no systematic courses in education: now nearly all spend a year in a University Department of Education and, for the most part, enjoy this period and consider they have profited from it. In addition, one should not overlook the fact that the means and techniques now at the disposal of and used by university teachers are numerous and complex. In this situation it is unwise simply to trust to memory, to the powers of adaptation and imitation, or to native common sense. Something more is needed if the resources available are to be fully mobilized and wisely employed for the improvement of university education in general and of that highly important part of it which is medical education.

The Ministry of National Insurance announces that foreign students who come to this country during their vacation and take up temporary employment related to the nature of their studies will not be required to pay National Insurance contributions until they have been continuously resident in Great Britain for 26 weeks. They will, however, still have to pay Industrial Injuries Insurance contributions. Apprentices coming from other countries will also be excused from paying National Insurance contributions if they have not reached the age of 25 when they take up employment here in work which is related to their work abroad and the employment is not expected to last, and does not in fact last, for more than three months. These changes have been effected by the National Insurance (Residence and Persons Abroad) Amendment Regulations, 1950.

THE ART OF LECTURING

BY

G. PATRICK MEREDITH, M.Sc., M.Ed., F.B.Ps.S.
Professor of Psychology, University of Leeds

I am not a theologian, but I was once privileged to attend, at a week-end conference, a lecture by a professor of theology. It was twenty-five years ago and it is still vivid to me to-day. The subject was Amos, of whom I previously knew precisely nothing. By the end of the lecture I had not only a dynamic impression of the character and message of the prophet but also a clear and colourful picture of the contemporary economic, political, and social structure of the people of Israel. The professor used no notes. He padded round the room, with his hands behind his back, and wearing felt slippers. From time to time he raised one foot to scratch the calf of the other leg. Now and then he looked at one or other of us directly in the eyes, with a kind of challenging glare. At other times he gazed through the window into the extreme distance, as if looking at Palestine, and describing what he saw, taking our gaze with him. I recall that he pronounced Jahweh with the sort of sound one makes in clearing one's throat.

I have listened to Professor Massey lecturing on atomic energy in a London lecture-room with traffic roaring outside, clinging to the knob of a wooden balustrade on the platform, stock-still for an hour, also without notes, powerful, compelling, consecutive, telling a story he knew from the inside, with no mannerisms. And to Professor W. P. Milne, many times, on mathematics. For him the history of mathematics was a hilarious breath-taking adventure, massive bodies were always elephants and infinite planes were all as flat as gramophone records; he always mingled mirth with mathematics. And to a shy, reserved, precise lecturer in physics who announced one morning, "I am going to introduce spherical harmonics to you. The day I grasped this subject was the happiest in my life." And to the late Charles Spearman, who lectured in a somewhat staccato and confusing manner, committing many faults of delivery, but who compelled attention because this branch of psychology—the Noëgenetic theory—was his own creation. I get the same thrill and more listening to Professor Astbury, not only because he is a much better lecturer but because biomolecular structure is a subject which he has brought into existence.

Vitality

I now ask myself, What have these exceedingly diverse performances in common? I ask this because, desirable as it might be for all university lecturers to have a training in lecture techniques, I cannot persuade myself that this would usher in a millennium of enlightenment. Of the lectures I really remember (as distinct from the thousands which helped me get through my examinations and thereafter faded) I can see little or nothing as regards common techniques. What was common was something less tangible. Though some of the lecturers were actual creators of their subjects this was not so in all cases, and the circumstance is necessarily a rare one. Certainly all were masters of their subjects, but this is also true of many ineffably dull lecturers through whose performances I have dozed my way. Unfortunately, mastery of a subject seems to be not incompatible with an academic necrosis of the personality.

You can wander about, you can indulge in irritating mannerisms, you can hum and haw, you can remain glued to a desk, you can twiddle your fingers, you can commit all the crimes on the statute book (the latter would make entertaining reading if someone would write it: "The Deadly Sins of the Lecture Theatre"), and you can get away with all of them if only you have the one supreme virtue. What is that virtue? The name I would give it is *vitality*. This was the common factor in all my remembered lectures.

Vitality does not mean flamboyance. It is not exactly the same as energy. It is compatible with a considerable variety of surface qualities. It combines well with originality but is not identical with this. There are noisy, restless lecture-rooms which yet lack vitality, and there are lecture-rooms in which a quiet, subdued atmosphere testifies to intense, creative man-to-man contact—a contact of both learning and personality. The still, small voice may hold something which the thunder lacks. But of course there are personalities whose vitality needs a boisterous expression. There can be no holds barred.

Techniques

I have been asked in this symposium to write on "techniques" and I am trying to do so, but perhaps not quite in the sense intended by the Editor. For how could principles for the technique of lecturing be established? Only by the systematic analysis of lecture successes on a wide scale—not by the formal application of *a priori* educational principles excogitated by theorists. The extraordinary gap between educational theory and educational practice in the scholastic world would merely be paralleled in the academic world. At present the academic world gets along without any particular theories about study and lecturing. There is certainly plenty of dissatisfaction with the methods and results of academic education, and it is sometimes suggested, or implied, that an injection of educational theory might remove the complaint.

Personally, I think that a dose of empiricism would be more effective—that is, a study of how good lecturers get their results. And from my own limited sample I should say, as a preliminary generalization, that good lecturers get their results primarily by having sufficient vitality to give good lectures. Their techniques are a direct consequence of their vitality. But this vitality is not an easy thing to define. It is a force which is called up by the joint challenge of a topic and an audience, a challenge which stimulates the organizing capacity of the man's mind to draw upon whatever material and mental resources he has. After all, what is a "technique"? A technique is a way of doing something. When we observe a certain effect being achieved we may pin-point all the details of the procedure, item by item, and yet fail to account for the achievement. The technique is more than the sum of the details. It is the organization of those details which sustains the process. We must grasp the organization if we are to understand the achievement. I would say, soberly and reluctantly, that educational psychology to-day, with all its progress, is not yet in a position to say to the teacher or lecturer: "Here are all the tricks of the trade; follow these and you are bound to succeed." Indeed, I am not sure that educational psychology ever will, or ever should, fulfil this aim.

The last thirty years have witnessed an unprecedented outburst of experimental activity in education. Every dodge, trick, and stunt, every device, mechanism, and apparatus, every system, procedure, and method which the ingenuity of dissatisfied educationists could think up—all

these have been pressed into service. Most of them can claim successes. Most of them have their intrinsic merits. But none is the panacea claimed by its promoters, and there have been plenty of successes in which all were ignored. The literature of educational experiment gives, as a rule, an account of the successes. A much more voluminous literature could be compiled if we were honest, describing the failures. But, as so often, "the operation was highly successful, but the patient died without recovering consciousness."

Now I am not a reactionary in these matters. I regard the modern developments in educational techniques (many of them referred to in the article by Professor Lauwerys) as being no less important than the atomic bomb, and indeed part of the answer to the menace of the latter. But as the release of nuclear energy has gone astray because of human conflict so, too, the use of modern educational techniques is missing fire because of a neglect of the human problems attendant upon their use. I want to discuss these problems.

Human Interaction

Not only does the use of a specialized educational technique—for example, the film—involve human beings both in its preparation and in its presentation, demanding training and insight if full justice is to be done to the medium, the matter, and the method, but—and this is the crux—*the actual educational occasion is essentially a pattern of human interactions.* By an "educational occasion" I mean any period in which instruction, stimulation, training, etc., is being given to a group of students. Whatever media and methods are being adopted we always have some kind of a performance *by* human beings and *for* human beings. And we know enough to-day about the psychology of the learning process to know that the transmission of knowledge is very, very unlike the process of recording sound on a disk or an image on a photographic plate. The disk and the plate have no "attitude" to the process or to the person performing it. The human learner has, and his attitude both to the task and to the teacher is decisive in determining the outcome. This does not mean that the details of the task are unimportant or that an inspiring atmosphere can compensate for neglect of material completeness and accuracy. But it does mean that attention to the latter can be rendered ineffective by ignoring the human factors.

If we consider some other occasions of human interaction we may get some clues to what is involved. In the stage performance of a play the whole production is carefully designed precisely to take account of the attitude of the audience. Every movement, every gesture, every inflection of the voice, every beam of light, every piece of furniture—all are under the producer's control and all play an exactly calculated part in building up the developing pattern of dramatic tension. There are many background factors too. Not only the architecture of the theatre, the time of day, and the season of the year, but the name and prestige of the author, the reputations of the star actors, the press reviews of the play, the fashionableness or otherwise of the play itself and its theme, the tradition of the theatre—all these conspire to create or destroy that final outcome—namely, the dramatic experience of the audience which is the goal of the whole complex game.

Mutatis mutandis, similar considerations apply to a broadcast, and they should (though seldom do) apply to the screening of a film. But how do these points apply in a university lecture to a class of medical students? Is it suggested that each lecture should be regarded as a dramatic performance to be scripted, produced, rehearsed, with spotlights and music and all the *impedimenta* of the modern stage? If I proposed this the answer would, of course, be, "Not Pygmalion likely!" What I am suggesting is that if such lavish attention to the requirements of the occasion can be devoted to entertainment, surely no less attention should be devoted to the requirements of learning—especially the learning of those who will be responsible for the nation's health. And, although "the play's the thing," just as a good play can fail in its effect by reason of a bad production, so, too, the most carefully thought-out piece of medical knowledge can fail to get across if badly delivered. On the other hand, the best production cannot make much of a bad play. These two essentials, matter and method, must both receive equal weight in considering the requirements of medical education.

Morale

Perhaps we can arrive at more clues by considering the problem in terms of morale. This is really the military term for what I have been calling "attitude." Troops who believe they have a just cause to defend; who have good reason for confidence in those responsible for the "logistics" of the campaign, and faith in their leaders; who have had a good training; who know clearly what their immediate objective is; and who have the challenge of the enemy himself in view—such seem to be the regular winners, if military history is to be believed. Medical education is something of a campaign. The student is the individual fighter and the enemy is his own ignorance. He has a long gruelling war of five or six years' duration, with tough fighting all the way. How can his morale be sustained through this long ordeal? The full answer to this would give us the complete dynamics of medical education. I can venture only some of the main headings, those bearing particularly on the art of lecturing. Lectures, laboratory work, and clinical work are the three great forces in the campaign and each has its own problems.

The "pep talk" has its place in study as in fighting. Mr. Churchill's wartime broadcasts at one extreme, the final words of a briefing to bomber pilots or commandos before a sortie at the other extreme, illustrate the force of sheer words. Sheer words, but not mere words. The essentials of "pep" are not so much energy and verbiage as sincerity and vision. Education is not solely an intellectual process. The distant achievement, the entry into a life-saving profession with a great tradition and immense contemporary power and opportunity for humane service—this is not a trivial goal. It calls for all that is best in a man. And whatever the difficulties, the discontents and disputes, the petty rivalries and squabbles, the cynicism and cheap jokes, and all the other superficialities with which the word "medicine" can become encrusted, its own essential vision and purpose are too high in the scale of human values to be allowed to fade from men's minds. They need to be particularly bright and sharp in the minds of students. There is a place, then, for the occasional introduction of this element into the lecture-room by the right man, in the right way, at the right time.

Historical Element

Allied to this is the historical element. Doctors need to know the history of their craft, but there is very definitely a problem of technique in teaching it. A formal course of lectures on the history of medicine is not likely to achieve what is wanted unless handled with exceptional skill. We have to ask, "What is the function of historical knowledge?" Certainly as part of the doctor's culture and general education it is important, but, more than that, an insight into its past growth is needed to appreciate the present growth of medicine.

The student is not mastering a body of static knowledge which will last him throughout his career. He is being given a start, at a particular epoch in time, in a system of developing skills and achievements, a system which will go on developing while he is practising it. Moreover, it is a system closely linked to the current techniques of civilization and scientific resources, to the current ways of life of the people, and to current beliefs and superstitions. In a sense all medicine is social medicine, and must be interpreted in the light of statistical knowledge of sickness and death, of wars and plagues, of poverty and wealth, of housing and diet.

A full, rounded, perspective view of modern medicine can be given only by those whose teaching intuitively refers to history because their own understanding is informed by a grasp of history. The history of medicine is not a separate subject but a dimension of the subject. The lecturer's technique must include the process of imparting to the student a sense that he personally is entering into this historical stream. One may compare the immense pains taken by great regiments not only to maintain the historical sense of their own traditions but to see that every recruit comes to possess this sense. This may not have much to do with the logic of learning, but it is an undoubted factor in morale.

"Logistics"

Thirdly come the "logistics"—the supply and movement of men and materials. I take the analogue of this to be the technique of planning time-tables, of not only preparing lectures but lecture-rooms, demonstration materials, visual aids, supplementary notes and reading references, and the uses of libraries. How far such matters are determined by tradition and habit, or by considerations of mere convenience, or by casual day-to-day decisions no one can say. But if we look at these matters from the point of view of the student and imagine them asking themselves, as well they may, "Is this medical school going all out not only to train us in the best modern techniques of medicine but to train us by the best modern techniques of instruction according to a genuine thought-out educational plan, or are our lectures mere episodes in the life of busy men with too many other irons in the fire to leave time for thinking about our needs?" this may focus the issue.

Students need to be exposed to the stimulating contact with vital personalities who have themselves contributed, and are contributing, to the advances of medicine. But my earlier remarks about vitality must not be taken as a plea for spectacular histrionic exhibitions of personal prowess. Medicine is one thing and medical education is another. Each is a great creative job. Those taking part in the second must have their hearts not only in medicine but in education. They are building for future health as surely as present practice is building for present health. The students need the assurance that the lecturer is as much interested in them as in his subject. This interest may be shown in a variety of ways. It may not, it seldom can with large classes, take the form of direct individual concern with each particular student—though each needs at least one tutor whose business it is to treat him as an individual. But students have, I believe, more awareness than is commonly realized of the extent to which their educational needs are respected. And a well-planned campaign of instructional progress has not only the strength of its technical merits but the additional strength which arises from the effect on students' morale of their awareness that it *is* a planned campaign. So I would suggest that one of the most important techniques in lecturing is to take the students into one's confidence with regard to the general plan of the course, and the reasons for whatever particular methods are adopted.

One of the best reasons for adopting a particular method is that one knows how to use it successfully. One man's meat is another man's poison. Universal techniques cannot be prescribed. This does not mean that techniques do not matter. They matter supremely. The trouble is that so many lecturers assume unreflectingly that there is just one droning, repetitive technique—the vocal textbook technique—and that their personalities have nothing to do with the case. There is a great range of techniques. It is for each man to find for himself which particular techniques suit both himself and his subject.

The upshot is that lecture technique is not a matter of a few simple tricks of the trade but something to be studied as closely as a piece of surgery. Lecturers, particularly at the beginning of their careers, would do well to have occasional voice-recordings made so that they can hear their own delivery. They would do well to invite experienced critics to come in and sit at the back and tell them frankly whether they could clearly hear and see all that was said, written, and shown; whether exposition was lucid; whether timing was right; whether information was lively or dull, pretentious, or hackneyed; whether justice was done to the subject-matter; whether it was made to seem significant, made to seem part of a connected scheme of knowledge, given colour and perspective and brought to life.

In short the art of lecturing, like any other art, must be learnt through the painful experience of practice and criticism. It will then become evident, through this empirical process, that lecturing is a living art, an art of moving the thoughts and feelings of human beings, an art in which, whilst the talk and the topic are in the foreground, there is a background of interaction between personalities, of historical achievement, and, in Medicine, of movement towards a proud participation in the most humane of labours.

Social insurance in Austria is the theme of an article by Dr. Reinhold Melas in the *Bulletin* of the International Social Security Organization for April, 1950. He describes how all employees and members of their family are insured against sickness. The scheme provides sickness benefits, lying-in allowances, funeral grants, and family assistance. Free medical care is provided; insured persons choose one of the doctors under contract to the insurance fund. The relations between the doctors and the sickness fund are regulated by collective or individual agreements. The expenses of diagnostic tests are borne by the fund. Drugs and other medical products are obtainable free of charge by the insured person on presenting a prescription at a chemist's, though members of his family must pay 20% of the cost of products prescribed for them. The preparations that may be prescribed are approved by the public health office, and number about 4,000; there are about 400 which may be supplied only with the consent of the sickness fund. Hospital care is also provided under the scheme for 52 weeks as a free benefit to the insured person, and for 26 weeks for members of his family, who must pay 10% of the cost. There are also dispensaries where people may go to be regularly examined by a doctor even though not complaining of any symptoms.

METHODS AND MEN IN THE TEACHING OF CLINICAL MEDICINE

BY

Sir HENRY COHEN, M.D., LL.D., F.R.C.P., F.F.R.

Professor of Medicine, University of Liverpool

Recent reports on medical education have been concerned primarily with the content of the medical curriculum. They have emphasized how such influences as the vast expansion in the corpus of medical knowledge due largely to the application to medical research of the newly discovered implements of science, the triumph of the functional concept of "disease" over the earlier notion of "diseases" as specific entities, increasing specialization, and more readily available hospital services have rendered necessary fundamental changes in the structure and orientation of the curriculum. There has been general agreement on the pattern which these changes should follow, and they have been embodied in the most recent recommendations of the General Medical Council and in the educational provisions of the Medical Act, 1950.

Too little attention has been paid to what is equally important—the methods and techniques of medical teaching and the selection of medical teachers. For, whilst exceptional men are the product of their exceptional talents rather than of any system of education, the average student will be better trained by the teacher who has mastered the main principles of pedagogy. The contributions of distinguished educationists to this symposium leave no doubt of the general applicability of Flexner's observation that "medical education presents a problem not of medicine but of education." In a measure the problems of medical education may well be simpler than those of general education, for the medical student may be presumed to want to be educated, whilst the scholars in our primary and even secondary schools (to whom most educational research has been directed) are too often the unwilling victims of our system of compulsory education; moreover, the vocational component of medical education gives to it a more defined objective than that of general education.

In common with the vast majority of clinical teachers I have had no formal training in the art and science of education. In over twenty-five years of teaching I have had perforce to learn largely by the heuristic method, though I have learnt much, both to emulate and to avoid, by observing others. It is from the basket of this experience that I pick some impressions and a few convictions which will, I hope, be helpful to the young clinical teacher.

The Clinical Teacher

Although some clinicians are born teachers and some, however eminent in their profession, are abject failures as teachers, most clinicians who possess certain natural attributes can be trained in the art and methods of teaching. If we are to choose our clinical teachers skilfully we must appreciate what their business is. We must recognize that their purpose is not only to transmit knowledge but also to stimulate the student to think for himself to some purpose, and to show by example the techniques, simple and intricate, of the science of medicine and of its human and social relationships. They have to teach both how to observe and what to observe; the need for thoroughness, accuracy, and freedom from bias; the significance of the analysis and synthesis of observations and the reaching of rational judgments on them.

The clinical teacher must then know the practice of medicine through long and intimate contact, for he cannot give what he does not possess. But competence in practice or research is not enough. He must be interested in teaching and in the taught. For him, behind the power to teach a subject must be the power to train a doctor, so that he must be a man of character as well as ability, for many students will model their lives on his personality. To an equable temperament, and courtesy and patience in dealing with patients of all social groups and of all degrees of intelligence and stupidity (for manners proclaim interest), he should bring an orderly mind and a balanced outlook, a sense of proportion, an ability to think for himself and to question authority, confidence in his own judgment, and a ready acceptance of the fact that, from the nature of medicine, blunders are inevitable, because summary decisions on inadequate evidence are often needed for action where a reasoned judgment must be postponed because of limited knowledge.

There are certain qualities indispensable to any efficient teacher whatever his subject. He must have, or acquire by training, a clear and unhurried diction, and he must be able to express himself in simple language. Ruskin held that "he who hath truth at his heart need never fear the want of persuasion on his tongue." But mumbling inaudibility can never persuade. Such simple but important faults as speaking to the blackboard with his back to the class, writing illegibly, and others have only to be noticed to be corrected. The good teacher must be able to sense the response of his class so that he knows when to repeat, to emphasize, or to remodel his explanations. But amongst the major considerations of special application to medical teaching are (i) the need for a clear objective in all forms of instruction whatever their content or type, (ii) the need to adjust teaching to the stage of the pupil's knowledge and understanding, and (iii) the methods and techniques of teaching, and especially the tools of clinical teaching.

Certain aims are generally accepted. Thus progress must be from the known to the unknown; there must be constant reference back by way of explanation and illustration to earlier work. The need for this has been recognized in the importance attached to the transition period between preclinical and clinical studies and the increasing emphasis on interpreting disease in terms of anatomy, physiology, psychology, and pathology rather than in describing "diseases" as if they were equivalent to the species of plants and animals. Moreover, if its purpose is to be achieved there must be a clear, and preferably in the earlier years a single, objective in any given lesson. The teacher should repeatedly ask himself, What point am I trying to make? In this patient with a failing heart what am I trying to demonstrate? Is it a cardiac irregularity, the pleural effusion, the mechanism of oedema, or dyspnoea, etc.? He thus will appreciate constantly the need for dealing with one problem at a time.

These principles are specially important in relation to the stage of his clinical studies which the student has reached. For example, the patient with carcinoma of the pancreas should in the early stages of the student's ward work be an object-lesson in obstructive jaundice and not a text for a discussion of neoplasms of the pancreas. It is well also to recognize that there will be patients in the wards who can offer but little material which is appropriate to early clinical studies.

Whatever the special aim of any course of instruction may be, the general aims of medical education should not be overlooked, and topics far removed from its purpose should not be laboured at the expense of more rewarding studies for the basic training of the doctor.

Methods of Medical Teaching

These are here discussed with special reference to the teaching of clinical medicine, though what is written applies *mutatis mutandis* to other clinical studies.

The methods of clinical teaching ("tools of the teacher") may be roughly regarded as (i) didactic—e.g., the systematic lecture and the lecture-demonstration, (ii) those designed to encourage the student to observe accurately and to think for himself—e.g., some aspects of ward work, out-patients, clinical conferences, and discussions, and (iii) those in which he sees the trained practitioner at work—e.g., in consultative out-patients, in the operating theatre, or in general practice.

Systematic Lectures

Doubt has frequently been expressed about the value of a course of systematic lectures in the teaching of medicine, but, provided that the lecture is not a mere reproduction of what is in the textbooks but expounds essential principles vividly and clearly, embodies recent work, and approaches the subject of the lecture from an individual, fresh, and novel angle so as to present an integrated conception of a problem, it is a most valuable teaching instrument. The lecture must, however, be carefully prepared, for few are competent lecturers without preparation, and all are better for it. The lecturer should have advised at the beginning of his course which textbooks should be used and before each lecture which chapters should be read; he may supplement these by predistributed cyclostyled notes, blackboard summaries, and diagrams. The student's time must not be wasted in writing detailed notes of the facts recorded in his textbooks. The lecturer and the students can then devote themselves to the proper purpose of the lecture, which is to act as a guide and stimulus.

In preparing the lecture, attention must be given to its proper timing and length. Special care should be devoted to the introduction, which creates an atmosphere and which should explain the lecturer's aim. The theme should then be developed rationally on the basis of prior knowledge. Spoon-feeding must be avoided and is unnecessary if the student is properly directed in the use of his textbooks. In any event he is not a mere receptacle for the storage of information nor is the lecture solely a medium for its transmission. The need for reiteration ("repetitio est mater studiorum"), and for emphasizing what are important principles and what minor details, should be appreciated. The apt illustration from personal experience impresses itself on the student's memory. References to the literature will encourage and direct the student in his further studies. For classifications and diagrams the blackboard is as a rule the best medium of visual instruction, for the able teacher can show them expanding from the broader generalizations to smaller details. Lantern slides, the epidiascope, and filmstrips have their place in the lecture—for example, in demonstrating morbid anatomy and histology, the variations in the clinical pictures of disease, graphs, and statistics. Radiographs and pathological specimens should also be available for purposes of illustration in the systematic lecture.

The place of films in systematic instruction has been widely debated. There is general agreement that their novelty and superficial attraction has led to their over-use. The films recording many surgical operations reveal less than do a few simple line drawings. But where the emphasis is on movement they are valuable. They can be used, for example, to illustrate abnormal gaits and involuntary movements, the expansile pulsation of an aneurysm as shown by the "match sign," the dramatic effect of blowing out a candle with the air escaping from a needle inserted into an area of extensive surgical emphysema; or as records of a series of cases—for example, of cranial nerve palsies—not readily available when needed for demonstration. The film is not, however, an adequate substitute for the living patient. Another use of films is to show technical methods, such as ventriculography, with which the student should have an acquaintance, and in which the procedure which takes a considerable time can be shortened to illustrate its essential features. A third use of films in lectures is to provide animated diagrams; these are especially useful in showing, for example, the relation of the spread of the cardiac impulse to changes in the E.C.G. or in demonstrating labyrinthine reactions.

The fewer notes the lecturer uses the better. The reading of a lecture is usually uninspiring, and the student may pointedly ask, If the lecturer has not learnt the subject, why should I? But no attempt should be made to memorize the lecture verbatim, for this will defeat one of its most vital purposes. The lecturer should always be sensitive to the reactions of his class, especially to those he has not foreseen, and he must modify his lecture accordingly by repetition, emphasis, and recasting. Although the importance of this must be recognized, there is still a place in the training of the inexperienced teacher for "shadow teaching"—rehearsing the lecture without his class.

Lecture-demonstrations

Much of the foregoing applies to lecture-demonstrations, especially to clinical lectures of the old type (and the young teacher would be well advised to read those of the masters—for example, Trousseau, Graves, Charcot, Gowers, and others, not so much for their content as for their form). The clinical lecture should be a complete and orderly presentation of a special topic or a carefully prepared clinical demonstration of a patient or group of patients illustrating a particular theme. There is, however, another useful type of lecture-demonstration in which both pathologist and physician can fruitfully collaborate. In this a particular topic is chosen, such as cerebral tumour; the pathologist and clinician expound their special aspects and then question each other before the class to illustrate how certain symptoms and signs are produced and what is their pathological basis. The scheme can be widened to include the radiologist, the clinical pathologist, and other specialists.

Ward Work

The main purpose of work in the wards is, to use Professor Lauwerys' phrases, "to stimulate purposive mental activity and to individualize instruction," and also to introduce the student to those personal relationships essential to the eliciting of accurate histories, conducting physical examinations, and the handling of human material. To these ends are directed his term of clerking, ward classes and tutorials, and ward rounds. The wards should be open to the student whenever practicable so that he may have the opportunity of studying and observing the patients assigned to him at any time and throughout the course of their illness. Clerking should be a modified apprenticeship,

and the student should be encouraged to believe that under proper guidance he is responsible for the patient. He should accompany the patient to the various diagnostic departments and see the specialists at work. The period of clerking is in medical education most analogous to the Dalton plan in general education, and gives the opportunity to the tutor to instruct the student on his individual problem. Ward classes and tutorials must be regarded as complementary to, and not a substitute for, clerking. The class must always be small (not more than 10 to 12 students to each tutor), and each member of the group should be at the same stage of study; mixed classes of senior and junior students are educationally indefensible. The tutor should plan but not overplan the work of the individual clerks. These classes serve to throw light not only on the work of the student but also reveal to the senior teachers the calibre of the tutors. In the ward classes the Socratic method is to be encouraged, and in them the student must take an active part. They must, therefore, be neither too formal nor too discursive. "It is not seeing much but seeing wisely that is valuable" (Osler).

I have earlier stressed that the ward round by the senior clinical teachers must aim at being appropriate to the stage which the student has reached in his clinical studies. The wrong way of conducting a ward round was graphically described in the B.M.A. report on *The Training of the Doctor*: "The chief, attended by his satellites, and followed by a throng of leg-weary students, moves from bed to bed, down the ward, briefly demonstrates case after case himself, and delivers unprepared discourses (however wise) on the patients or their diseases." The duty of the chief is to reveal in his teaching a wisdom and judgment which the junior teacher cannot from his lack of experience possess, and he should aim at presenting a synoptic view and stressing the importance of fundamentals, for there is a real danger that the tutor, having recently studied for his higher examinations, will be a little prone to exhibit his mastery over advanced medicine, and to over-stress detail. Moreover, the senior teacher should as part of his ward round take the opportunity of interviewing not only the patient himself but also his relatives if they can provide useful information, in the presence of the students, and for this purpose a special consulting-room attached to the ward is, in the interests of privacy, most desirable. It is here also that the final interview with the patient should take place after the hospital has completed its service so that the students may hear the chief's discussion with the patient on his condition and treatment; here also the work of the almoner and other social agencies should be brought into the clinical picture. There is one other point which, in my experience, is rarely recognized; it is that a teaching ward round should be primarily directed to teaching. The physician should pay additional visits to the ward in the absence of students so that the required service to the patient may be given. There is then no temptation by the physician to go beyond the students' comprehension on his teaching rounds, and the patients receive all necessary attention; and even those who may not be so suitable for clinical demonstration are ready to co-operate in the work of medical education. I have found that patients with no spectacular physical signs too often feel themselves neglected in the wards of a teaching hospital.

Out-patients

Teaching in out-patients should come at a later stage when the student is familiar with the commoner expressions of disease. The teacher must here take the opportunity of stressing the earlier, less severe, and more reversible manifestations of illness, and he must emphasize that in out-patients is seen a cross-section of disease which more closely reflects that met with in general practice. The opportunity for seeing emergencies and minor accidents, especially in urban and industrial areas, should be taken. In teaching hospitals where out-patients are essentially consultative, the physician should stress the technique of consultation. It is here that he can show how to tackle the patient seen for the first time, how to put the patient at his ease, how to extract and assess the salient points in the history, how to pick out the essential features on physical examination and to decide what investigations might reveal the nature of the patient's complaint and so lead to rational management without the need for admission to hospital. But if admission is necessary then the teacher should ensure that there is continuity of teaching from out-patients to wards. For the senior students out-patients provide the opportunity for practical exercises in diagnosis. The provision of single rooms in which a student can examine a patient and then discuss his findings and conclusions with his teacher should be an essential feature of all teaching hospital out-patient departments. There are, of course, difficulties. The number of out-patients and the appointments system have led to a prior selection of cases which is educationally often disadvantageous. In out-patients, too, the opportunity should be made by the teacher to illustrate the course of disease and the effects of treatment by paying particular attention to the work of his follow-up clinics; and here again the precepts of social medicine should be stressed.

Conferences and Discussion Classes

In the wards and in out-patients the dominant emphasis is laid on accurate, thorough, and unbiased observation, and in this I include the taking of accurate histories, for history is essentially observation in time. Simple inferences in terms of structure and function and, as the student's knowledge increases, in pathology, aetiology, therapeutics, prognosis, etc., will be made. But in conferences and discussion classes the educational emphasis is on the rational inference, for in most instances observations will have been recorded and completed. Hence clinico-pathological and clinico-therapeutic conferences have most to give to the senior student, but conferences at the bedside in which clinicians and specialists take part are most valuable at all stages of the clinical course provided that the teachers modify appropriately their teaching. The discussion class in which such problems as pituitary disorders, disturbances of carbohydrate metabolism, malignant disease, etc. (the "projects" referred to by Professor Lauwerys), which may be suggested by the teacher or by members of the class, and in which by question and answer the student may be encouraged to develop a theme and after preliminary discussion be referred to patients, case records, the relevant literature, etc., and at a later session be asked to expound, demonstrate, and review, is for the best students a most valuable experience; but the less able tend to shrink from the publicity which this type of class entails, and we are still far from having convinced our students that to expose their ignorance is educationally sound.

Seeing the Teacher at Work

A valuable educational instrument for the advanced student is provided by the following type of demonstration. A patient who has been fully investigated and in whom a diagnosis has been established by a colleague is presented to the teacher, who has not previously seen the patient but who in the presence of a senior class takes the history and examines the patient; he then discusses the diagnostic problem presented and might venture on the relative probability of various diagnoses. After this he specifies the investigations which could serve to confirm his provisional diagnosis or clarify the problems of differentiation. He may, for example, examine *x*-ray films or take note of blood and marrow reports; he will then express his considered views, in the light of his examination and the investigations, on the diagnosis. Those who have seen this kind of class at work describe it as a vivid and memorable experience. As an illustration of method in observation and inference and their importance for clinical studies it can hardly be bettered, and it has on the teacher a sobering influence however well developed may be his *prima donna* instinct.

There is as yet too little experience on which to form a judgment on the place in which training in general practice or in a health centre is for the undergraduate a fruitful addition to our methods of medical teaching.

I have not attempted a systematic or exhaustive thesis on medical pedagogy. I concur wholly in the views expressed by other contributors to this discussion, about the need for the novitiate in medical teaching to know something of general educational principles and of the psychological factors involved in learning, and to be aware of the scope, uses, and potentialities of the various aids to teaching and of the educational techniques which their use involves; of the value in learning the art of teaching of observing the technique and methods of the most successful teachers, and of discussing his problems with them and seeking their criticism. I have, however, been impressed with the fact that most successful teachers have developed methods of teaching which are suitable to their own personalities and which cannot be fitted into a particular pattern, and that "in the long run systems of education stand or fall by virtue of effort and ideas, not machinery."

The Social Psychotherapy Centre which was recently opened at 7, Fellows Road, Hampstead, has held its first "view day," when groups of interested people—psychiatrists and social workers—were shown round the departments. The activities include art and occupational therapy, therapeutic social clubs, individual treatments, physical treatment in suitable cases, child guidance for those under 7 and those from 7 to 16, and remedial teaching. It is in fact a "day hospital," the patients to the number of a score or more attending at all times from 9 a.m. to 10 p.m. They sleep at home if the home environment is suitable, and if it is not an endeavour is made to find them suitable lodgings. Thus they retain touch with their ordinary environment, and their time at the centre is so fully occupied that they forget their own condition. Patients are also admitted who have been in a mental hospital and are in need of the rehabilitation which is brought about through social clubs, enabling them to return to ordinary life in the most favourable circumstances. Dr. Joshua Bierer, the medical director of the clinic, explained to the visitors the multidimensional treatment employed. He expressed his thanks to the Central Middlesex Group Hospital Management Committee, under whose auspices the centre is working, for making the experiment possible. It was really, he said, a very simple experiment. Its most important feature was co-operation, directed towards the encouragement of self-realization and self-fulfilment of the patients. Various schools of psychiatry were represented on the staff, but staff and outside friends and former patients all worked together in the effort to help the maladjusted and to give each patient the individual attention that he needed. The centre depended largely upon the group idea for its results. The patients at first tended to remain solitary, and then they discovered a group whose feelings they could share and the way was open for normal social life.

THE TRAINING OF CLINICAL TEACHERS*

BY

R. D. LAWRENCE, M.D., F.R.C.P.
Physician, King's College Hospital

This subject is very difficult and ploughs nearly virgin soil. So far as I know, no discussion has taken place directly on this question and little writing has been done. True, for years, and especially in current post-war years, voluminous publications have dealt with the curriculum and the training of medical students and, recently, of practitioners and the need for change. All this impinges closely on our subject but has not tackled the equally important question of the teachers, their capacity, their choice, their training—so fundamental a matter because on it the full success of medical education must be based. I am glad, therefore, to raise the question before a meeting of the best young brains and the future intellectual leaders of our College. I feel quite humbly inadequate, but shall do my best to stimulate more sense and knowledge than mine.

The argument behind the need for improving teaching and the teachers in medicine is simple and was briefly stated in my short letter in the *British Medical Journal* of September 10, 1949 (p. 594). It drew attention to the training, and criticism, that elementary teachers have, not only in the matter to be taught but in the method of presentation and how to teach. In the teaching of medicine, and perhaps especially clinical medicine and its application to practice, training is entirely lacking, and teaching capacity is not considered profoundly when the staffs of teaching hospitals are chosen. I consider that clinical medicine is, for many reasons, the most difficult of subjects to teach, and that some training in it is of paramount importance. Of course, if you accept the old platitude that teachers are born, not made, there is little to be done about it. But I am sure that the educationists would not agree, and I believe that, though bad teachers cannot be made good ones, moderate ability can be improved, and even the born teacher, too. Certainly, the definition of a good teacher would not be agreed upon; but he must, above all, be personally stimulating and questioning. The conference and the academic lecture need other treatment and qualities than those required of the all-important bedside teacher: the manner, the mode, and the material are quite different.

When I reflect that the material to be taught is vast in its details and ever changing, with all our temporary fixities and ultimates becoming penultimate, and that no clear philosophy of medical thought and teaching has been evolved, I am appalled by the complexity of the subject before us. I think, however, that it is possible, and useful, to regard the whole subject from two main aspects.

Diction and Delivery

The first aspect is relatively easy to deal with but is very important. We have all suffered on too many occasions, from our earliest lectures in physics and chemistry to such occasions as this, from inaudible whispering and mumbling, from humming and hawing, from distracting mannerisms, until our attention died and we relapsed into restless boredom or uncomfortable sleep; suffered, too, from mumbling into blackboard drawings, from boring over-explanations of a simple slide, or from bad and complicated diagrams with no explanation. Perhaps worst of all is the opener of a discussion (I must be careful) who wastes time with his prolixity or those following who take fifteen

*An address opening a discussion by Members of the Royal College of Physicians at Bristol.

minutes instead of three. I need not elaborate. Surely we could all be helped and improved in these venial sins by the elocutionists, the educationists, and the friendly criticism of our peers, especially at an early and malleable stage.

Mental Processes of Thought in Medical Teaching and Diagnosis

This second aspect is more deeply important and much more difficult, because it raises the unknown profundities of brain functions and capability, thinking habits and processes, and other abstruse matters.

There is no doubt that, innate ability being equal, the trained mind conscious of the processes and methods of thought will go further and truer than the untrained. This applies to all fields of science, philosophy, and perhaps art. It certainly applies to medicine, but so far as my reading goes I have not been able to find any profound and detailed exposition or analysis of the mental process and principles underlying medical practice and teaching. Many of the best minds in medicine have been aware of the lacuna, and in the last 25 years several authors have written on it—Crookshank, Ffrench, Capon, Lewis, Cohen, Walshe, being particularly stimulating. But nowhere has been enunciated a logical or philosophical approach to the difficult mental processes involved in making a diagnosis, mental methods to which we can systematically turn in dealing with the difficult and ever-widening problems to which the progress of medical science is continuously adding. Hence a well-ordered and wide-viewing mind is more necessary than ever, but its conscious production is entirely omitted in the training of the student and hence those who become teachers.

The mental background of the disciples of medicine has probably deteriorated in the last 50 years, for our forerunners were widely trained in the classics and the arts, and often in logic and philosophy. There is thus a big cultural gap which must be filled in the training of our students and still more of their teachers: some logic, philosophy, psychology of teaching processes, would help to develop and sharpen the mental acuteness and awareness which we need so badly to increase our capacity and diminish our errors.

I think that medical diagnosis, the application of a vast and expanding body of factual knowledge with no fixed ultimates to the problem of one sick person, is often supremely difficult. What makes our problems still more difficult is that we must usually work and make *rapid decisions* on partial ignorance and imperfect knowledge of disease. Philosophers and religionists can consider their arguments at leisure, and they have no immediate new decisions to make. The lawyer acts on social history and precedents. The man who applies the momentary stabilities of physics and chemistry to material ends has his fundamentals to build on. Patients who work with more inert matter than ours, such as engineers and architects, are often impatient with our ignorance of fundamentals and our incertitude about disease and diagnosis. We can remind them that man did not make the human body nor doctors invent disease—and, if necessary, that disorders even in our man-made motors often defy diagnosis.

The Process of Diagnosis

I propose now to touch on diagnosis and mental processes, more to raise questions than to solve them. The main object of medical education is to train doctors for their life-work in treating—preventing, curing, or alleviating—disease. The first step is the identification of the body disorder we have to deal with—what we call the *diagnosis* of the *disease*. The importance of diagnosis as the be-all and end-all in medicine has been stressed perhaps *ad nauseam*, and, while the word should really mean a thorough knowledge of the disease process and the body's reaction to it, it is commonly used to mean giving a name to the disorder to fit it into a suitable pigeon-hole in the vast system of nomenclature of disease. No doubt names must be given, but they have the drawback that the name may suggest an unreal entity by no means corresponding to all the facts of the case, and may close the mind to an appreciation of all the facts—the danger of undue nominalism.

The process of diagnosis involves two main steps—(1) the collection of facts, symptoms, and signs, and (2) their collation, interpretation, and meaning—and the teacher who does not separate these aspects can never teach well or practise at the highest mental level of efficiency.

The first of these steps is the easier, and the student is well taught in the collection of data, but in his first clinical year he is pitched too unguided into a new and bewildering world. He has, or should have, a sound glass-case background of the normal functioning and pathological processes of the body, but cannot relate these to the multitude of signs and symptoms and diseases of the patients he meets. It is at this stage, before his memory becomes overpacked with the names and nature of diseases and syndromes, that his mind is most malleable, most ready to feel the need for, and to accept, a co-ordinating system of thought to apply to and put in order the mass of new material. But I believe it is rare that his teachers, however well they instil the techniques of observation and examination, impart a clarifying and unifying system of critical thought, because they have no wide system of their own or are not conscious of it.

The second step—the collation and interpretation of these facts, the making of a diagnosis—is much more difficult and the process hard to analyse and describe, but let me attempt to probe into the mental processes of an expert clinician. By the time a careful history is taken he has already and inevitably formed a primary concept—a first idea of the case—a provisional diagnosis. He must then, by more questions or examinations, search for further evidence which his experience of disease shows is needed to support or refute his first idea. Backwards and forwards he goes from induction to deduction, from general laws, patterns, syndromes of disease he knows, down to the particular problem of the moment and the facts he has found. At any moment his clinical instinct (I prefer to call it intuitive experience) may make a "snap" diagnosis to his own satisfaction and the admiration of students. Such diagnoses are often right, but frequently they are wrong, and if not subjected to further critical analysis have the worst possible effect. The student with limited knowledge cannot see or appreciate such a mental process, which is the exact opposite of the reasoned approach he should be taught.

It seems to me that the detection of disease processes is one of the most difficult of mental exercises; the constant questions of where, what, and why have to be solved positively or negatively, and acted on immediately, as action in treating the patient cannot wait. The detective problems of criminology are relatively simple. Here, in contrast, the question "where and what?" is usually answered by the presence of a corpse and only "why and who?" remains, although I admit the latter question does not bother us in medicine. Fortunately these mental exercises, though hard, are fascinating and natural to the human brain, one of whose innate characteristic needs is to search for an explanation, a logical sequence or pattern of events in

everything. The natural and eternal "why" in human cerebration is seen at all ages, from the simple puzzles of the juvenile to the more complicated problems of the philosopher and doctor—a theory which I have elaborated in a little book (Lawrence, 1947). So if we are mentally alive at all, diagnosis is fun.

Need for a Systematized Method

Now let me stress from another aspect the necessity for acquiring a systematized method of thought in practising and teaching, a defence against the overwhelming difficulties of detailed knowledge, ever expanding. And these details are necessary—detailed knowledge and techniques—for the best treatment of our patients. How is the detailed specialist, in his necessary learning of "more and more about less and less," to retain sufficient knowledge of the "more" and wider aspects to avoid the calamities often arising from narrow specialisms? And how is the hurried practitioner, overwhelmed by superhuman details of all kinds, to be able to retain a balanced sanity by which he can bring to bear on the problem of the moment what wide knowledge he has learned? No doubt the medical curriculum must be changed and be pruned of its impossible burden on pure memory, but it is equally important that the student should acquire a definite basic mental process of thought as a stand-by for ever. This is difficult to evolve on paper, to elucidate in words, to inculcate to many illogical and unreceptive minds, but we must, in order to avoid incompetence, try to retain interest and to continue to progress.

There has been a tendency in certain quarters to suggest a partial division in medical education into two aspects: the first, theoretical or intellectually educative, to be mainly the concern of academic whole-time intellectual highbrows and research workers; the second, the vocational or technical, the concern mainly of part-time clinical practitioners of clinical medicine. Nothing, I think, could be more unreal or disastrous. Both aspects must be welded into a sound fundamental training from which all later activities must constantly stem.

Medicine: Art or Science?

So far I have not touched on the vexed question of the art and/or science of medicine, because to me medicine ought to be a science, and the former word mainly implies a humane and kindly consideration of our patients, an appreciation of their fears, their family ties, their social difficulties. Without the appropriate pat on the shoulder and the well-considered and blessed "white lie" no one can be fully either a good or a successful doctor. Can we teach the art of medicine? Probably only by kindly example. I find it useful, in emphasizing the human side, to ask the student, "If this were your father or mother, your brother or sister, how would you handle the situation and what would you do?" But I think the students, and we teachers in hospitals, too, are apt to neglect the social life and conditions of our patients and could be helped by the house-to-house and day-to-day experience and guidance of a wise and humane practitioner in our midst.

A Diagnostic System

And now may I give you, as an example, the defensive mental mechanism I have produced for my own use to safeguard myself against narrow specialism and to marshal the knowledge I may have vicariously absorbed, but which all too frequently lies latent and intangible—as I have a poor memory? Perhaps it is more an aid to memory than a scheme of thought. It is an attempt to recall always the where, what, and why of medicine in a simpler way than the "systems of nomenclature." I have put the aetiological "why" first, as it repeats itself constantly in relation to the "where and what."

Causal Agents (Why?)

I. *Physical and Mechanical.*—External: Trauma, heat, cold, radiations, habitat and environment, etc. Internal: Developmental, stones, obstructions, etc.
II. *Chemical.*—Poisons and drugs, inorganic and organic.
III. *Living Agents* (Biology).—Viruses: exanthemata, etc. Organisms: cocci, bacteria, etc. Multicellular: parasites, etc. ? New growths: benign and malignant.
IV. *Resulting Degenerations and Regenerations.*—Fibrosis, etc.

System Diseases and Syndromes (Where and What?)

Cardiovascular and blood and lymph. Respiratory. Alimentary. Urogenital.
Locomotion.—Bones and muscles. Skin and special senses: position obvious.
Nutrition.—Metabolism, chemical and vitamin disorders. Endocrines.
Nervous system.—Autonomic; central nervous system; psychosomatic ("functional").

There is nothing particularly original in this scheme except perhaps the arrangement of aetiological factors in the order of the subjects which we learn in the medical course. No doubt others will evolve different and better schemes to suit their own experience, needs, and individuality. No doubt, too, every specialist must evolve a more detailed sub-branch to cope with his own subject. But I have found the above of great value as an aid to memory to marshal and call to mind facts I really know but might not recall at the moment of need. If all students could acquire and be habituated to use some such scheme they would be equipped with something far more useful than the widest mass of detail that the best memory can hold.

Some Suggestions

You may think I have not said anything directly practical about the training of clinical teachers and that I have so far done little except air a few general principles for further discussion. Some others have written on and discussed the matters I have reiterated, and an address of Professor Capon's (1945) has covered the whole field. There is wide agreement that clinical medicine is supremely hard to teach, that the teachers are not trained, and that consequently their efficiency and their students suffer. I suggest that the following steps should be taken.

A special course on medical teaching must be established by concerted effort. This would be for the registrar grade; also for some junior and perhaps some senior consultants—perhaps even for some students. The teachers present a more difficult problem, but no doubt there would be some interested and capable people available from the medical profession; and it should be easy to find teachers of elocution, lecturers on logic, psychology, perhaps philosophy, and certainly the principles of education (if there are any!). In the first place the course would be short—perhaps a half-day for four weeks would suffice. It would be experimental—extremely so. If, in the first place, it only managed to improve the teachers' elocution and delivery it would have done enough to justify its existence. If it managed to inculcate general principles and an awareness of mental processes it would be doubly justified. In the long run I would hope that these teachers, getting together to form some group, might evolve a philosophy of medical teaching and thought, produce a stimulating book on the subject,

tackle the problem of the medical curriculum, and promote the essential rewriting of textbooks. The whole medical world would be stimulated and benefited. I think that, with the new medical system in Britain based as it is on the soundness of the past, it is possible for this country more than any other to start such an experiment and make it a success.

Conclusion

And who is concerned in originating this worth-while move we are discussing? Obviously the Royal Colleges, the Postgraduate Federation, and the universities. I know, too, that many important bodies such as the Rockefeller and Nuffield Foundations and Unesco are interested. But surely out of all these our own College seems pre-eminently suited, as it should be, to serve so uniquely useful a purpose in modern medicine. But what a pity it is that the conception of an Academy of British Medicine died stillborn.

I will finish by quoting some stimulating words from Walshe's (1948) Harveian Oration: "This College can, and, if it is to survive as something significant in the intellectual life of medicine, must remain a fountainhead of academic medicine, or true learning: the home wherein a philosophy of medicine finds a permanent abiding-place and disciples eager to learn and teach it." I hope this meeting will show we are imbued with this spirit, this faith, and this endeavour.

CLINICAL EVALUATION OF EFFECTS OF DRUGS ON MEDICAL STUDENTS AS A TEACHING METHOD

BY

ANDREW WILSON, M.D., Ph.D., F.R.F.P.S.

(From the Department of Pharmacology, University College London)

In the past the medical student often first became acquainted with drugs when faced with the laborious task of trying to write and compound prescriptions to the satisfaction of his teachers. He had little first-hand knowledge of the action of drugs, and the clinical evidence of their effects on patients was often confusing and difficult to interpret. The drugs in use to-day are potent and valuable remedies. It is therefore the responsibility of those who train medical students to ensure, as a prerequisite to safe and effective therapy, a sound knowledge of the principles of pharmacological action.

Numerous experimental methods have been devised to demonstrate the action of drugs on isolated tissues and in the intact animal. Such methods provide the fundamental approach, but the criticism has been made that the student often fails to appreciate the connexion between these effects of drugs and their clinical application. The experimental study of the action of drugs on normal man is a logical step in the process of understanding the effects of drugs in disease. For this reason part of the practical course in pharmacology given to preclinical medical students at University College, London, consists in observing the effects of various drugs administered to members of the class. The experimental methods used and the results obtained in a class of approximately 70 students are described below.

The class was held once a week and lasted approximately five hours. The students worked in pairs, each acting in turn as subject and observer; during the experiment they were housed in cubicles, each cubicle accommodating two pairs of students and one member of staff acting as supervisor. The subjects were all normal healthy male or female medical students. In each experiment the selection of drugs to be studied was at random, and each student drew from a hat a numbered card representing a dose of a particular drug or inert substance the identity of which was not revealed until the experiment was concluded and the observations fully recorded.

Three types of experiment were carried out, in each of which the drugs were administered by a different route, in order to assess the following: (1) the analgesic activity of certain drugs when given subcutaneously; (2) the effects on voluntary sensory-motor co-ordination during inhalation of mixtures of nitrous oxide and oxygen; and (3) the effects of drugs, which were taken by mouth, on the performance of three tasks involving rate of voluntary movement, sensory-motor co-ordination, and sustained attention and muscular control respectively.

1. Assessment of Analgesic Activity

Method

Thirty-five subjects were used for estimating the analgesic potency of the following drugs: morphine, 10 and 15 mg., amidone ("physeptone"), 10 and 15 mg., pethidine, 100 and 150 mg., and physiological saline, 2 ml. Thus each dose of each substance was tested on five students.

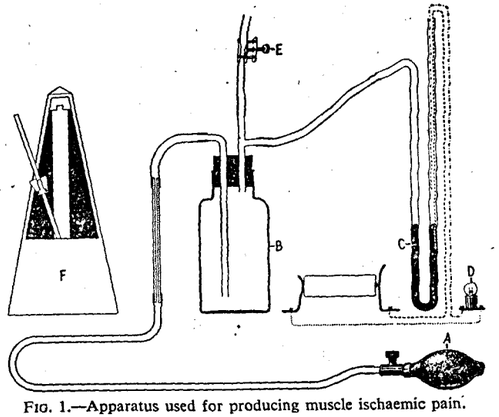

FIG. 1.—Apparatus used for producing muscle ischaemic pain.

The apparatus used to test the effect of these drugs was one that produced the pain of muscle ischaemia of the forearm in a manner resembling that originally described by Lewis, Pickering, and Rothschild (1931) and later modified by Harrison and Bigelow (1943).

The subject lay on a couch and a sphygmomanometer cuff was placed on each upper arm. Muscle ischaemia was produced by inflating the cuff to 160 mm. Hg, and the subject contracted the muscles of the corresponding forearm by squeezing the rubber bulb (A) shown in Fig. 1. The contraction of this bulb forced air into the bottle (B) and thus displaced the mercury in the U-tube (C). When the mercury was displaced sufficiently it completed an electric circuit and lit the lamp (D). To enable the apparatus to be adjusted for subjects with different strengths of grip the resistance to pressure could be modified by means of the variable leak (E) on the T-tube. The frequency of squeezing was determined by a metronome (F) set at 90 beats a minute.

Before each estimation the subject's arm was raised and gently stroked to empty the veins. The cuff was rapidly inflated to 160 mm. Hg and the arm lowered; simultaneously the subject began to squeeze the bulb, in time to the metronome, with enough pressure to light the lamp. The observer noted (1) the time of onset of pain, and (2) the time of onset of "exhaustion," which was determined by the failure of the subject to light the lamp in six consecutive attempts. When the exhaustion point was reached the cuff was deflated and the estimation was repeated on the other arm. The whole procedure was repeated every 15 minutes.

After three or four estimations on each arm the analgesic drug was given subcutaneously and observations were continued at 15-minute intervals for two to three hours. The observer also recorded changes in respiration, pulse rate, and the appearance of the skin; any sensations reported by the subject were also noted.

Results

The typical effects of one of the drugs on an individual subject are shown in Fig. 2. The times of onset of pain and of "exhaustion" were measured in seconds, and a curve for each has been plotted. The first three readings indicate the normal performance; after the drug was injected there was an increasing delay in the onset of pain and a decrease in the time before "exhaustion" occurred.

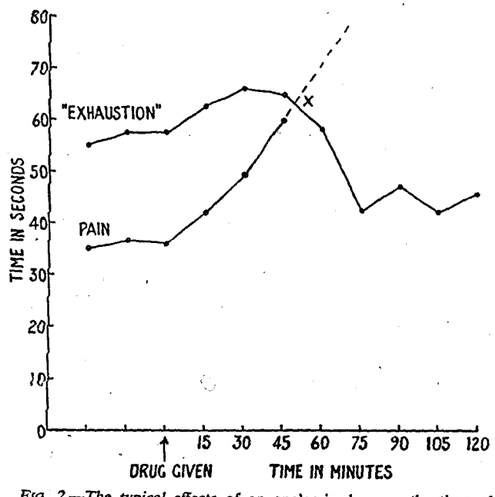

FIG. 2.—The typical effects of an analgesic drug on the time of onset of "exhaustion" and of pain. At about the time indicated by X the subject failed to compress the bulb for long enough to produce pain before the onset of "exhaustion."

This method of assessing pain is limited by the fact that the time of onset of pain cannot be measured when it is preceded by the onset of "exhaustion." For example, at the point X the subject ceased to contract his hand effectively, and useful estimations of the time of onset of pain could not be made unless and until pain occurred again before the onset of "exhaustion."

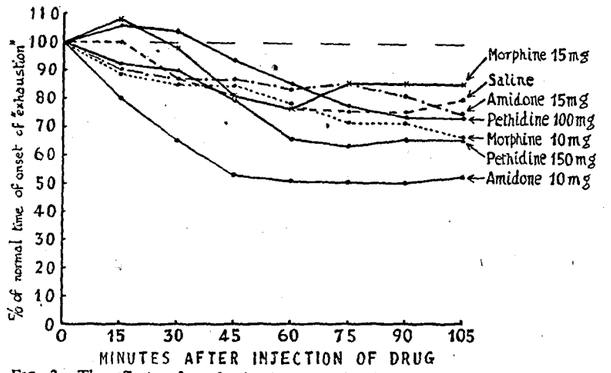

FIG. 3.—The effects of analgesic drugs on the time of onset of "exhaustion." Each curve represents the average results from five subjects.

Average curves (five subjects) of the percentage decrease in time before onset of "exhaustion" with each drug are shown in Fig. 3. In comparison with the relatively slight effect of the other drugs it is surprising to note that with amidone in the smaller dose of 10 mg. "exhaustion" occurred earliest of all.

The difference between the mean values for all "exhaustion" times for saline and amidone, 10 mg., was tested for the "significance of trend differences" (Lindquist, 1947). The F-ratio thus obtained was 2.37 (d.f. $n_1=7$, $n_2=56$, $0.05>P>0.01$). The difference in trend between the two curves is therefore significant. It is evident from inspection of the graph that significant differences are not to be expected in the case of the other drugs. We find it difficult to advance an explanation for this singular effect of 10 mg. of amidone, which was also observed in a previous class. This anomaly might be further investigated.

It was not possible, for the reasons already described, to construct complete average curves of the effect of the analgesic drugs on the time of onset of pain. However, if the drug had no analgesic effect, pain would have been expected to occur well before the onset of exhaustion, as in the case of saline. Since with all drugs except amidone, 10 mg., the onset

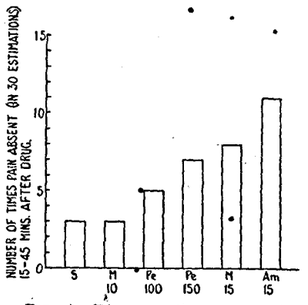

FIG. 4.—Diagrammatic representation of the comparative potencies of the analgesic drugs, assessed by the number of times pain was absent when the subjects were tested during the period 15 to 45 minutes after injection of the drug. S = saline, M = morphine, Pe = pethidine, Am = amidone. The number beneath each drug indicates the dose in mg.

of exhaustion did not differ significantly from that following the injection of saline, it is possible to assess the analgesic effect of the drug in terms of the number of times when pain failed to occur by the time "exhaustion" had set in. A block diagram (Fig. 4) has been constructed on this principle for each dose of each drug, from the results of estimations carried out at 15, 30, and 45 minutes after the injection of the drug. The height of each block may be regarded as an indication of the relative analgesic potency of the different drugs. Our experiments fail to distinguish between the effects of saline and those of 10 mg. of morphine, and the greatest analgesic activity was observed with 15 mg. of morphine and 15 mg. of amidone. Moreover, reference to Fig. 3 suggests that these two drugs in doses of 15 mg. produce the least effect on "exhaustion." In the choice of drug to be used clinically analgesic potency combined with minimum effect on "exhaustion" is obviously a factor to be taken into consideration.

Incidence of Subjective Effects

The numbers of subjects who reported side-effects are shown in Table I. Drowsiness and "muzziness" occurred in nearly three-quarters, and nausea and vomiting in more than half of the group. In one-fifth of the subjects the respiratory rate fell below 15 a minute.

TABLE I.—*Incidence of Subjective Effects in 30 Subjects Given Analgesic Drugs*

Subjective Effects	No. Showing Effects
Drowsiness and muzziness	23 (77%)
Dizziness	22 (73%)
Nausea (without vomiting, 8; with vomiting, 10)	18 (60%)
Sweating, pallor, and flushing	11 (37%)
Dryness of mouth	11 (37%)
Respiration below 15/min.	6 (20%)

With amidone, 15 mg., and morphine, 15 mg., nausea and vomiting, or dizziness, occurred more often than with pethidine, 100 and 150 mg., or amidone, 10 mg. These effects are particularly apt to begin when the subject assumes an upright position at the end of the experiment.

2. Effect of Gas Mixtures on Voluntary Sensory-motor Co-ordination

Method

This experiment was designed to show the effect of different mixtures of nitrous oxide and oxygen on a task involving sensory-motor co-ordination.

The gas mixtures were measured by rotameter type flowmeters (estimated accuracy within 2%) and delivered to a large reservoir bag of 3½ gallons (15.9 litres) capacity which was connected to an R.A.F. oxygen mask. This type of mask incorporates a small microphone by means of which the subject can communicate with the experimenter. All gas mixtures delivered to the mask were perfumed by inserting into the circuit a filter paper impregnated with lavender oil.

For the test of sensory-motor co-ordination we used a tubular apparatus with a hole at the top just large enough to admit small steel ball-bearings, which were inserted with a pair of forceps. (This apparatus resembles the R-V manual dexterity test developed by the National Institute of Industrial Psychology.) The subject's performance was measured by the average time taken to insert 25 ball-bearings.

Every subject first practised the task in sets, each of which consisted of four consecutive trials, until his performance did not improve further; this usually involved four to five sets. The average score of the last set was then taken as the subject's normal performance and was compared with his performance while inhaling the gas. The normal performance ranged from 41 to 56 seconds, the average being about 50 seconds.

Each subject, according to the card which he drew, was then given 40% nitrous oxide in oxygen, or 50% nitrous oxide in oxygen, or oxygen only. The subjects were told that they would be unable to distinguish between the gas mixtures and the oxygen on the basis of smell or taste.

After inhaling the gas for 1½ minutes at rest, the average performance on four trials of the ball-bearing test was again assessed during continuous inhalation of the gas mixture. Most subjects continued the experiment for six to eight minutes.

After the experiment they were asked to describe subjective effects noted during inhalation; any signs observed by the experimenter were also recorded.

Results

The mean scores on the ball-bearing test are shown in Table II. It will be seen that only a proportion of those subjects who received nitrous oxide mixtures were able to

TABLE II.—*Effect of Gas Mixtures on Ball-bearing Test*

	O_2		N_2O 40%		N_2O 50%	
	Before	During	Before	During	Before	During
No. of subjects who attempted experiment	10		10		15	
No. of subjects who completed experiment satisfactorily	10		7		5	
Mean scores (seconds)	49·0	54·9	50·3	76·0	50·8	96·2
Standard deviations of mean scores	±6·4	±7·4	±4·5	±17·7	±3·1	±16·6
Mean % decrease of speed under gas		11		52		89

complete the experiment. Several pulled off the mask; two, whose scores have not been included, completed the test only after continuous prodding and encouragement from the demonstrators; and seven lost consciousness.

The mean scores of the three groups of subjects before inhalation—that is, their normal performances—are practically identical. The mean scores during inhalation of the different gas mixtures all show an increase in the time taken, equivalent to a decrease in speed: 11% with oxygen, 52% with the 40% nitrous oxide mixture, and 89% with the 50% nitrous oxide mixture.

Analysis of variance has been applied to the differences in score of the three groups, and has shown the results to be highly significant ($F=16.2, [n_1=2, n_2=19]$; for $P=0.001$, $F=10.16$—that is, with the given degrees of freedom, one would expect an F-ratio as great or greater than 10.16 to arise less than once in a thousand times.)

The general trend of the quantitative results was very much what one would expect: the higher the dose, the less efficient the performance. The deterioration of performance under oxygen should also be noted. The difference from the normal of 11% may seem small, but it is consistent and statistically significant ($t=4.47$, [d.f.=9], $0.01>P>0.001$). Some of this might be attributable to

discomfort caused by wearing the mask, but it seems likely that psychological factors such as suggestion and expectation were also involved. This was confirmed by some of the reports given by the subjects, and by the fact that occasionally a subject showed quite marked symptoms with oxygen alone. For instance, one student, after inhaling oxygen for one minute, told the demonstrator that he was sure that it was nitrous oxide, and subsequently described his experiences in great detail as "typical nitrous oxide symptoms," such as giggling, talkativeness, difficulty in concentrating, and "twitchings."

The wide range of individual responses, especially under the higher drug concentration, is also noteworthy. One subject, for example, was no more inefficient under 50% nitrous oxide than another who received only oxygen, while, as has already been pointed out, seven others lost consciousness and could not complete the test at all.

Subjective Effects

The most commonly reported subjective effect was a general "muzziness," variously described as feeling vague, dreamy, or "being distant." One subject reported, "I've just had the most frightening dream about relativity I have ever had." Sporadic chuckling was quite frequent, though it decreased noticeably when no appreciative audience was present. Pleasant symptoms were often indicated by comments such as "Enjoyed the experience," "Was sorry to take the mask off," or "Nice giggly feeling." Several subjects described changes in time sense, asserting that time during inhalation seemed to drag and a few minutes appeared like several hours. One subject under 40% nitrous oxide persisted in dropping imaginary ball-bearings into the apparatus long after the experiment was over. These various symptoms, however, were usually of short duration.

3. Effects of Other Drugs which Stimulate or Depress the Central Nervous System

Methods

This experiment consisted of three types of tests, which were used to demonstrate the effects of drugs which stimulate or depress the central nervous system. The drugs were given by mouth and were selected as previously described, so that five students each received one of the following: amphetamine sulphate, 15 or 25 mg.; "seconal," 3 or 4½ gr. (0.2 or 0.3 g.); cyclobarbitone, 3 or 4½ gr.; tablets or capsules of lactose as control.

The tests used were: (*a*) The ball-bearing test (already described). (*b*) The tapping test, which was used to measure the speed and consistency of voluntary motor movement. The apparatus consisted of a morse key connected to an electric numeral counter, and the performances were scored as the number of taps which were recorded during a standard period of continuous tapping for three minutes. (*c*) A disk-dotting machine of the McDougall–Schuster type was used to test sustained voluntary attention and muscular control (Smith, Culpin, and Farmer, 1927). The performance was scored as the total number of dots aimed at and hit before five consecutive misses were recorded.

Two of these tests were chosen by each subject, who practised the tests until consistency in performance was attained, the last score being taken as his normal performance. The drug was then given with a draught of water; the tasks were repeated at intervals of 15 minutes for two to three hours.

Results

Average curves have been plotted showing the effect of several of the drugs on the performance of the tapping test. These are shown in Fig. 5 as the percentage increase

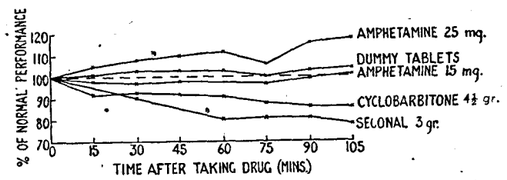

FIG. 5.—The effects on the performance of the tapping test after administration by mouth of amphetamine sulphate, cyclobarbitone, and seconal. Dummy tablets containing lactose were used as controls.

or decrease of normal performance. On the whole the dotting test provided the most sensitive index of the action of the various drugs.

We were unable to obtain sufficient records for statistical analysis of the effects of all the drugs on the three different tests. It was possible, however, to average the maximum responses for two doses of each of the sedative drugs on the tapping test, of which Fig. 6 is a diagrammatic representation. Although this gives no information about the time of onset or of maintenance of the maximum effect, it illustrates to the student one method of assessing the nature of and the quantitative differences in the effect of drugs. It is not intended to suggest that this is an ideal method for testing hypnotic drugs—the best way to do this is by observing their power to produce sleep. This they often did in the course of the experiment, but the conditions in the class were not quiet and consistent enough to make this effect a valid criterion.

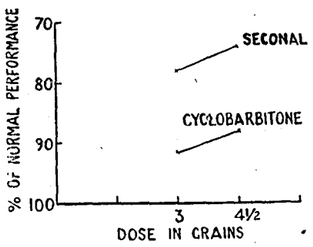

FIG. 6.—Comparative effects of seconal and of cyclobarbitone on the performance of the tapping test. The results are expressed as the maximum percentage decrease in performance for each drug given in doses of 3 and 4½ gr.

Discussion

It might be asked, "What does the medical student learn from this method of teaching pharmacology?" It is well to point out, of course, that these experiments are only part of the practical course in pharmacology and are, moreover, preceded and followed by systematic lectures on the subject, so that the student is able to appreciate the general nature of the action of drugs. We consider that the outstanding advantage of this part of the practical class is that the student experiences at first hand the effects of certain drugs and learns to assess some of the qualitative and quantitative changes produced. By comparing his own experiences with those of the other members of the class, he begins to appreciate the individual variation in response to the

same dose and drug. In addition, different methods of administering drugs are illustrated.

The importance of control observations and the influence of suggestion are illustrated by studying the effects of inert substances. This provides a valuable basis for the appreciation of the function of the "placebo" in therapeutic practice. The undesirable side-effects of drugs are also demonstrated, and the student learns that these effects must be taken into consideration in the choice of a drug for a particular purpose.

On the whole there was little disturbance of the normal routine of the student; the overall incidence of subjective effects in the class is shown in Table III. With the exception of five students, all the members of the class were

TABLE III.—*Total Incidence of Subjective Effects in 70* Subjects Performing Experiments 1 and 3*

Subjective Effects	No. Showing Effects
Nausea (without vomiting, 8; with vomiting, 13) ..	21 (30%)
Dizziness	33 (47%)
Other minor symptoms	39 (56%)
Sleep the following night:	
Sounder than usual	20 (29%)
Less sound than usual	13 (18%)
Same as usual	37 (53%)
Spent night in hospital	5 (7%)

* This number includes 11 who received dummy tablets or saline injections.

conducted safely and without incident to their home or lodgings by one or more persons not under the influence of any drug. Because of persistent vomiting or dizziness, or because the journey home involved a long period of travel, five students were accommodated overnight in hospital. For them it was an interesting experience, and they had all fully recovered by the next morning. There was little disturbance of sleep, except with those who had taken amphetamine, and this also served to illustrate the action of that drug.

Although it was clearly understood that attendance at the class was optional, all students eagerly participated and co-operated well in the arrangements necessary for the conduct of the experiments. Indeed, many of them welcomed the opportunity later of acting as subjects in further research on the action of drugs on man.

According to *Time* magazine Dr. Willard Cole Rappleye, dean of the faculty of medicine at Columbia University, is reported to have said recently: "Medicine is becoming a social as well as a biological science. We would rather have a student with intellect . . . and a rounded capacity for life than one whose only view of humanity was gained as he passed from one laboratory to another. So-called 'premedical' education should be abolished in the colleges. . . . There is no such thing as 'premedical' education nor should students in colleges who plan to enter professional schools be regarded as premedical or predental students. [College] education is not 'pre' anything, but should be devoted to the objective of providing as broad a cultural education as the institution can provide. It should be a preparation not for medicine or dentistry or public health, but for life."

SOME MECHANICAL AIDS TO INSTRUCTION

BY

ROBERT OLLERENSHAW, B.M., D.M.R.D., F.I.B.P., F.R.P.S.

AND

PETER HANSELL, M.R.C.S., F.I.B.P., F.R.P.S.

(From the Departments of Medical Photography, Manchester Royal Infirmary and Westminster Hospital)

Over the last two decades there has been a very marked shift of emphasis in instructional method from the aural to the visual. The two are, of course, complementary and neither can readily stand alone, but perhaps one of the greatest positive experiences emerging from the war was the wide realization of the great efficiency of the eye compared with the ear as a receptor of instruction. The Army Bureau of Current Affairs (ABCA) succinctly modernized the old Chinese proverb "One picture is worth a thousand words" to "One in the eye is worth two on the ear."

The newer methods of teaching are undoubtedly of very great value. Yet they often run the risk of being "oversold" by their enthusiastic backers and of falling into disrepute for failing to do what they were never meant to do. They are "aids" to instruction, not instruction in themselves; they must never be used as a form of escape for the lazy teacher. To use these mechanical methods correctly requires more, not less, effort than the preparation of a lecture of the traditional type.

School-teachers have been quick to realize the value of the new methods, and many of the more enlightened local education authorities have set aside substantial resources to provide the material; to date most medical schools have lagged sadly, and the few that are progressing are often more impeded than helped by ill-informed enthusiasm. There is a widespread tendency to say, "Let's make a film of this, or a filmstrip of that," without consideration of the limitations or suitability of the media, or without proper understanding of the audience for which the

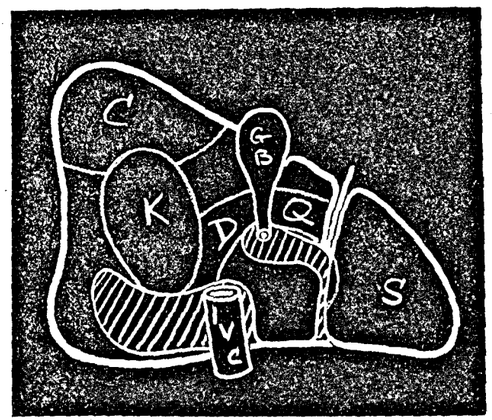

FIG. 1.—The simple type of drawing suited to the chalkboard.

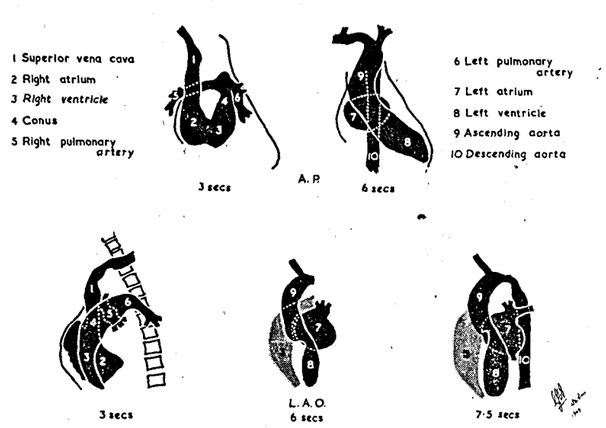

FIG. 2.—The wall chart is usually more detailed than the chalkboard drawing, but must still retain clarity.

material is to be produced. Medical-school budgets are not elastic, and their resources must be directed to the greatest good of the greatest number.

The present article is a précis only, describing mechanical aids to instruction as they now exist and designed for the teacher who is to use them; it sets out to summarize their capabilities and their limitations.

The Blackboard

Better called the *chalkboard*, for it is easier to see when the board is blue and the chalk yellow. This is the simplest and yet the most abused class-room accessory (Fig. 1). A technique must be acquired and teachers must avoid overcrowding and poor legibility. The surface requires, but rarely receives, regular maintenance, and the local illumination should be high. It is possible to project a partially completed diagram on to a well-cleaned board, finishing it in chalk during the class, with consequent saving of time. To meet the request for a board which can be used in a darkened room at the same time as a projector, experiments are being made with ultra-violet light and fluorescent chalks.

The Wall Chart

Not unlike a permanent blackboard, the wall chart can be prepared in greater detail, as this is done in advance (Fig. 2). As with the blackboard, overfilling should be avoided, and the maximum use may be made of symbols on the lines of the familiar "isotype." To leave several charts exposed during the whole of a class is merely to distract the attention of the audience, and arrangements should be made for a chart not in actual use to be covered or rolled. In the preparation of instructional charts much can be gained from a study of the best class of advertising, though it should be remembered that a wall chart is for study and a poster is for instant reaction.

Models

The use of models is rather restricted in medicine, except in association with museum display (Fig. 3). The modern plastics have opened up a new field in the presentation of anatomical material, and for the more elementary forms of instruction plastic bones and viscera are more robust than the earlier plaster casts (*B.M.J.*, 1950). Serial scale reproductions of histological sections, cut in plastic sheet and cemented together, provide striking three-dimensional reconstructions in such fields as embryology. If a model is to be used in the lecture theatre it must be big enough for all to see, and great care is needed to light it to advantage.

The Epidiascope

There are two main methods of projection of material on to a screen. The image of an opaque original may be transferred to the screen by intense reflected light in an *episcope*, or a transparent original, the more familiar lantern slide, may be lit by transmitted light and projected on to the screen in a *diascope*. The *epidiascope*, most commonly seen in lecture theatres, is a double instrument designed to fulfil either of these functions at choice (Fig. 4).

Opaque projection can never make efficient use of the available light, for reflection never approaches 100%, but in spite of this the episcope offers certain advantages. Material from books or existing photographs may be employed, and subject to a limitation on depth of about 2 cm. it is possible to project solid objects such as instruments. The field size varies slightly with the maker, but

FIG. 3.—Model in conjunction with other exhibits.

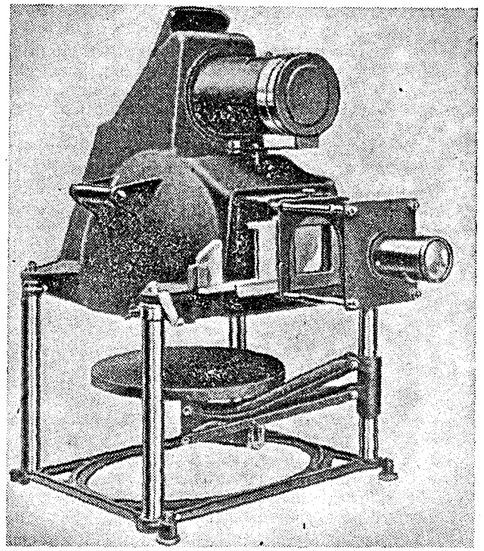

FIG. 4.—A modern epidiascope.

in general the effective area of the original may be taken as a 6-in. (15-cm.) square. This area should be *filled* if the projected image is to fill the screen, and much episcopic projection fails because of the selection of too small an original; few books, in fact, have figures of adequate size, nor is it possible to change the pages of a book without much distracting "fiddling," all of which is thrown on the screen. It is therefore desirable to have material of more than ephemeral value mounted on standard 8-in. (20-cm.) cards, or a series may be mounted on a fan-fold strip for ease in storage or filing. It will be seen that the proper use of this instrument involves rather more than merely picking a book off the shelf and marking the page. Because of the greater contrast, the episcope is most effective with line material.

Subilluminators

Certain epidiascopes have provision for lighting the platform from below. This enables the full area to be used for large transparencies—e.g., an 8½ by 6½-in. (21.5 by 16.5-cm.) radiograph or the larger sizes of colour transparency. A warning is, however, necessary regarding the density of the diagnostic radiograph, which is rarely seen to advantage by this method. A special instrument accepting 17 by 14-in. (43 by 35.5-cm.) radiographs has been described (Dillon and Murphy, 1949); but on this the smaller sizes of film will not fill the screen, and there seems little advantage, as the preparation of a reduced transparency is not unduly difficult.

An instrument of perhaps greater possibilities has been marketed recently. In this the subilluminator throws its light through a horizontal band of transparent plastic on which the lecturer writes in grease pencil. The image is thrown on the screen as he writes. The use of this on a second screen while slides are thrown on the main screen suggests another possible means of communicating with a class in a darkened projection theatre.

Lantern Slides

The *diascope*, the oldest and best known of the optical aids, needs little introduction, yet, like the blackboard, even the slide is not always used to the best advantage. As stated above, the transparency makes far better use of the available light than does any form of opaque projection, although it generally involves rather more work in its preparation. The common British size is 3¼ in. (8 cm.) square, though organizers of international meetings should not forget that the American slide is 3¼ by 4 in. (8 by 10 cm.) and the Continental sizes are 83 mm. square and 9 by 12 cm. The projector should be equipped with carriers for all these sizes. A more recent introduction is the 2-in. (5-cm.) square slide, which is discussed below (Fig. 5). The marking of the slide to ensure correct positioning in the lantern is now international (British Standard 777: 1947), consisting of a single spot in the lower left corner when the slide is held to be viewed in the hand. The older British system of two spots in the top corners is obsolete and should be discontinued.

One of the most vexed questions is the amount of information which may be included on a single slide. While not going to the extremes of a peripatetic correspondent of the *Lancet* (*Lancet*, 1947), who needed a telescope in the back row, it must be admitted that the obscure overcrowded slide is far too common. The textual slide should bear the same relation to the lecture as the headlines of the evening paper do to the news. It is rarely necessary to throw a mass of figures or a long involved statement on the screen. A few salient words will canalize the audience's attention while the lecturer supplies the verbal detail. Visibility is paramount, and it is not reasonable to assume that the back row of the audience have better vision than 6/6 Snellen. It is easy, by a simple similar triangle relation, to estimate the distance at which a slide should be viewed in the hand in order to produce the impression of its size when projected on a screen of known size.

In general, typescript should be avoided, but where some better form of lettering is not available it may be assumed that only the amount of ordinary typescript which will fit on a postcard will be legible on the screen. Furthermore, typescript for reproduction must be perfect, and be preferably done through a new carbon without a ribbon, after

FIG. 5.—The two British standards of lantern slides (showing correct spotting) and an emergency carrier for 2-in. slides in a 3¼-in. projector.

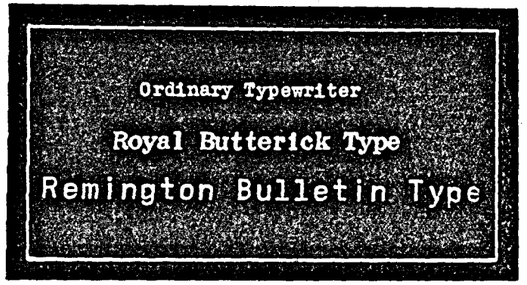

FIG. 6.—Special typewriter faces—showing the advantage of a clear image on an opaque ground.

cleaning the type. Certain bold-type machines are available and are of value (Fig. 6). It is the boldness rather than the size of the type which tells. Script is always more legible when projected as a white image on a black field than in the more usual black on white, as the glare is lessened; this has the additional advantage that selected words or lines may be washed in easily with transparent colour.

While discussing clarity it may not be inopportune to stress the need for regular cleaning and maintenance of both projectors and screens.

The 3¼-in. slide is firmly entrenched in British teaching, and it will not easily be replaced, if only because there are very large collections in existence. Furthermore, this size of slide is just big enough to be viewed directly when set up on an illuminator, and can thus be made part of a static display.

The Miniature Projector

Why, then, has the 2-in. slide made its appearance, and what are its advantages? The original demand arose from the provision of 35-mm. colour material for use in cameras of the Leica or Contax type, which produced small transparencies (24 by 36 mm.) requiring projection. These were too small when mounted up for 3¼-in. projectors, and special instruments were produced. From this idea the modern miniature projector (Fig. 7) has evolved as an extremely efficient optical instrument designed not only for the small slide but also for the handling of 35-mm. film in continuous lengths, the filmstrip, while several models can be fitted with a head for medium-power microscopical projection. The 2-in. slide may be mounted in glass in the traditional manner, or it can be satisfactorily preserved as a section of film in a cardboard mask, a method valuable in these days of air travel. It has every virtue of the large slide except the possibility of direct viewing, while it has the enormous advantage of being cheap, light, and virtually unbreakable. And it is an international standard, a point of increasing importance with the post-war resurgence of international conferences.

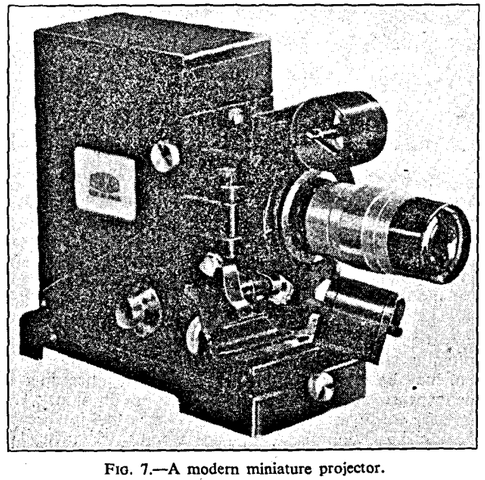

FIG. 7.—A modern miniature projector.

The miniature projector provides a meeting-point between the slide and the filmstrip, a medium generally less well understood. The 35-mm. filmstrip (Fig. 8), a series

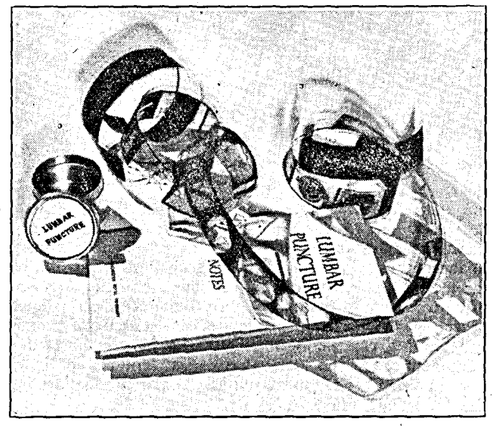

FIG. 8.—A 35-mm. medical filmstrip with its teaching notes and storage can.

of still pictures, with or without captions, is not merely a convenient substitute for a set of slides. Indeed, if that were the case the slides would be more suitable, for their sequence is easily changed. The strip is designed as a coherent whole, and the sequence must be logical and must evolve as a train of thought. The relation is far closer to the motion-picture film than to the slide. For the experimentally minded teacher it is, of course, perfectly simple to have a duplicate of the strip cut up and made into separate 2-in. slides, and if major changes are needed a strip can be reprinted. But essentially it is as complete as a book, and must be as carefully prepared and used.

There is a fairly wide range of filmstrips commercially available, but any teacher with a good illustration department behind him should be in a position to produce his own material. Furthermore, the projector is light and easy to handle, and there is much to be said for a medical school possessing a machine which the staff can borrow when they go afield to lecture to societies. This at least brings independence of the local projectionist, and ensures that the

machine will fit the film. It must not be forgotten, however, that there are still places where the electrical supply is not 230 volts 50 cycles A.C.

The Motion Picture

This is probably the most attractive and certainly the most dangerous of the mechanical aids to instruction (Fig. 9) : in most schools the film has not yet outgrown

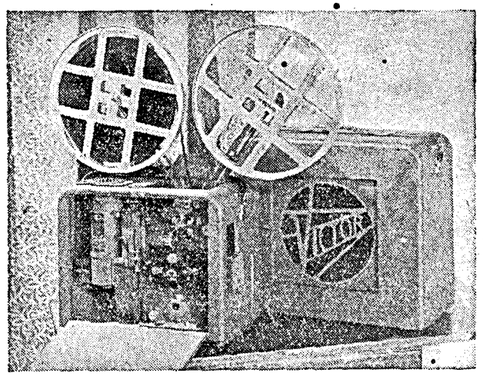

FIG. 9.—A 16-mm. sound film projector with its loudspeaker unit.

the status of an "extra"—a distraction thrown in, but not really part of the instructional sequence. In spite of this there exist many excellent films, due almost entirely to the enthusiasm of individuals ; such films are made by the teacher for his own ends, and because of this they are often parochial in outlook and are therefore rarely shown except by the maker. In view of the amount of money and work expended in making it the film is thus often uneconomical. The real value of the film will begin to be seen when the schools co-ordinate their production and the "prestige" film is no more.

The great need, which can be met with comparative ease within the schools, is for the short factual film which can be used with as little self-consciousness as a lantern-slide or a blackboard. Many simple techniques can be initially taught by film when they involve movement. Where there are, on the other hand, a series of static stages, the filmstrip is the better medium. A repetitive movement, or any cyclical event, is suited to the *film-loop*—a few feet of film joined end to end and allowed to run continuously, repeating the movement as often as required (for example, a kine-radiograph of a joint movement).

The instructional film is almost invariably made on 16-mm. stock, and may be either silent or sound (Fig. 10). Silent film, perforated along both edges, runs at 16 frames a second. Sound film is perforated on one edge only and runs at 24 frames a second. All sound projectors may be set to run at 16 f.p.s., and will project silent film satisfactorily. Silent projectors, having teeth on both sides of the driving sprockets, cannot be used to project sound film, and, moreover, would ruin the film. It is therefore essential to examine a film with great care before projecting it, to determine its type and to ensure that it is correctly wound, in order to avoid this disaster.

Many teachers, using films which they know in great detail, have been accustomed to speak a commentary while the film is run silent. This of course limits use of the film to occasions when the maker is present, and a new development has made it possible to get over this difficulty.

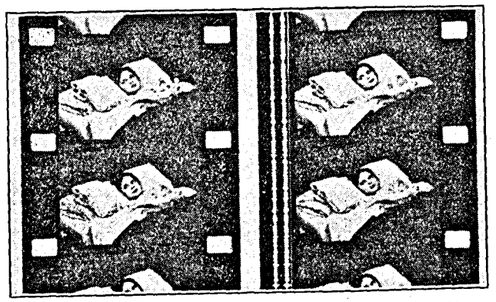

FIG. 10.—16-mm. silent film (double perforated) and sound film (single perforated), showing the sound-track.

Tape and Wire Recorders

In these machines sound is recorded magnetically on a moving tape or wire which can be played back any number of times. Sections can be erased and re-recorded at will.

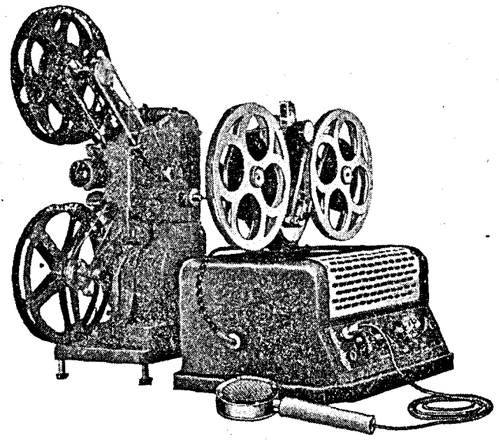

FIG. 11.—A tape recording outfit coupled to a 16-mm. projector.

A modern machine of this type is designed to be coupled to a film projector (Fig. 11) and thus, by simple synchronization marks at the beginning of the tape and the film, it is possible to fit a commentary to a film without the elaborate procedure of recording and placing the sound-track actually on the film. This machine has other uses which may be of value in the medical school. It can record discussions ; a lecturer may practise, and may hear himself (often a chastening experience) ; and commentaries for film may be rehearsed and polished before proceeding to the expense of a final recording session on film. The organizers of international conferences may find in the tape recorder a solution to the language problem when showing films.

Screens

Various types of projector have been mentioned ; it is necessary also briefly to discuss the screen. In most lecture theatres this is a neglected piece of apparatus, dirty and sagging. Yet as much care should be given to its selection as to the projector. The screen surface may be *silvered* (approximating to a mirror and therefore suited only to a long narrow room) ; *glass-beaded* (efficient, but costly and difficult to keep clean) ; or, best of all, a pure *matt white*, sprayed rather than brushed with zinc or titanium white, which does not darken in an industrial atmosphere. The size is a matter of some importance, and must be related to the projection equipment and to the room (Fig. 12).

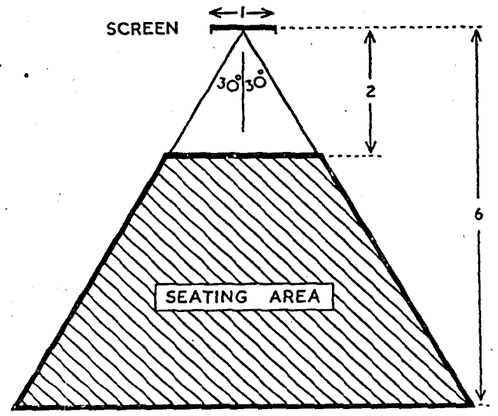

FIG. 12.—The recommended proportions of a projection theatre using a matt white screen.

The picture should not be wider than half the distance from the front row of seats, nor less than one-sixth of the distance from the back row. The frame should be of dead black material, to absorb any "overspill" of the projected picture. In many of the older theatres it will be found that certain side seats are quite unsuitable, as they put the observer at a very oblique angle to the screen. When possible, these seats should be removed. With a matt screen the permissible angle is 30 degrees either side of the projector axis.

Screen brightness is an involved subject, and it is not proposed to discuss absolute levels in foot-lamberts, but a practical test should aim at permitting a level of house-lighting which will allow the student to make essential notes without noticeable degradation of the screen image (*B.M.J. Supplement*, 1950). Where a higher light level is required, the possibility of *rear-projection* on to a well-hooded translucent screen should be considered. Many local education authorities have provided this equipment so that the teacher may have greater control over the class than is possible in a darkened room.

Television

The latest newcomer to the field of instruction is the television camera (*B.M.J.*, 1949 ; *Lancet*, 1950) (Fig. 13), now transmitting colour over closed circuits. It would seem that this is likely to be of value to the postgraduate audience in surgery, but that its applications to medicine beyond this will be rather limited, and its very novelty may make it dangerous—in the same way as the motion picture.

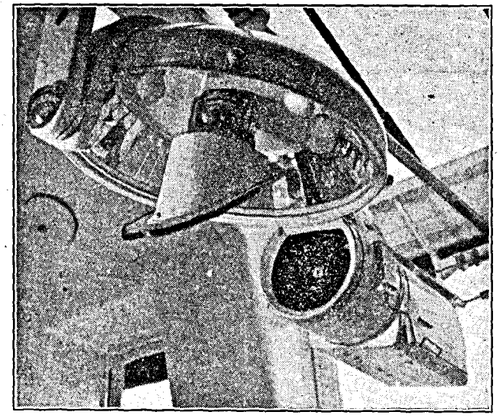

FIG. 13.—Television equipment in an operating theatre at Guy's Hospital.

Certainly television from the operating theatre permits of no cutting or editing, and it may well prove to be merely boring—as so many operations already are to the onlooker.

We acknowledge with gratitude the provision of illustrations by Miss S. Treadgold, Dr. K. D. Keele, Neville Brown and Co., Ltd., Electric and Musical Industries, Ltd., the Pullin Optical Co., Ltd., Scophony-Baird, Ltd., and the Victor Animatograph Corporation, Ltd. Our thanks are also due in no small measure to the staffs of our departments.

A G.P. ON HIS CLINICAL TRAINING

BY

DONALD McI. JOHNSON, M.B., B.Ch.

My opening gambit in this article must be to shift the responsibility for what I have to say to higher authority in the shape of my friend, the Editor. First, in that he asked me to write this account of "what I found both good and bad" in my own hospital education as a preparation for general practice. Secondly, in that, despite my evasive assurances that anything I could possibly say seemed to be covered by those numerous excellent reports that are the feature of these enlightened times, he has insisted on my delving back into those dark ages of 25 years ago when, no doubt in expiation of the sins of some former incarnation, I was for the space of two years and six months a hospital student at one of our older teaching hospitals.

Though I have a natural reluctance to make sweeping remarks, particularly when they are damnatory, in a scientific journal, I have no alternative as regards the hospital part of my education 25 years ago, for I believe it was wholly bad. It had certain minor features that might be described as good, but they did not redeem the whole.

Surgical Training

Let me recall myself, therefore, in January, 1924, as the somewhat unwilling, but not entirely uninterested, student of medicine who, after completing the primary subjects at Cambridge, took up his first hospital student appointment as junior dresser in the Bart's surgery. "Somewhat unwilling," since I had, like many another, had my medical career chosen for me rather than choosing it myself, owing to my being a doctor's son. All the same, I had become interested enough in the primary subjects to obtain the entrance scholarship to Bart's in the previous October.

I was an unusual type perhaps, but not so unusual as all that. The Bart's surgery of that day, on the other hand, did not overcome unwillingness or stimulate interest. The sudden and unprepared jump from the cosy realms of theoretical learning to the harsh realities of human pain and suffering was a mental shock the effect of which persisted for some time to come: certainly it coloured my outlook throughout my hospital years. Every morning for three months I had the experience of seeing and inflicting pain in the Bart's surgery, entirely unaccompanied by any form of teaching. All I learnt during that time was a painful and unsatisfactory method of treating carbuncles, septic fingers, and so on (a method which I quickly taught myself to discard as useless once I was able to acquire experience for myself)—for it was to this offal of surgery that our experience was confined, except on those rare occasions when it was our firm's duty turn and our own personal turn on a roster of some six or eight dressers to see the fresh cases that arrived in the casualty department.

The "teaching" part of our day started when, at 1.30 p.m., we gathered in the Square to embark on the ward rounds as the least important part of the hierarchy which constituted the "firm." Here horror became replaced by boredom as one shambled round on the outer fringe of the cortège accompanying the chief, gathering up such crumbs of wisdom as one's general ignorance of what was going on allowed one to appreciate—one's appetite for this being sadly impaired by the ache in the leg that ensued during these many weary hours.

However, there was but three months to wait before I was promoted as senior dresser to the inner circle of this gathering. The principal advantage of this, so far as I was concerned, was that I could edge nearer the bottom of the patient's bed, where I could surreptitiously find support for each leg in turn on the horizontal rail which is the fortunate feature of most hospital beds. But, alas, there was no convenient bed rail in the operating theatre, which claimed my presence for so many hours a week during this appointment, where I stood, shifting from one foot to another, either doing nothing or perhaps, if particularly honoured, being allowed to hold one end of a tourniquet, and only occasionally, very occasionally, being allowed to look at what was going on, and still less often having this explained to me.

Thus passed six months of hospital education which seemed to lack any guiding principle behind it other than that common to most educational establishments of that day—namely, giving the neophyte a bad time to start with. As a summing up, I can lay claim to having learnt very little—a certain amount of operating-theatre drill, a certain amount of system in physical examination and taking case notes, and a small amount of surgery, though probably not as much as could have been learnt in a few afternoons' intelligent demonstration. There was no attempt at systematic teaching whereby the new opportunities of practical experience could be correlated with what had been learnt in the primary subjects. I believe that at Bart's we had one lecture on surgery a week, at 5 o'clock in the evening, but this was of a general nature and unrelated to what we had been doing during the day, so that, as attendance was optional, one did not often attend after spending a day in the surgery or the wards. Meanwhile the hard-learnt knowledge of primary subjects slipped away.

Who among those educated at one of the older teaching hospitals can doubt that the monastic tradition has descended in strong measure through the hundreds of years from their early foundation? Who but is conscious of the feeling that, once within these portals, one must acknowledge that the entire universe has contracted itself to the area within these walls, and that one is expected to make the mental surrender to this cosmos before partaking of such gifts as this foundation may confer? To the majority this mental surrender perhaps comes easily; it is made temporarily in most cases, permanently in some. In others, however, the reaction is the opposite, and I was one of the others. I became the victim of a wild, tearing claustrophobia.

Once through the ties of my surgical dressership and with my finals still in the distance my main object in life was to pass as little time as possible in hospital and, during the remainder of the considerable amount of time available, to gather the widest range of alternative interests. Literature, art, drama, sociology, all the things that in a liberally run educational establishment, however specialized its purpose, could have been used to build up and promote an interest in the main subject being taught, became in my own case escapist diversions that served to take me as far as possible from the narrow confines of the world in which I found myself.

Medical and Pathological Posts

My medical clerkship (spent amongst obscure diseases which, for the most part, I was not to see again) occupied the next three months. Here, at least, I picked up a certain amount of knowledge of chest signs and methods of examination. To a large extent I was free to pick and choose what I should do and to arrange my further activities as I saw fit. Reasonably confident that I could pass my final examinations by the acquisition of book knowledge, I was therefore concerned only with what I felt would be of use to me in the future—general practice being my acknowledged destination during my whole time at hospital. As I looked with a discriminating eye at the curriculum that lay before me, it seemed that most of the appointments suggested for me were just as little related to what I would be doing later as to what I had done before I came to hospital. With scarcely a sigh, and using all the artifice known to the medical student, I ruthlessly eliminated one after the other from my own programme. I soon concluded that special departments consisted merely of desultory standing on the fringe of a crowd in an overcrowded out-patient department—I eliminated special departments.

Pathological clerking promised but a further three months' tedium in counting blood cells, and, since my heretical mind told me that this was an occupation in which I was never likely to indulge, I took (in this case) the legitimate alternative of a pathological course at another hospital at which I not only saved some six weeks of my time but had the advantage of learning some pathology.

It might be argued that, in adopting these tactics, I missed something that might have been invaluable to me, but I did not miss very much—certainly nothing that would have filled in the gaps of my education as a doctor. I passed my final examinations, as I had expected, by the acquisition of book knowledge, combined with an element of practical experience culled from demonstrations in surgical out-patients—the one part of my training in which every minute seemed to be of some value and in which at least one could sit around on chairs in reasonable comfort and absorb useful knowledge. Here I actually learnt something about tumours and the necessity for their early diagnosis.

A Qualified Doctor

Eventually, of course, I became a general practitioner—a reasonably competent general practitioner, so I flatter myself. However, "reasonably competent" was scarcely the description that would have applied to me when, a qualified doctor, I returned home and was sent out by my father, who was still in practice, on an evening emergency call to see an elderly workman who had that afternoon started to lose the use of his right arm and right leg. I seem to remember recognizing hemiplegia, but so wrong was my prognosis that I remember even more clearly my surprise when the family attended the surgery next morning for a death certificate after having called on a near-by doctor later the same night. This was, of course, the first case of its kind that I had seen.

It is a sobering thought that I would have shown the same lack of knowledge if faced by a rash or, in fact, any skin trouble, whether of an infectious or non-infectious character. Words such as papules, macules, and erythema merely swam round in my head in meaningless fashion as the result of a short course in fevers. My lack of knowledge would have been the same had I been asked to write any prescription, other than that of plain mist. gent. cum rheo or perhaps mist. bismuth., in its composite form—I had no idea what the ingredients were. It would have been the same if faced with a sick baby, or if I had had to give even a hypodermic injection, or if I had been asked to give detailed instructions of any of the more elementary nursing treatments.

All this I eventually acquired: that is, with the exception of the last-named, which had to be replaced throughout my days in practice by a particularly haughty look of omniscience when ordering douches or other nursing treatments. But I did not gain my knowledge through teaching hospital or in any way remotely connected with it. My general diagnostic knowledge was won through trial and error when I had the good fortune to obtain a six-months appointment as casualty officer at the Metropolitan Hospital, Kingsland Road. My knowledge of the medical treatment of minor complaints, which was, after all, the means by which I was to make my living, I learnt from the "old-timer"—a graduate of Dalhousie University, Halifax, Nova Scotia, in the late nineteenth century—from whom I bought my practice. The treatment of skins and skin troubles I absorbed from my dispenser, a former warrant officer in the R.A.M.C., with many years' overseas service to his credit. Thus, in this highly fortuitous way, did I pick up my complement of knowledge that equipped me as a doctor.

What did I learn from my three years at hospital? The answer is: almost nothing, except for being impressed with the importance of systematic note-taking and of the early diagnosis of malignant disease; some chest signs and, again, the necessity for systematic examination. These, after all, are something, but they are scarcely enough to produce as a result of three years' training. To say that I also learnt to pass my exams will not do, for I could have passed these by virtue of book knowledge, regardless of anything I learnt in hospital.

Some Suggestions

Society, shocked at the incompetence and inexperience of its newly qualified doctors, has determined in the new Medical Act that they shall have a further year in hospital as "interns" before being unleashed on to the public. Proposals are put forward for increasing the period of tutelage even longer than this. However, it would seem that, before these are seriously considered, equal consideration might well be given to the possibility of taking some of the "slack" out of the existing curriculum, or to the improvement of the teaching methods adopted therein.

Frequently, since my student days, I have asked myself in the innocence of my own heart why some of those dreary hours spent in the operating theatre gazing at the back of the white gown in front of me, in the wards sidling up to beds with a view to gaining a foothold on the bed rail, or in making blood counts (this refers to others, if not to me) could not have been used in the inculcation of knowledge that would be of use in medical practice.

Also would it not have been possible, perhaps by a more gradual transition, to have made the new atmosphere of hospital more acceptable to the student coming in from the academic atmosphere of Cambridge or Oxford? Surely it would have been better to engage his interest first rather than to "throw him in at the deep end" and make him fend for himself? Instead of this, however, I was left to grope in haphazard and unguided fashion through an existence of boredom, and even worse, because of the lack of any systematic attempt to organize my studies so that they related to what I had done before or to what I knew I was going to do afterwards.

In my criticism of the teaching process it has not been my intention in any way to disparage the distinguished gentlemen in whose steps I followed: they were the victims of the system as much as I was. But inevitably the student had to take his place in their world, and in the world of hospital routine, as one of several competing interests. The first interest of a physician or a surgeon is naturally to be an expert physician or surgeon, it cannot be otherwise: the first interest of a hospital must be the cure of the sick. Into this *métier* the student must be fitted. However, even when the surgeon or physician is transformed into the teaching unit we still find competing interests that take precedence over the work of education. As in all scientific establishments, there is the pressing claim of research—a claim that is bound to take prior place so long as the teaching staff not only have to combine research with teaching but in addition have to depend on research results rather than on teaching prowess for their prospects of advancement. We inevitably find this position reflected in the nature of the cases that fill the beds in the hospital wards where the student must, or at least should, gain his experience that is to stand him in good stead in his future struggles with the commonplace of general practice. This in turn can but be a reflection of the position which the student occupies in the minds of those who instruct him. He is apt undoubtedly to come a rather poor third to the claims of practice and research, and real improvement cannot be expected until he is "upgraded" in the attentions of at least some of his instructors. It is not to be denied that many of the distinguished gentlemen who make up senior hospital staffs have developed in empirical fashion their own reasonably effective manner of imparting

knowledge; but who has so far had the temerity to suggest that, before they are qualified for their appointment, they should undertake a course at a teachers' training college to learn the elements of modern teaching methods? Who can deny that medical education would be much improved thereby?

SOME COMMENTS ON MEDICAL EDUCATION IN GREAT BRITAIN

BY

A LONDON MEDICAL STUDENT

This article was written when the author was a final year medical student. He found on inquiry that the curriculum varied so greatly in the medical schools of this country that it was impracticable to write an article which would represent student opinion as a whole. But, though he is to some extent expressing a personal point of view, the first draft of the article was read and discussed at a meeting attended by representatives of students from a number of medical schools in London, Scotland, and the provinces, and they expressed general approval of the theme.

The state of flux in British medicine at the present day is inevitably reflected in the unsatisfactory state of British medical education. The curriculum has been under discussion since organized medical teaching began, and during the past 30 years this debate has become increasingly heated. In the meantime, however, the training of the medical student continues to follow much the same lines as it has done since the beginning of the century. As each new report appears, some minor adjustments, amounting to no more than running repairs, are made. The system is patched up here and there, but remains essentially unaltered. Looking back, with the memory of the six-year course still fresh in one's mind, the feeling that medical education in this country is adrift becomes inescapable. Much of the time was wasted, much energy was misapplied, and the ultimate goal of qualification seems to have been achieved more by good luck than by effective training.

What are We Training For?

The test of any system of training or education is empirical—Do the means serve the ends? Does the system turn out good doctors?

Much heat has been generated in a fruitless argument about the kind of doctor which our training should produce. This is not the place in which to discuss the merits or demerits of general practice as it obtains in this country. It is enough that the general practitioners support the whole edifice of British medicine, that they far outnumber doctors in any other field, and that the medicine which they practise is the basis of all other medicine. Of the 2,000 doctors who qualify each year in the United Kingdom, about one-half become general practitioners. It is imperative that the remainder, whether destined to become consultants, public health workers, or any other breed of doctor, should first master the basic knowledge which is the stock-in-trade of the G.P. The further training required by specialists of all kinds (be they research workers or surgeons) should be additional to the basic knowledge required for general practice. For this cogent reason, and in accordance with a principle that underlies all forms of education, first things must come first, and the first things are the simple things.

Do First Things Come First?

If the above argument is accepted the newly qualified doctor should know more about sore throats than large spleens. He should be capable of treating the common cold, but he may be forgiven some uncertainty about the therapy of myasthenia gravis. In fact, however, the newly qualified man or woman can discuss at length the aetiology and treatment of acute osteomyelitis, but finds himself unable to advise his friends, relatives, or patients when they consult him about their corns. He is often incapable of composing a simple prescription, and may even be unfamiliar with the use of the *National Formulary*. To say that he will learn these things in general practice is to beg the question. The object of any training is to impart the knowledge required for the job, not to turn out glorified graduate apprentices. Furthermore, if it is agreed that the principal task ahead is to raise the standards of general practice, then it is essential that the appropriate knowledge should be acquired during training rather than picked up in the field. It is the latter practice which perpetuates the use of outmoded methods. One of the reasons for the demoralization of the general practitioner is the fact that he is doing a job for which he was not trained.

Where Does the Fault Lie?

The General Medical Council exercises its control over medical education in this country through the examining authorities. It lays down the courses which the student must have attended before presenting himself for the qualifying examination, and it approves the standard of the examinations that are set. It might be thought, therefore, that the weaknesses of our medical education could be attributed to the examination system. It is true that certain features, such as the unnecessarily long time devoted to surgical dressing, are based upon the stipulations of the G.M.C. So far as the actual examinations are concerned, however, it must be admitted that the questions set in the papers and asked in the "vivas" are usually simple and straightforward. The training of a medical student makes it unlikely that he will know much about the treatment of constipation, yet it is surprising how often the examiners set this very question. In fact, more students fail from ignorance of simple things than from inadequate knowledge of obscure conditions. It does not seem probable, therefore, that the examining bodies are responsible for the orientation of the student's learning, though it might be argued that the ever-present danger of a compulsory question on a rare disease necessitates the acquisition of much relatively useless knowledge.

On the whole, however, the atmosphere of his teaching hospital is the factor which ultimately determines a student's outlook. It is a mistake, often recognized but never corrected, for students to be taught solely by specialists; it is a calamity when these teachers fail to appreciate that most of their pupils are preparing for general practice.

"Appointments"

Turning from the general to the particular, it is not hard to discover specific weaknesses in the detailed working of the medical curriculum. Clinical teaching in the English and Welsh schools is based upon a series of student "appointments" to the various departments of the hospital. Our teachers like to think that this enables their students to acquire at first hand the practical and theoretical knowledge which a doctor needs. Whatever these appointments may have involved in the way of responsibility and activity in days gone by, they are now nothing less than a gigantic fraud. The chief may speak affectionately of "my clerks," suggesting that they are an integral part of his firm, as essential to its working as every other member, but the clerks know differently. They may correspond to the apprentices of an earlier age, but their duties and responsibilities have been so drastically reduced that they are left with the status of technicians, a constant nuisance to the nursing staff, performing for six months on end the simplest of tasks which they could master in a fraction of the time if they were properly taught.

There are, of course, a large number of practical procedures which a doctor must be capable of carrying out, and carrying out well. Only a small proportion of these are learned by clerks or dressers, however, and the time comes when any further advance in the art of, say, venepuncture is more than offset by the loss of time which it entails, time which could be better spent on ward rounds or in the library. It is preposterous that, as often happens, a clerk should miss a teaching visit in order to take a clean specimen of urine or do a pre-operative shave. It is equally preposterous that his appointed duties should not include the much more intricate lumbar puncture. If practical procedures are to be learned during the clinical course the number and nature of such procedures should be as clearly defined as they are for nurses. They should be properly taught and, once mastered, they should not be indefinitely repeated. Students still pay fees to be taught medicine: they should not be used as a form of cheap labour. If, on the other hand, it is decided that the practical aspects of medicine should be mastered during the pre-registration house appointment, then the students should be true students and should be allowed to make the best possible use of their time in the wards.

The student's principal task in the ward is to learn to examine a patient systematically from head to foot and to elicit physical signs. This art is well taught in the introductory course at most schools, but thereafter the student is largely left to his own devices, and it is rare indeed for a teacher to observe him examining a patient and developing the habits, good or bad, which will remain with him for life. In fact, too much ward time is spent in taking blood or washing out bladders, and too little in examining patients in the presence of an experienced teacher.

The above remarks apply particularly to the medical clerkship, but are equally true of the surgical dressership and, in a general way, of the other appointments. It seems so admirable that students should be responsible for surgical dressings, and it is true that during the first month or so some very useful knowledge is acquired. From then on, the rate of learning becomes very much slower, and at the end of six months the dresser is amazed to find that he still knows little of the elements of bandaging; less, in fact, than a boy scout or first-aid worker. Considering the relative positions of medicine and surgery in general practice to-day, it is remarkable that the surgical dressership should still occupy as many months as the medical clerkship, and equally strange that many surgeons should insist on "their" dressers being present at operations. Major surgery is essentially a postgraduate subject, and if six months are to be spent on surgical firms very much more of this time should be spent on minor surgery.

This brings us to a consideration of the part which the casualty department plays in a teaching hospital. Many students believe that their casualty appointment was not only the most interesting but also the most useful period of their training because it taught them simple surgery of immediate practical value and gave them for the first time some genuine responsibility. Even in this department, however, the lack of purposeful teaching may be as much in evidence as it is in the rest of a teaching hospital. Dressers may be expected to perform casualty duties within a few weeks of beginning surgical studies, and they may be entrusted with minor operations and stitching without ever having been taught how to do them correctly. However trivial the task may be, there is always a right way and a wrong way of doing it.

Systematic Teaching

In addition to the pseudo-apprenticeships discussed above, there is a varying amount of systematic teaching in every medical school. Pride of place is taken by the ward visit, but there are also lectures and tutorials.

The ward visit at its best is superb—at its worst it is unbearable. The British habit of gathering students round a bed and teaching on the case is the best feature of our system. Apart, however, from the frequent disregard for the patient's feelings, which is all too common in ward teaching, it may fail in its purpose for various reasons. One is that too long may be spent on a single case: half an hour standing still at one bed is about as much as most students can manage. Again, teachers may wander too far from the case they are discussing and allow the discourse to degenerate into a straightforward lecture. Finally, there may be such a lack of co-ordination between the teachers in the hospital that several similar cases are made the subject of visits in one week, to the exclusion of other conditions which have not been discussed for many months.

A full-dress systematic lecture is of little value. Routine bread-and-butter information which can be found in the standard textbooks provides poor material for a 60-minute discourse. Lectures should present aspects of medicine which are not discussed in the textbooks, and, whenever possible, they should be based on the personal experience of the lecturer. They should transcend the narrow limits of the set subjects and touch upon the wider implications of doctoring as seen in its historical and social setting. They should, in fact, serve as a stimulant rather than as a narcotic.

Finally, there is the tutorial or rag class—an intimate question-and-answer class for the benefit of a small circle of students which may be based upon bottles or specimens. Of the value of this class for teaching or revision purposes there is not the slightest doubt.

Teachers and Tutors

It is often alleged that medical teachers should be trained not only in medicine but in teaching. This point has been unduly laboured. Among the galaxy of talent available at every teaching hospital (thanks to our numerous part-time consultants) it is not hard to find several capable teachers, and it is almost surprising how many of our physicians and surgeons are outstanding in this respect. Their time is limited, however, and the burden of junior teaching is not adequately borne by those of registrar status. It should not be necessary to appoint full-time clinical teachers so long as the present surfeit of registrars continues, and it should be a part of the registrar's very

limited duties to teach junior students in the wards. This arrangement already exists on paper; it is time it was fully implemented.

Tutoring of a kind exists at a number of medical schools, but is applied throughout the course at very few. At many centres students do not have ready access to the dean, and they have no tutor to whom they can turn for advice on reading, for guidance on methods of work, or for help in choosing a career. This is unforgivable.

Art or Science?

The above remarks are aimed at some of the weaknesses in our present system of imparting factual, technical medical knowledge. It is, however, a striking feature of British medical education to-day that the non-technical aspects are scarcely mentioned. Medicine is a great liberal profession, not a trade, and one would have thought that some effort would be made to bring this home to medical students. In fact, very little is done to teach the doctors of to-morrow how to handle patients, how to tell them about their own disease, how to deal with their relatives, and how to tackle the host of more or less related problems which will begin to face them on their first day in practice. It may be contended that such lessons can be learnt only by experience, or that our teachers' example serves as the best guide to our future behaviour. Unfortunately, this example is not always worthy of emulation, though with the passage of time one becomes inured to those constant acts of thoughtlessness towards the patient which struck one with horror in the early stages. A patient expects sympathy and understanding from his doctor, not only technical skill. The selection of medical students for character rather than brains would be a step in the right direction, but it is equally important that emphasis should be placed throughout the course on those aspects of medicine which make it an art as well as a science.

Medical Memorandum

Spontaneous Amputation of Cervix

The following case is worth recording in view of the interesting cases reported by Arnott (1949) and Uhma (1949).

Case Report

The patient, a woman aged 33, had had two previous pregnancies, one in 1945 resulting in the birth of a normal infant weighing 9¼ lb. (4.3 kg.) at term, and the other in 1946 ending in miscarriage at five months. Her present pregnancy had been uneventful and the expected date of delivery was January 21, 1949. She was admitted in labour as an emergency case at 2.30 p.m. on February 6, 1949, as the district midwife found her unmanageable. Labour had apparently started at 2.5 a.m. that day, and from the beginning she had insisted on using strong expulsive efforts. Unfortunately there is no record of the exact time of rupture of the membranes.

On admission her general condition was good. The foetus was in the left occipito-transverse position, with the head engaged in the pelvic brim. Vaginal examination revealed a cervix which admitted three fingers, which was markedly oedematous, and which had two old lateral lacerations, one on each side. The membranes had ruptured. She was given 200 mg. of pethidine and the midwives were instructed to prevent her "bearing down."

At 6 p.m. I was summoned by the Sister, who reported that a fleshy mass had presented at the vulva. This was found to be the posterior part of the cervix, which had become almost totally avulsed, being attached only by a narrow pedicle of tissue. There was some bleeding. Preparations were made to deliver the infant by forceps, but, before these were complete, delivery of a female infant weighing 10 lb. (4.5 kg.) occurred spontaneously, the placenta following in ten minutes.

As there was still some bleeding, the woman was anaesthetized and the cervix explored. It was confirmed that the whole of the posterior part, limited by the two lacerations, had been amputated. A few bleeding points were secured and ligated and thereafter bleeding stopped. The puerperium was uneventful.

On June 22 all that remained of her cervix was a small finger-like process anteriorly which was the seat of an erosion. There did not seem to be any pronounced fibrosis such as one finds after operative amputation, and what remained of the cervical canal admitted the tip of a finger. The erosion was cauterized.

Comment

In many cases of spontaneous amputation of the cervix one of the main underlying factors seems to be some organic condition preventing dilatation of the cervix, and the majority of cases have occurred in primigravidae (De Lee and Greenhill, 1943b). Other factors are contracted pelvis, prolonged labour, and premature rupture of membranes (De Lee and Greenhill, 1943a, 1943b), though the latter two are probably results of the other causal factors rather than contributory causes. In most cases of amputation after operative treatment the de Ribes bag has been used (Uhma, 1949; De Lee and Greenhill, 1943b).

In my case the factors concerned were undoubtedly the size of the child and the strong expulsive efforts used by the woman from the beginning of labour. Her pelvis was of average size, and with an infant of 10 lb. there must have been considerable nipping of the soft tissues. This would tend to cause oedema of the cervix as in contracted pelvis, which in turn would prevent full dilatation, and the strong expulsive efforts of the uterus aided by the abdominal muscles would force the head downwards, carrying the cervix in front of it (De Lee and Greenhill, 1943b), the line of separation occurring where the head was compressing the cervix against the sacral promontory.

The line of separation was bounded at each side by the two old cervical lacerations. It would be interesting to know to what extent separation would have occurred had the cervix previously been intact.

Opinion seems to vary on the question of future pregnancies and labours. De Lee and Greenhill (1943b) consider that the resulting scar nearly always closes the uterus but agree that spontaneous deliveries do occur after the injury. In Arnott's case subsequent delivery was easy. In many cases following surgical amputation of the cervix there is difficulty in labour (Calvert, 1949; Kosmak, 1949). In my case there did not seem to be any pronounced fibrosis and the cervical canal did admit the tip of a finger. It will be interesting to observe events should the patient become pregnant again.

Reviews

FRESH APPROACH TO PATHOLOGY

An Introduction to Pathology. By G. Payling Wright, D.M., F.R.C.P. (Pp. 569; illustrated. £1 10s.) London: Longmans, Green and Co. 1950.

The teaching of pathology over the last twenty years or so has evolved along dangerous lines. More and more emphasis has been laid on the practical application of laboratory investigations to the purely clinical problems of diagnosis and the control of treatment, while less and less care has been taken to ensure that the student shall acquire an adequate understanding of the basic mechanisms which underlie disease processes. As the author of this book points out, "any further curtailment in the study of what is conveniently known as general pathology . . . would, by starving the student of a training in principles, have undesirable repercussions in clinical subjects also." Professor Payling Wright has planned his book to meet this danger. It is "an introductory exposition of the principles of pathology in terms of the more fundamental sciences of biology and physiology."

The treatment of the subject is above all things dynamic, and the functional approach to pathology forms one of the main themes running through the book. The author tells the story of disease against the background of time and pathogenesis, and emphasizes the march of events in the evolution of disease. The old static facts of morbid anatomy and histology are skilfully blended with the relevant modern discoveries in biology, physiology, experimental pathology, and immunology. The student is persuaded that to understand disease he must train himself to think in terms of morbid physiology, but he is warned that to define his problems he must acquire knowledge of altered structure by personal observation of the "stilled" life of the post-mortem room, the museum jar, and the microscope slide.

The book is written in lucid and distinguished English, and will be read with ease and enjoyment. The introduction is impressive. It consists for the most part of a skilfully condensed account of the history of pathology in terms of the evolution of science and has the same dynamic quality as the rest of the book. Other arresting chapters are those on the body's defences against infection, the inheritance of abnormalities, haemorrhage, thrombosis, and the aetiology of tumours. The references have been selected with care and cover an exceptionally wide field, and the illustrations, more than half of which are photomicrographs, are of excellent quality.

Those who teach general pathology and are convinced of its importance in undergraduate and postgraduate education have been waiting for such a book as this for a long time. They will be gratified to discover that it has at last been written by an English author with so wide a knowledge of the scientific aspects of pathology and so outstanding a talent for accurate generalization.

GEOFFREY HADFIELD.

INTRODUCTION TO PATIENTS

Clinical Examination of Patients. By John Forbes, M.D., M.R.C.P., and W. N. Mann, M.D., F.R.C.P. (Pp. 323; 60 illustrations. 18s.) London: Edward Arnold and Co. 1950.

This book is intended to be a guide to the student during his introduction to clinical medicine, and the authors hope that it will help to clarify and to systematize bedside instruction. They emphasize the importance of history taking, devoting a chapter to this essential feature of the clinical examination. There follow chapters on the general examination of the patient and on the investigation of the special systems and of abnormal psychological states. All these sections are excellent. The laboratory tests and *x*-ray and electro-cardiographic findings are of necessity considered somewhat briefly. The chest radiographs, such as Fig. 17, are blurred and poorly produced. In the introductory chapters the authors give advice on good manners during the clinical examination, and tell the student that he must refrain from sitting on the patient's bed without asking his permission. I have never witnessed this formality; perhaps it is an old Guy's custom.

The authors have achieved what it is possible to achieve in an elementary book of this size, and the student who reads it during his introductory course to clinical medicine should derive much profit. He will, however, soon outgrow it and require stronger meat.

G. E. BEAUMONT.

DIAGNOSIS

Major Symptoms in Clinical Medicine. By John Almeyda, M.R.C.P., D.P.H.(Lond.), M.R.C.S. Volume I. With foreword by Sir Adolphe Abrahams, O.B.E., M.D.(Camb.), F.R.C.P. (Pp. 378; 185 illustrations, including 10 in colour and 13 charts. £1 5s.) London: Henry Kimpton. 1950.

Practical Procedures in Clinical Medicine. By R. I. S. Bayliss, M.D.(Camb.), M.R.C.P. (Pp. 445; 62 illustrations. £1 5s.) London: J. and A. Churchill. 1950.

In his foreword to Dr. Almeyda's *Major Symptoms in Clinical Medicine*, which should be read by anyone wanting a favourable review, Sir Adolphe Abrahams speaks of the necessity in the practice of medicine of recognizing physical signs and eliciting symptoms by clinical and extra-clinical methods. In his own preface Dr. Almeyda expresses his intention of discussing the anatomical and physiological aspects of symptoms, their mechanism, significance, and mode of investigation.

I do not think he has been successful in these intentions, for the student will learn little about the scientific elicitation or understanding of symptoms from this book. It is true that a number of phenomena such as obesity, pruritus, haemoptysis, and constipation are discussed, but the author's powers of description are weak and he lacks the basic knowledge for the analysis of symptoms. I do not think Mackenzie or Lewis would have approved of the sections on dyspnoea and thoracic pain, and that on purpura will merely confuse those who are not knowledgeable enough to be exasperated. The lists in which symptoms are classified are rarely helpful and sometimes inaccurate. Pigmentation is arranged in an arbitrary colour scheme, in which pernicious anaemia is classified as brown, brown-black, or reddish-brown, without reference to the lemon and biscuit tints with which the patient's colour is commonly compared. Mepacrine is not included in the list of exogenous pigments which discolour the patient by the actual deposition of the chemical in the tissues of the body, but sulphonamide is. Surely sulphanilamide cyanosis is due to methaemoglobin? This is not a complete manual of physical diagnosis like "Hutchison and Hunter," and there are no references or bibliography. The book is reasonably priced and well printed, but the originals of the clinical photographs and sketches must often have been poor.

Bayliss's *Practical Procedures in Clinical Medicine* is a much better book and can be whole-heartedly recommended.

A little time ago I compared the length of stay in the same hospital thirty years ago with that to-day, and was surprised to find that it had not greatly diminished. It is the pace which has changed, and the time formerly spent in quiet observation is now devoted to special investigations and treatment. The range of knowledge which a house-physician must have for these purposes is extensive and requires the medical equivalent of the manual of surgical handicraft. It is this which Dr. Bayliss has provided, and his book can be regarded as a supplement to the still essential manual of physical diagnosis.

In twelve chapters he discusses the methods of laboratory investigation of the various systems and the different special procedures. From artificial pneumothorax to A.C.T.H., these last thirty years have kept the house-physician busy, and this book will save him a good deal of time in discovering how to do it all. A book of this kind is out of date before the manuscript leaves the hands of the author. There is no mention of such fashionable topics as potassium infusions or the eosinophil count, or of the growing volume of criticism of the cricothyroid route for bronchography. New editions will clearly be needed, and in these one would like to see rather more references to the original papers from which methods are taken.

L. J. WITTS.

SIGNIFICANT DOODLES

On Not Being Able to Paint. By Joanna Field. (Pp. 173; 48 figures. 10s. 6d.) London: William Heinemann. 1950.

The sale of the Graham Robertson collection of Blake's drawings last year inevitably raised speculation on how they were received when Blake created them in comparison with how they are assessed now. Surely we can perceive something of their significance better now than could Blake's contemporaries.

With charcoal, ink, and paint Miss Field has set down over the years the apparently aimless movements of her undirected hands. We might call them her doodles. And she has latterly found a significance in them and recalled the delight in their execution far different from the arid response that followed her earlier more normal representational efforts. The reality of these emotions is partly responsible for her efforts to find a significance in these doodles, which she interprets as the expression of her thwarted inner life. Critics may find plenty to carp at in such interpretations. Yet the reviewer notes that psycho-analytic theories are expressed in a much less disturbing way than they often are. Some of Miss Field's conclusions are set out in ways that convince by their simplicity. She claims that her drawings enabled her to solve the problem of falling short of her ideals and yet being calm and not ashamed. And she hints that the task of education is to allow, whether by free-drawing or otherwise, the expression of those sides of our imagination which tend more and more to be denied expression in a sophisticated age.

This book, therefore, should be welcome to many besides amateur artists. It might be said to be an introduction to surrealism, to aesthetics, and for all who genuinely wish to appreciate children's paintings, psychotic drawings, or modern art. Miss Field's work approaches philosophy, and in so far as she quotes Traherne (extensively), Donne, Blake, and Francis Thompson she raises many fascinating and unsolved questions. It is not a primer for holiday sketching.

TEACHING THE TEACHER

Six years ago the Goodenough Report observed that "too little attention has been paid to the training of teachers of medical students," and suggested that the intending teacher might benefit if he received some instruction in this difficult art. In last year's Educational Number Professor R. W. Niblett contributed a short paper on the training of the teacher, and in a leading article in the same issue of the *Journal* comment was made that "it is unusual, to say the least, to find so plainly stated the need to improve the teachers as well as the taught and the teaching." This stimulated Dr. R. D. Lawrence to suggest in a subsequent issue that there was need for a school for medical teachers, a suggestion made in this *Journal*[1] by Dr. Ffrangcon Roberts in 1944. During the past year many teachers of clinical medicine have been discussing their training as teachers, and the subject was debated at a meeting in Bristol attended largely by members of the Royal College of Physicians. Dr. Lawrence's contribution to this debate is included among a number of articles published this week on the methods and techniques of teaching.

As Sir Henry Cohen points out, recent reports and articles on medical education have been concerned almost entirely with the content of the medical curriculum, and too little attention has been paid to methods and technique and to the selection of teachers. The purpose of teaching, Cohen notes, is not only to transmit knowledge but to stimulate the student to think. Dr. Johnson's account of how he was taught as a medical student 25 years ago, and the article by an anonymous medical student—from a different hospital—suggest that at least in some of our medical schools the system of teaching does neither of these things very well, or at least not well enough for training the student in the general practice of medicine.

While many would disagree with Dr. Roberts's projected school for medical teachers if it were a permanent institution, few would deny that the young man or woman appointed to the teaching staff of a hospital would benefit from some pedagogical instruction. As Professor Niblett observed last year, the doctor in training and the teacher in training have much to give one another. We should therefore go to those who make a special study of education and see what help and advice they can provide us. In our opening pages Dr. J. A. Lauwerys, professor of comparative education in the University of London, and Mr. G. P. Meredith, professor of psychology in the University of Leeds, have set down for the benefit of those who teach medicine some of their observations on the technique and art of teaching. As Professor Lauwerys suggests, the problems of teaching and what is taught cannot be separated from a consideration of the times in which we live and the shifting scenes of social and scientific thought. "All teachers," he says, "face problems which arise through the adoption by statesmen and Parliament of policies the roots of which lie elsewhere than in the sciences." One result of these policies is that more boys and girls are seeking higher education. They come, Professor Lauwerys points out, often enough from homes which may have a poor educational background. They have not acquired the habit of reading "or of individual self-directed study." Their anxiety is more to acquire knowledge to pass examinations than to become educated in the widest sense of the word. But Professor Lauwerys adds the comforting observation that they are not less intelligent than students of previous generations. An awareness of the conditions of life and the social background of the modern student is essential if the teacher is to choose wisely methods and techniques which will not only instruct the student but bring out of him the best he has to give. In medicine, especially, the length and burdensome nature of the curriculum, and the economic anxiety to pass a series of examinations at the first attempt, put a premium on cramming and encourage passive reception of facts and figures and so-called theories. This, too, encourages the lazy, or indifferent teacher to use the method which Professor Lauwerys describes as one "involving mainly chalk and talk," instead of what he calls "activity methods." The essence of these is that students are encouraged to solve certain problems themselves, a method intended to encourage purposive mental activity. Professor Lauwerys suggests that students could learn by attempting to find answers to questions by experiment.

An account of an attempt to use this method is given by Dr. Andrew Wilson and his colleagues of University College, London, in which they describe how, as part of the pharmacology course, students, under the supervision of instructors, tried the effects of various drugs on each other. "We consider," they state, "that the outstanding advantage of this part of the practical class is that the student experiences at first hand the effects of certain drugs and learns to assess some of the qualitative and quantitative changes produced." This

[1] *British Medical Journal*, 1944, 1, 728.

experiment of Dr. Wilson and his colleagues would seem to be an admirable example of an "activity method" in the teaching of pharmacology, and at a time when this is a subject of such rapidly growing importance it may be hoped that other schools will try the same method. If it were widely adopted its influence on the future practice of medicine would be considerable.

The modern teacher now has many technical aids at his disposal, some of which are discussed elsewhere in this issue. Professor Lauwerys makes the interesting observation that these new ways of imparting information come from the oldest of all methods—the drawing, the painting, the hieroglyph. When books were scarce and television and the filmstrip undreamt-of, the lecture had perforce pride of place in the teaching process. Any student not possessed of a photographic memory or the ability to write at the speed of shorthand was able to transmit only some of the information to his notebook. Too often he was torn between the desire to listen and the obligation to scribble down facts and figures. Surely the time has come when *all* students should be given in advance of the lecture cyclostyled notes containing the main facts, and should listen to the lecture with the aim of enlarging their comprehension of them.

On the art of "putting it across" Professor Meredith has many wise and witty things to say. His vivid description of a few outstanding lecturers who have influenced him would seem to demonstrate that there are no short cuts to effective lecturing. From his own experience he concludes that the one quality that is desirable in a lecturer is vitality, which he defines as "a force which is called up by the joint challenge of a topic and an audience, a challenge which stimulates the organizing capacity of the man's mind to draw upon whatever material and mental resources he has." It is obvious that some knowledge of the technique of lecturing would help the inexperienced to avoid the mistakes referred to by various writers in this symposium; and it is equally obvious that no educational device or trick of lecturing will turn a bad lecturer into an inspiring one.

From his experience as a professor of education Dr. Lauwerys is opposed to any systematic instruction of the university teacher in the art of instruction. He suggests that every beginner should be given the chance of having an experienced teacher attend his lectures during the first year. It would, too, he believes, be an advantage if departmental heads were to have regular conferences with their staff at which they could discuss educational and pedagogical problems. His last proposal for helping the young teacher is the holding of week-end meetings of the staff in one of the many conference homes now available. It is much to be hoped that some of those responsible for medical teaching will take the initiative in trying out some of the suggestions made by Professor Lauwerys. It seems evident that, though there may be exceptions in this school or that, the present methods of teaching medical students are unsatisfactory. If the methods were reformed it might be easier for some teachers to become more accomplished in their performance.

DOCTORS AND POPULATION

The average population served by a medical practitioner varies greatly between one country and another, and has to some extent varied in Britain during the last 50 years. The *Medical Directory* includes a table which shows the numbers of doctors whose addresses are recorded as being in England and Wales and in Scotland when the volume is made up each year. Other particulars are given also, but it is these that are analysed below. The figures for Northern Ireland and Eire are tabulated together, but since conditions differ in the two countries it was thought desirable not to use them in the comparisons made here.

The numbers of doctors tabulated in the *Medical Directory* are not an exact account either of the number of doctors practising or of the number of doctors living in England and Wales and in Scotland. For various reasons a few doctors do not have their names recorded in the *Directory*. On the other hand, some of those recorded are retired and therefore ought not to be counted as serving a population. The difference between these figures is unknown.

The figures for populations in Tables I and II are derived from the Registrar-Generals' publications and are for civilian populations. They are given in thousands to the nearest thousand. Although the figures for population per doctor in Table I and for population per general practitioner in Table II are not exact, they are probably correct to within a hundred.

Table I.—*Medical Practitioners and Population in England and Wales and in Scotland*

Year	England and Wales		Scotland		Population per Doctor	
	Doctors	Population in Thousands	Doctors	Population in Thousands	England and Wales	Scotland
1901	23,501	32,413	3,569	4,464	1,379	1,251
1910	25,398	35,792	3,947	4,739	1,409	1,201
1920	26,619	37,596	4,544	4,864	1,412	1,070
1930	31,936	39,801	5,905	4,828	1,246	817
1939	37,429	41,460	6,091	5,007	1,108	822
1949	45,547	43,785	8,607	5,175	961	601

It is clear from Table I that during the last 50 years there has been a higher proportion of doctors to the population in Scotland than there has been in England and Wales. The difference cannot be accounted for by the fact that a higher proportion of people qualify as doctors in Scotland, and that some of these subsequently

migrate to England and Wales, for the Scottish doctors enumerated have given their addresses as being in Scotland, and it seems to be a reasonable assumption that if any of them later travel south they will be replaced in Scotland by a roughly similar number. That every six-hundredth person in Scotland should, in 1949, have been a medical practitioner seems to be a remarkable achievement.

In both countries the last 50 years have seen a great reduction in the average number of people per doctor, but the reduction by one-half in Scotland is striking. This reduction has occurred in spite of the increasing population of both countries and is the result of a more rapid increase in the number of doctors.

In order to gain some idea of the average number of people served by a general practitioner in England and Wales and in Scotland some figures obtained by the B.M.A. for the years 1947–8 were used. It was found by counting in 1947–8 that there were 17,769 active general practitioners in England and Wales, and 2,636 in Scotland. These figures were divided, for the respective countries, by the mean of the number of medical practitioners recorded by the *Medical Directory* for the two years 1947 and 1948. In this way the number of general practitioners in England and Wales was found to constitute 0.4 of the number of doctors shown in the *Directory* as living in England and Wales, and the number of general practitioners in Scotland 0.31 of the whole body of Scottish doctors shown.

On the somewhat hazardous assumption that these fractions have not changed much in the last 50 years, they were applied to the figures in the last two columns of Table I to show (in Table II) the average population served by one general practitioner in England and Wales and in Scotland during the last 50 years.

Table II.—*Average Population Served by One General Practitioner in England and Wales and in Scotland*

Year	Population per General Practitioner	
	England and Wales	Scotland
1901	3,447	4,035
1910	3,522	3,874
1920	3,530	3,452
1930	3,115	2,636
1939	2,770	2,652
1949	2,402	1,939

The decrease in the figures for Scotland is again of interest. From having more people per general practitioner in 1901 than England and Wales, Scotland came to have fewer in 1949.

In 1948 the World Medical Association gave some figures in a draft report[1] on the numbers of doctors and of general population in various countries. These have been treated somewhat differently here and are shown in Table III. The figures have been rounded off, but are probably not very accurate for some countries.

[1] *Draft Report on the Medical Profession in Twenty-three Countries.* W.M.A., New York.

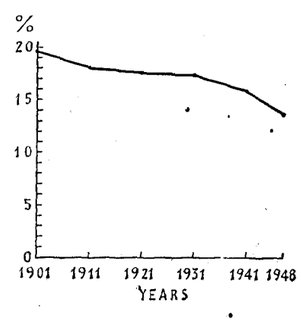

Table III.—*Average Population Served by One Medical Practitioner and by One General Practitioner in Various Countries*

Country	Population per Doctor	Population per G.P.
Palestine (Jewish)*	260	
United States	710	1,400
Great Britain	880	2,400
Iceland	880	1,000
Denmark	950	2,000
Canada	970	
New Zealand	970	
Australia	1,100	1,700
Switzerland	1,100	1,900
Sweden	1,100	
Spain	1,100	
Norway	1,100	1,400
Netherlands	1,100	2,300
Luxembourg	1,200	1,900
Czechoslovakia	1,300	4,300
France	1,300	1,500
Eire	1,500	
Bulgaria	1,500	2,400
Finland	2,200	
Union of South Africa	2,400	2,800
Egypt	4,200	11,100
Palestine (Arab)	4,500	
China	25,000	

* The low figure "for the Jewish section of Palestine is probably attributable to special temporary circumstances."

The young men and women wanting to become doctors continue to outnumber the vacancies in the medical schools, and the numbers admitted by the medical schools have remained fairly constant for some time. There does not in the near future seem to be any likelihood of a shortage of aspirants to medical training. But the age group from which most of them are drawn is shrinking in relation to the total population.

The great majority of medical students start their medical training when they are aged 15 to 24 inclusive. The percentage of the total population (including the Services) in England and Wales represented by this age group is depicted for a number of years in the Graph.

The actual number of young people in this age group increased from 1901 to 1931, but the total population increased faster. However, while in 1931 there were 6.9 million men and women aged 15–24, in 1939 there were 6.6 million, and in 1948 there were 5.99 million (approximate figures). Between 1901 and 1948 the percentage that this group forms of the total population has declined from 19.58 to 13.76. That is, in 1948 the percentage was 0.7 of what it was in 1901. The "ageing population" in England and Wales is responsible for this, and the relative lack of young people may some time in the future have a serious effect on recruitment to the medical profession.

TRAINING FOR THE JOB

In an attempt to find out what students themselves think of their clinical education we asked one of them coming to the end of his course to draft a short report which would be based on a questionary sent to students in different medical schools in Britain. He found, however, that there were such variations in the curriculum that anything like a succinct report would be impossible to draft. So he wrote down an account of his own reactions and observations, and having done this discussed his paper with a member of the staff of this *Journal* and with students from medical schools in London, the Provinces, and Scotland. As a result of this discussion some minor amendments of the paper were made. It stands, of course, as a record of personal experience, but the small conference of students generally approved and endorsed what our anonymous student-author has written. The essence of his charge against present clinical teaching is that it does not prepare the student for the job the majority have to do—the general practice of medicine. He makes the sound suggestion that all students should "first master the basic knowledge which is the stock-in-trade of the G.P."; and those who are going to take up other kinds of work should have subsequent specialist training. It is possible that those who teach students imagine that they are doing something like this, but the students are satisfied that this is not the case. If confirmation were needed it is amply provided by Dr. Donald Johnson, who, having spent many years in general practice, looks back to his student days of 25 years ago in order to discover how far the training he received was in fact the training for the job. Dr. Johnson's condemnation of the system, though perhaps exaggerated in parts, is as emphatic as that of the student of to-day. It is a melancholy reflection that despite all that has been said and written about medical education so little has been done in the past 25 years to get to grips with the real problems of training those who have to care for the sick. Thousands upon thousands of words have been written and volumes of eloquence have been poured out on this subject, yet the inertia of the medical schools has been so great that practically nothing seems to have been done to remedy a state of affairs that everyone must deplore. There are of course exceptions, and devoted teachers have here and there made efforts which deserve to be emulated. But in general the painful accusation that the medical schools are not really training students to be practical doctors seems to be substantiated.

The student-author observes that "the atmosphere of his teaching hospital is the factor which ultimately determines a student's outlook." According to Professor Lauwerys, the common factor in all proposals for the reform of school curricula is the stress laid on the social importance of what is taught. He believes that the true reason for this is the realization that Western civilization has to adapt itself to a changed technology and to meet the challenge of Russian communism and of the new conditions created by the reawakening of Asia. Whatever may be the explanation, he finds students most receptive to lectures on sociology and the social aspects of science. Professor Meredith echoes this in an observation that "in a sense all medicine is social medicine, and must be interpreted in the light of statistical knowledge of sickness and death, of wars and plagues, of poverty and wealth, of housing and diet." He stresses the need for the medical man to have a sense of the history of his profession. He finely says that medicine's "own essential vision and purpose are too high in the scale of human values to be allowed to fade from men's minds. They need to be particularly bright and sharp in the minds of students." The teaching of medicine should be set in the framework of its history and with a far more lively awareness of the sociological implications of health and disease. This is not likely to happen if students have to stuff their memories with facts about rare diseases they are never likely to see and with unsubstantiated theories of the causes of disease the cause of which is unknown. They have to learn these because of the examination bogy. And yet, as the student-author points out, examination questions are often refreshingly simple. There would seem to be a strange dichotomy in the teacher's mind. He teaches his students one thing and questions them on another. This may be because he fears that other examiners may set those questions he would not be likely to set himself. Perhaps the examiners in the qualifying examinations could come to some agreement about the exclusion of questions remote from the ordinary practice of medicine and let the students know this.

MORE ON MEDICAL EDUCATION

Two years ago Dr. Ffrangcon Roberts, in a book[1] which is as pertinent to-day as it was then, probed with good and trenchant English many of the themes touched on in this number. The individual has the advantage over the formal committee in that he has not the same compulsion to accommodate other views besides his own or to indulge in an excess of tact when he comes to a critical examination of the findings of august medical institutions. The committee approach, however, gains strength from the fact that no conclusion is reached without a thorough sifting of the evidence through diverse minds exposed in different ways to the educational process. The final formulation will depend much upon the character and mastery of the chairman. The report of the Goodenough Committee in 1944, of the Royal College of Physicians in 1944, and of the two B.M.A. Committees in 1948 and 1950 presided over by Sir Henry Cohen, all had an authority which any individual contribution must necessarily lack. These reports will have, and are having, an effect on medical education. But the reformer must feel impatient over the slowness with which change takes place, with the inertia of the schools and the conservatism of the teacher moving comfortably along well-worn tracks. The value of such a contribution as Dr. Roberts's is that this impatience is kept alive and saves us from the rosy optimism of Dr. Pangloss. Much of what he notes in his book is echoed in this symposium. Discussing the training of teachers, he reminds us that more than a hundred years ago Pestalozzi and Froebel insisted on educating a child through its own activity, and tells us of the current observation of the County Education Officer for Cambridgeshire: "In my experience the daily struggle in education is to get away from the printed word to the

[1] *Medical Education.* By Ffrangcon Roberts, M.D. H. K. Lewis. 12s. 6d.

reality, from the abstract to the concrete. Words are always being substituted for things." The clinical student reads the report of special investigations instead of observing the patient by the classical approach of inspection, palpation, percussion, auscultation. At least that is the trend. There is a great risk that the modern student may be encouraged to believe that the former is more scientific than the latter. Dr. Roberts is surely right when he says: "The lively interest shown in child education stands in marked contrast to the stagnation which pervades the medical schools." In the school, he observes, the emphasis is on method; in the hospital, on the subject taught. Roberts advocates the establishment of a college for training medical teachers in the techniques and methods of education. This may well be impracticable, but, even if it were, could we feel sure that stagnation would not once more set in? What is needed is something more flexible, more experimental. Professor Lauwerys's suggestion of country-house conferences would offer a chance for the lively interplay of active minds drawn from various teaching schools. There they could learn much from educational theorists and psychologists.

"Schools have been classroom-ridden, lesson-ridden, textbook-ridden, information-ridden." Such is the view of the Cambridgeshire Education Officer. How much more true it is of medical schools. Dr. Roberts, with his interest in adding things up, tells us that in 1907–12 the number of words in five textbooks of anatomy and physiology was 2,186,000: in the current editions of these books the number has increased by more than a million. In 1907–12 the number of words in five standard textbooks respectively of medicine, surgery, midwifery, gynaecology, and pathology was 4,562,000: the number of words in the current editions has increased by just short of two million. It may be possible to read, mark, and even learn this surfeit of words: but attempt at inward digestion can lead only to flatulent dyspepsia. Dr. Roberts shows himself to be an "activist" in education, and is in line with those who rightly believe that a student should learn by doing. The big fault in education, he considers, is the failure "to inculcate the habit of accurate observation"; and the biggest task before the medical schools "is to reform teaching so that curiosity is not deadened." Some of the observations made in this issue of the *Journal* suggest that the medical schools generally have a long way to go before they attain this end.

TEACHING BIOLOGY

Discussion of biological education in school and university has been particularly active in recent years, stimulated in part by the ferment of ideas about medical teaching. Most of it has a strangely unscientific flavour when one considers that the discussion is carried on by trained scientists. It tends to consist of confident assertions the evidence for which, made up as it is of rather intangible personal impressions, is rarely mentioned. Consider this bald statement, which appeared in a distinguished educational report: "The teaching of science to the young student needs to be essentially dogmatic until, at the age of 16 or 17 years, the mind of the average boy is becoming attuned to the dialectic method." Who would guess (if he did not know from long experience of educational pronouncements) that a questionable hypothesis, not an established fact, is here put forward? What scientist would phrase an equivalent remark in his scientific work in such an unqualified way? A vast tissue of hypotheses about education has been given authoritative tone in the same way. Much of it is of course stimulating; and we need not doubt that much of it, based on the experience, however casual, of very acute minds, will prove to be right when we are at last able to assess its validity. But an attitude which seems so often to disregard the importance of objective validation surely ought to trouble the consciences of scientists.

There is a different approach—to treat biological education as a scientific problem, capable of examination in the light of the evidence, subject even to experimentation. This attitude permeates a most stimulating recent book on biological education.[1] Professor T. L. Green, the author, deals mainly with schools, though he takes occasional despairing glances at the universities. He shows that there already exists objective evidence on many problems. Admittedly much of it is weak, much of it only partly relevant to present conditions in this country. It needs the critical and cautious handling which Professor Green gives it; but it certainly does not merit the neglect it usually receives. This book, however, does more than call attention to the literature; it should have the effect of encouraging investigation, the results of which are the only sure foundation for educational advance. The need for such experimentation in medical education was repeatedly emphasized in the report of the Medical Curriculum Committee of the B.M.A.[2] Of course, education, like the patient, cannot always wait for scientific advance before being taken in hand. But the least teachers can do is to seek objective evidence and, when it cannot be obtained in time, to treat subjective "hunches" with the cautious respect they deserve. Meanwhile a steady trickle of research on problems of school biology has for a long time appeared in such journals as *School Science Review*. The universities on the whole have preferred pontificating; but it is gratifying that a few preclinical departments are in the vanguard of the scientific approach to biological education.

EXAMINATION RESULTS

Examinations are always looming up in the life of medical students, and both they and their teachers will find points of interest in Dr. Lewis-Faning's analysis[3] of examination results in a group of 517 medical students who enrolled at University College, Cardiff, during 1933–42. Ninety-five of the students were exempted from taking not more than two, and 58 were exempted from all three, preliminary subjects. The different standard of teaching in boys' and girls' schools is shown by the proportions exempted. Of the 329 men and 141 women who studied for the Welsh degree 18.8% of the men were let off the examination in physics compared with 7.8% of the women, but for biology 28.4% of the women were granted exemption against 14.9% of the men. Approximately one-quarter of both males

[1] *The Teaching and Learning of Biology in Secondary Schools—With Special Reference to Grammar Schools*, 1949, London.
[2] *The Training of a Doctor*, 1948, London.
[3] *Report on the Examination Performance of Medical Students, 1933-1948.* Published in 1950 by the Welsh National School of Medicine, Cardiff.

and females were allowed to omit chemistry. The percentage of students who obtained the Welsh degree without a single examination failure was 24 for the group without any exemptions in the preliminary subjects, 40 for the group with partial exemption, and 48 for the group with total exemption. The average number of unsuccessful attempts per student for these three groups were 2.7, 1.5, and 1.0 respectively. These comparisons are subject to the limitation that the students who obtained one or more exemptions had fewer examinations to sit than those who were not let off preliminary subjects and hence had a smaller risk of failure; but it does seem that the groups excused one or more subjects contained the most successful students.

The proportion who passed an examination at the first attempt varied considerably for the different subjects. In the final examinations the group which had to take all the preliminary subjects found medicine and forensic medicine the most difficult, with 74% passes in each, while hygiene and surgery, each with 82% passes, were their best subjects. The group with partial exemption also found medicine the most difficult (76% passes), with forensic medicine next (84% passes), while their best efforts were hygiene (94% passes) and pharmacology (90% passes). The experience of the group excused all the preliminary subjects was different: they found surgery and obstetrics and gynaecology the most difficult final subjects, each with 85% passes, while 94% passed in medicine and hygiene at the first attempt. For each subject separately approximately 10% more passed at the first attempt in the groups with exemptions of preliminary subjects than in the group that had to take the lot. Among 2nd-M.B. subjects physiology gave each of the three groups of students some trouble. This examination had the largest average number of unsuccessful attempts of any subject: for the group without exemptions in the preliminary subjects the percentage of unsuccessful attempts was 59, for the partial-exemption group 27, and for the group with total exemption 19.

The report also discusses the performance of students at examinations for the Welsh degree, the conjoint board diploma, and the London degree. Of the 517 students enrolled, 52% attempted the Welsh degree only; 10% the London and Welsh; 23% Welsh and conjoint; 4% Welsh, London, and conjoint; 1% London only; 5% London and conjoint; 2% conjoint only; and 3% never sat an examination. A comparison of performance by kind of qualification is difficult, since only a small number persist in attempts to obtain a dual qualification, and a larger number, after failure in the examinations of one body, concentrate entirely on the other. This self-selection introduces some bias into any comparison of results of different examining boards. The duration of study must also be considered, since almost any student can eventually graduate if the period of study is prolonged. In the final examination the percentage who passed at the first attempt in pathology, obstetrics and gynaecology, and surgery was the same for the Welsh degree and the conjoint diploma, but in medicine 89% passed the conjoint at the first attempt compared with 70% in the Welsh final. These figures do not support the common belief that the conjoint examinations are easier than those for a University degree.

HOW MANY DOCTORS?

It is commonly said that the answer to the problem of the harassed G.P. with an overlong list and to the drooping patient waiting hours in out-patients is simply "We must have more doctors." Enthusiasts for regular health examinations for all in the Peckham manner also base their plans on an increase in the size of the profession. Meanwhile, to judge by the hordes of applicants who continue to besiege medical schools, the National Health Service does not seem to have lessened the attractiveness of medicine as a profession in spite of pessimistic forecasts, and numbers if not quality are certainly available. Bart's, for instance, reports roughly 2,000 applicants for about 100 places this year, King's College Hospital has over 600 for the 40-odd vacancies for men, and the same picture emerges from the general survey of the schools given elsewhere in this issue. The Goodenough Committee in 1944 recommended an annual intake of 2,500–2,600 students in Great Britain and Eire, a range which came close to the *1939–40* entry of 2,623 and which has been followed in all the post-war years. Should this figure be reconsidered and the entry increased?

A glance at the tables under "Doctors and Population" on page 502 of this issue at once reveals three little-known facts with an important bearing on the answer. Since 1920 the average number of people per doctor has dropped very considerably and is now down to about 2,400 per general practitioner; this means we have relatively more doctors for our size of population than any other country except the United States (and Israel); and meanwhile the number of young people in the 15–24 age group from which the majority of students come has shrunk markedly. This group at the same time has other increasing demands on it. The Barlow Committee on scientific man-power estimated the number of qualified scientists in the United Kingdom in 1946 as about 55,000 and reckoned on a demand for 90,000 by 1955. This need has not yet been fully met, but already there is a serious shortage of science teachers, and more applied scientists are wanted in industry.[1]

Since the number of young people capable of higher education to the requisite standard is finite and decreasing, any further increase in the proportion of doctors inevitably implies a decrease in some other category of professional employment. Where do we propose to cut down? It seems more reasonable to accept the present size of the profession as satisfactory, and to concentrate on making more efficient use of its members. It is foolish to spend six or more years training a man and then demand routine work for him which could be much better done by a clerk or auxiliary after six months' instruction. There is clearly an ideal ratio of consultants to general practitioners. And last, but not least important, there is medical training itself, which must produce an efficient man competent for the job he has to do. General practice is very different from hospital practice, and a man who is merely a failed hospital officer is not fully prepared for his work.

POSTGRADUATE EDUCATION IN LONDON

The British Postgraduate Medical Federation, which is a school of the University of London, comprises the Postgraduate Medical School at Hammersmith Hospital, with its university departments of general medicine, general surgery, and pathology, and Institutes of Cardiology, Child Health, Dermatology, Diseases of the Chest, Laryngology and Otology, Neurology, Obstetrics and Gynaecology, Ophthalmology, Orthopaedics, Psychiatry, Urology, and Dental Surgery, each associated with a special hospital. These institutes are in various stages of development, and the number of students who can be admitted to the clinical practice of some of the hospitals is limited. Appointments of the house-officer and registrar types in the hospitals and institutes provide the most valuable form of postgraduate education, and there are opportunities for research for selected graduates. At all the institutes courses of instruction are given throughout the academic year; these are suitable for graduates in the early stages of their specialist education, and also for those who have completed their practical training. Two or more years of hospital work in general medicine and general surgery after graduation are normally advisable before beginning work in the special branches. The work at the institutes is of an advanced type and is comprehensive enough to enable graduates with suitable practical experience to prepare for higher degrees and diplomas. Emphasis is placed on clinical and laboratory teaching, supplemented by lectures and demonstrations. The address of the British Postgraduate Medical Federation (director, Sir Francis Fraser) is 3, Gordon Square, London, W.C.1.

To effect co-operation between the Federation and the three Royal Colleges in providing postgraduate education in the medical specialties in London, supplementing the provisions of the undergraduate medical schools and teaching hospitals, there is a Joint Board. Each of the three Royal Colleges arranges courses of lectures in the clinical aspects of its specialty, and the Royal College of Surgeons provides, in addition, courses of lectures and demonstrations in the basic sciences for those intending to be surgical and dental specialists, and in anaesthetics. Each Royal College also provides expert advice and guidance on suitable hospital appointments and programmes of study for candidates for its higher qualifications and other graduates visiting this country for further study.

The Federation is arranging a course of advanced lectures entitled "The Scientific Basis of Medicine" on Tuesday and Thursday afternoons during the autumn and winter terms of the *1950–1 sessions*. The lectures are held at the London School of Hygiene and Tropical Medicine, and are designed specially for research workers and specialists in training; they are open to all registered medical practitioners without fee. A detailed syllabus of the course appeared in the advertisement columns in last week's *Journal* (p. 38).

The regional advisers in postgraduate education to the four metropolitan regions of the National Health Service have continued their surveys of the hospitals in their regions with a view to ascertaining the educational facilities for specialist and general-practitioner training and grading them accordingly. Attendance on the practice of these hospitals and their resident appointments afford valuable opportunities for graduates in need of further clinical experience. Information on these facilities is available at the Central Office of the Federation.

A programme of refresher courses for general practitioners has been arranged at the non-teaching hospitals of the four metropolitan regions. These include several week-end courses and courses spread over two months. Those interested are referred again to the programme of these courses which appears in our advertisement columns.

Prospective postgraduate students should make their arrangements well in advance. Those sponsored by their universities, governments, or other official bodies receive first consideration in the allotment of vacancies. Established specialists from overseas, here for a relatively short time, who wish to see something of the practice in this country, are always welcome; they are regarded as visiting colleagues, and the experts in their specialties are always ready to receive them and let them accompany them in their work and teaching. The Federation maintains an information bureau of postgraduate activities in London and other university centres. All inquiries should be directed to the office of the Federation at the address given above.

Specialist Institutes

Below are given brief particulars of the Postgraduate Medical School and the Institutes associated with the Federation:

Postgraduate Medical School of London (associated with Hammersmith Hospital, Ducane Road, W.12).—University departments in medicine, surgery, and pathology. Teaching in clinical departments, which is of an advanced nature and based on ward work, continuous throughout the year and supplemented by lectures and demonstrations during three 10-weeks terms beginning in October, January, and April. A formal 12-months course beginning in October available for the postgraduate diploma in clinical pathology of the University of London; selection of students usually made in June. Department of pathology has separate suites of laboratories for bacteriology, histology, biochemistry, haematology, and experimental pathology. Department of radiology provides courses for D.M.R. of the University of London and Conjoint Board. Students accepted for practical training in anaesthetics for periods of from two weeks to six months. Resident clinical appointments usually made from suitable students at the school.

Institute of Cardiology (associated with National Heart Hospital, Westmoreland Street, W.1).—Seven appointments of registrar type available each year for physicians in training as cardiologists. Three terms annually, beginning October, January, and May. Training includes clinical cardiology, radiology of the heart, and electrocardiography. Research facilities available for limited number of advanced students. General physicians may enrol for full or part-time instruction for one or more terms of three months' duration. Three intensive courses of lectures and demonstrations, each lasting a fortnight, held in February, June, and November.

Institute of Child Health (associated with Hospital for Sick Children, Great Ormond Street, W.C.1, Postgraduate Medical School at Hammersmith Hospital, and Queen Elizabeth Hospital for Children).—Tuition provided throughout the year in three terms, beginning September, January, and April, and in addition a series of lectures by specialists and experts in various spheres is given each term. Every student has the opportunity of holding a clinical clerkship for one month during his study.

Institute of Dental Surgery (associated with Eastman Dental Hospital, Gray's Inn Road, W.C.1.).—Dental practitioners are trained in the special branches of preventive and therapeutic dentistry, and departments are being developed for orthodontics, children's dentistry, periodontia, prosthetics, and oral surgery. Appointments of house-officer, registrar, and clinical assistant types available for selected graduates.

Institute of Dermatology (associated with St. John's Hospital for Diseases of the Skin, Lisle Street, W.C.2).—Clinical teaching takes place in out-patient department twice daily. A long and systematic course of lectures during winter months and a shorter course during the summer. Owing to restricted accommodation, no ward instruction is yet possible.

Institute of Diseases of the Chest (associated with Brompton Hospital, S.W.3, and London Chest Hospital).—Courses of instruction in diseases of the chest, including tuberculosis, conducted during three terms of twelve weeks' duration, beginning in September, January, and April. Courses consist of clinical work in the wards and out-patient departments, lectures, and demonstrations. A larger number of graduates can be accepted for part-time study. Part-time courses of instruction in radiology of the chest, each lasting twelve weeks, are held three times a year for suitably experienced graduates.

Institute of Laryngology and Otology (330, Gray's Inn Road; associated with Royal National Throat, Nose, and Ear Hospital, Gray's Inn Road, and Golden Square).—Full-time comprehensive courses of lectures and demonstrations, lasting for nine months, begin in February and September. First three months spent in the study of the anatomy, physiology, and pathology of the subject, and following six months with clinical aspects. Part-time advanced revision course, suitable for students preparing for higher qualifications, held twice yearly. A number of paid appointments open to students after completion of basic training in specialty.

Institute of Neurology (associated with National Hospital for Nervous Diseases, Queen Square, W.C.1, and Maida Vale Hospital for Nervous Diseases).—Teaching mainly by attendance on hospital practice; more advanced students appointed as clinical clerks in wards or attached to special departments and research laboratories. Two 10-weeks whole-time courses in clinical neurology held in autumn and spring terms, and in summer a six-weeks course in neurosurgery.

Institute of Obstetrics and Gynaecology (associated with Queen Charlotte's Maternity Hospital, the Chelsea Hospital for Women, and the Department of Obstetrics and Gynaecology at the Postgraduate Medical School).—Teaching based on ward work and supplemented by lectures and demonstrations during three 10-weeks terms, beginning in October, January, and April. Short intensive revision courses of a fortnight's duration held twice a year, in June and December. During vacation selected postgraduates may attend practice of hospital at Queen Charlotte's or Hammersmith. Resident house appointments and registrarships available for selected graduates.

Institute of Ophthalmology (Judd Street, W.C.1; associated with Moorfields, Westminster, and Central Eye Hospital).—Clinical work in out-patient department, wards, and operating theatres of the hospital, supplemented by lectures, practical classes, and tutorials at the institute. A routine lecture and tutorial course, normally covering two terms of about eighteen weeks each, begins in March and October each year. Laboratories for bacteriology, histology, and biochemistry, and research in all associated fields.

Institute of Orthopaedics (associated with Royal National Orthopaedic Hospital, Great Portland Street, W.1).—Training in orthopaedics to selected graduates afforded by means of clinical appointments covering a period of from two to three years, with opportunities for research. Formal courses of varying lengths on selected subjects connected with the specialty are given during the academic terms. Twice a year, in April and September, a short revision course.

Institute of Psychiatry (associated with the Maudsley Hospital, Denmark Hill, S.E.5, and Bethlem Royal Hospital, which jointly form a teaching hospital).—Training normally covers two to three years after adequate experience elsewhere in general medicine, and is based on responsible hospital duties under supervision. Appointments available as registrars and research assistants. Regular series of lectures and demonstrations by experts in various fields relating to psychiatry are given throughout each of the university terms, which begin in October, January, and April. Clinical teaching continues throughout the year, and includes seminars and case discussions. Besides the wards and clinical departments there are laboratories in neuro-anatomy, electro-physiology, biochemistry, and psychology.

Institute of Urology (associated with St. Peter's and St. Paul's Hospitals, Henrietta Street, W.C.2)—Three courses of fourteen weeks' duration held annually, beginning in September, January, and April. These courses include systematic lectures covering the whole subject of urology, out-patient sessions, ward visits, operation sessions, and tutorial demonstrations. In addition an intensive revision course of two weeks' duration is held in September, March, and June. Resident appointments and clinical assistantships available for selected students already adequately trained in general surgery.

Advanced Revision Courses in Surgery

Of the London Medical Schools, Guy's, the London, St. Bartholomew's, St. Thomas's, and Westminster provide full-time advanced revision courses in surgery of from eight to twelve weeks. The fee is 40 guineas, save at Westminster, where it is 50 guineas. The North London Postgraduate Medical Institute provides an eight-weeks course (fee 25 guineas). The Royal College of Surgeons has a part-time demonstration and lecture course, lasting 2½ weeks and beginning in October and April, the fee being 12 guineas.

The Royal College of Surgeons has also arranged a number of other lectures and demonstrations. Between October and January and also between April and July there will be a series of 20 lectures and practical demonstrations in anatomy, applied physiology, and pathology. In anaesthesia two series, each of 45 lectures, will be given in October and April. In addition courses extending over a period of from one to two years are being arranged. Lectures and demonstrations in oral, dental, and general surgery, in conjunction with the Eastman Dental Clinic, will be given in October and November and also in March and April, and lectures and practical demonstrations on the application of the basic sciences to dental surgery have been arranged. In surgery two series, each of 24 lectures, will be given during October and April.

Facilities are available for advice on postgraduate orthopaedic training through the Postgraduate Orthopaedic Committee which, with its headquarters at the College, has been established under the aegis of the College, the Royal College of Surgeons of Edinburgh, the Royal Faculty of Physicians and Surgeons of Glasgow, the British Orthopaedic Association, the Institute of Orthopaedics of the British Postgraduate Medical Federation, and the Department of Orthopaedics of the University of Liverpool.

Residential accommodation is now available within the College at Lincoln's Inn Fields for postgraduate students.

The Royal College of Physicians of London holds a series of lectures for postgraduates on advanced clinical subjects. The lecturers are specially distinguished in their respective fields and are drawn from the provinces as well as London.

Courses of advanced postgraduate lectures are given at the Royal College of Obstetricians and Gynaecologists, and there are frequent special lectures by men and women eminent in this field. There is a library and museum in the College House at Queen Anne Street which is open to all who are interested in these subjects.

An important step forward has been taken by the Middlesex Hospital in increasing the number of registrars. This means that more men can receive postgraduate instruction with a view to becoming future consultants and specialists.

The North London Postgraduate Medical Institute (Prince of Wales's General Hospital, London, N.15) holds courses in advanced medicine, advanced surgery, and obstetrics and gynaecology, and instruction is given in pathology, anaesthetics, and radiodiagnosis. Clinical instruction is given at Bearsted Memorial Hospital, Chase Farm Hospital, North Middlesex Hospital, Prince of Wales's Hospital, and St. Ann's General Hospital. During the coming year there will be eight-week courses in advanced medicine suitable for those taking the M.R.C.P. examination, eight-week courses in advanced surgery suitable for those taking the F.R.C.S. examination, and two-week courses for those taking the D.Obst.R.C.O.G. examination.

The Tuberculosis Educational Institute (Tavistock House North, Tavistock Square, W.C.1), which is composed of representatives of the Joint Tuberculosis Council and the National Association for the Prevention of Tuberculosis, undertakes responsibility for the organization of regular refresher courses for doctors, nurses, and social workers. A course, for doctors only, dealing with the pathology and immunology of tuberculosis will be held at the Sir William Dunn School, Oxford, from September 19 to 22. Preliminary arrangements are being made for a course in industrial tuberculosis at Birmingham in 1951. Three-day clinical courses are held at certain provincial sanatoriums throughout the year.

The Royal London Homoeopathic Hospital (Great Ormond Street and Queen Square, London, W.C.1) provides a course of lectures in homoeopathy for postgraduates. These include a course on homoeopathic materia medica and therapeutics on Mondays and Thursdays from October, 1950, to March, 1951, and a course at the Glasgow Homoeopathic Hospital from January to March, 1951.

A refresher course for general practitioners, extending from September to December, 1950, and covering general medicine and obstetrics and gynaecology, is being held under the auspices of the British Postgraduate Medical Federation at various hospitals in and around London, including hospitals at Rochester, Folkestone, Brighton, Southend-on-Sea, Horsham, and Ilford. Some of the courses are for one or two weeks, and others for the week-end. These courses are available to N.H.S. practitioners for whom fees and allowances (travelling expenses, fees for locumtenents, etc.) are provided for courses equivalent to 22 half-day sessions a year, on certain conditions. Other practitioners may attend on payment of a fee of 10 guineas for two weeks, 5 guineas for one week or for equivalent extended courses, and of 1½ guineas for week-end courses.

Fellowship of Postgraduate Medicine

The Fellowship of Postgraduate Medicine (1, Wimpole Street, W.1) provides general information on postgraduate work and arranges courses of instruction as follows:

1. Courses suitable for, though not restricted to, candidates for the D.A., D.C.H., D.Obst.R.C.O.G., M.R.C.P., and F.R.C.S. (Final). These include general medicine, general surgery, neurology, neuro-ophthalmology, proctology, obstetrics, and children's diseases. Some are full-time courses lasting from one to two weeks; others are spread over longer periods, either in the mornings, afternoons, or late afternoons, and are intended particularly for postgraduates who are not free for full-time study.

2. Week-end courses, occupying the whole of a Saturday and Sunday. These are given in various hospitals, and include such subjects as general surgery, general medicine, orthopaedics, rheumatic diseases, and infectious diseases.

THE LONDON UNDERGRADUATE SCHOOLS

The past year has seen little change in the London medical schools. One of the deans, in answer to our request for information, writes regretting that his account is "an annual monotony and a lack of really exciting things."

To begin in the East, the London Hospital Medical College has seen no major changes in the clinical curriculum. The introductory course has been further co-ordinated, and the system of lectures is being reorganized to provide greater integration. The students benefit increasingly from the tutorial system, and the fact that this system requires a large number of registrars increases the facilities for giving postgraduate training. Registrars meet once a fortnight for a ward-round, during which cases of interest in different parts of the hospital are shown and discussed. The clinico-pathological conferences held every two weeks during the last three years have become a valuable addition to the training of undergraduates and postgraduates alike. Structural alterations have much improved the facilities of the departments of anatomy and physiology.

The London Hospital now maintains 885 beds, of which 699 are at the hospital itself and 186 at the annexe at Brentwood. About 40 students are admitted to the clinical course each half-year.

At the Medical College of St. Bartholomew's Hospital the total number of students remains at approximately 800. Until the new regulations for the work to take the place of that now done in the first and second M.B. are agreed and passed from the University to the schools it is not possible to do very much in the way of altering the preclinical curriculum. Preparations are being made for knitting together the work of the zoologists with the anatomists, and that of the chemists and physicists with that of the physiologists, biochemists, and pharmacologists. But so long as the first and second M.B. remain very much in their present form these plans cannot be put into full action. In the clinical years the policy at "Bart's" still remains to teach medicine as a single subject, and not let its main branches of surgery, obstetrics, and clinical medicine fly into too many splinters and specialties. The pressure to do so is great, because with the increasing specialization in the clinical work it is difficult to avoid any special courses in thoracic surgery, neurosurgery, cardiology, and the like; but it is felt that such courses are for the postgraduate rather than the undergraduate.

Many of the problems at West Smithfield are still wrapped up with the difficulty of getting sufficient buildings. Progress is being made, but much more is expected in the replacement of war damage and in catching up with the new buildings which would have been needed in any case had a war not taken place.

Across the river at Guy's there are 80 vacancies in the preclinical period, of which roughly two-thirds are for the first year, the remaining third entering the second year, the first M.B. having been already passed. In addition, 25 places are reserved for Oxford and Cambridge men for the clinical period of studies. All students take a three-months preliminary course before entering the wards.

The accommodation at Guy's has been increased during the year by a small extension to the new pathology building which, with some additions to the existing building, has provided accommodation for a department of bacteriology. An academic department of bacteriology was instituted in October of last year, when a professor was appointed. The extension has also afforded some additional animal-house accommodation, and a research laboratory for the clinical departments has been provided by reconstructing a floor of the old pathology building. Most departments of the School are in need of more space, and it is hoped to begin to provide this during the course of the next year. An important development will be the institution of a number of research fellowships in the clinical departments, made possible by the Endowments Committee of the hospital.

Reorganization at St. Thomas's

The past year at St. Thomas's Hospital Medical School has seen a complete reorganization in equipment and accommodation of the medical and surgical clinical units; the former has a particularly fine range of laboratories. The School is now back to pre-war conditions, except for shortage of beds and temporary loss of hostel accommodation, though extra space is badly needed in nearly all departments. Various small research laboratories have been completed and work is actively proceeding in them. The photographic department is proving a great boon to both school and hospital. At Cobham, Surrey, which is 45 minutes away, the athletic ground purchased two years ago is now fully developed and provides excellent facilities.

Over 70 new students have entered the Westminster Hospital Medical School in the academic year now closing. This brings the total of clinical students to 175, of whom 20 are women. It is not the policy of the School to exceed this entry, but it is considered that there are adequate clinical facilities for such a number.

With the object of increasing the clinical material available for Westminster students a medical "firm" of 12 students is sent to the near-by St. Stephen's Hospital every three months, and this arrangement is working well. Five members of Westminster staff are also on the St. Stephen's staff, and with the keen co-operation of the remaining St. Stephen's physicians a very sound course is assured. In addition, two students at a time are resident at St. Stephen's for practical midwifery instruction, and this arrangement substantially augments the facilities available in the parent hospital. During the past year the surgical teaching resources have been greatly increased by attaching a surgical "firm" to the Gordon Hospital, Vincent Square, a hospital which originally specialized in diseases of the rectum but now admits general surgical cases. The paediatric course is held each three months at the Westminster Children's Hospital, Vincent Square. The incorporation of this hospital and of the Gordon and All Saints' Hospitals in the teaching group has added enormously to the clinical facilities since the "appointed day," and has permitted a balanced clinical curriculum to be secured. An inspection was held by the University in December, 1949, and the inspectors' report commented favourably on the standard of work and facilities in the School.

Medical Curriculum Revised

At King's College Hospital Medical School, Denmark Hill, the medical curriculum has been revised and has been operating successfully since January of this year. The tradition of the apprenticeship method has been maintained, and students are allocated to medicine, surgery, and obstetric "firms" for periods of six months, as it is considered impossible for teachers to get to know their students properly in less than that time. The new curriculum provides for the integration of some of the specialties into the six-monthly periods of medicine and surgery and also for an additional period of three months' senior medical clerking and three months' senior surgical dressing in the third year, when the student is attached to a different "firm." Three months is devoted to child health, including attendance at school and infant-welfare clinics and a two-weeks residential period at the Belgrave Hospital for Children. Revision courses on the work of the clinical period are conducted by the tutors preceding the final degree examinations. During the 12 months up to May, 1950, 43 students gained qualifying degrees in medicine in the Universities of Oxford, Cambridge, and London, including two with honours in one or more parts. A student of the School was awarded the University of London Medal in the April, 1950, M.B., B.S. examination.

Each year 50 medical and 25 dental students are admitted to the King's College Hospital School. The School provides the clinical training for men and women students reading for the medical degrees of the above-named universities. The preclinical course for students reading for the University of London

degrees of B.M. and B.S. is taken in the Faculty of Medical Science, King's College, Strand, where students are admitted once a year, in October. Thus for the first two to three years of their medical training King's College students have the great advantage of college life in association with students of all faculties. Students are admitted for clinical training twice a year—in April and October. The first three months are occupied by an intensive introductory course designed to familiarize the student with clinical methods, the examination of patients, hospital nursing and routine, and the basic principles of pathology.

Eighty students have been accepted for entry into St. Mary's Hospital Medical School, and the number of applications for places available is still very large. Arrangements have been made for St. Mary's students to attend at Paddington Hospital for part of their medical and surgical appointments, thus increasing the number of beds available for the teaching of these important subjects. Use is being made of the hospitals associated with the St. Mary's group for clinical teaching. A new appointment has been made to the chair of surgery, and new readers in anatomy, bacteriology, pharmacology, and physiology were also appointed at the beginning of the session. Alterations are being made to the anatomy, physiology, and physics departments in order to increase the facilities for teaching and research. It is hoped to provide new laboratories for the surgical and paediatric units shortly. A large block of houses near the medical school has been purchased for conversion into a students' hostel for the accommodation of about 200 students, to be ready in two years' time. No great changes have been made in the curriculum, but consideration is being given to the period of each clinical appointment in order that the best use may be made of the 36 months available to cover the clinical course.

New Plans for Charing Cross

On the basis of the present entry at Charing Cross Hospital Medical School about 40 students will qualify each year. In addition to the 27 house posts available in the parent hospital, there are nearly as many at the associated hospitals—Harrow, Mount Vernon, and Wembley—and it is not anticipated that there will be any difficulty in providing every student with satisfactory posts. The plans of the new Charing Cross Hospital and School to be built at Northwick Park have been formally presented to the Ministry of Health, the Court of the University, and the University Grants Committee. They provide for a hospital with 800 beds and a school to admit 80 medical and 40 dental students a year to cover all subjects of the medical curriculum. The plans of the school include a hostel, a union building, a teaching block, refectory, hall, library, and administrative section with their ancillaries. It is hoped that official approval will shortly be given to the plans and that the work of building will begin. As a measure of short-term expansion a lease has been taken of certain premises in the vicinity of the School at Charing Cross, and when alterations are complete the departments at present housed in the School will be transferred there, enabling extension to be effected not only of the transferred but also of the departments remaining at Chandos Place.

The Royal Free Hospital School of Medicine is now open to men as well as women, and this year has had 487 students in attendance. Candidates for admission in 1951 will be selected by an interviewing committee during the coming autumn term.

The new wing which is being added to the School building in Hunter Street will be available for use next session and will provide additional teaching and research laboratories and a students' common-room. Clinical teaching is given throughout the hospitals associated with the Royal Free Hospital group, which includes the main hospital in Gray's Inn Road, the hospitals in Liverpool Road, Islington, and Lawn Road, Hampstead, the Elizabeth Garrett Anderson Hospital, and the Hampstead General Hospital. This provides a total of 800 beds, and it is hoped that more beds will shortly be available at Liverpool Road. Arrangements have been made for the sharing of social and recreational clubs between the Students' Union of the School and the Students' Union of Guy's.

The West London Hospital Medical School at Hammersmith is for the moment admitting no further undergraduate students, and the present undergraduate population will probably all have completed their course by 1952. The only change at this School during the past year has been that a certain number of postgraduate students from the Postgraduate Medical School at Ducane Road, Shepherd's Bush, have been attending during the past two academic terms. The extent of future co-operation with the Postgraduate School is still undecided.

The Middlesex Hospital has now been fully reopened, and in fact there are more beds available for teaching than before the war. Facilities for instruction in the clinical period are enhanced by the fact that the majority of students in their clinical period have the advantage of being attached to the Central Middlesex Hospital, Willesden, for at least three months' instruction. Two improvements in the clinical period have been recently introduced. The students now do three weeks' resident instruction in infectious diseases at the North-Eastern Fever Hospital. Still more recently the students have been enabled to visit the Harefield Hospital for instruction in pulmonary tuberculosis.

The advantage of the link with associated hospitals is also enjoyed by most of the London Schools. University College Hospital, for example, has associated with it the Obstetric Hospital and the Royal Ear Hospital in Huntley Street, the Hospital for Tropical Diseases, and the St. Pancras Hospital (formerly an L.C.C. institution).

King's College (University of London) provides education in the preclinical stage for the University of London, M.B., B.S. degree. On completing their preclinical studies students proceed to King's College Hospital, St. George's Hospital, or Westminster Hospital, according to their personal choice. No student is allowed to begin preclinical studies at the College who has not also been provisionally accepted by the hospital for clinical training. Men making application for entry to King's College should apply at the same time to one of the hospitals. The maximum number of women to be admitted in any one year is eight for King's College Hospital Medical School, six for St. George's, and six for Westminster. Applications for women students should reach the Sub-Dean of the Faculty of Medical Science, King's College, Strand, W.C.2, by the end of the year preceding the session in which admission is desired.

POSTGRADUATE COURSES OUTSIDE LONDON

We cannot pretend to give a complete list of the courses of postgraduate instruction held at universities and colleges in the United Kingdom outside London. Courses of advanced instruction in general medicine and in general surgery are held at Edinburgh (Postgraduate Board for Medicine, Surgeons' Hall, Nicolson Street, Edinburgh) and advanced revision courses in general medicine at Liverpool and Sheffield. A nine-months course in general surgery at Liverpool, beginning in October, is directed towards the Ch.M.(Liv.), but is suitable also for F.R.C.S. candidates. Courses in anaesthetics are given at Bristol, Liverpool, and Oxford; in anatomy, physiology, and pathology at Edinburgh; in neurology and in ophthalmology at Birmingham; in orthopaedic surgery at Liverpool; in paediatrics at Bristol, Glasgow, and Liverpool; in physical medicine at Bristol; and in psychiatry at Bristol, Edinburgh, Glasgow, and Leeds. Some information about other courses is given under the heading of "Special Diplomas."

The course in general medicine at Liverpool is part-time, and intended for postgraduates holding registrar or similar appointments and at the same time studying for a higher degree. Graduates attending the course who do not hold hospital appointments may be offered facilities for clinical experience in the wards. Part-time extended courses in obstetrics and gynaecology are held at Liverpool from time to time, as well as refresher courses for general practitioners, but it is said that the number of general practitioners seeking to avail themselves of such courses does not appear to be very great.

At Leeds there is a part-time course for the Diploma in Psychological Medicine. The course lasts two years. For general practitioners, weekly clinical meetings are organized at Leeds University from October to May, while week-end courses on special subjects are also held at intervals throughout the year.

At Glasgow postgraduate medical instruction is available, in the form both of clinical attachments and of organized courses. The transition from the Class I and Class III Government-subsidized posts to the registrarships of the National Health Service has led to the abandonment for the present of prolonged full-time postgraduate courses in general medicine and general surgery, but it is hoped to resume organized instruction in these subjects during the coming session. Courses in child health and in mental deficiency have been held during the past year, and the latter will be repeated at the beginning of the ensuing session. Periodic refresher courses for general practitioners are also held.

The Postgraduate Medical Education Committee of the University of Oxford (91, Banbury Road) has arranged a programme of ward rounds, clinics, and lecture-demonstrations at the United Oxford Hospitals. Some eight or ten of these in different departments take place each week-day. The programme extends from September to December, and another programme, with other physicians and surgeons on duty for postgraduate teaching, is arranged for January to July, 1951. Short courses in special subjects (otolaryngology, paediatrics, and dermatology) are available at the United Oxford Hospitals during the Michaelmas term provided that not less than six general practitioners apply to attend each course. These programmes provide for practitioners who wish to attend one or more short courses, those who wish to spend a week, a fortnight, or longer in intensive study, and those who wish to attend any number of "sessions" convenient to themselves during the postgraduate year. The programmes are circulated to general practitioners by the various executive councils in the Oxford region.

UNIVERSITY MEDICAL CENTRES OUTSIDE LONDON

All the provincial medical schools report an excess of applicants. Birmingham: "The number of students wishing to enter the Faculty still far outnumbers the vacancies." Bristol: "The applications for admission remain extremely high, and we are able to accept only about 1 in 10 of the applicants." Liverpool: "The number of applications for admission is slightly less than in previous years, but is still greatly in excess of the number of places available." Durham: "Selection of candidates for entry to the courses has again been difficult owing to the very large list of applicants." Leeds: "Applications for entry to the School have continued to exceed by many hundreds the places available."

In the Faculty of Medicine at Birmingham a new method of selection has been used. Those whose names are included in a preliminary short-list made by the sub-dean are interviewed by a selection committee. It is thought that by this means greater emphasis can be placed on the personality and general suitability of the candidate; the academic record, although important, is not regarded as the sole criterion for entry. The committee has two or three permanent members, but in addition all the professorial members of the Faculty and some of the senior members of the staff of the teaching hospital are asked to serve in rotation. At Leeds also, while examination results and headmasters' reports are taken into account, considerable weight is also attached to the impression made by a candidate at interview. This interview is carried out by a panel of interviewers, each candidate being seen by three members of the panel.

Integration of Subjects in Curriculum

The integration of subjects in the medical curriculum in the Birmingham Medical School has been carried a step further during the present year. Following the three-months introductory clinical course in medicine and surgery, obstetrics, paediatrics, pharmacology, pathology, and social medicine, the teaching in these subjects is now spread over the whole of the three clinical years, and these subjects are all included in the final examination. This examination has been divided into three parts, the first of which can be taken 12 months before the other two. There is now only one examination between that in anatomy and physiology and the final examination. Moreover, for the final examination boards of examiners have been formed so that, for instance, the professor of pathology will take part in the examination in surgery and medicine. In this way it is hoped to demonstrate to the student an essential unity in the subjects which he has to study and, particularly, that pathology is the fundamental basis of medical practice. In the School of Medicine at Leeds a major review of the entire curriculum is being undertaken, and in this the views of the Goodenough, the B.M.A., and the Royal College of Physicians Committees, together with the recommendations of the General Medical Council, are being taken into account.

At the Medical School, King's College, Newcastle-upon-Tyne (University of Durham), several changes will be made in 1951 in the courses of study for the M.B., B.S. degree. The pharmacology course will be spread over a period of three terms, in place of the previous two terms, and will be given in the first clinical year. The course in pathology and bacteriology will be increased from three to six terms, and the examination, which forms Part I of the third M.B., B.S., will be taken at the same time as Part II (public health and medical jurisprudence)—that is, in the Epiphany term of the fifth year. There will also be changes in the arrangements for clinical appointments in the teaching hospital. The introductory clinical course will be given during the Easter term of the third year, and clinical appointments will begin in July in place of the previous arrangement whereby these appointments began in October. The clinical appointment in midwifery and gynaecology has been increased from three months to six months, and the requirements as to residence in midwifery increased from one month to two months. Junior and senior appointments will be held with one month's residence in each period. By agreement with the Newcastle-upon-Tyne Regional Hospital Board and the Newcastle Management Committee, part of this residence will be at the Newcastle General Hospital.

At Liverpool there have been no changes of a major kind in the curriculum, but classes in clinical pathology and clinical psychiatry are being more closely related to the study of clinical medicine in the wards. Dressing in the casualty department has also been more closely related with surgical ward work.

One interesting departure at Liverpool is the extension of facilities to students (already exempted from some of their premedical subjects) to attend, without further fee, classes of general cultural interest in other faculties. Many students have availed themselves of this, and it has proved a very successful venture. The classes attended have been principally in languages, social science, psychology, law, philosophy, and statistics, all of which will prove of undoubted use at a later stage of their career.

New developments at Leeds Medical School during the year include the institution of a chair in medical physics, and it is hoped that full-time chairs in surgery and in obstetrics and gynaecology, which have long been planned, will be filled in the near future. Accommodation in the School of Medicine is now insufficient for the needs of many departments, including the library, where the problem is very acute. The difficulty is being overcome so far as possible by the acquisition and conversion of suitable houses in the neighbourhood. This, of course, is a temporary expedient, and the problem will not be wholly met until the long-term plans for a new medical school are put in operation.

Curriculum Rearrangements

At Bristol the curriculum for social and preventive medicine is being rearranged, and the teaching in this subject has been advanced into the preclinical years, some lectures on vital statistics being given in the second year, and the main course of social and preventive medicine proper will in future begin in the third year, and be continued with lectures and demonstrations in the fourth and fifth years. By this means it is hoped

to give the students an insight into social problems from their earliest years and to maintain this interest throughout their course.

In the Sheffield Faculty of Medicine, from October of this year, the chair of obstetrics and gynaecology will be established upon a full-time basis. The first occupant of the chair under the new conditions will be Mr. Charles Scott Russell, lately reader in this subject in the University of Manchester. The new orientation in regard to respiratory disease is shown in the change of title of the lecturer in tuberculosis to that of "lecturer in chest diseases." The recently appointed venereologist for the Sheffield area becomes lecturer in this subject at the University.

The increasing number of students at Sheffield has recently raised difficulties in relation to residential hospital accommodation and refectory facilities. These difficulties have been greatly eased by the opening of a residency within the precincts of the Royal Hospital, providing living accommodation for 10 students and refectory facilities for some 70 to 80. The student health service (which, of course, covers not only the Faculty of Medicine but the whole University, as well as the nursing staff of the United Sheffield Hospitals) continues to expand. A second assistant medical officer has just been appointed. B.C.G. vaccination is available to all who require or wish it.

From Birmingham Medical School it is reported that the experiment of appointing two professors of pathology is proving a great success, and the extent of the research work now being undertaken by them is impressive. The provision of new accommodation for cancer research is almost complete, and negotiations are being undertaken with the British Empire Cancer Campaign whereby the cancer research laboratories will be taken over by the department of pathology. The anatomical research laboratories are, at long last, nearing completion. The department of neurological studies still lacks a professor or a reader in psychiatry, but the staff has been strengthened by the appointment of a first assistant. The dean mentions the continued help and encouragement which the medical faculty and the teaching hospital receive from the regional hospital board. "The occasions on which this has occurred are too numerous to detail, but mention should be made of the joint appointment of regional consultant advisers in plastic surgery, neurosurgery, and thoracic surgery, and of the provision at Dudley Road Hospital of residential quarters for students attending that hospital for clinical instruction in obstetrics. The cost of this building has been defrayed by the University Grants Committee."

Clinical Research Laboratories at Manchester

Before the war, laboratory facilities for clinical research in the Faculty of Medicine in the University of Manchester were confined to one laboratory. An important development in recent years has been the provision of clinical research laboratories for the departments of medicine, haematology, research in rheumatism, and cardiology at the Manchester Royal Infirmary. A new operating theatre and ancillary accommodation for neurosurgery was opened by Lord Webb-Johnson earlier in the summer. In addition, a temporary clinical sciences building is now in course of erection and this will provide accommodation for research in pathology, rheumatic diseases, experimental medicine and surgery, occupational health, child health, and oto-rhino-laryngology. There are also laboratory facilities at the Manchester Royal Eye Hospital for the department of ophthalmology.

The first full-time professor of psychiatry at Manchester has now taken up his appointment, and it is hoped shortly to provide more extensive accommodation and better arrangements than now exist for undergraduate and postgraduate teaching in psychiatry.

Until a year ago the clinical subjects in the final examination for the degrees of M.B., Ch.B. had to be taken together. A recent development has been the division of this section of the final examination into Part II (obstetrics and gynaecology, and paediatrics) and Part III (medicine and surgery), though both parts of the examination may be taken concurrently if the student so desires.

When the period of compulsory residence is introduced about 100 posts will be required, but there should be no difficulty in providing these in the hospitals of the Manchester Regional Board and of the board of governors of the United Manchester Hospitals.

Lectures in the history of medicine are to be instituted next session.

The Welsh National School of Medicine

The most important development in the Welsh National School of Medicine (University of Wales) is in connexion with an entirely new medical teaching centre. This scheme has been under continuous consideration and negotiation for several years, but is now taking concrete form. The Cardiff City Council has agreed to sell land—at present open space within easy reach of the centre of the city—extending to 53 acres for an entirely new general hospital and medical school. It is possible that other units serving the Welsh Regional Hospital Board will also be erected on this site. Application has been made to the Treasury to acquire the site and proceed with the scheme.

Other developments in the Welsh National School have included the reallocation among the visiting staff of beds in the Cardiff Royal Infirmary and the Llandough Hospital (formerly municipal but now one of the United Cardiff Hospitals), and transport to Llandough has been arranged which enables the beds to be much more fully used for teaching. A new chair and department of child health have been established, centred mainly on Llandough Hospital. A new central library for the Medical School was formally opened by the vice-chancellor of the University, and in conjunction with it an examination-room has been added in order to cope with the increased number of candidates for the Welsh degrees. The new Institute of Pathology, which has been under construction for some years, is nearing completion. When it is finished accommodation at present used for pathology will become available for research in anaesthetics, which is recognized as the responsibility of the Medical School. A new maternity hospital of 87 beds, with accommodation for teaching students in midwifery and in the health of the newborn, the erection of which was begun before the war, but was suspended, is now being completed.

QUALIFYING DEGREES AND DIPLOMAS

In Great Britain medical degrees or diplomas are awarded by the universities and also by certain licensing corporations. The abbreviations for registration following a pass in the final examinations are: M.B., Ch.B., U.Birm.; M.B., Ch.B., U.Brist.; M.B., B.Chir., U.Camb.; M.B., B.S., U.Durh.; M.B., Ch.B., U.Leeds; M.B., Ch.B., U.Lpool.; M.B., B.S., U.Lond.; M.B., Ch.B., V.U.Manc.; B.M., B.Ch., U.Oxfd.; M.B., Ch.B., U.Sheff.; M.B., B.Ch., U.Wales; M.B., Ch.B., U.Aberd.; M.B., Ch.B., U.Edin.; M.B., Ch.B., U.Glasg.; M.B., Ch.B., U.St.And.; M.B., B.Ch., Q.U.Belf.; M.B., B.Ch., U.Dubl. (also L.Med., L.Ch., U.Dubl.); M.B., B.Ch., N.U.Irel.; L.M.S.S.A.Lond.; L.A.H.Dubl.; L.R.C.P.Lond., M.R.C.S.Eng.; L.R.C.P., L.R.C.S.Ed.; L.R.F.P.&S.Glas.; L., L.M., R.C.P.Irel.; L., L.M., R.C.S.Irel.

The Conjoint Boards

About one-fifth of those who qualified last year took the diplomas in the English Conjoint. Candidates for the English Conjoint are examined by the examining board in England of the three Royal Colleges (Examination Hall, Queen Square, W.C.1). Three examinations have to be passed: a pre-medical examination; a first examination in anatomy, physiology, pharmacology, and materia medica; and a final examination in pathology and bacteriology, medicine, surgery, and midwifery and gynaecology. Candidates are required to complete the medical curriculum extending over not less than 57 months of study at recognized medical schools and hospitals, and to pass the professional examinations in accordance with the regulations after passing any two parts of the pre-medical examination.

The examining board does not itself conduct the preliminary examination in general education, but it recognizes a number of matriculation examinations and school-leaving certificates.

The board's examinations are conducted four times a year, and candidates are required to give notice to the secretary of the board 21 days before the examination. The first medical examination is in two parts: (1) anatomy and physiology, written, oral, and practical, and (2) pharmacology and materia medica, oral only. In the final examination, medicine and surgery and midwifery and gynaecology are written, clinical, practical, and oral; pathology is written and oral only, and may not be taken alone as the last part of the examination.

Candidates with evidence of not less than 27 months' recognized clinical study subsequent to passing in anatomy and physiology are admissible to any one part only of the examination; on the completion of 30 months' study they are admissible to one or two further parts, or to three parts if presenting themselves for the first time. Candidates may not enter for the last part of the examination until they have completed 33 months' clinical study.

The board will be issuing new regulations regarding the acceptance of the general certificate in education, but as the Royal Colleges have not yet given final approval to those regulations they cannot be incorporated in this article.

The two Royal Colleges of Edinburgh and the Royal Faculty of Glasgow have an arrangement by which after one series of examinations students may obtain diplomas of the three co-operating bodies. Each of these bodies grants its single diploma after examination, but this does not confer the right to qualifying registration. Professional study embraces a certified period of not less than five academic years, in the last three of which clinical subjects must be studied. The first examination embraces physics, chemistry, and biology; the second, anatomy and embryology, and physiology, biochemistry and biophysics; and the third, pathology, materia medica, and pharmacology. The final examination is in two parts: the first, forensic medicine and public health; and the second, medicine, surgery, and obstetrics and gynaecology. Candidates for the Scottish Conjoint may work at any of the medical schools of Great Britain and Ireland. Details may be obtained from the Registrar, 18, Nicolson Street, Edinburgh, 8.

The Royal College of Physicians of Ireland and the Royal College of Surgeons in Ireland issue a joint licence in medicine, surgery, and midwifery, and candidates are accepted from most of the medical schools at home and overseas. The regulations are obtainable from the secretary of the Conjoint Board, Royal College of Surgeons, St. Stephen's Green, Dublin.

Other Registrable Diplomas

The Society of Apothecaries of London (Apothecaries' Hall, Blackfriars Lane, London, E.C.4), which was constituted by the Royal Charter of James I in 1617, confers a diploma registrable under the Medical Act, 1886. Examinations for the final subjects are held monthly except in September. Examinations in anatomy, physiology, and materia medica are held in January, April, July, and October.

The licentiateship of the Apothecaries' Hall of Ireland (95, Merrion Square, Dublin) also entitles to registration under the Medical Act, 1886. It enables the holder to practise pharmacy as well as medicine, surgery, and midwifery, which means that he may if he so desires open a medical hall.

Diplomas in medicine and surgery registrable in the Commonwealth List are granted by the Universities of Sydney, Queensland, Adelaide, and Melbourne, Ceylon Medical College, University of Ceylon, University of Hong Kong, Royal University of Malta, Newfoundland Medical Board, University of New Zealand, the Universities of South Africa, Capetown, and the Witwatersrand, the King Edward VII College of Medicine, Singapore, and the University of Malaya. Under certain conditions diplomas of universities and colleges in the several provinces of Canada are registrable; also, with some exceptions, and subject to dating, the Universities of India, the Punjab University, Pakistan, and the University of Rangoon.

Higher Qualifications

The Royal College of Physicians of London confers its membership (M.R.C.P.Lond.) by examination. The pass for membership is a written examination in the form of a paper on questions of medical anatomy, pathology, principles of medicine; a paper on questions of the practice of medicine, including the principles of public health, and on psychological medicine; a clinical examination in the clinical wards of a hospital; and oral examinations. Fellowship of the College is subject to election by the Fellows.

The Royal College of Surgeons of England grants its Fellowship (F.R.C.S.Eng.) to those who pass its primary and final Fellowship examinations. The primary examination, partly written and partly oral, is held in January and July, and the final examination, partly written, partly practical, and partly oral, and including the examination of patients, is held in May and November. The College also grants a Fellowship in Dental Surgery (F.D.S. R.C.S.Eng.) to those who pass its primary and final Fellowship examinations.

The examination for the Membership of the Royal College of Obstetricians and Gynaecologists is designed for practitioners who wish to specialize in obstetrics and gynaecology. All candidates must have been entered on the *Medical Register* for at least three years. Before entering the examination they must fulfil regulations by holding resident appointments recognized by the College for six consecutive months in general medicine, six consecutive months in general surgery, 12 months in obstetrics, and 12 months in gynaecology. Following this training candidates are required to present records of cases under their care and written commentaries, all of which must be accepted before the candidates proceed to the examination. The examination consists of two written papers of three hours each, a clinical examination, and a *viva voce* examination including pathology. The Fellowship (F.R.C.O.G.) is granted to members who are considered to have advanced the science and art of obstetrics and gynaecology.

The Royal College of Physicians of Edinburgh elects as a member any licentiate of a British or Irish College or any graduate in medicine of an approved university with whose knowledge of medical and general science the College is satisfied. No candidate is admitted to the examination before the expiration of two years from the date of original qualification. The examination is in the principles and practice of medicine and also in a department of medicine selected and offered by the candidate and approved by the council, in which a high standard of proficiency is expected. The fee for the membership examination is 35 guineas. Fellows of the College must, before election, have been Members of the College for at least three years. Elections are made at quarterly meetings of Fellows, and a three-fourths majority by ballot is necessary.

The Fellowship examination of the Royal College of Surgeons of Edinburgh consists of two parts: the first, a written paper and an oral examination in anatomy and physiology and in pathology and bacteriology; the second, a written paper, a clinical or practical examination, and an oral examination in the principles and practice of surgery, and in an optional subject chosen by the candidate from the following: surgical pathology and operative surgery; laryngology, otology, and rhinology; obstetrics and gynaecology; and ophthalmology.

The Royal Faculty of Physicians and Surgeons of Glasgow grants, after examination, a Fellowship *qua* physician and a Fellowship *qua* surgeon registrable by the General Medical Council as an additional qualification (F.R.F.P.S.G.). Admission is by examination and subsequent election. Candidates for the Fellowship in medicine must have been in possession of a recognized medical qualification for not less than three years and must have been engaged during one of these years in full-time clinical work in a recognized hospital and have spent two other postgraduate years in approved medical work. The examination comprises a clinical examination in medicine, written and oral examinations in the principles of medicine and medical pathology, and written and oral examinations in the practice of medicine and therapeutics. Candidates for admission to the Fellowship in surgery are required to possess

a recognized medical qualification and to pass a primary and a final examination. The primary examination consists of written and oral examinations in anatomy, physiology, pathology, and bacteriology. For admission to the final examination candidates must have been in possession of a recognized medical qualification for not less than three years and produce evidence that they have been engaged, after qualifying, for one year in full-time clinical work in a hospital approved by the council and a further two years in the study of surgery. The Final examination comprises a clinical examination in surgery, written and oral examinations in surgical anatomy and surgical pathology, and written and oral examinations in surgery. Alternatively, candidates may submit themselves for examination in one of the following subjects: obstetrics and gynaecology, ophthalmology, and oto-rhino-laryngology, with such medicine and surgery as is related to the special subject.

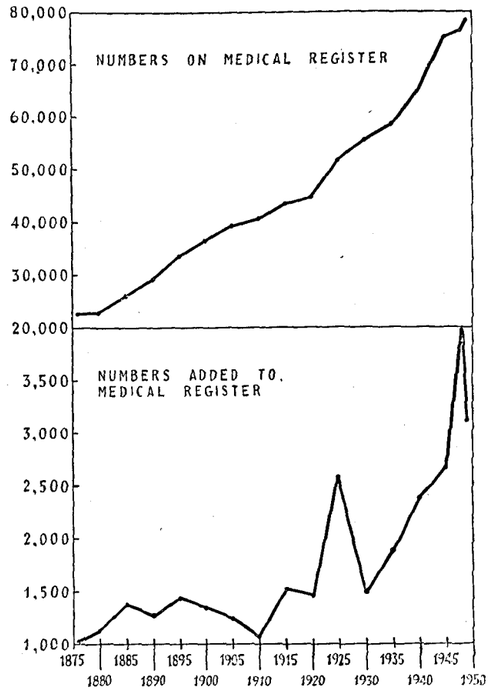
The Royal College of Physicians of Ireland grants to registered medical practitioners, as the result of examination, its membership (M.R.C.P.I.), its licence in medicine (L.M.), and its licence in midwifery (L.Mid.). The College grants its Fellowship (F.R.C.P.I.), for election to which only members of the College are eligible.

The Royal College of Surgeons in Ireland requires two examinations — primary and final — for its Fellowship (F.R.C.S.I.). The first is in anatomy, physiology, and pathology, and the second in surgery. A one-year course for the primary starts in October each year and lasts three terms.

All the universities confer the higher qualification of Doctor of Medicine and Master of Surgery. Liverpool confers the degree of Master of Orthopaedic Surgery (M.Ch.Orth.U.Lpool.), intending candidates for which must be holders of an F.R.C.S. or F.A.C.S. before beginning the course. The Mastery of Midwifery of the Society of Apothecaries of London (M.M.S.A.) is designed to give evidence of practical experience in antenatal care, midwifery, and infant welfare, and their relation to hygiene and preventive medicine. Examinations are held twice yearly, in May and November. The Irish universities offer the degree of Master in Obstetrics (M.A.O.).

The Mastery of Surgery of Oxford, which is conferred as the result of an examination, is a degree admitting primarily to the *Register*. To obtain the D.M.Oxfd. requires the presentation of a thesis satisfactory to the Faculty Board. University requirements for the higher qualifications vary, and particulars should be obtained from the one selected.

THE ENROLMENT IN MEDICINE



The total number of names in the current *Medical Register* is 78,140, which is higher by 5,000 than the average of the last ten years. Of these registrations, 69,611 were in Great Britain and Ireland; 6,570 were in the Commonwealth, and 1,905 were foreign. Only 54 remained on the temporary list, from which, following the passage of the Medical Practitioners and Pharmacists Act, 1947, over 4,400 names were removed in 1948. The names remaining are those of persons whose applications under the new Act have not been finally determined.

The following table gives the position of the *Medical Register* during the last ten years:

Year	Added by Registration	Restoration	Death or Removal	Total No.
1940	2,384	37	1,102	64,697
1941	3,296	16	996	66,992
1942	3,556	7	1,127	69,428
1943	3,532	13	1,091	71,882
1944	2,971	11	1,218	73,646
1945	2,666	11	1,190	75,133
1946	2,237	14	1,092	76,292
1947	2,787	10	1,160	77,929
1948	3,968*	16	4,467*	76,292
1949	3,109	19	1,280	78,140

*Unusual figures due to removals from temporary list and (in lesser number) additions to permanent list.

The numbers of medical practitioners on the *Register* at each five-yearly period since 1876, when the information was first compiled, as well as the number of additions, are shown in the following graphs:

The task of training students to be doctors is shared between the teaching hospitals and the universities. In London the twelve undergraduate teaching hospitals, each with its group of satellite institutions, have been designated as teaching centres. In the regional hospital centres of England and Wales the existing teaching hospitals, again with their groups of associated hospitals, have been similarly designated. The teaching hospitals remain separate from, though closely linked with, both the regional services and the university. They are specially selected centres for medical training, drawing their patients from a wider area than the ordinary hospital. The board of governors of each teaching centre comprises nominees of the university, of the regional board, and of the doctors actually teaching in the hospital, as well as other persons appointed by the Minister in consultation with local health authorities and other interested bodies. In Scotland, hospitals are not designated as teaching hospitals, and all of them come under the jurisdiction of the five regional hospital boards, but special provision is made for inclusion in the boards of management of these hospitals of nominees of the university on which the region is centred and also of the teaching staff of the hospitals. In Northern Ireland there is a duty upon the hospitals authority—a body corporate appointed by the Minister of Health and Local Government—to provide the Queen's University of Belfast with adequate facilities for medical teaching.

The Student Entry

The number of medical students admitted to the schools of Great Britain and Ireland during the academic year 1949–50 was approximately 2,734. Returns are still awaited from three of the schools, but an estimate has been made of the number of admissions in these schools, based on the average of the last four years.

The table of student admissions for recent years is as follows:

1942–3	2,468	1946–7	2,533
1943–4	2,426	1947–8	2,797
1944–5	2,612	1948–9	2,653
1945–6	2,610	1949–50 (approx.)	2,734

The number of passes and rejections in the final or qualifying examinations held in 1949 by the various examining bodies was as follows:

	Passes	Rejections
Medicine	2,925	1,561
Surgery	2,933	1,802
Midwifery	2,916	1,615

The proportion of passes in all three subjects was highest at St. Andrews (86, 87, and 91% respectively), and lowest at Leeds (47% in all three).

In the examinations in anatomy and physiology the highest percentage of passes was in the University of Wales for anatomy (86%) and in the University of Durham for physiology (90%). Nearly a quarter of the students took these examinations in the University of London, where the pass rate was 79 and 78% respectively.

The following table, which has been compiled from the report of the University Grants Committee (H.M. Stationery Office, 1949), shows the number of professors and other teachers in the London medical schools:

Medical School	Professors	Readers, Assistant Professors	Lecturers	Assistant Lecturers and Demonstrators	Others
Charing Cross	4	2	1	8	—
Guy's	8	5	8	19	—
King's College	2	1	5	4	—
London	7	7	12	8	—
Middlesex	10	4	3	12	16
Royal Dental	1	—	—	—	4
Royal Free	3	7	5	18	—
St. Bartholomew's	8	3	2	36	—
St. George's	—	—	4	4	—
St. Mary's	6	6	17	6	—
St. Thomas's	7	4	7	9	3
University College	7	2	2	18	—
Westminster	2	—	8	7	1
British Postgraduate Medical Federation	9	5	47	13	12
London School of Hygiene and Tropical Medicine	11	5	13	4	1

The number of students in these schools was 4,491 men and 785 women. Just over 20% of the full-time students in British universities are training for medicine and dentistry.

The number of men and women entering as medical students is not yet up to the level of 1947–8, the year which saw the influx of those whose studies had been delayed by war service, but it is likely that the number will grow despite the difficulty of the schools in accepting a larger admission. It was estimated in 1948 that that year's output of qualified people from the schools (2,156*) would need to be increased by at least 14% if the demands of the Health Service were to be met, and probably that figure was an underestimate.

The Dean of the Faculty of Medicine of Birmingham University writes as follows:

"The National Health Service has had one unfortunate effect on medical education because a far greater number of students than previously wish to become consultants and not general practitioners. Complaints have been received that the recruits for general practice from this university have been few in number. Professon Smout is making inquiries abut the subsequent careers of all medical students who have gone down from the University during the last ten years.

"A large number of young graduates, after holding a house appointment, now become registrars in teaching and other hospitals, intending to train as consultants. Whilst holding these appointments, which may last for seven years, they are paid a salary rising from £670 in the first year to £1,200 in their last year. Although larger numbers of consultants are required, saturation point, or financial consideration, may call a halt, and it is estimated that less—some people believe much less—than 20% of new medical graduates will be able to secure positions as consultants; the great majority will have to go into general practice. Although the holding of a junior registrarship should be of great advantage to anyone taking up general practice it will be unfortunate if general practitioners have to be recruited from the ranks of disappointed 'trainee consultants.'"

*The registration figure for 1948 given in the table includes a very large number of foreign and Commonwealth registrations.

THE TRAINING OF PATHOLOGISTS

In 1948 the Royal College of Physicians appointed a Committee on Pathology "to inquire into the training and recognition of medical specialists in pathology, and to make recommendations concerning this branch of medical practice in the future." The following were the members: The president; Dr. J. H. Dible (chairman); Dr. G. S. Wilson; Sir Lionel Whitby; Dr. S. C. Dyke; Dr. E. N. Allott; Dr. R. J. Pulvertaft; Dr. W. G. Barnard; Dr. G. Payling Wright; Dr. T. F. Hewer; Dr. S. P. Bedson; Dr. W. H. McMenemey; Dr. A. H. T. Robb-Smith; Sir Philip Panton; Dr. A. W. Downie; Dr. A. F. S. Sladden; and the registrar.

The committee's report emphasizes that the specialist in pathology should be adequately acquainted with clinical work. To ensure this it is recommended that a minimum of one year should be spent in clinical training after registration; six months of this should be spent as a resident house-physician in general medical wards and the remainder in clinical appointments, not necessarily medical. Service in the Forces should be counted as clinical training up to a maximum of six months. A higher qualification in general medicine or surgery is regarded as valuable, but the report also recommends that the Colleges should consider instituting a joint postgraduate diploma in pathology. "Such a diploma should ensure that a high standard is demanded of the trainee pathologist, clarify the status of pathologists, and be of assistance to administrative bodies concerned with the grading and appointment of hospital pathologists." Though the acquisition of a diploma is considered desirable it should not be regarded as the hallmark of a specialist or as entitling its possessor to consultant or specialist status.

Specialist Training

The specialist, continues the report, should receive at least five years' training, most of it in a teaching hospital. Since teaching hospitals now have insufficient facilities for training all the pathologists required, the committee recommends that during the first two years the trainee should receive a general training in all branches of clinical pathology in a laboratory approved for this purpose by the university of the region. Of the subsequent three years, one year should be spent in a university laboratory or a laboratory associated with a university department of pathology, where the trainee should be free from routine responsibility and able to study fundamental principles. Alternatively, he might spend this year on an approved course or holding a research scholarship. For the remaining two years the trainee would study the specialty in which he intends to work. A generous provision of posts is needed in hospital laboratories and in the departments of clinical pathology of universities and teaching hospitals. Candidates for training should be selected by boards of governors or by regional boards in consultation with the appropriate university, though this recommendation is not intended to interfere with the freedom of selection now exercised by such bodies as the universities and the Medical Research Council.

Recognition of Pathologists

The recognition as consultants or specialists of those holding appointments in the National Health Service should be based in particular on the following criteria:

(1) Age. This should be the same as that recommended in the Spens Report for full consultants in other specialties—namely, in general 32, and in exceptional cases 30–31.

(2) There should have been a minimum of five years' work in a pathological laboratory after qualification.

(3) Consideration should be given to the position now held—whether in charge of a laboratory of fair size, or a department in a large laboratory, or comparable post. The fact of holding such a post should not of itself necessarily qualify the incumbent as a consultant.

(4) It is desirable that a consultant should have had an adequate training and experience in all branches of pathology, but the absence of experience in all branches should not necessarily be a disqualification.

(5) The general training of the consultant should have been in a laboratory of satisfactory status with special training appropriate to the post held.

(6) Consideration should be given to the possession of special experience, whether clinical experience or training in some other branch of science, before entering into pathological work.

(7) Consideration may be given to the possession of higher degrees or qualifications, but the absence of these should not be a disqualification.

(8) Due consideration should be given to contributions to knowledge in the subject.

(9) Consideration should be given to the professional standing of the pathologist among his colleagues.

TRAINING COURSES IN PSYCHIATRY

A full training in psychiatry is obtainable in London at the Institute of Psychiatry, associated with the Maudsley Hospital and Bethlem Royal Hospital (see also "Postgraduate Education in London" at p. 507). Basic training normally covers a period of three years after adequate experience elsewhere in general medicine, and is based on responsible clinical work under supervision. The aim is to provide a wide training in the many branches of clinical psychiatry and its basic sciences.

Vacancies for registrars and house officers are available each quarter with the Maudsley Hospital and Bethlem Royal Hospital. The fees payable by those who attend the teaching at the Institute of Psychiatry without holding hospital appointments are: for clinical instruction only, 10 guineas for three months; 15 guineas for six months, and 20 guineas for twelve months; for clinical instruction and all first- or second-year lecture and demonstration courses, 20 guineas for one term and 50 guineas for one year; and for first- or second-year lecture and demonstration courses only, 12 guineas for one term and 30 guineas for one year. The enrolment fee is £1. By arrangement with certain regional authorities, trainees in psychiatry holding posts at mental hospitals in the region in question are granted a reduction in fees. Fuller information may be obtained from the Dean, Maudsley Hospital, Denmark Hill, S.E.5.

The National Association for Mental Health (39, Queen Anne Street, W.1) arranges training courses in child psychiatry. Fellowships are given to enable qualified psychiatrists to obtain special training in child guidance at a recognized training clinic, and these are tenable at a number of clinics in Great Britain. The usual course of training covers 12 months, half-time, and is recognized as a qualification for the medical directorship of a child-guidance clinic. The association also runs each year two courses, each of three weeks, on educationally subnormal children and mental defectives. These are in conjunction with the extra-mural department of the University of London and are recognized by the Ministry of Education in relation to the approval of medical officers under the Handicapped Pupils and School Health Service Regulations. A week's refresher course is being organized in conjunction with the same department of the University for doctors who attended the association's three weeks' course prior to the passing of the Education Act, 1944.

The Tavistock Clinic (2, Beaumont Street, W.1) specializes as a centre for the out-patient treatment of children and adults with psychiatric disabilities. The educational programme includes courses for psychologists and social workers as well as doctors. It organizes with the National Association for Mental Health (see above) the 12-month half-time course for psychiatrists specializing in child psychiatry.

The Institute of Psycho-Analysis (96, Gloucester Place, W.1) furnishes a part-time course, lasting about four years, in psychoanalytic theory and technique. It includes a personal analysis, attendance at lectures and seminars, and clinical work under supervision. The Institute does not set out to teach all aspects of psychiatry, and general psychiatric experience must be obtained at other clinics and hospitals.

Courses in psychiatry, full-time, beginning in October, are given at Bristol (two terms) for Part I D.M.P.(Bris.), fee 15 guineas; at Edinburgh (five weeks) for Dip.Psychiatry(Ed.), fee 25 guineas; at Glasgow (two and a half weeks) for course in mental deficiency, fee 15 guineas; at Leeds (two and a half years) for D.P.M.(Leeds); and at Manchester (one year). These courses are usually taken in conjunction with clinical appointments at a mental hospital or similar institute. Arrangements have been made in Birmingham for full courses of instruction for the Diploma in Psychological Medicine.

ENTRY INTO PRACTICE*

The young doctor newly admitted to the *Medical Register* will usually begin his professional career by serving one or more terms as a resident hospital officer, but very soon he will have to decide in which branch of practice his future lies, and once this choice has been made he should seek the training and experience which will best fit him for his vocation. It may become more difficult as time goes on to change from one form of practice to another without retracing his steps and starting again from the beginning.

Specialist Practice

A young practitioner who contemplates a specialist career should seek guidance from a senior consultant in the specialty of his choice, from the dean of the medical school, or from the director of the British Postgraduate Medical Federation. The introduction of the National Health Service has not affected the mode of entry into specialist practice. After the initial house appointment the trainee specialist competes for promotion to more senior resident posts, his ultimate aim being appointment to the staff of a hospital or hospitals in either a whole-time or a part-time capacity. Meanwhile, one of his first steps should be to obtain the higher qualifications and diplomas, without which he cannot hope to compete for suitable appointments in the hospital or public health services. The crucial step is that from registrar or similar status to the higher grades, and it is to be hoped that, once the needed increase in hospital establishments can take place and the demand for specialists be equated with the supply from new entrants, allowing for the normal wastage, the would-be specialist will be able to plan ahead with confidence in his ability to obtain appointments appropriate to his ability and experience.

General Practice

The impact of the National Health Service has been most felt in the field of general practice. The introduction of a service available to the entire population has brought about changes in the distribution of doctors which have profoundly modified entry into practice. These changes, together with the cessation of the buying and selling of goodwill, have swept away many traditions and introduced new problems.

Every doctor who has chosen a career in general practice will aim at becoming a principal as soon as possible. But he must first gain experience, and to this end should seek a post as an assistant. It is now possible for a young doctor who has had no previous experience in general practice to serve an apprenticeship as a "trainee assistant" with a senior practitioner selected for the purpose, the principal receiving a grant for training and also a sum intended to cover the assistant's salary and other expenses involved. A trainee assistantship lasts only for one year, after which the young doctor may wisely seek other temporary appointments, designed to secure him experience in different types of practice.

There are three methods of becoming a principal in general practice:

1. *To put up a plate.*—Always an uncertain and expensive method. A doctor starting a new practice may apply for a basic salary of £300 a year, the granting of which is vested in the executive council or on appeal to the Minister. But there are other factors to be considered, such as obtaining a house, a car, furniture, and equipment. Even in advantageous conditions the outlook facing the "squatter" is hard.

2. *To take over a practice vacant by death or retirement.*—It is the responsibility of the executive council to fill such vacancies, though actual appointments have to be approved by the Medical Practices Committee (see below). There is very keen competition for vacancies with large lists or in desirable surroundings. When the list is smaller it may be easier to obtain a vacancy, but the successful applicant faces, though in less degree, the difficulties that beset the "squatter." Even when there is no delay a practice suffers to some extent on change of hands.

3. *To obtain an assistantship with a view to succession or partnership.*—This method offers security from the outset and is the method of choice for those who cannot command the resources to enable them to wait for their list of patients to grow. Introduction is effected by the Medical Practices Advisory Bureau or one of the medical agencies, and after a probationary period the assistant either becomes logical successor when his principal retires or is made a partner.

Where a practitioner wishes to become a principal in a practice he is required to apply for admission to the list of practitioners undertaking to provide general medical services under the Act. His application is to the executive council, and permission to practise is granted as a matter of course unless the area has been officially declared by the Medical Practices Committee to be adequately served.

*Condensed from Section IV of the B.M.A. Annual Handbook, 1950–1.

The Medical Practices Committee

The Medical Practices Committee is mainly a professional committee with headquarters in London, established to supervise the distribution of general practitioners under the National Health Service Act. It determines those areas in which the number of doctors is adequate, and in these areas no additional principal is likely to be accepted on the list except where replacement is necessary. The Medical Practices Committee has also an important function in relation to transactions which might be thought to involve concealed sales of goodwill.

The Medical Practices Advisory Bureau

Soon after the Act came into force there was seen to be a need for some central source of information where advice could be obtained by practitioners needing partners, assistants, or locumtenents, and by practitioners seeking such appointments or desiring to transfer to another area. It was felt that advisory functions of this kind should be undertaken by a body which was not linked with central or local government, yet with a status and resources enabling it to establish and maintain effective liaison with executive councils, local medical committees, and the Medical Practices Committee, and at the same time commanding the confidence of the profession.

The Medical Practices Advisory Bureau was accordingly established as a department of the British Medical Association, under the direction of a member of its medical staff. Its functions are to maintain an information service about openings, to introduce partners, assistants, and locumtenents, and to advise on all associated problems. The facilities of the Bureau are available to any doctor, and free of charge to members of the British Medical Association.

Address inquiries: Medical Director, Medical Practices Advisory Bureau, B.M.A. House, Tavistock Square, W.C.1, or to the Branch Offices: 33, Cross Street, Manchester, 2, and 7, Drumsheugh Gardens, Edinburgh.

PROFESSIONAL TRAINING OF ARMY MEDICAL OFFICERS

Officers appointed to a regular commission in the Royal Army Medical Corps receive postgraduate professional training at the Royal Army Medical College, Millbank, S.W.1. This College has a director of studies and a tutorial staff for the teaching of Army health, military surgery, tropical medicine, psychiatry, radiology, dermatology, venereology, and entomology.

At the College newly commissioned lieutenants on first appointment are given an introduction to the clinical problems and procedures peculiar to military service in both temperate and tropical climates. Regular R.A.M.C. officers between their eighth and tenth years of service pass through the senior officers' postgraduate course of professional studies. This course, divided into two parts, lasts approximately for five months. The first part, of 10 weeks' duration, includes revision in Army health and certain of the other subjects mentioned above. The second part, which lasts for three months, consists of demonstrations and tutorials in clinical medicine and surgery, dermatology, and venereology. Those officers who qualify at the termination of this course and are recommended by the College council may undergo up to 12 months' individual advanced study for different specialties at approved university medical centres.

The Queen Alexandra Military Hospital, Millbank, also provides clinical instruction, tutorials, and demonstrations for R.A.M.C. officers.

The Department of Army Health at the College, in addition to the teaching of military hygiene, provides facilities for special study in the maintenance and enhancement of the health of the Army. There are laboratories for instruction in chemistry as applied to hygiene, and also in biochemistry, while in addition there is an instructive and well-equipped hygiene museum. Officers intending to specialize and become Army health officers are given the opportunity of taking the D.P.H. during their specialist course and are assisted in obtaining their D.T.M.&H.

The Department of Military Surgery gives instruction in the principles and practice of up-to-date military surgery, both general and regional. The syllabus includes the surgery of tropical diseases and the management of surgical conditions peculiar to service both at home and abroad.

The Department of Tropical Medicine provides instruction and clinical demonstrations in tropical medicine, particularly in those disease processes to which Service personnel and their families are exposed in tropical areas. The College is recognized for the full course of instruction for the D.T.M.&H.

The Entomology Department provides instruction in applied entomology as it affects Service personnel, while research is also carried out into insecticides, insect repellents, and various methods of pest control. Insects from all commands at home and overseas are referred to this department for identification.

In the Department of Pathology there are lectures, demonstrations, and practical classes covering the laboratory diagnosis and pathological aspects of general, tropical, and preventive medicine and military surgery. Candidates for specialization in pathology receive six months' training at the College, comprising bacteriology, haematology, chemical pathology, and morbid anatomy. A further period of six months' study in a particular branch of pathology is taken at a selected university medical centre.

Finally, the Department of Psychiatry provides lectures and clinical demonstrations in psychiatry and psychopathology and the application of psychological principles to morale, discipline, personnel selection, and other purely military matters. Clinical demonstrations of cases and the use of modern methods of physical treatment and group therapy are held at Banstead Military Hospital and Belmont Hospital, Sutton. Demonstrations of selection tests are given by a personnel selection officer.

Two revision courses in surgery a year are held at Westminster Hospital Medical School for senior officers of the Millbank College.

Commissions in the R.A.M.C.

Civilian doctors and released medical officers who have held a non-permanent commission in the Royal Army Medical Corps during the emergency will be considered for appointment to short-service commissions in the R.A.M.C. for a total of eight years, the first period of which will be on the Active List and the remainder in the Regular Army Reserve of Officers. Civilian doctors will have direct appointment in the rank of lieutenant, and released medical officers, on certain conditions, in the rank of captain. Candidates must at the time of application be (*a*) normally not over 30 years of age; (*b*) British subjects or citizens of the Irish Republic, and sons of British subjects or citizens of the Irish Republic; and (*c*) registered under the Medical Acts in force in Great Britain and Northern Ireland. During their service on the Active List they will be considered for appointment to a regular commission, and if they do not want, or are not selected for, such commission they will receive

at the end of their period of service on the Active List a gratuity of £150 a year for each year's completed service (three years or over).

Conditions of service and forms of application can be obtained from the Assistant Director-General, Army Medical Services (A.M.D.1), Lansdowne House, Berkeley Square, London, W.1 (GROsvenor 8040; Ext. 548).

On the nomination of the Central Medical War Committee (B.M.A. House, London) doctors are appointed to national service commissions in the rank of lieutenant. During their service they can apply for a short-service commission and subsequently be considered for a permanent commission under the conditions stated above.

MEDICAL SCHOOLS AT OXFORD AND CAMBRIDGE

At Oxford University the number of new preclinical students continues to be restricted by decree. During the coming academic year 55 men and 10 women will again be admitted. Students who have done recognized national service and who were born before January 1, 1929, may be admitted in addition. The selection of candidates is made by a central university committee from names put forward by colleges, so that preliminary acceptance by a college is essential for any prospective medical student.

All new students at Oxford are required to take the second public examination of the University in order to qualify for the B.A. degree. Although almost all medical students continue to take the final honours school of animal physiology, a few students take instead the final honours school of psychology, philosophy, and physiology. This course normally occupies a medical student for two years after he has passed the first B.M. examination in anatomy and physiology, and the number of students who may read for this honours school is limited. A new final honours school of biochemistry has been created which lasts four years and is not primarily intended for medical students. A new University laboratory of physiology is now being built, and some of the other preclinical departments will be enlarged in due course.

The clinical section of the medical school at Oxford continues to develop. Despite increases in the number of applications for admission, it has been decided to limit the entry to 32 students during the year 1950–1, so that a high degree of personal supervision (including the tutorial system) and opportunities for practical experience may be retained. A limited number of the available places are open to students from other universities who elect to do their clinical training in Oxford and take the degree of their own university. The Radcliffe Infirmary (520 beds) remains the main teaching hospital, but the other hospitals of the United Oxford group (1,250 beds) also provide clinical material. In addition the Wingfield-Morris Orthopaedic Hospital is available for orthopaedic training. Students are taught partly by the whole-time Nuffield professorial units of medicine, surgery, obstetrics and gynaecology, anaesthetics, orthopaedic surgery, and plastic surgery, and partly by the consultant staff of the Radcliffe Infirmary. In this way they are provided with a mixture of academic and vocational training. For example, in general medicine all students spend three months with a consulting physician and three months with the professor of clinical medicine. The Radcliffe Infirmary is an active centre of clinical research, and it is hoped that students will be stimulated by being taught in this environment. At the same time the large share in the teaching taken by the consultant staff ensures that the course is rich in practical instruction.

Rearrangements at Cambridge

In 1949 the regulations for the Cambridge degrees in medicine and surgery were revised. The most important change consists in a rearrangement of the final M.B. examination. Part I of this examination, which may be taken after two and a half years of clinical study, will in future include pathology and pharmacology and therapeutics instead of surgery, midwifery, and gynaecology. Part II, which may be taken after three years of clinical study, will include medicine, surgery, and midwifery and gynaecology, instead of medicine, pathology, and pharmacology and therapeutics. Under the new arrangements a candidate who fails in only one or two of the subjects in Part II will not necessarily have to sit the whole of that part again, provided he attains a reasonable standard in the subjects in which he has failed to satisfy the examiners. Papers in medicine will cover the ancillary subjects of paediatrics, social medicine, and psychiatry, which are mentioned in the General Medical Council's recommendations. The revised regulations will come into operation in December, 1950, with latitude for the taking of the examination under the old regulations for all who matriculated before October, 1946.

The Long Vacation course at Cambridge in elementary clinical methods for undergraduates who have qualified in anatomy and physiology covers adequately the intermediate period between preclinical and clinical work in accordance with the G.M.C. recommendations. Teaching is directed to the fundamental principles of how to examine patients at the general and special departments of a hospital. Undergraduates also have the opportunity of attending an introductory course in psychology during the Long Vacation term of their residence, as well as lectures on the social background of disease, epidemiology, and medical genetics.

The staff of the United Cambridge Hospitals now regularly gives courses on various special subjects for postgraduates, including general practitioners, who are offered an attractive programme of "at home" days in each department on regular days of the month, whilst one-day symposiums on set subjects have proved popular.

The most important plans in the University of Cambridge concern the further development of the department of human oecology, in which a chair was established in October, 1949. A permanent building for the department will be ready in 1951. Epidemiological and statistical studies are proceeding. The University department of radiotherapeutics has pursued research work designed to improve the treatment of cancer and allied diseases by the combined use of radiotherapy and chemotherapeutic agents, and the department of experimental medicine has carried out studies on various aspects of undernutrition.

SCOTTISH AND IRISH SCHOOLS

In the Faculty of Medicine of the University of Edinburgh the number of applicants for admission to the School to study for the degrees of M.B., Ch.B. again greatly exceeds the number of places available, and many applicants who might in ordinary circumstances have been accepted have had to be refused admission. There is no sign of any marked falling off in the demand for places in the School. A new curriculum covering a period of six years' study for the degrees of M.B., Ch.B. was introduced in October, 1948, and during the session 1950–1 the medical students enrolled will comprise first-, second-, and third-year students under the six-year curriculum, along with fourth- and fifth-year students and a comparatively small number of third-year students under the old five-year curriculum.

Courses and examinations for the various medical diplomas granted by the University have been conducted during the past year with the exception of the Diploma in Industrial Health. The five-weeks intensive course which candidates for the Diploma in Psychiatry are required to take in the University after completion of the prescribed hospital work and special study, and before they appear for the Diploma Examination, was held for the first time in the autumn term 1949. Ten graduates attended.

In Glasgow University the number of students in attendance continues at a high level, especially in the clinical years, where the classes are augmented by a large number of students transferred from the extramural colleges in 1947, when they were then in the preclinical stages of their studies. The preclinical classes of to-day, however, are returning to more normal proportions, with advantage to both students and teachers. The session just ended sees the termination of the former five-year curriculum in so far as it governed preclinical instruction, and from 1950–1 onwards the preclinical students will all be undergoing a six-year curriculum in accordance with the recent recommendations of the General Medical Council.

At Aberdeen also the medical curriculum now extends over six academic years. After the present summer vacation there will be no vacation term for medical students as there has been during the last few years.

In the School of Medicine of the University of St. Andrews instruction in the clinical years is given in Dundee, while the pre-medical and preclinical subjects can be taken either there or at St. Andrews. The annual intake of students is limited to between 70 and 80. The six-year curriculum, recommended by the General Medical Council, was introduced in 1948. At both St. Andrews and Dundee there are excellent student residences which accommodate undergraduates from all or any of the faculties, and there is also the William Low Residence for Medical Students situated near the principal teaching hospital, which is devoted exclusively to undergraduates in their clinical years of study.

At Queen's University, Belfast, clinical teaching is carried on at the Royal Victoria Hospital, the Mater Infirmorum Hospital, the Belfast City Hospital, and certain special hospitals in Belfast, totalling a very large number of beds. A department of child health has lately been established, and the department of social and preventive medicine (formerly public health) has been reorganized to meet the requirements of the General Medical Council.

The School of Physic at Trinity College, Dublin, will start in October with a full complement of students. The number of applications has greatly exceeded the number of available places. Arrangements for post-qualification hospital appointments to be introduced under the new British Medical Act are being considered in consultation with the other Dublin Schools. The Dublin teaching hospitals will not be able to provide such posts for all the graduates of the three Dublin Schools, but it is hoped that suitable accommodation can be found in some of the provincial Irish hospitals, and perhaps in some English hospitals. Professor D. S. Torrens succeeds Professor J. W. Bigger as Dean as from October 1.

The National University of Ireland has three constituent University Colleges—those of Dublin, Cork, and Galway. Over 200 students graduated in medicine from these Colleges last year. The winter session begins in October. Address inquiries to the Registrar, National University, 49, Merrion Square, Dublin.

VISUAL EDUCATION

The Medical Teaching Film

The film as an aid to teaching is becoming more appreciated. Four years ago the deans of the medical schools were asked for suggestions for subjects on which films would be welcomed, and the results of the questionary showed that what were chiefly wanted were short illustration films for use with lectures. Recently a British Universities Film Council was set up, but, having much ground to cover with only limited resources, it was decided that the field of medical films should be left in the hands of the Medical Committee of the Scientific Film Association (4, Great Russell Street, W.C.1). This committee has recommended that the British Film Institute through its national library should be asked to take over the running of a central medical sciences teaching film library, to which the medical schools should make an annual grant for the purpose of acquiring suitable films. It is estimated that a grant of £2,000 would permit of the purchase of 10 films at £50 each, the copying of 20 films at £15 each, and the re-editing of 20 films at £35 each, as well as meet the expenses of arranging viewing and collection and so forth.

More recently the British Film Institute has set up in its distribution section a library of films for use in university teaching. Films will be placed in this library on the recommendation of the British Universities Film Council, which will, in the case of medical films, be advised by the Medical Committee of the Scientific Film Association. The British Film Institute has already made a grant to the Universities Film Council for the copying of films, but it is hoped that owners of films which have been made for research and teaching purposes will consider making a gift of copies wherever possible.

The Central Film Library of the Central Office of Information holds the largest number of good modern medical films, but the increasing demands on its services and the restrictions of the Treasury have meant that on several occasions it has had to suspend bookings.

In addition to films made specially for use in medical schools, films on medical subjects, which are often suitable for use in medical schools, are made by the Ministry of Health and by the Services. Such bodies might welcome suggestions from medical school teachers.

B.M.A. Film Library

The British Medical Association has a Film Library to which during the past year a considerable number of films have been added both by presentation and by purchase. A B.M.A. film on "Infections of the Hand"—a sound film in colour, made at the Hand Clinic of University College Hospital—has been produced and is considered excellent by all who have seen it. It was the main feature of the film showings at the recent Annual Meeting of the British Medical Association at Liverpool. A film theatre has lately been completed in B.M.A. House.

The British Medical Students' Association has presented its film "Acute Inflammation" to the B.M.A. Film Library in appreciation of the generous concession by the B.M.A. of free access to the library by the Students' Association.

There are many good medical films in overseas countries, but at present licences to purchase films from hard currency areas are withheld. An approach has been made to the Ministry of Health by the Film Committee of the B.M.A. with a view to facilitating the purchase of films from abroad.

Wellcome Museum of Medical Science

A teaching institution in which visual aids to learning are widely used is the Wellcome Museum of Medical Science (183–193, Euston Road, N.W.1), which was founded in 1912. The museum consists of descriptions of diseases under the following headings: general, aetiology, epidemiology, pathology, clinical, diagnosis, treatment, prognosis, and prevention. The teaching standard aimed at is general medical postgraduate, but the museum is equally useful to medical undergraduates. Most, but not all, of the material has been rearranged since the war. The museum is divided into bays by screens erected at right-angles to the walls, and on these screens are panels in which summaries of diseases with illustrations and diagrams are mounted. Accurate, up-to-date, and useful descriptions are given, and the emphasis is entirely on usefulness in practice. Pathological and entomological specimens and drugs are placed on a single shelf below the screens, and in boxes attached are files of abstracts from journals under the same headings as in the panels. The museum is open on weekdays from 9 a.m. to 5.30 p.m., without fee or formality, to all medical graduates and students, nurses and student nurses, and workers and students in the medical sciences. It is not open to the general public, for whom the material and arrangement are unsuitable.

The Wellcome Historical Medical Library is installed in the same building. It contains approximately 200,000 books and journals concerning the history of medicine and the allied sciences, some 5,000 MSS, and 100,000 autograph letters of medical and scientific interest. The Wellcome Historical Medical Museum is now installed at 28, Portman Square, W.1. Its collections cover all aspects of the history of medicine and certain allied sciences, from the earliest times to the nineteenth century. The prehistory, classical, and eighteenth and nineteenth century collections are especially important. Exhibitions of material from the collections are constantly held, and are open to the public from 10 a.m. to 5 p.m. daily (except Sundays). At present the main exhibition deals with "Medicine in 1850." Catalogues of the various exhibitions are published by the Oxford University Press. Students working on special branches of historical research may obtain permission to study individual items in the collections on application to the director.

SPECIAL DIPLOMAS

Public Health

Diplomas in sanitary science, public health, and State medicine are registrable in the *Medical Register* as additional qualifications. The D.P.H. is conferred not only by the universities but by the Royal College of Physicians of London and the Royal College of Surgeons of England (D.P.H., R.C.P.S.Eng.), the Royal Colleges of Physicians and Surgeons of Edinburgh, and the Royal Faculty of Physicians and Surgeons of Glasgow (D.P.H., R.C.P.S.Ed. and R.F.P.S.Glasg.), and the Royal College of Physicians and Surgeons in Ireland (D.P.H., R.C.P.S.Irel.). The degrees of Bachelor and Doctor in Hygiene are conferred by the University of Durham (B.Hy., D.Hy.Durh.), of Bachelor of Science in Public Health by the University of Birmingham (B.Sc.(P.H.)Birm.), and of Bachelor and Doctor of Science in Public Health by the University of Glasgow (B.Sc., D.Sc.(P.H.)Glasg.).

At most of the universities there is a full-time course in public health, lasting for nine months and beginning in October. A preliminary three-months course for the Certificate in Public Health is included. The University of Wales has a three-months full-time course for the C.P.H., preliminary to the D.P.H., and a 12-months part-time course for the D.P.H. The fees at most of the universities are round about £50.

The London School of Hygiene and Tropical Medicine (Keppel Street, W.C.1) offers a course for the Certificate and Diploma in Public Health, beginning in October and lasting for one academic year (the preliminary part, from October to December, being followed by the examination for the Certificate). During the second part of the course students may elect to make a special study of (1) industrial health; (2) statistics and epidemiology; (3) institutional administration, or (4) tropical hygiene. The elective course in industrial health is recognized in part as qualifying for the examination for the Diploma in Industrial Health (see below), and opportunities are given for visits to factories and other industrial establishments.

References to a paucity of candidates for the D.P.H. come from several quarters. From Birmingham it is stated that postgraduate courses in public health (as well as in radiology and ophthalmology) have been in abeyance this session owing to the lack of sufficient applicants. Now that the post-war rush for diplomas has ceased, the number of graduates choosing these specialties is insufficient to justify the many courses now advertised, and it is considered that it might be wiser for such instruction to be given mainly in special postgraduate institutes which do not have the burden of undergraduate teaching. Provincial universities might, by mutual agreement, concentrate on one or two subjects for which they have special facilities, rather than try to cover the whole field of postgraduate instruction. In Birmingham public health and industrial medicine would seem obvious choices. At Durham postgraduate courses were held for the C.P.H. and the D.P.H., but very few students entered, and it has been decided not to hold courses in public health during the next academic year.

In 1949 there were 172 passes in examinations for the D.P.H. and 13 rejections. London had the largest number of examinees (50), followed by the English Conjoint Board (38). The number of passes in the examinations held for the C.P.H. was 182, with 29 rejections, and here again the examining bodies having the largest numbers were London (58) and the English Conjoint Board (46). None were examined for the diploma in Durham, Manchester, and St. Andrews, and none for the certificate in Birmingham, Manchester, and Aberdeen.

Other Diplomas

The London School of Hygiene and Tropical Medicine also provides courses for the academic postgraduate Diploma in Bacteriology and for the Diploma of the Conjoint Board in Tropical Medicine and Hygiene, and a short course in medical statistics. The course for the Diploma in Bacteriology, starting in October, lasts one academic year and is intended to give advanced instruction to graduates in medicine or veterinary science who intend to follow a career in bacteriology. Two courses in tropical medicine and hygiene are held each year, beginning in March and October and continuing for five months. No course for the new *academic* D.T.M.&H. will be offered in the current year. The course in medical statistics occupies two days a week for three months, beginning in April, and also in January if applications are sufficient.

The Incorporated Liverpool School of Tropical Medicine (Pembroke Place, Liverpool, 3) offers two courses of instruction, each lasting about five months, for the Diploma in Tropical Medicine and Hygiene (D.T.M.&H.). The fees for the course are 40 guineas and for the revision course 20 guineas, and there are fees by arrangement for research and advanced students. The examination for the diploma by Liverpool University is held twice yearly, in January or February and April or May. The syllabus includes tropical medicine, dermatology, ophthalmology, and surgery, also bacteriology, entomology, parasitology, and tropical hygiene. The Liverpool School also gives courses of instruction in public health, parasitology, and entomology for students taking the D.P.H., and in veterinary parasitology and entomology for students taking veterinary diplomas or degrees.

The University of Edinburgh has courses for D.T.M.&H.Ed., lasting two terms, beginning in October.

The Royal Faculty of Physicians and Surgeons of Glasgow grants a Diploma in Industrial Health. Candidates for the diploma (D.I.H.Glasg.) must complete courses of instruction and pass the examination. Copies of the regulations respecting the diploma may be obtained from the secretary of the Royal Faculty, 242, St. Vincent Street, Glasgow, C.2. The Diploma in Industrial Health is granted by the Conjoint Board, the University of Edinburgh, and other bodies. Full-time postgraduate courses in industrial health are given at Edinburgh, Glasgow, and Manchester, all beginning in October and lasting for nine months. The Society of Apothecaries of London holds an examination for this diploma, taking the history of the subject, legislation, occupational diseases, the industrial environment, the practice of industrial medicine, and clinical medicine and surgery as applied to industry.

London and Manchester have Diplomas in Bacteriology. Edinburgh, Bristol, Leeds, and the Conjoint Board have Diplomas in Psychiatry or Psychological Medicine. Bristol, Edinburgh, Liverpool, and London Universities and the Conjoint Board have Diplomas in Radiodiagnosis and in Radiotherapy. At Liverpool holders of the Diploma (Dip.Rad.) may be awarded the degree of M.Rad. after a further two years' study and the presentation of an acceptable thesis.

At Sheffield University there has recently been introduced a Diploma in Microbiology. This will be awarded after a full-time course of study extending over one University session, and it is intended that the first course shall start in the Michaelmas term, 1950. Entrants upon the course will normally be expected to be graduates of a university, but the senate may deem other qualifications as equivalent for this purpose. The course will embrace (*a*) cultivation and isolation of micro-organisms; morphology, structure, growth, taxonomy; (*b*) metabolism, nutrition, and genetics of micro-organisms; (*c*) oecology of micro-organisms—symbiosis, commensalism, parasitism, antibiosis; and (*d*) pathogenicity and immunity.

The Faculty of Medicine of the University of Bristol offers ordinary postgraduate facilities—and in addition special courses—for the University's Diplomas in Radiology, Public Health, and Psychological Medicine, and also courses of instruction for the Diploma of Child Health and the Diploma of Anaesthetics of the Conjoint Board. It adds, however, that unfortunately there has been a diminishing admission for these diploma courses during the past year, and no evidence of any increased interest on the part of general practitioners for other postgraduate facilities, in the form either of fortnightly courses or of weekly demonstrations.

A Diploma in Ophthalmology is granted by the University of Oxford, a Diploma in Clinical Pathology by the University of London, and the English Conjoint grants Diplomas in Anaesthetics, Ophthalmic Medicine and Surgery, Child Health, and Laryngology and Otology, and the Irish Conjoint grants diplomas in the first three of these subjects. The University of Wales has a Diploma in Tuberculous Diseases. For other special diplomas available the programmes and prospectuses of the various bodies should be consulted.

Fellowship in Radiology

The Faculty of Radiologists (45, Lincoln's Inn Fields, W.C.2) offers a Fellowship (F.F.R.) to medical graduates of five years' standing who have spent at least one year in general clinical work at approved hospitals, hold a radiological diploma, and have practised radiology exclusively for at least two years after obtaining that diploma. Candidates are required to pass an examination and submit a thesis. Candidates who hold higher medical or surgical qualifications may be exempted from the examinations in general medicine, general surgery, or pathology.

Royal Institute of Public Health

The Royal Institute of Public Health (23, Queen Square, London, W.C.1) furnishes recognized courses of instruction for the Certificate and the Diploma in Public Health and for the Diploma in Industrial Health. The course for Part I of the latter examination is the same as, and runs concurrently with, that for the C.P.H., and holders of the latter are exempt therefrom. The courses for the Certificate start, approximately, at the beginning of April and October, and those for the D.P.H. (Final Examination) in February and August. The course for Part II of the examination for the D.I.H. begins in February and July of each year. All these courses, which may be taken as either whole-time or part-time, are conducted at the Institute.

MEDICAL SOCIETIES

The advice given to the newly qualified man or woman to become a member of the British Medical Association and to join one or other of the defence organizations is as cogent as ever. The introduction of the National Health Service has made it even more desirable that practitioners should seek unity in the profession for the purposes of establishing the Service on right lines so that the doctor can carry out his work under acceptable conditions and that the greatest good for his patients can be secured. The practitioner has also the same need as ever to safeguard himself against the medico-legal hazards which attend medical practice, however careful and conscientious he may be.

The British Medical Association

The British Medical Association (Tavistock Square, W.C.1) has a membership of more than 62,000. In the United Kingdom its membership represents 76% of the total profession and 78% of the working profession. Members are elected by the council of the Branch in whose area they reside, or, if not resident in a Branch area (for example, serving in the Forces), by the Central Council. The privileges of members include participation in all activities, local and central, in its government and the formulation of its policy; the weekly receipt of the *British Medical Journal* and its *Supplement*; the use of the houses of the Association in London and Edinburgh; and the help of the central staff in professional matters. The Association offers a number of prizes for research and the encouragement of important work. It has a library of over 50,000 volumes. Two new developments in the Association—an Empire Medical Advisory Bureau and a Medical Practices Advisory Bureau—are referred to elsewhere in this number.

The ordinary subscription for members resident in Great Britain and Northern Ireland is four guineas per annum, but certain classes of members come in at lower rates, and the newly qualified practitioner who is elected within two years of registration pays only two guineas per annum during the four years after registration. Members residing outside Great Britain and Northern Ireland pay one and a half guineas, and Service members, wherever resident, two and a half guineas.

The British Medical Guild is an independent parallel organization for the better protection of the interests of the profession in disputes with public authorities and other bodies and the compensation of members for financial loss incurred through loyal acceptance of B.M.A. policy. Local organizations of the Guild are being formed.

The National Insurance Defence Trust was formed in 1919 to assist in defraying expenses incurred in protection of the interests of the profession in connexion with the National Health Insurance system, and to give, where required, financial support to practitioners who may be suffering owing to action taken by them in accordance with the policy laid down by the former Conference of Local Medical and Panel Committees. With the inception of the National Health Service Acts a new General Medical Services Trust has been formed, the trustees of which are the members for the time being of the General Medical Services Committee of the B.M.A. Its principal objects are to take such action as may be deemed expedient in the interests of general practitioners in the National Health Service, and to assist financially practitioners or classes of practitioners who have suffered or are likely to suffer hardship in consequence of loyalty to approved policy.

Society of Medical Officers of Health

The Society of Medical Officers of Health (Tavistock House South, Tavistock Square, W.C.1) is a society of medical officers engaged in public health work in all its branches. Its official organ is *Public Health*. In matters of policy it works in conjunction with the British Medical Association, and nominates two members to the Public Health Committee of the Association, and the Association has similar representation on the Society's council.

Medical Women's Federation

The Medical Women's Federation (Tavistock House North, Tavistock Square, W.C.1) is the only professional organization in this country consisting solely of medical women. It was founded in 1916, but its forerunner, the Association of Medical Women, dated from 1879. It endeavours to bring before the main body of the profession the special minority difficulties of medical women and when necessary to press for the full application of the principle of equality. It works in close and friendly relationship with the British Medical Association. The Federation has active local associations all over the country and in Northern Ireland, as well as a large London association and an overseas association linking up members all over the world. The Federation is non-political.

Defence Societies

The Medical Defence Union (address from mid-September, Tavistock House South, Tavistock Square, W.C.1) has a membership of over 34,500. It has thrown open its doors to dental as well as to medical practitioners, and has made special provision for overseas medical and dental practitioners practising in the Dominions and other countries. Its work has been increasing by leaps and bounds during the past three years. It furnishes advice and unlimited financial indemnity to any member threatened with or involved in litigation raising a question of professional significance or, more commonly, based upon a charge of professional negligence. The accumulated funds are now about £140,000, while the subscription income is mounting annually, though costs of litigation and of settlements out of court are mounting even more rapidly. Since its foundation the Union has spent £300,000 on damages and costs incurred in protecting members.

The Medical Protection Society (Victory House, Leicester Square, W.C.2) has a membership of over 26,000. During the past year it has gained nearly 2,000 new members—a record in the history of the Society. Membership is open to registered medical and dental practitioners. There are special provisions for members practising overseas and also for practitioners who visit the United Kingdom for postgraduate work. Members are afforded advice and assistance in all matters of professional difficulty, with unlimited indemnity against adverse costs and damages. This indemnity is secured by financial resources exceeding £150,000 and a reinsurance at Lloyd's for an unlimited amount. The council considers the financial position is such as not to justify any increase of the subscription, which is £1 per annum.

The Medical and Dental Defence Union of Scotland (115, St. Vincent Street, Glasgow, C.2) has a membership of 6,634, but with the summer influx of new graduates it is expected that at the time of the annual balance the membership will be in the region of 6,700. The total assets are about

£40,000. The policy of the council has always been to give careful consideration to the interests of its members who have claims made against them for negligence.

BRITISH MEDICAL STUDENTS' ASSOCIATION

The British Medical Students' Association (B.M.A. House, Tavistock Square, W.C.1) was founded in 1941 to promote the interests of medical students. It is a highly enterprising body, publishing a lively quarterly journal, organizing clinical conferences in university centres, and holding an extended annual general meeting in the autumn. One proposal which the association is considering is the establishment of a rehabilitation centre for tuberculous students. This year its main activities have been in connexion with the Medical Bill before Parliament, which vitally affects the future of medical students. Its executive has vigorously pursued a well-determined policy with regard to this Bill, has been in constant touch with Members of Parliament and with the Minister of Health, and has seen that the various points of principle have been ventilated in the national press. It has also taken up the question of student health, various international relations, medical teaching films, and vacation residences. With regard to this last, for the past three years it has assisted students to obtain posts in hospitals during their vacations. With the object of retaining the interest of its old members the B.M.S.A. has created a category of membership for qualified men and women.

EMPIRE MEDICAL ADVISORY BUREAU

The Council of the British Medical Association in 1948 decided to set up at B.M.A. House, Tavistock Square, London, W.C.1, an Empire Medical Advisory Bureau with a view to welcoming and providing a personal advisory service to practitioners visiting the United Kingdom from the Dominions and Colonies. An Advisory Committee has been formed under the chairmanship of Sir Lionel Whitby and is fully representative of Government departments and societies interested in the welfare of Empire and Overseas visitors during their stay in this country for postgraduate or other purposes.

One of the main objects of the Bureau is to welcome overseas visitors. All such visitors are most cordially invited to contact the Bureau as soon as possible after arrival and talk over with the Medical Director (Dr. H. A. Sandiford) any points on which advice or assistance may be needed. During its first two years nearly 1,500 inquirers have made use of the Bureau's services and over 800 visitors have visited the Bureau.

Detailed information is available at the Bureau on postgraduate education facilities and on the courses of study necessary for higher qualifications. The Bureau is in close touch with the British Postgraduate Medical Federation and other organizations and authorities concerned with postgraduate work, and, where required, the necessary contacts and introductions can be provided. The visitor who wishes to see something of the latest medical and surgical techniques can be put in touch with the appropriate experts.

A register of suitable hotels and lodgings is maintained by the Bureau. "At Homes" and other social functions are held at regular intervals, and practitioners from the Dominions and Colonies are enabled to meet each other and prominent members of the profession in this country. A number of United Kingdom doctors have notified the Bureau of their wish to entertain overseas visitors, usually for week-ends, in their homes.

General information is afforded by the Bureau concerning food rationing, Customs duties, facilities for sport and travel, exhibitions, and the like. It will enable the Bureau to be of most service if a visitor gives as long notice as possible of his intended visit to this country, date of arrival, mode of travel, period of stay, and so forth. On arrival a letter of introduction from the local honorary secretary of the medical association to which the visitor belongs, whilst not essential, would be welcome and might be helpful if references are required when taking furnished flats. All communications should be sent to the Medical Director.

SERVICE OVERSEAS

Colonial Medical Service

The Colonial Medical Service offers an interesting career. Vacancies occur in all parts of the Colonial Empire, the greatest number in tropical Africa and Malaya. Candidates must ordinarily be British subjects holding medical qualifications registrable in the United Kingdom, and should have had at least 12 months' postgraduate hospital experience before appointment. Those applying for entrance into the permanent service must be under 40 or 45 years of age, according to the age of compulsory retirement (50 in West Africa and 55 in most other territories) in the area to which they are appointed. Contract appointments for short terms are available for candidates who are above the age limits or who, while below the age limit, do not wish to commit themselves to a colonial career at the outset. Officers appointed to the permanent service are normally required to take a course in tropical medicine and hygiene either before proceeding overseas or during their first leave.

In the first instance medical officers are usually appointed for general duties, often involving the charge of a district hospital and responsibility for the medical administration of a district, though many officers are employed on clinical duties in the large hospitals. Some posts are concerned purely with public health work, and for these the possession of the D.P.H. or special experience in preventive medicine is necessary.

A large number of specialist appointments, calling for a very high standard of professional attainment, are normally filled from within the service by officers possessing the necessary aptitude and qualifications. Senior administrative appointments are also almost invariably filled by the promotion of serving officers. Officers possessing qualifications or experience in pathology would be considered for appointment to the laboratory establishments. Vacancies exist for women doctors, particularly for those with special experience in obstetrics, school health, child welfare, and nutrition.

Doctors in the National Health Service may also avail themselves of a scheme which is to be brought into operation in most Colonies whereby they take up appointment in the Colonial Medical Service for temporary posts up to six years without loss of pension rights in the National Health Service. The scheme provides for the payment of a generous gratuity at the conclusion of the doctor's service abroad, but those wishing and eligible to transfer to the permanent and pensionable establishment of the Colonial Medical Service will have opportunities to do so. The Colonial Medical Service offers special opportunities and experience not obtainable at home, and that experience will be of great value to the doctors both in practices and in hospital appointments if they elect to return to this country.

Full particulars of terms and conditions of service may be obtained from the Director of Recruitment, Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1.

During the past year the British Medical Association has been in negotiation with the Colonial Office concerning the revision of salary scales in the Colonial Medical Service. The endeavour has been to arrive at a fair colonial equivalent of the Spens recommendations for the remuneration of the profession in the United Kingdom, but the Colonial Empire has a wide range of variation in taxation, cost of living, and conditions of work, so that a scale which would be a fair equivalent in one colony would be far from fair in another. The attempt to draw up a single uniform scale applicable to all colonial territories has therefore been abandoned in favour of the achievement of a broad equality of real reward. The conclusions reached up to the end of last year were set out in the *Supplement* of December 31, 1949 (p. 278).

Medical Missions

To medical men and women with a sense of vocation and a desire to express and spread their faith through their professional work, medical missionary service offers vast opportunities. In China, Christian missions have given the country a medical and a nursing profession, and despite recent restrictions and difficulties doctors continue their witness. In Africa they have responded to the urgent call of physical need, have pioneered rural health services, and contributed to leprosy research and control, as well as taking a part in the building up of the Christian Church. In India and Pakistan they have helped to maintain high ethical and professional standards, and demonstrated in time of crisis the Church's ministry of reconciliation.

The missionary societies regard 18 months' postgraduate work in resident appointments as a minimum, and often advise work for specialist diplomas or higher degrees. In addition special missionary training is recommended. Terms of service vary in length from 18 months to six years, according to climatic conditions. While it is generally hoped that offers of service will be for life, short terms are also considered. Salary is on a missionary basis, with children's allowances and a pension scheme.

Applications from students and qualified men and women should be made direct to the missionary societies or through local branches of the Student Christian Movement or the Intervarsity Fellowship, or to the chairman of the Medical Advisory Board of the Conference of British Missionary Societies, Edinburgh House, 2, Eaton Gate, London, S.W.1.

THE SYRIAN UNIVERSITY

FACULTY OF MEDICINE

The Faculty of Medicine of the Syrian University at Damascus consists of branches in medicine, pharmacy, dentistry, midwifery, and nursing. The Medical Faculty is the University's oldest institution and was originally known as the Arab School of Medicine. It was established in 1919 to succeed the Turkish School of Medicine, started in Damascus under Sultan Abdul Hamid II in 1901.

A decree passed in 1925 placed under the Medical School the Syrian General Hospital, which hitherto had been run by the Ministry of Health. The radiology department was established in 1926, the maternity section in 1937, and the children's department in 1948.

The teaching staff includes in its 44 members ten professors, eight assistant professors, five lecturers, and eight assistant lecturers. There are 327 students of medicine.

Inquiries about vacancies on the staff should be addressed to the Middle East Secretariat, Foreign Office, London, S.W.1.

The faculty has the following laboratories: anatomy; physiology; biochemistry; pathology; bacteriology, parasitology, and hygiene; medicine; forensic medicine; chemical pharmacy and chemistry; clinical dentistry; dentistry (three).

The faculty's hospital has 365 beds. It is divided into eight sections attached to the different branches as follows: internal medicine; surgery; gynaecology; nose, ears, and throat; eyes; children; skin diseases; infectious diseases. In addition to these sections the hospital has an out-patient department, a radiology department, a special laboratory for medical and chemical analysis, and a blood bank. The students in their last year receive intensive training in practical medicine and surgery at Government and military hospitals as well as at the various branches of the faculty's own hospital.

THE PUBLIC HEALTH SERVICE

Many departments of the Government have health functions. The Ministry of Health makes annual grants to local authorities as a contribution towards the expenses of local health services, and receives an annual report from the medical officer of health for each area. The Ministry of Education makes similar grants to local education authorities for the administration of school medical services. The Ministry of Labour administers the Factory Acts; the General Post Office provides a medical service for certain of its employees; the Ministry of Fuel and Power appoints medical officers for mining districts. The Ministry of Food has its own medical advisers. Over a period of nearly 20 years the local authorities ran rate-aided general hospitals, but these, along with the voluntary hospitals, have, save in a very few cases, been taken over under the National Health Service Act by regional hospital boards.

The entrant into public health work usually begins as an assistant medical officer, doing maternity and child welfare or school medical work or both. Such medical officers are now tending to specialize more directly either on the obstetric or on the child health side. The Society of Medical Officers of Health has suggested that special experience in maternity or children's hospitals and the acquirement of such a diploma as the D.C.H. might be more useful than the D.P.H. itself. But the Certificate in Public Health is regarded as the basic qualification for entrance into the public health service.

The L.C.C. Medical Service

The London County Council employs a larger number of medical staff than any other local authority. Sir Allen Daley, Medical Officer of Health and School Medical Officer to the council, kindly sends the following note:

"Whole-time appointments in the Public Health Department of the London County Council, apart from those of medical officer of health, deputy medical officer of health, and principal medical officer, include five senior medical officers, nine divisional medical officers, five senior assistant medical officers, nine assistant divisional medical officers, and 73 assistant medical officers. Their duties in the higher grades are mainly administrative. The officers, speaking generally, have graduated through the clinical field and have special knowledge in at least one branch of the service. The assistant medical officers are mainly engaged in the school health and maternity and child welfare services. Suitable qualifications are the D.C.H. and the C.P.H. or the D.P.H. Arrangements are made for some of them to have clinical responsibilities at hospitals and to gain experience of the environmental health services in the Metropolitan boroughs.

"For the grades assistant medical officer to senior or divisional medical officer the present salaries range from £910 to £1,800 per annum, but a Whitley Council, at national level, is now reviewing public health salaries.

"In addition the council employs nearly 500 part-time medical officers in a variety of work—for example, in residential nurseries, welfare institutions, staff examinations, and sessional work at clinics, and in school medical inspection. By arrangement with the London School of Hygiene, the Institute of Child Health, and several undergraduate schools, students are given opportunities of gaining experience in the council's various medical services."

MEDICAL AUXILIARY SERVICES

The desirability of having a national register of trained persons engaged in technical work or practice ancillary to the work of the medical profession was seen clearly many years ago by the British Medical Association, and it was principally at its instance that there was formed a Board of Registration of Medical Auxiliaries (Tavistock House North, Tavistock Square, W.C.1). The register comprises many thousands of names and includes radiographers, dispensing opticians, chiropodists, speech therapists, orthoptists, dietitians, and physiotherapists and biophysical assistants. The Board, the majority of whose members are members of the medical profession, is a registering and disciplinary body, not an examining one. Examining bodies in the various branches are approved by the Board and appoint representatives to its council.

The function of the Board is to co-ordinate the work of these various auxiliaries, to ensure that they are qualified, to maintain and improve their standard of training, and to afford liaison between them and medical practitioners. All those whose names appear on the register hold a qualification in their particular sphere recognized and approved by the Board. With the exception of the chiropodists, all those on the register, as a condition of admission, undertake not to carry out any medical auxiliary work save under a medical practitioner's direction

and control. The chiropodists, while not acting under medical direction, confine their practice to the treatment of malformed nails and superficial excrescences occurring on the feet.

The qualifying bodies for the respective branches are the Society of Radiographers, the Association of Dispensing Opticians, the Society of Chiropodists, the College of Speech Therapists, the British Orthoptic Society, and the British Dietetic Association. All the qualifying bodies have established periods of training. That for the radiographers, for example, is two years at a recognized training centre, and for speech therapists a three-years full-time course at a recognized school.

Correspondence

Ministry of Health Streptomycin Conference

SIR,—In your issue of August 12 (p. 413) you kindly published a summary of the findings of the conference organized by the Ministry of Health to investigate the use of streptomycin in the treatment of tuberculous meningitis. Your introductory note to this summary is liable, however, to give a wrong impression of the history of this conference, and this is due, no doubt, to the fact that the body organizing these trials was, owing to its very large size, called a conference instead of a committee. The facts of the matter are that preliminary trials on this treatment were carried out by the Medical Research Council, who in 1947 informed the Minister of Health that their results to date justified the wider use of streptomycin in the treatment of tuberculous meningitis and acute generalized miliary tuberculosis. It was decided, therefore, that the Ministry of Health should organize clinical trials in relation to these two conditions, and teaching hospitals in different parts of England and Wales, as well as the Department of Health for Scotland and the Ministry of Health and Local Government of Northern Ireland, were invited to organize groups known as centres to carry out these trials. The first supplies of streptomycin for this purpose were issued in August, 1947, and thereafter quarterly meetings of representatives of the centres were held at the Ministry of Health under my chairmanship. In January of this year a report on the results of this investigation was approved which, for various reasons, it was decided should be confidential, and in July a short summary was approved for publication.

You will see, therefore, that though the original limited trials were carried out by the Medical Research Council and their experience and the co-operation of their experts were of the greatest assistance in the later trials, yet the latter were the responsibility of this Ministry and the "conference" was not a meeting held on a single occasion but an organization conducting and assessing these larger trials.—I am, etc.,

Ministry of Health, S.W.1. W. DALRYMPLE-CHAMPNEYS.

Science before History

SIR,—In the *British Medical Journal* of August 12 we have had the privilege of reading two outstanding addresses. In the first, Dr. F. M. R. Walshe (p. 379) points out that a full diagnosis must be based on the integration of two different disciplines; first, the technique of the natural scientist is needed in order to elicit and evaluate physical signs and laboratory investigations; secondly, the method of the historian is used to elucidate and interpret what the patient and relatives say. He suggests that in medicine the discipline of the historian is usually the more difficult one. Dr. F. Gray (*Supplement*, p. 85) states that the essential activity of the general practitioner should be the detection of small but significant degrees of ill-health. He also says that teaching hospitals are mainly concerned with the diagnosis and treatment of patients displaying major deviations from the normal and that knowledge of these, though an important step, is by itself quite inadequate to make a good doctor.

The logical result of these ideas would be that the student should first be grounded in the elicitation and interpretation of physical signs and laboratory tests, both relatively easy techniques which link up naturally with his scientific studies. When he has learned the essentials of physical diagnosis the student should then be initiated into the difficult art of taking a history, for which his preclinical studies have been a *poor preparation*. This programme is the reverse of what usually occurs nowadays, where the student is set to take a history but the teacher examines the patient. *I believe that the traditional procedure* of taking a full personal and family history before examining the patient is usually a mistake, both in teaching and in practice. It is often wiser first to discover whether the patient suffers from any detectable abnormality and then from the history to try to determine its significance, and this is the order in which students should be instructed.—I am, etc.,

Liverpool. ROBERT ROAF.

Preparing Students for General Practice

SIR,—Dr. Frank Gray in his very fine address "The Way Divides" (*Supplement*, August 12, p. 85) says that one way of raising the status of general practice is for general practitioners to pool their experiences and help to educate each other. I suggest that a more fundamental method is necessary—*namely*, to have lectures by general practitioners to future general practitioners in our medical schools. The gap between the teaching of the consultants and the practice of *the family doctor* is very great. The young doctor entering general practice, even after a year or two in hospital, still has to learn by bitter experience how to deal not only with the "*trivial*" complaints but with many other aspects of medicine requiring a great deal of knowledge. I am recently enough qualified to remember how *little* I was taught in medical school about domiciliary midwifery, breast-feeding, the investigation of sterility, the control of the common fevers in the home, the treatment of *the rheumatic* diseases, and above all the psychological approach which is the hallmark of the good practitioner.

Few consultants have the necessary experience of these subjects, as encountered from the viewpoint of the general practitioner, to teach them well. For instance, how many consultants can lecture about breast-feeding as ably as Dr. Charlotte Naish, who opened the discussion on the subject at the Annual Meeting last month? Her book, written as a result of her own observations in general practice, leads to a deeper understanding of this difficult subject than any other literature I have read. Dr. William N. Pickles and Dr. Grantly Dick Read are well qualified to lecture on their own subjects, and there are many other able "physicians and surgeons" who have not hit the medical headlines but whose abilities should be made use of by the teaching schools. The bulk of any good doctor's medical education is acquired after he qualifies, but let him at least have a good grounding in the fundamentals of individual and family as well as scientific medicine.—I am, etc.,

Clare, Suffolk. D. CRADDOCK.

The Teaching of the Medical Student

SIR,—When I graduated in 1888, the course of teaching was limited to four years, provided you jumped the hurdles as they came along. The first winter was devoted to chemistry, zoology, and anatomy, and the following summer to botany (at 8 a.m.), practical chemistry, and anatomy. The second year was devoted to anatomy and physiology, and we started clinical surgery. The surgery was easily learned, as it was chiefly concerned with fractures, tuberculous abscesses of bones, hip-joint, glands, etc. Strictures of the urethra were common and were treated by bougies, and occasionally by Syme's operation. Cancer of the breast was not uncommon, and usually removed by operation. We also saw some patients suffering from fracture of the base of the skull. Amputations were rather common, especially of the foot and occasionally at the knee-joint. Lister's antiseptic technique was half-heartedly applied. No surgeon, so far as I know, had ever seen the staphylococcus, nor, I fancy, believed in germs causing so much disease. Every major operation I saw was followed by local sepsis and suppuration, and actually two forms of pus were recognized: the healthy pus was called laudable, and was expected as a matter of course. Only once in three years did I see the abdomen opened, and that was in a stout woman, when the bowels gushed out and were with great difficulty replaced, the patient dying in the night.

In the dispensary we picked up some useful knowledge regarding diseases of the ear from Dr. T. Barr, but Dr. Maitland Ramsay gave an excellent course of operative surgery on the eye on Saturday mornings; and Dr. Walker Downie, just beginning his career, on throat diseases. Looking back over the vista of years, I think, so far as I was concerned, botany and zoology should have been left out, and we should have got to grips with anatomy, physiology, and chemistry straight away. A good grounding in practical anatomy, to know when we are examining a patient what really lies below the skin, whether it be nerve, artery, muscle, or valves of the heart, the topography of the organs, the distribution of nerves, and the anatomy of the spinal cord and brain, is in my humble judgment the most valuable knowledge any general practitioner should aspire to, particularly for diagnostics. The new course for a student is going to be a tremendous task, practically requiring him to profess an encyclopaedia of medicine.

After I was a few years in practice I studied bacteriology with Dr. Arkle at Charing Cross Hospital, having the laboratory to myself, and diseases of the skin with Morgan Dockrell at Leicester Square; he summed up the treatment of diseases of the skin in these words: "Ask yourself if the skin requires to be stimulated or soothed, then add the suitable antiseptic." Following that advice I have had little trouble in treating the ordinary run of skin cases. I had the pleasure of the company of two American doctors in visiting many of the hospitals in London. Their opinion was that there was far too much theory and far too little ocular demonstration of patients and their diseases.

I believe there is now room for two classes of doctors: one class who will take, say, a B.Sc. in scientific knowledge, and another class who are content with practical knowledge and who are not mentally fitted to carry too many impedimenta in their heads for their day's work.—I am, etc.,

Renton, Dunbarton. J. T. MACLACHLAN.

Amoebiasis and Personality

SIR,—The paper by Dr. C. A. Hoare (July 29, p. 238) and your annotation on amoebiasis (p. 259) stress the point that *E. histolytica* lives mainly as a commensal in the bowel. It seems probable that the higher incidence of amoebic dysentery in hot countries is due to the mucosa being often rendered susceptible to the invasion of *E. histolytica* by bacillary dysentery or non-specific epidemic entero-colitis. Recovery from these attacks is usually complete with treatment and in many cases probably without it. There are, however, a group of patients who persistently relapse in spite of all forms of therapy for some years, even after leaving the Tropics. The evidence seems to point to differences in individual susceptibility. I should like to offer some personal observations which may be relevant to this matter.

In 1948, while investigating the incidence of the colitis personality among controls, I took a patient from a surgical ward who was recovering from appendicectomy. My assessment of his personality was that he was potentially a case of colon neurosis (irritable colon) or even ulcerative colitis. Examination of case notes then revealed a long history of recurrent bouts of abdominal pain with diarrhoea and mucus since he had been in Iraq in 1943. (On closer questioning he admitted attacks of "enteritis" in this country before the war, usually related to stress.) The operation note recorded that his caecum was inflamed, and that the purse-string sutures tended to cut out. I examined the abdomen and found a soft, enlarged, and slightly tender liver. After discussing my suspicions with the surgeon we made a sigmoidoscopic examination, and I was able to demonstrate active haematophagous forms of *E. histolytica* from small ulcers in the rectum. I then remembered some of the chronic relapsing cases I had treated during the war, and, though I had not made a psychological study at the time, my memory of a few of them fitted well with certain traits I have since found associated with the colon personality. In the next few months I pursued and interviewed a further three cases of chronic relapsing amoebic dysentery, and my findings were similar. Since then only one more has come my way, but again he had a colon personality. I drew attention to these observations in 1948,[1] and at about the same time Crede and his colleagues[2] recorded a similar case. It therefore seems possible, apart from changes due to infection by the dysentery group of organisms, that the hyperaemic, oedematous, and even ulcerated mucosa found in colon neurosis and colitis may be important in rendering the bowel wall vulnerable to invasion by *E. histolytica*. Such an explanation, though it may seem far-fetched to those who have not studied personality traits in colitis, might account for some of the mystery of the symptom-free cyst-passer in relation to the chronic amoebic invalid.—I am, etc.,

Nurses and Tuberculosis

SIR,—At the annual conference of the National Association for Maternity and Child Welfare, Dr. Fraser Roberts is reported (*B.M.J.*, July 22, p. 211) to have said that people with a bad family history of tuberculosis should be discouraged from entering the tuberculosis nursing service. Whatever justification there may have been for such a statement in the past, these remarks surely do not apply to-day when the nursing profession as a whole, especially in sanatoria and general hospitals, is subjected to more detailed supervision, with the use of B.C.G. vaccination as necessary, than men or women in other walks of life? In point of fact the person with a bad family history entering the nursing profession, and developing active disease, is in a much more fortunate position than her opposite number employed in some other occupation. In the one instance the disease will be detected at an early treatable stage, whereas in the other the disease may drag on undetected until she becomes an advanced sputum-positive case for whom nothing can be done, thus adding yet further to the reservoir of infection in our midst.

As regards rehabilitation this should present little difficulty in the case of the nurse, but in the other case the matter is frequently extremely complicated, despite the provisions of the 1944 Disabled Persons Act.

It is hoped that Dr. Roberts's remarks will not be taken seriously and that candidates for the nursing profession who are deeply convinced that their life's work lies in this direction and who are themselves in good health will not be deterred from entering the service simply because of their family history.—I am, etc.,

Birkenhead. DAVID W. TOUGH.

Sulphapyridine for Dermatitis Herpetiformis

SIR,—In your issue of August 12 (p. 408) Professor Dunlop says unkind and mostly quite justifiable things about sulphapyridine. Curiously enough, however, and any dermatologist will so testify, it is often the only drug which will control dermatitis herpetiformis. In a disappointing number of cases the drug cannot be endured by the patient, but there are also those who can tolerate the drug, sometimes for years, and their lives are bearable only when they take a regular maintenance dose. For the moment, may we continue to prescribe it?—I am, etc.,

London, W.1. DAVID I. WILLIAMS.

Domiciliary Treatment of Tuberculosis

SIR,—I was glad to see the answer in the *Journal* (August 5, p. 369) by Dr. FitzGerald and others to the allegation made by Dr. William D. Gray at the meeting of the Sections of Diseases of the Chest and Tuberculosis and of Preventive Medicine at the Annual Meeting of the B.M.A. at Liverpool. I, however, am certainly not satisfied with his reply. Does Dr. Gray really believe that we should ask the permission of the tuberculosis officer before treating our patients with streptomycin or P.A.S.?

Perhaps Dr. Gray also believes that we should also ask the permission of the medical officer of health before treating a case of puerperal sepsis with penicillin.

It is the primary responsibility of the general practitioner to treat these diseases, and he is certainly under no obligation to consult the tuberculosis officer first. I have long since by-passed the tuberculosis officer in all cases of tuberculosis. All *x*-ray examinations, sputum tests, and E.S.R. determinations are arranged at the local hospital, and all difficult cases referred to the chest physicians at the teaching hospitals. Previously I found it so difficult to prevail on the tuberculosis officer to arrange these investigations that I found it essential to make the arrangements. If a tuberculosis officer did arrange an *x*-ray examination I found it almost impossible either to see the film or to obtain a report.—I am, etc.,

London, S.W.2. R. CROSBIE WALSH.

Carcinoma of Islets of Langerhans

SIR,—In the *British Medical Journal* of April 29 (p. 982) Drs. B. F. Brearley and J. W. Laws reviewed a case of carcinoma of the islets of Langerhans accompanied by hypoglycaemia. The patient died. Microscopical examination showed carcinoma of the islet cells of the pancreas with metastases in the abdominal organs. Some years ago, in 1932, I had the opportunity to observe a similar case. The history of this case is as follows.

The patient, a man of 63 years of age, owner of a public-house, suffered from diabetes mellitus for three years. He consumed alcoholic drinks regularly before the diabetes. Since his illness was discovered he drank regularly daily about 1–1.5 l. of wine on prescription, besides following a meat and vegetable diet. On this diet he had glycosuria. During half a year he lost considerable weight. Before he weighed 200 lb. (90 kg.), but now, even with his huge ascites, he weighed altogether 168 lb. (75.6 kg.). The legs were also swollen. Later no sugar was to be found in his urine. He was admitted to hospital on February 25. On this occasion, and later too when undergoing regular examination, there was no sugar in the urine, but urobilinogen was positive and the blood-sugar level was 120 mg.%. The patient had no jaundice. The Wassermann reaction was negative. The patient suffered permanently from high temperature up to 102.2° F. (39° C.). After some "novurit" diuretic injections we performed puncture of the ascites and drained more than two gallons of the ascites fluid. After puncture a tumour as big as two fists became palpable in the epigastrium. Glycosuria did not occur though his diet contained pure carbohydrates. The general state of the patient gradually grew worse and he died on March 12. Some of the more significant details of the necropsy were as follows. There were about two gallons of ascites fluid in the abdomen. The liver had a granular surface, and under the stomach and on the lesser curvature a mass of lymph glands as big as a child's head was situated. The head and body of the pancreas were changed into a big soft mass of tumour tissue, which together with the lymph glands formed one body. The tumour was soft like marrow, with an abundant pulp and sulphur-yellowish necroses and haemorrhages. The stomach was intact: the tumour did not touch it. The liver was full of granules of a greenish-red colour; metastases were found in the liver too. Diagnosis: interstitial hepatitis, and carcinoma of the pancreas with metastases.

No histological examination took place; therefore it could not be precisely ascertained which cells of the pancreas were the source of the tumour; but it was a fact that simultaneously with the growth of the tumour the diabetes disappeared and the patient showed no glycosuria in spite of the pure carbohydrate diet, and his blood-sugar level also became normal. Consequently the tumour contained insulin-producing cells.—I am, etc.,

Csorna, Hungary. ALEXANDER FERENCZI.

Sulphonamide Dosage in Kidney Infection

SIR,—Professor D. M. Dunlop in his paper on sulphonamide therapy (*Journal*, August 12, p. 408) states that in coliform urinary infections it is unnecessary to give large doses of sulphonamides, as they are concentrated by the kidneys in their passage from the blood into the urine. This would be true if we could be certain in any given case that the infection has not penetrated into the interstitial tissues of the kidney. In these cases it is obvious that what matters is not the urinary concentration of the drug but the blood concentration. This was pointed out clearly and vigorously by Birchell and Alexander in an outstanding paper on the medical aspects of pyelonephritis. The distinction at the bedside and in the clinical side-room between pyelonephritis and more innocent infections of the urinary tract is notoriously difficult. Pyelonephritis is responsible for a not inconsiderable number of cases of hypertension and renal failure in children and young adults. It is, therefore, a disease which merits great consideration and thorough treatment. For these reasons Birchell and Alexander very correctly advocates that sulphonamides be given in full doses and for five to seven days in all cases of coliform urinary infections.—I am, etc.,

London, N.21. E. MONTUSCHI.

Imported Helminthic Infections

SIR,—Your annotation under this title (July 22, p. 206) recalls how little is reliably known of the incidence of these infections in communities in this country. It is indeed as much a matter of clinical as of epidemiological importance that surveys should be undertaken and reported on the prevalence of parasite eggs and larval excretion not only of tropical helminths but also of endemic cestodes and nematodes. The possibilities of diphyllobothrium becoming established as a public health risk here have been mentioned by some of your contributors (July 22, p. 188). Immigrants and returning Servicemen, prisoners of war, and civilians from countries where helminthiasis is widespread may unwittingly harbour one or more species of intestinal parasite acquired abroad and responsible for deceptive or equivocal symptoms.

Last week I found 48 West Africans living at one of the more salubrious of London's common lodging houses, and was reminded of the findings in 1945 during a survey of the stools of 100 apparently normal uncomplaining West African native soldiers stationed at Benghazi (Cyrenaica). Ninety-nine showed helminthic ova or larvae; 72 of these were infected with two, three, or four different species, and one man's stools showed five. The species identified were *Taenia saginata* (3), *Ascaris lumbricoides* (31), *Trichuris trichiura* (59), *Ankylostoma duodenale* (55), *Trichostrongylus columbriformis* (77), and *Strongyloides stercoralis* (14). Seventy-eight of the 100 "normal" men showed a blood eosinophilia of 10–40%. There is another important aspect of this problem. So many helminths invade the lung at one stage of their life cycle in men that lung symptoms due to their unsuspected presence may create difficulties in accurate diagnosis, especially when such symptoms are accompanied by changing areas of radio-opaque pulmonary collapse or consolidation and marked eosinophilia.

In some of the puzzling lung cases met with in practice parasitological examination of sputum and stool for ova or larvae can be very helpful. Similarly, ova and developing *Enterobius vermicularis* may sometimes be demonstrated in the purulent nasal discharge of young children and indicate the more appropriate orifice to which treatment should be directed. —I am, etc.,

Westminster, S.W.1. W. HARTSTON.

Hyperemesis Gravidarum and Oestrogens

SIR,—I was interested to read in your issue of July 29 (p. 275) that Professor W. I. C. Morris, a renowned and revered obstetrician, had asserted that "hyperemesis gravidarum was the one complication of pregnancy in which obstetricians had accepted the major importance of the psychological component."

Although nausea and vomiting in early pregnancy can be caused by several conditions—e.g., pyelonephritis—hyperemesis gravidarum is a characteristic syndrome. The most prominent symptoms are intense wretchedness, depression, nausea, vomiting, and the development of marked acetonuria within a period of a few weeks. In my cases the onset of symptoms has been abrupt and they have increased in severity with alarming rapidity. In my opinion, hyperemesis gravidarum, far from being caused by psychological factors, is a toxaemia caused by an endocrine or metabolic upset with a vicious-circle action.

In my first case, in 1947, after a trial of all the usual methods of treatment, when termination of pregnancy was being considered, I hit on the idea of giving synthetic oestrogen (*dienoestrol*) in comparatively large doses by mouth. Within two to three days the effect was dramatic and the condition cleared up completely. My last case occurred this year. During the sixth week of pregnancy it became necessary to institute treatment. Ethinyl oestradiol was used and the dose was 2 mg. t.i.d. At the 13th week this dose was gradually reduced over a period of one month, at the end of which it was discontinued. This method completely controlled the hyperemesis gravidarum. When dummy tablets were substituted, the condition recurred. I might add that in the few cases of the disorder I have seen there was no evidence whatever of psychological disorder.

There is one piece of laboratory evidence in favour of treatment with oestrogen. Smith and Smith[1,2] found in the toxaemias of pregnancy an increased output of gonadotrophin and a diminished output of oestrogen and progesterone.—I am, etc.,

Intermittent Dosage with Streptomycin

SIR,—I was interested to read Dr. R. Munro Ford's letter (August 5, p. 369) commenting on a recent paper in the *Journal* concerned with intermittent dosage in the treatment of pulmonary tuberculosis with streptomycin (May 27, p. 1224). I quite agree that there are theoretical reasons for suggesting that a dosage of, say, 3 g. of streptomycin every third day might diminish the high incidence of streptomycin-resistant organisms which occur when 1 g. is given every day. In addition, such high intermittent dosage might be more effective clinically, and there is evidence to suggest that it would be no more toxic. In fact, a clinical trial of such a regime has been advocated from time to time in this country, but it has not been possible to arrange it owing to pressure of other investigations. The great success of P.A.S. in reducing the incidence of streptomycin-resistant tubercle bacilli now makes it unjustifiable to try out any regime using streptomycin alone. It is possible that a high intermittent dosage of streptomycin might be employed in an attempt to avoid streptomycin resistance completely, but a very large number of cases would have to be used to demonstrate that it had any advantage over the more conventional regime. In the meantime, I do not think that high intermittent dosage should be advocated for general use until there is practical evidence both of its value and of its freedom from undesirable effects. We thought there were good theoretical reasons for hoping that one of the methods of intermittent dosage which we tried would succeed in at least postponing the emergence of resistant organisms, but we were wrong.

I should add that these are my personal views and do not necessarily represent those of the other authors of the paper or of the Medical Research Council.—I am, etc.,

London, W.12. JOHN W. CROFTON.

Folic Acid and Pernicious Anaemia

SIR,—I have read Dr. Rutledge W. Howard's letter in the *Journal* of August 12 (p. 417), and also the articles in the *New England Journal of Medicine* of March 23, 1950, to which he referred, and which were not printed at the time when I submitted my article to the *Journal*. I failed, however, to find any evidence of the proof that folic acid does not harm the nervous system in pernicious anaemia in either the editorial or the article by Harvey, Howard, and Murphy, who are concerned only with the effects of folic acid on normal persons or patients not suffering from P.A. On the other hand, the experience of several workers in this country and the United States appears to be that there is more than a suspicion that folic acid treatment of pernicious-anaemia patients may either bring about or accelerate the development of neurological lesions, which are, of course, not primarily caused by folic acid but are a part of the P.A. syndrome. From this point of view I agree with Dr. Howard that folic acid by itself is not the causal factor of the neuropathy.

I cannot agree with his suggestion that folic acid should be given in combination with liver extract or vitamin B_{12} in the treatment of pernicious anaemia. I think this would be a dangerous procedure, as it would rob us of the only criterion with which to judge the adequacy of our therapeutic measures. It is only by keeping the red cells up to 5,000,000 and the haemoglobin up to 100% that we can prevent subacute combined sclerosis of the cord. The simultaneous administration of folic acid and liver or vitamin B_{12} will blur the picture. It would be impossible to assess how far a normal blood finding was due to folic acid or due to the liver principle which alone can prevent neurological lesions.

I agree with all Dr. Howard said about the value of folic acid in certain types of anaemias, other than P.A., although I have quite recently found vitamin B_{12} most effective in a case of idiopathic steatorrhoea in which folic acid had failed.—I am, etc.,

Liverpool, 1. H. FULD.

A Simpler Method of Bronchography

SIR,—Dr. E. G. Sita-Lumsden has described a simple method for introducing iodized oil into the trachea (*Journal*, June 24, p. 1491). I will describe one which is simpler still.

The patient sits on a chair facing the operator, who holds the tongue forward while the following four steps of the procedure are done.

(*a*) The pharynx is thoroughly painted with a 10% solution of cocaine.

(*b*) Three minutes later 2 ml. of 2% cocaine in a syringe without the needle is slowly poured down the nostril, along the floor of the nose on the desired side, while the patient's head is held upwards and slightly towards the side concerned.

(*c*) After three minutes step (*b*) is repeated.

(*d*) After five minutes the required quantity of the oil in a syringe is poured down in the same way, only a bit more slowly.

No premedication is necessary. It is easy to do and definitely more comfortable for the patient than injection and catheterization. There is no coughing out of oil. I have a very limited experience with this method. The results have been very good. I learnt this technique from another Indian Army doctor—Lieutenant-Colonel H. B. Lal, A.M.C.—I am, etc.,

Military Hospital, Jullundur (India). JAGDISH CHANDRA CHUGH, Captain, A.M.C.

Collapse During Spinal Analgesia

SIR,—Much interest has been shown recently in the matter of collapse following spinal analgesia, and we consider the following case to be of sufficient interest to be reported.

Wilson Hey prostatectomy was proposed for a male aged 71 for relief of acute retention of urine of 36 hours' duration. He suffered from dyspnoea and palpitations on exertion and there was radiographic evidence of left-sided cardiac enlargement. Pulse was 84 per min., regular in rhythm; B.P. was 150/100 mm. Hg. Following premedication with morphine 1/6 gr. (10 mg.) and atropine 1/100 gr. (0.65 mg.), spinal analgesia was induced with 1.4 ml. 1:200 "cinchocaine" in 6% glucose ("heavy nupercaine"). He was turned on to his back immediately and appeared very pale and shocked. His pulse rate was now about 160 per min. and grossly irregular; systolic blood pressure was 100 mm. Hg. A 1:250,000 adrenaline drip was started immediately and the blood pressure raised to 130/90 mm. Hg within 30 seconds. Oxygen was administered, and as the patient would not tolerate the face-mask sleep was induced with 10 ml. 2½% thiopentone. It was not possible to adopt a steep Trendelenburg position for fear of spread of the solution to the upper thoracic segments. As the operation was no longer considered feasible, the patient was catheterized and 50 oz. (1.5 l.) of urine withdrawn. On return to the ward one hour later his pulse rate was 100 per min. and rhythm was still grossly irregular; B.P. was 140/100, without adrenaline. An E.C.G. taken 24 hours after the spinal showed auricular fibrillation with right bundle branch block of the Wilson type and ventricular extrasystoles.

As catheterization only produced temporary relief of his prostatic obstruction he was given a general anaesthetic (curare, thiopentone, nitrous oxide, oxygen, and ether), and the operation was successfully completed 30 hours after the first attempt. Digoxin 0.5 mg. was given

intravenously during the anaesthetic, the course of which was uneventful. The auricular fibrillation continued for eight days, when normal rhythm returned spontaneously. An E.C.G. on the tenth day showed nodal rhythm with frequent extrasystoles.

Dr. Wyn-Jones (physician to the Heart Department, Liverpool Royal Infirmary) comments: "The patient had sufficient evidence of myocardial damage that a lumbar puncture alone, or the psychological upset of preparation for operation, may have been enough to bring on auricular fibrillation without any fall in blood pressure due to the spinal. His pre-operative condition could have been termed pre-fibrillation, but there was, unfortunately, no E.C.G. taken before the operation."

Skin sensitivity tests were carried out on the patient and on 100 medical students as controls, 0.1 ml. solution being injected intradermally. With 1:1,500 cinchocaine the patient reacted with a flare and a ½-in. (1¼-cm.) weal. Of the controls 6% showed a flare only. Using 1:200 cinchocaine the patient produced a flare and weal 1¼ in. (3.2 cm.) in diameter. In the control series only five weals were seen, and none more than ½ in. across.

These tests show that our patient had a definite sensitivity to nupercaine given intradermally, but it is not easy to say whether this sensitivity played a part in initiating or aggravating his original collapse. This occurred so suddenly after the spinal tap that it is difficult to visualize even a minute quantity of cinchocaine entering the circulation in such a brief interval.

The advisability of giving adrenaline in the presence of auricular fibrillation can be questioned, but it has been used for control of blood pressure in a large series of prostatectomies, many of which were fibrillating, with no untoward effects.

It might be argued that on account of his poor circulatory state general anaesthesia should have been used on the first occasion. He was a big man with a thick neck, and an endotracheal tube would certainly have been used; and the mere insertion of such a tube, or the inflation of its cuff, might have initiated auricular fibrillation as easily as the prick of a spinal needle.—We are, etc.,

Liverpool. E. H. WINTERBOTTOM.
J. W. DUNDEE.

Forms of Consent for E.C.T.

SIR,—The form of consent for E.C.T. prepared by the council of the Medical Defence Union and published in the *Journal* of August 5 (p. 370) may well be made obligatory in some hospitals, and one wonders if the council could consider the matter again. The sentence beginning "Notwithstanding . . ." is frightening and can be justified only if it is legally necessary. Personally I do not think it is, for once consent to the treatment has been given the question of breaking bones is not relevant to trespass, and an action would turn upon whether the practitioner had been negligent in the way he carried out the treatment. If he was in fact negligent, the M.D.U.'s form would not save him, for the patient cannot be taken as consenting to negligent treatment. If he exercised proper care, then the form does not bear upon the matter.

It is insufficiently recognized that bony injury in E.C.T. is uncommon. In the case of the most usual complication—compression fracture of a vertebra—disability is only material in a manual worker and then only for a few weeks, and is certainly much less than would have accrued from his untreated depression. Since this is so, why frame a form which it is difficult to imagine any volitional patient agreeing to sign? It corresponds with a surgical invitation to have one's appendix out provided it is clearly understood that one may develop pulmonary collapse, acute retention of urine, or subsequently find the surgeon has left the scissors behind inside one.

I wonder if the council of the M.D.U. could look at this again, and produce something that would be "considered appropriate" by the doctors and patients as well as by the solicitors. As well as deleting the offending sentence, I would suggest replacing "convulsive therapy" by E.C.T. or electroplexy, which somehow make one shudder a good deal less.—I am, etc.,

London, W.1. GERALD GARMANY.

Haemorrhage from Peptic Ulcer

SIR,—Perhaps you will allow us to reply to the comments of Dr. A. M. Nussey (August 5, p. 366) on our recent article reporting a series of cases of haemorrhage from peptic ulcer (*Journal*, July 15, p. 138). First of all, there is absolutely no selection of patients admitted to the Royal Victoria Infirmary. All those who are sent to us, and who require in-patient treatment, are admitted. We have not claimed that a larger series would not have resulted in a higher mortality. Quite possibly, and even probably, it would have done so. We simply do not know. Our personal experience has, however, led us to favour the present practice of the medical management of these cases, provided that the surgeon is called in as required: and we wished to record this.

Our main object in publishing our figures, however, was to urge that in future reports the deaths should be more fully analysed. We ourselves have frankly admitted that in two cases out of four death might perhaps have been avoided. It is our opinion that the records of every fatality should be reviewed and that the mortality should be recorded as "inevitable" or "preventable." We believe that this would be much more helpful than a mere total mortality figure, and would be a healthy exercise. It is, surely, to the close study of the individual case rather than to any radical change in the control or general principles of treatment that we must look for a reduction in mortality.—We are, etc.,

A. G. OGILVIE.
Newcastle-upon-Tyne. I. O. B. SPENCER.

The Dumping Syndrome

SIR,—May I respectfully suggest that the two syndromes referred to by Mr. T. J. Butler (*Journal*, July 22, p. 218) are well recognized by most men interested in gastric surgery? The delayed syndrome is of little practical interest.

With regard to the operative procedure (July 1, p. 15), I did not claim it to be original, though I had found no evidence to the contrary. Before publication I tried, with the kind help of the secretary of the Royal Society of Medicine, to unearth every type of gastrectomy with gastro-jejunal anastomosis; this search failed to disclose any description of a central stoma with double valve anastomosis. In the last analysis all such anastomoses are modifications of the Billroth II operation. In this connexion, Lake (1948), quoting Ogilvie, says, "If we must have names let credit be properly attributed and call the operation the high posterior Finsterer–Lake–Lahey modification of the Mikulicz–Krönlein–Hofmeister–Reichel–Polya improvement of the Billroth II gastrectomy with a large valve and a small stoma." To my knowledge none of the methods published by any of these authors resembles the one I described.

Wakeley (1947) includes a figure showing 12 different types of gastric anastomoses, one of which, attributed to Willns and stated to have been published in 1911, shows a central gastro-jejunal stoma. I failed to find a report of this operation, the nearest I could get to it being an article by Wilms in, I think, 1918. The latter infolded the edges of the lesser and greater curvatures, but could not be said to have produced a central stoma with double valve anastomosis. I should therefore appreciate it if Mr. Butler would kindly give the reference of the article he refers to.

Finally, I think the description of the operative technique is difficult to follow, as it was found possible to include two only of the ten sketches submitted. I hope to publish descriptive details later.—I am, etc.,

Dublin. T. O'NEILL.

SIR,—Whatever the mechanism of this syndrome it generally appears to become operative immediately after operation, partial gastrectomy, gastro-enterostomy, etc. The following case history is unusual in that symptoms appeared only after an interval of 23 years.

The patient, aged 61, is a sheet metal worker and follows a strenuous occupation. In December, 1949, he called me in after collapsing at work, but he was quite recovered when examined. In the past two years he has had queer attacks occurring about half an hour after meals. These are characterized by a feeling of nausea, palpitation, cold sweats, and general weakness, leading to fainting on several occasions. The attacks have varied in severity, but, the more strenuous his activity after food, the more severe were the resultant symptoms—e.g., on the particular occasion referred to above he had been late for work and had taken a short cut which required climbing up and down a long steep flight of steps to cross a bridge, and "at the double" to make up lost time. The attacks have lasted about 20 minutes, with spontaneous recovery. He has discovered that eating a toffee hastened such a recovery, and, if taken about the time of onset, prevented or lessened the severity of the attack.

Physical examination revealed no cause for the symptoms, the only unusual feature being a very neat upper abdominal operation scar. The blood sugar curve was 80 mg. fasting; 280 mg. at half-hour after 50 g. glucose; 160 at 1 hour; 70 at 1½ hours; 60 at 2 hours; 70 mg. at 2½ hours; the urine containing sugar in the 1-hour specimen. Barium meal showed a gastro-enterostomy, with the stomach emptying through the stoma and afferent loop: no ulceration was present.

This gastro-enterostomy was performed 25 years ago for intractable peptic ulcer with vomiting, until with a little care and diet he has been symptom-free until the onset of the "dumping syndrome" two years ago.—I am, etc.,

Lancaster. GRAHAM H. ANDERSON.

Division of Popliteal Vein for Varicose Ulceration

SIR,—It was a pleasure to me to read in the August 5 number of the *Journal* your annotation on varicose ulceration (p. 338), in which, in my opinion, the whole problem is very fairly stated. There is, however, one point upon which I do not wholly agree with the opinion voiced by you. Your statement that in the resting patient the pressure in a dependent vein (in this case the popliteal vein), whether normal or abnormal, will represent the hydrostatic pressure exerted by a column of blood extending up to heart level is without a doubt true, provided that no ligatures have been applied to the vein. In the test, mentioned by you, which I have devised for the purpose of making sure, at the operating table, that femoral-vein incompetence is present, the most important detail is the ligation of the popliteal vein below the point of introduction of the needle connected with the pressure manometer. This technical detail may have escaped your notice, probably because it was not sufficiently emphasized by me in the Liverpool discussion; it is, however, quite clearly described in my original article. It seems to me that by the application of this distal ligature the hydrostatic pressure must be eliminated, and that the rapid rising of a blood column in the manometer glass tube must necessarily indicate a valvular incompetence in the femoral vein. If blood is allowed to escape from the popliteal vein, blocked at its lower end, this must result in a lowered pressure in the vein and immediate closure of all valves above, if functioning normally. The blood column in the glass tube could not rise more than a few centimetres, and not, as it has been observed to do in over 200 pathological cases, 50 to 70 cm. Hence, I do think that this test is of considerable value. If positive, there probably is no need for hesitation in proceeding with the final steps of the operation.—I am, etc.,

Mariestad, Sweden. GUNNAR BAUER.

Lung Cancer and Petrol Lighter

SIR,—Amongst the many causes of lung cancer listed to-day, from road-tarring, exhaust from motor-cars, and excessive tobacco smoking, there appears to be one important factor which has so far been overlooked: the almost universal use of the petrol lighter. The smoker to excess uses this method of igniting tobacco at least twenty to thirty times a day and must inhale the end-products of petrol combustion.

My excuse for this letter is that it may prove to be of some help in research on this difficult problem.—I am, etc.,

London, S.W.1. R. W. IRONSIDE.

Every Breech an Abnormality

SIR,—I have read with much interest the letter from Dr. Jean Hallum (August 12, p. 418) with regard to breech deliveries, and I should like to support her contention that every breech should be considered an abnormality. Dr. T. Redman (April 8, p. 814) has shown that, contrary to general opinion, the outlook for the foetus in the primiparous breech is not notably worse than in the multipara. Miss Hallum has shown what excellent results can be obtained in hospitals with the use of a properly trained team. I would differ with her on the question of anaesthesia. I consider that any internal manipulations, including the application of forceps to the after-coming head, are applied with less trauma to the child if general anaesthesia is used, and for this purpose I have found it important to have an anaesthetist standing by, prepared to induce anaesthesia with thiopentone. The use of pudendal block, with its relaxant effect on the perineum, is of enormous value.

There is no doubt that many thousands of breech deliveries have been successfully performed by midwives, and many thousands more by doctors under domiciliary conditions, but the difficult case cannot be successfully managed at home, and it should always be remembered that breech presentation may indicate a pelvic deformity or some other abnormality which can seriously complicate delivery. Only hospital management, with the best facilities available, will give the best results, and in fairness to the mother and child this service should be available for every case of breech presentation.—I am, etc.,

Inverness. J. A. CHALMERS.

SIR,—Dr. J. L. Hallum (August 12, p. 418) urges the revision of the Central Midwives Board rules regarding breech deliveries, and I wish to support this suggestion most strongly. All midwives seek medical aid with a primigravid breech delivery, but there is far too much complacency about the breech presentation in a multipara. Only recently I saw a case of shoulder presentation in which quite an experienced midwife had diagnosed a breech presentation and did not realize anything was amiss until the arm prolapsed. It should be quite clearly laid down that a breech presentation is a malpresentation and medical aid must be summoned.

Another subject which might be dealt with by the rules is the operation of manual removal of placenta. Most obstetricians will agree that this operation should be performed only under general anaesthesia with full aseptic precautions, preferably with an intravenous drip set up. Now that midwives have been granted permission to give ergometrine intramuscularly before the birth of the placenta in cases of severe post-partum haemorrhage, there can be no justification for a midwife attempting this operation on her own, save under the most exceptional circumstances, such as where medical aid would be unobtainable for a number of hours. In teaching pupil midwives I am most reluctant to describe this operation at all, but I am constantly urged to do so "in case some examiner asks them how to do it."—I am, etc.,

London, W.12. SAMUEL LASK.

Saving Money on N.H.S. Prescriptions

SIR,—It has been stated that much of the expense of the National Health Service is due to doctors prescribing a proprietary prescription instead of the standard equivalent. Though this may sometimes be deliberate, from my own experience I would suggest that it is frequently due to the doctor being ignorant of the name of the standard preparation. For instance, I was taught as a student to use "theominal," and it was not until I had been in general practice for some years that I discovered that tab. phenobarbiton. et theobrom. *B.P.C.* was a much cheaper preparation; more recently I have been impressed by the effects of "benzedrine," and have only just found—and memorized—the more complicated name of amphetamine sulphate. It is not practical to ask a busy practitioner to write out a list of all the drugs he uses, to check whether any of them has a standard equivalent, and to memorize all these for

future prescriptions; on the other hand every pharmacist must know at once if such a preparation exists. This difficulty could be easily got over by printing just above the signature space on E.C.10, "Please substitute the standard equivalent for any proprietary preparation prescribed above"; this could be struck out by the doctor if he wished the proprietary preparation to be prescribed. I for one would welcome this, as it would show that I was anxious to co-operate in reducing expenditure and at the same time relieve me of continually searching pharmacopoeias for standard equivalents—particularly of new preparations.—I am, etc.,

Henley-on-Thames. K. NEVILLE IRVINE.

Amalgamation of Radiological Societies

SIR,—In a recent number of the *Journal* (August 12, p. 410) you have devoted a long notice to the International Congress in Radiology which has recently taken place in London. This congress was magnificently organized and managed with the utmost efficiency, and the greatest possible credit should be given to all those concerned. There was a great number of foreign visitors, and all those to whom I spoke were most enthusiastic about the arrangements, and there can be no doubt that the organizers have done a great service to radiology in general and to British radiology in particular.

Before the competent team that ran the congress disbands, there is one domestic problem to which I feel they might with advantage turn their attention, and this is the co-ordination of radiological activity in this country. There can be no doubt that radiologists, as a whole, are perturbed about the multiplicity of radiological bodies in this country. The British Institute of Radiology, the Faculty of Radiologists, and the Radiological Group of the B.M.A. all have a hand in looking after the interests of radiologists; while the B.I.R., the Faculty, and the Section of Radiology of the Royal Society of Medicine are all concerned in promoting knowledge of radiology. There are, in fact, four bodies to which radiologists should belong. In addition, there are certain local radiological bodies which are concerned with their own business matters in their respective areas. It cannot be denied that there is a certain amount of rivalry between these bodies. Would it not be possible for those who ran the congress to get together and evolve some sort of amalgamation of all the bodies referred to above, so that there would be only one radiological authority in the country?

Nobody is more conscious than I am of the difficulties inherent in this suggestion, but I am certain that the present schism leaves us all at a disadvantage, and there can be no doubt that if the various radiological bodies in this country could be co-ordinated the greatest possible benefit would ensue. This is a problem which bristles with difficulties, but I am sure that the team that ran the congress could surmount them.—I am, etc.,

Newton Abbot, Devon A. ROBINSON THOMAS.

An Adjustable Bed for Patients at Home

SIR,—Just before the war while on holiday in Skye I came across a simple lightly constructed bed which appeared to fill a real need for the bed-ridden patient; it was certainly in constant demand in that district. The frame was so balanced and jointed that by pulling a lever at the side of the bed the patient could change from the lying to the sitting posture at will. The lever was detachable and could be inserted in a slot on either side of the bed.

When I saw it in use, the patient was a frail lady of 70 with a right-sided hemiplegia, yet by having the lever on the left side she was able to manipulate it unaided and could sit propped up for meals or for reading or for receiving visitors, and could equally well lie down flat when she wished. In these days when so many patients cannot get admission to hospital or sanatorium a bed of this sort would seem to meet a real need; there may possibly be disadvantages in a hospital ward in having the adjustment of a cardiac type of bedstead under the patient's own control, but in the home it would often add enormously to the patient's comfort and well-being. Have any of your readers had experience of this type of bed, and is it still obtainable?—I am, etc.,

Ilkeston. T. H. GILLISON.

Inoculation Certificates Required Abroad

SIR,—I wish to refer to a letter by Sir Philip Manson-Bahr in the *Journal* of July 22 (p. 215). The British Overseas Airways Corporation has the most up-to-date information in this country on the requirements of various Governments regarding certification of vaccination and inoculation needed for travellers by air. This information is obtained from the World Health Organization through their *Weekly Epidemiological Record* and their daily broadcasts, as well as from the Ministry of Health by means of their *Weekly Record of Certain Infectious Diseases*, and by day-to-day advice received from the Corporation's agents in various countries throughout the world. If the British Medical Association secretariat were to maintain such an up-to-date dossier of information as recommended by Sir Philip Manson-Bahr, doubtless it would be necessary for them to obtain the information through the British Overseas Airways Corporation. It is considered, therefore, that the simplest procedure is for any medical practitioner who wishes up-to-date information on this matter to apply to the Medical Department, British Overseas Airways Corporation, Stratton House, Piccadilly, W.1, Telephone Mayfair 6611, or to the representative in this country of the country or countries which the traveller intends to visit in transit.—I am, etc.,

London, W.1. HAROLD E. WHITTINGHAM, Director of Medical Services, B.O.A.C.

POINTS FROM LETTERS

Amoebiasis in Great Britain

Mr. JAMES MILLER (Painswick, Glos) writes: Although Dr. Cecil A. Hoare's paper on this subject (July 29, p. 238) has special reference to the question of carriers and quotes only literature from 1913 onwards, it may be of interest to recall what the authors claimed (and the claim has, so far as I know, not been denied) was the first published case in a patient who had never been abroad. The paper was published by Sir Robert Saundby and myself in the *British Medical Journal* of March 27, 1909. Here are the main facts: A male aged 40 who had never been out of the Birmingham district was admitted to the Birmingham General Hospital, where Sir Robert Saundby was at that time senior physician and I was pathologist. The patient died after nine days, during which period his only localizing symptom was the passage of one stool containing a considerable quantity of blood. He developed fluid in the right side of the chest, whence 15 oz. of blood-stained fluid was removed. At the post-mortem a large abscess was found around the head of the caecum, where there was a rupture blocked by slough. On opening the gut a large ulcer with black adherent slough was present in the caput coli, with numerous smaller ulcers, most of them the size of a pea, in the ascending and transverse colon, becoming less numerous in the lower portion of the bowel. These ulcers had raised overhanging margins and contained adherent sloughs. In these and in the neighbouring bowel wall amoebae were found. The liver, which weighed 102 oz. (2.9 kg.), showed a large abscess the size of a foetal head. It contained brownish-red pus and necrosed liver. Cultures from this material proved sterile. The pus, necrotic material, and the surrounding liver showed numerous amoebae, some of them in bile ducts. So far as we were able to ascertain at the time of publication, this was the first case of the kind recorded in Great Britain. The case, with slides, was shown at a meeting of the Pathological Society of Great Britain and Ireland. No doubt it is one of the cases of amoebiasis, stated by Dr. Hoare to number now not more than three dozen, reported among persons who had never been abroad.

Refresher Course on Psoriasis

Colonel S. HAUGHTON (I.M.S., retired) writes: No mention is made of any internal medicine for psoriasis (July 22, p. 207), yet the fact remains that sulphur given by the mouth is most helpful. Suck one to three *large* sulphur tablets daily, if necessary for one to three months. In spite of all teaching and textbooks there is nothing that eases the condition so quickly in many patients. Of course it does not cure it. I learned this many years ago from a psoriasis patient who complained he could get no large sulphur tablets during the war. I was sceptical, but obtained them. The result after two weeks was dramatic, and his psoriasis remained under control, with no other treatment, for years. I have had equally good results with some half-dozen other patients.

Obituary

P. L. DANIEL, F.R.C.S.

Mr. R. W. Raven writes: May I be permitted to pay my tribute to the memory of my friend and colleague, the late Mr. Peter Daniel (about whom an obituary notice appeared in the *Journal* of August 19)? An outstanding feature of his work, carried out over a period of so many years, was the great kindness and consideration given to his patients. He never spared himself where their welfare was concerned, and there are many with cause to be profoundly thankful for all he did for them and their families. The appeal exerted by the "widow and the fatherless" was very real to him. At the Gordon Hospital, where he was a member of the surgical staff for 44 years, we loved him, and at the staff meeting—with nursing, medical, and administrative representatives—which was held on his retirement, the affection and esteem in which he worked were apparent to all. Although he had reached the age of 77 his mind was always searching for new ideas, and it was a real joy to talk with him about new aspects and techniques of surgical work. Since he possessed a sound and mature surgical judgment, we sought his advice in our work and valued his opinion. In committee he was excellent in every way and never afraid to speak his mind or to carry out that which, after careful consideration, he considered to be right. He came from another generation fast dying out, and these men leave behind them indelible impressions and influences for good on those who follow. Belonging to a different age from ours, they speak of those things which inherently we love so well and perhaps stand in danger of losing awhile.

Dr. WILLIAM LYLE, M.P., who died with tragic suddenness at his home in Belfast, was a son of the manse. He was educated at the Intermediate School, Newtownstewart, and at Queen's College, Belfast. Entering the medical school, he graduated M.B., B.Ch. in 1893 at the Royal University. He then practised for a year as an assistant at Bacup, Lancashire, returning to Newtownstewart as dispensary doctor and medical officer of health. A skilled physician, he was much esteemed by all the people of the district in which he practised. When he retired in 1936 he was succeeded by his son, Dr. Leslie A. Lyle, who is carrying on the family tradition of public service. Dr. Lyle also took an active interest in public affairs and was a member of Tyrone County Council for several years. After his retirement he came to Belfast in 1936. Always imbued with the spirit of service to the community, he succeeded the late Colonel A. B. Mitchell in 1942 as a representative at Stormont of Queen's University. During this period he took a keen interest in Parliamentary affairs, and it was largely owing to his efforts that the Select Committee on Health Services, which sat in 1943 and 1944, was set up under the chairmanship of the late Howard Stevenson, M.P., F.R.C.S. Following the report of this committee the present Ministry of Health and Local Government was established. At the 1945 election Dr. Lyle was narrowly defeated, but he regained his seat at the election held in February, 1949. In Parliament he was a fearless advocate of the rights of the people of Northern Ireland, and his speeches in the debates of the House were always marked by a singleness of purpose and a forthrightness of utterance that were characteristic of the man. During his long career Dr. Lyle held many offices. He was president and treasurer of the Northern Ireland Branch of the British Medical Association; he was a representative for six years on the Representative Body; and he was a member of Council. He acted as chairman of the Poor Law Medical Officers' Association, and was a county director and later president of the Belfast Branch of the British Red Cross Society. He was also joint honorary secretary and treasurer of the Ulster Joint Committee of the Order of St. John of Jerusalem and the British Red Cross Society. Dr. Lyle took a practical interest in education and was for many years a Governor of Princess Gardens School, Belfast. A vice-president of Queen's University Unionist Voters' Association, he acted for many years as its honorary treasurer and as a member of its executive committee. He was a Past Provincial Senior Grand Warden of the Masonic Province of Tyrone and Fermanagh, and when he came to live in Belfast he affiliated to Queen's University Masonic Lodge, No. 533, to which he rendered service for several years as honorary treasurer. During the recent war and up to the time of his death Dr. Lyle was a very capable chairman of a medical board for the examination of recruits. Busily engaged up to the last in his multifarious duties, he has left behind him treasured memories among his many friends. He is survived by his widow and daughter, and by three sons who are engaged in general practice.

Dr. CLIVE ROWLAND BISHOP VINCENT was killed in a motor-cycle accident on July 11 aged 28 years. He was house-surgeon at the Brook General Hospital at the time of his death. He was educated at the Lancaster Royal Grammar School, where his father had been a popular master for well over 30 years, King's College, London, and King's College Hospital. He qualified in 1947 and obtained resident appointments at the Connaught Hospital, Walthamstow, and the Nelson Hospital. Later he worked as resident anaesthetist at the Miller General Hospital, Greenwich, for over a year and commenced to study for the D.A. He designed and made several instruments for intubation for his own use. Dr. Vincent had a very real love of nature, and he was a remarkably successful landscape photographer. With his sensitive and conscientious temperament, his quiet and ready wit, and his dry sense of humour he will be greatly missed by his colleagues and his patients, whose sympathy will be extended to his widow.

Dr. HUGH LLOYD-WILLIAMS, of Waenfawr, Caernarvonshire, died on July 23 in his eighty-eighth year. He was the younger son of the late Mr. and Mrs. Pierce Williams, of Waenfawr, and was educated at George Watson's College, Edinburgh, and at the Middlesex Hospital and the Royal Dental Hospital, London. He qualified as a dental surgeon in 1885 and as a doctor in 1886. He was appointed dental surgeon to the Royal Dental Hospital and also dental surgeon and lecturer to the Post-Graduate College at the West London Hospital in 1890. He held the latter post until 1920, when he was appointed consulting dental surgeon to the West London Hospital. He was at one time president of the Odontological Section of the Royal Society of Medicine—being on the finance committee of the R.S.M. when the new premises were built in Henrietta Street—and of the Metropolitan Branch of the British Dental Association. He was appointed a justice of the peace for the county of Middlesex in 1920. Dr. Lloyd-Williams, who was a member of the B.M.A. for 50 years, retired from practice in 1932 and had lived ever since at his old home at Waenfawr. He was made a justice of the peace for the county of Caernarvon in 1935. He is survived by his wife and by two sons.

Dr. ROBERT WATT died in Belfast on July 24, aged 88. He was born in Aberchirder, Banffshire, and served his apprenticeship as a pharmaceutical chemist in Huntly. He qualified as a chemist in 1885 and did not become a medical student until 1889, when he entered Queen's College, Belfast. His academic career was marked with many distinctions, including the Coulter Exhibition in medicine and surgery in 1893. He qualified M.B., B.Ch. in 1894, and, after holding a residential appointment in the Belfast Union Hospital, he became a general practitioner in Agnes Street, Belfast. He remained in general practice for 53 years, retiring to a new home in Belfast only a year ago. He was an examiner for the Pharmaceutical Society of Ireland. Throughout his lifetime he strongly advocated the rightful place of the family doctor, and he was a worthy example of honesty and integrity to his fellow practitioners and to all his patients. His presence, bearing, and ever-ready wit invariably inspired confidence in the sick-room. He was clerk of session in the Rosemary Street Presbyterian Church for many years. He was also a keen freemason. Dr. Watt married in 1895, but his wife died suddenly 24 years ago. He is survived by two daughters.—D. C.

Dr. JAMES WILSON HENEY, tutor in anaesthetics at the Royal Victoria Hospital, Belfast, died at his home in Belfast on July 30. He was born in 1900 at Mosside, Co. Antrim, where his father, the Rev. Thomas Heney, was Presbyterian minister. He studied medicine at the Queen's University of Belfast and graduated M.B. in 1922. He took the D.P.H. in 1923 and proceeded M.D. in 1927; he obtained the D.A. of the English Royal Colleges in 1929. He was a most skilful anaesthetist, and as tutor in anaesthetics in the Royal Victoria Hospital he was an excellent teacher of his subject. He was also anaesthetist to the Belfast Ophthalmic Hospital. The active phase of James Heney's life was ended all too soon by the onset of chronic myelitis, and for the past six years he was an invalid. But this tragedy never dimmed his courage or the brightness of his welcoming smile; no visitor ever heard him complain. Dr. Heney is survived by his wife, who was Dr. Gertrude Glenn, and whose unremitting care maintained his life and made it bearable.—R. M.

Dr. MARGARET RANKEN, of Sunderland and Newcastle, died on August 7 after a short illness. She studied medicine at Durham University and graduated M.B., B.S. in 1924. After holding various resident appointments she specialized in ophthalmology as her life's work. She had been associated with the eye department of the Royal Victoria Infirmary, Newcastle-upon-Tyne, for almost 25 years as house-surgeon, refractionist, registrar, and associate surgeon. Miss Ranken was surgeon in charge of the orthoptic department at Sunderland Eye Infirmary from its inception. This is the orthoptic teaching school of the region, turning out a steady flow of qualified orthoptists. In 1943 she was appointed ophthalmic surgeon to Durham County Hospital, where she was in charge of the eye department until 1946, when she was appointed ophthalmic surgeon to the Ingham Infirmary, South Shields. Miss Ranken's great interest was in the treatment of squint, on which she was a recognized authority, and she elected to operate while the patient was still very young. Her success in this field of ophthalmology was due to her surgical skill, her unlimited patience, and her fondness for children, whose confidence and friendship she could always win. She had an entirely altruistic outlook on life, and if she could do a good turn to anyone she did so without counting the cost to herself. She was concerned with the benefits which she in her profession could convey to humanity rather than in any personal gain. Among her general interests Miss Ranken was a member of the Central Orthoptic Board and an active member of the Medical Women's Federation. By her death the community has lost a modest and well-loved doctor and the profession a skilful and dependable ophthalmic surgeon and a colleague who will be difficult to replace.

Major-General RICHARD HEARD, who retired from the Indian Medical Service in 1927, died in Peebles on August 16 at the age of 80 after a long illness. He was educated at Trinity College, Dublin, and graduated M.B., B.Ch. in 1892. Later he proceeded M.D., Belfast, in 1912. He obtained a commission in the Indian Medical Service in 1893 and soon saw active service on the North-West Frontier of India in Wazaristan and with the Chitral Relief Force. He received the campaign medals with clasps. A little later he entered the civil branch of the service and in 1909 became professor of midwifery and gynaecology at the Lahore Medical College, where he was a valued colleague. On the outbreak of the first world war he returned to military duty and served throughout the war; he was promoted to brevet-colonel for his good work. Soon after his return to civil employment in India he became Inspector-General of Jails in Assam and in 1924 was promoted to the more responsible post of Surgeon-General with the Bengal Government. A little earlier he had been Surgeon to the Viceroy, and in 1924 he was awarded the C.I.E. and also became honorary surgeon to the King. He was the author of a work on feeding in infancy and early childhood. Major-General Heard was an unassuming but thoroughly competent officer, always ready to lend a helping hand to brother officers, with whom he was deservedly popular. He was typical of those who have lent distinction to the Indian Medical Service, most of his contemporaries in which he outlived.—L. R.

EPIDEMIOLOGICAL NOTES

Poliomyelitis

Notifications of poliomyelitis in the week ended August 12 were: paralytic 275 (262); non-paralytic, 117 (105); total, 392 (367). The figures for the preceding week are in parentheses. There was therefore during the week under review an increase of only 13 paralytic and 12 non-paralytic cases—a total of 25 over the previous week, which is very much less than might have been expected.

The main increases compared with the previous week were: Lancashire 10 and 4, Cumberland 7 and 1, and Glamorgan 6 and 1 paralytic and non-paralytic cases respectively; Isle of Wight 10 and Kent 8 paralytic; and Lincs (Kesteven) 14 non-paralytic. These were offset by small decreases fairly generally distributed.

The following county areas, with notifications as given, contributed 73% of the total notifications for England and Wales in the week under review:

	Paralytic	Non-paralytic
London	13	12
Essex	10	2
Gloucester	12	3
Kent	12	4
Lancashire	25	11
Lincs (Kesteven)	4	14
Middlesex	11	3
Northumberland	8	6
Stafford	15	7
Surrey	8	7
Warwick	25	9
Isle of Wight	14	1
Worcester	13	3
Yorks (W.R.)	15	6
Glamorgan	9	4
Totals	194	92
Grand total	286	

Isle of Wight

A statement issued by the medical officer of health on August 20 says that centres in which no cases of poliomyelitis have so far occurred include the towns of Ryde, Cowes, Sandown, Ventnor, Yarmouth, Bembridge, and other populated areas. There are outbreaks in Newport and Freshwater only, and visitors with children have been advised to avoid these places. The statement goes on to say that apart from these areas "the hazards of a holiday in the island are no greater than anywhere else in the country."

The Isle of Wight is one of the 62 counties in England and Wales. It contains six sanitary districts. The permanent population is 92,000 and there are 28,000 inhabited houses. In the holiday season about 80,000 are added to the population. Notifications have been as follows:

Week Ending		Newport M.B.	Cowes U.D.	Rural District	Ryde M.B.	Sandown-Shanklin U.D.	Ventnor U.D.
July 22	Paralytic	—	—	—	—	—	—
	Non-paralytic	—	—	—	—	—	—
July 29	Paralytic	1	—	3	—	—	—
	Non-paralytic	1	—	2	—	—	—
Aug. 5	Paralytic	2	—	2	—	—	—
	Non-paralytic	2	—	—	—	—	1
Aug. 12	Paralytic	3	1	8	1	—	1
	Non-paralytic	—	—	1	—	—	—
Aug. 19	Paralytic	4	1	8	—	2	—
	Non-paralytic	—	—	3	—	1	—
Totals	Paralytic	10	2	21	1	2	1
	Non-paralytic	3	—	6	—	1	1

These notifications include five relating to visitors who were infected outside the county. The remaining 32 paralytic cases have occurred in 22 households. With a few exceptions permanent residents are involved, and the infection appears to have moved through a very limited line of contacts originating with three cases in the infants' class of a school at Freshwater in the rural district council.

Quarterly Report for England and Wales

The infant mortality rate during the first quarter of this year was the lowest ever recorded for this quarter, being 37 per 1,000 related live births, compared with 40 in the corresponding quarter of 1949, and an average of 59 for the 10 March quarters 1940–9. The stillbirth rate was the lowest on record; the rate was 22.9 per 1,000 total births, being 0.2 lower than the rate for the first quarter of 1949. The birth rate was 16.7 per 1,000 and was 0.6 below the rate for the preceding first quarter. The general death rate was 14.0 per 1,000 and was 0.9 below the rate for the March quarter of 1949 and 0.6 below the average for the first five quarters 1944–8.

Quarterly Report for Eire

The birth rate during the March quarter of this year was 21.2 per 1,000, which was 0.7 below the rate for the first quarter of 1949. Infant mortality was 59 per 1,000 registered births, 4 above the rate for the preceding first quarter. The general death rate was 15.0 per 1,000, being 0.3 above the rate for the first quarter of 1949. There were 578 deaths attributed to respiratory tuberculosis and 131 to other forms of tuberculosis; these were 53 and 22 respectively fewer than in the first quarter of 1949.

Discussion of Table

In *England and Wales* a decrease was recorded in the number of notifications of measles 318, scarlet fever 56, whooping-cough 27, and an increase was reported for acute poliomyelitis 62 and dysentery 13.

The largest decreases in the number of notifications of measles were Cheshire 162, Yorkshire West Riding 153, Middlesex 76, and the largest rises were Lincolnshire 89, London 84. The only variation of any size in the local trends of scarlet fever was a decrease of 26 in London. No changes were reported in the regional incidence of diphtheria. A decrease of 98 in the number of notifications of whooping-cough in Yorkshire West Riding was the only fluctuation of note in the returns.

The increased incidence of dysentery was mainly contributed by Leicestershire, where the cases rose from 2 to 24 (Leicester C.B. 22). The other important centres of infection were Lancashire 53 (Middleton M.B. 13, Preston C.B. 11); Yorkshire West Riding 39; London 14.

The largest returns of acute poliomyelitis were Warwickshire 38 (Birmingham C.B. 18, Coventry C.B. 9); Staffordshire 33 (Rowley Regis M.B. 7); London 28 (Lewisham 11, Woolwich 5); Worcestershire 26 (Dudley C.B. 11, Halesowen M.B. 5); Yorkshire West Riding 24 (York C.B. 7); Lancashire 22; Lincolnshire 20 (East Kesteven R.D. 9); Essex 17; Surrey 12; Southampton 11; Middlesex 11; Gloucestershire 11 (Bristol C.B. 9).

In *Scotland* the only fluctuation in the trends of infectious diseases were decreases in the number of notifications of whooping-cough 86 and measles 53. The largest returns of dysentery were Glasgow 51 and Edinburgh 14. The largest centres of acute poliomyelitis were Glasgow 13, Dundee 5, Kirkcaldy 5, and Fife county 5.

In *Eire* an increase of 21 was recorded in the number of notifications of measles and a decrease of 27 was reported for scarlet fever. In Dublin C.B. a decrease of 16 was recorded in the notifications of measles; the largest fresh outbreaks during the week were Meath, Dunshaughlin R.D. 18, and Westmeath, Mullingan R.D. 17.

In *Northern Ireland* decreases were reported for measles 56 and scarlet fever 9. The fall in the incidence of measles was mainly due to the experience of Antrim county, a decrease of 16, and Down county, a decrease of 23. The largest returns of acute poliomyelitis were Down county and Belfast C.B. 4.

Week Ending August 12

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 695, whooping-cough 3,422, diphtheria 49, measles 6,420, acute pneumonia 256, acute poliomyelitis 392, dysentery 211, paratyphoid fever 2, typhoid fever 5.

No. 31

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended August 5.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each Infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1950 (a)	1950 (b)	1950 (c)	1950 (d)	1950 (e)	1949 (Corresponding Week) (a)	1949 (b)	1949 (c)	1949 (d)	1949 (e)

* Measles is not notifiable in Scotland, and the returns are therefore an approximation only.

† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

‖ Includes puerperal fever for England and Wales and Eire.

¶ Primary pneumonia no longer notifiable in Eire.

Medical News

A Ross Commemoration

To commemorate the discovery by Sir Ronald Ross on August 20, 1897, that malaria is transmitted by *Anopheles* mosquitoes, members of the Ross Institute in London laid a wreath on his grave in Putney Vale cemetery on August 21. Sir Eric Macfadyen, chairman of the standing committee of the Ross Institute, said that they did well on an anniversary such as this to recall the great benefits to mankind which had followed from Ross's discovery. Sir Malcolm Watson, who also participated in the ceremony, said that the Poet Laureate had described Ross as the most gifted, most beneficent, and most forceful man it had ever been his privilege to know. His work had been neglected for many years, and people were inclined to say that while it was interesting scientifically it was of no practical value. But it was now being applied, said Sir Malcolm, in every part of the tropical world in increasing volume. The Ross Institute, which was founded at Putney in 1926, and of which Sir Ronald Ross was the first director-in-chief, now has branches in India, Ceylon, and Africa. In 1933 it amalgamated with the London School of Hygiene and Tropical Medicine, whose origin is linked with Ross's great collaborator, Sir Patrick Manson.

Colyer Prize

The Colyer Prize was founded in June, 1926, to commemorate the twenty-five years' service of Sir Frank Colyer as Honorary Curator of the Odontological Museum at the Royal College of Surgeons of England. The accumulated income of this fund is used every third year for the purpose of awarding a prize for the best original work in dental science completed during the previous five years by a dental surgeon educated at any duly recognized dental school in Great Britain or Northern Ireland, and who has not been qualified to practise for more than five years at the date of the award. The prize committee has power to withhold the prize if they consider there has been no work submitted of sufficient merit to justify the award. Applications from candidates, together with a general account of their researches, should be submitted to the prize committee at the Royal Society of Medicine, 1, Wimpole Street, London, W.1, not later than December 1.

Alvarenga Prize

On July 14 the College of Physicians of Philadelphia awarded the Alvarenga Prize for 1950 to Ephraim Shorr, M.D., Associate Professor of Medicine, Cornell University Medical College, for his outstanding work in shock which has provided a clearer understanding of the mechanism of this condition. The prize was established by the will of Pedro Francesco DaCosta Alvarenga, of Lisbon, Portugal, an Associate Fellow of the College of Physicians of Philadelphia, to be awarded annually by the college on the anniversary of the death of the testator, July 14, 1883.

Medical Women's Federation

Dr. Doris M. Odlum has been elected president of the Medical Women's Federation for 1951, and will take office at the annual general meeting of the Federation in October. Among the many posts held by Dr. Odlum is that of senior psychiatrist at the Elizabeth Garrett Anderson Hospital, and she is chairman of the B.M.A. Committee on Psychiatry and the Law.

Report on Midwives

The report of the Central Midwives Board for the year ended March 31, 1950, shows that in 1949 there were 18,053 midwives practising. The number of midwives and pupil midwives trained in the administration of nitrous-oxide–air analgesia was 19,447 at March 31; of these 11,118 were in practice in 1949. The most pressing administrative problem under the National Health Service was found to have arisen from the division of the maternity services under separate types of authority each entrusted with powers and duties to operate a particular section of the Service. A marked decline in domiciliary midwifery is recorded, particularly in cases available for the training of pupil midwives. The report comments that if the present standard is at least to be maintained the co-operation of the separate authorities responsible for domiciliary and hospital midwifery in each area must be assured. The board has decided to conduct experiments on training at some six or seven centres, chosen so far as possible with differing local conditions. It will take at least another year for the first of the experiments to be completed.

COMING EVENTS

Royal College of Obstetricians and Gynaecologists

The annual dinner of the Royal College of Obstetricians and Gynaecologists will be held at Dorchester Hotel, Park Lane, London, W., on Friday, September 29, at 7 for 7.30 p.m.

Middlesex Hospital Medical School

The annual dinner of the Middlesex Hospital Medical School will be held at the Savoy Hotel (Victoria Embankment entrance), London, W.C., on Thursday, September 28, at 7 for 7.30 p.m.

Law of Abortion

After the annual meeting of the Abortion Law Reform Association a public meeting will be held at 7.30 p.m. on September 27 at the Conway Hall, Red Lion Square, London, W.C.1.

British Medical Students Association

The Liverpool National Clinical and Preclinical Conference will be held at Liverpool on September 12–15. *Full details* may be obtained from the Liverpool University Medical Students Society, Medical School, Liverpool University, Liverpool.

Refresher Courses for General Practitioners

The British Postgraduate Medical Federation (University of London) has arranged a programme of refresher courses for general practitioners to be held at certain non-teaching hospitals of the four metropolitan hospital regions during the months September to December. The programme includes several week-end courses and extended courses spread over two months as well as concentrated courses of one or two weeks' duration. Further information will be found in the advertisement columns of this week's *Journal*.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Thursday

EDINBURGH POSTGRADUATE BOARD FOR MEDICINE.—At University New Buildings (Anatomy Lecture Theatre), Edinburgh, August 31, 4.30 p.m., "*Muscles in Action*," by Professor R. D. Lockhart.

Correction.—In the *Journal* of August 12 (p. 402) we listed under "Books Received" *Illustrations of Anatomy for Nurses*, by Dr. E. B. Jamieson. The price of this should have been given as 12s.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Marshall.—On August 13, 1950, at The Croft, Buxton, to Dorothy (formerly Ead) and Dr. W. E. S. Marshall, Chapel-en-le-Frith, a *second child*—Desmond John.

Roads.—On August 11, 1950, at St. Mary's Hospital, Paddington, London, W., to Evelyn (formerly Daniel), wife of Dr. Peter Roads, a son.

Snaith.—On August 13, 1950, at Newcastle General Hospital, to Mr. and Mrs. Linton Snaith, a daughter.

Varian.—On August 8, 1950, at the Forbes Fraser Hospital, Bath, to Katha (formerly Greene), wife of S. N. Varian, *M.B.E., F.R.C.S.I., a daughter.*

Zaki.—On August 14, 1950, at Beach Lawn Nursing Home, to Irene (formerly Hope), wife of Dr. Y. E. Zaki, Wintonlea, Dowhills Road, Blundellsands, Liverpool, a brother for Stuart—Michael Simpson.

DEATHS

Ball.—On August 13, 1950, Ralph William Codrington Ball, M.R.C.S., L.R.C.P., of 40, Keswick Road, Putney, London, S.W.

Barton.—On August 16, 1950, at his home, 61, Wellington Road, Hatch End, Pinner, Middlesex, Bertram Henry Barton, M.C., M.D., aged 67.

EFFECTS OF HYPERVITAMINOSIS A ON FOETAL MOUSE BONES CULTIVATED IN VITRO

PRELIMINARY COMMUNICATION

BY

HONOR B. FELL, D.Sc.

Foulerton Research Fellow, Royal Society

(From the Strangeways Research Laboratory, Cambridge)

AND

Sir EDWARD MELLANBY, G.B.E., K.C.B., M.D., F.R.C.P., F.R.S.

(From the Nutrition Building, National Institute for Medical Research, London, N.W.7)

It was shown in 1938 that vitamin A has the remarkable property of controlling the shape and texture of certain bones in young animals, so that when it is deficient or absent from the body these bones grow abnormally (Mellanby, 1938). The effect of this loss of ability of vitamin-A-deficient animals to control the shape and texture of bone is that the growing bones fail to adapt themselves to the developing nervous tissue and often destroy the nerves, both peripheral and central, by pressure. It was later shown that this dysplasia of bone is due to the fact that vitamin A has the function of controlling the position and intensity of activity of osteoclasts and osteoblasts (Mellanby, 1944). In some places normal osteoclastic and osteoblastic activity in growing bone of vitamin-A-deficient animals was reversed, so that where bone ought to have been removed it was laid down and vice versa, with disastrous effects on the nervous system. The restoration of vitamin A to the defective diets brought back the osteoclastic and osteoblastic activity to the normal position and the bone to a nearer normal shape.

The question was asked in the 1943 Croonian Lecture at the Royal Society whether this action of vitamin A was direct on the bones, or indirect by an action on some intermediary organ or humoral mechanism, and it was pointed out that an answer to this question could probably be obtained by tissue-culture experiments. This was one of the reasons why the present investigation was undertaken.

Although, in view of the foregoing results, it might be thought more natural to investigate the effect on bone growth of reducing the vitamin-A concentration in the culture media, for technical reasons it was found easier at first to test the effect of abnormally large quantities of this vitamin. As these experiments not only gave interesting results but also answered the question of whether the action of vitamin A on bone is direct or indirect, this preliminary account is being published.

The effect on bones of giving animals diets containing excessive amounts of vitamin A has often been observed. Collazo and Rodriguez (1933) and Bomskov and Seemann (1933) described the fragility and subsequent fracture of leg bones in rats given large amounts of vitamin A concentrates in their food. Similar observations were made by Davies and Moore (1934), Strauss (1934), and many others. It was later demonstrated that bone fragility and fracture could be produced by large doses of pure vitamin A (Herbst, Pavcek, and Elvehjem, 1944; Pavcek, Herbst, and Elvehjem, 1945; Moore and Wang, 1945).

As for the pathological processes in bone associated with the production of fragility and fracture, Strauss (1934) found that in hypervitaminosis A there was retardation of osteogenesis, reduction of endochondral bone formation, and a variable degree of osteoclasis only in the region of fractures. A more detailed description of the histology of this condition was given by Wolbach and Bessey (1942), who pointed out that the decalcification and osteoporosis were accompanied by a large number of osteoclasts, and that there was a greater degree of osteoporosis where the remodelling of bone was a normal process—namely, at the ends of long bones. Wolbach (1947), in studying the effect of hypervitaminosis A on bone in growing dogs, found that it accelerated the growth sequences. It caused rapid consumption of epiphysial cartilage and, in appropriate species, greatly premature closure of epiphyses and excessive rapidity of remodelling processes unrelated to linear growth of bone. He also found that the substitution of compact bone for cancellous bone in conformity to normal growth patterns was greatly accelerated, and stated that the fractures and sites of occurrence were fully explained by acceleration of remodelling.

Barnicot (1948) studied the direct action of vitamin A on bone by applying crystalline vitamin-A acetate locally to the bone. He found that it caused intense absorption by osteoclastic action, and suggested that the fractures observed in rats with hypervitaminosis A might be due to local action on the bones.

It will be seen in the following work that, in tissue cultures, bones under the influence of excessive vitamin A develop many of the changes described in the feeding experiments referred to above, and the results show that these changes are due to the vitamin acting directly on the bone.

Material and Methods

Material.—The tibiae, fibulae, radii, and ulnae of 17- to 21-day foetal mice were used. At this stage the epiphyses and the distal part of the diaphysis are cartilaginous, but for most of its length the shaft consists of a well-developed tube of bone enclosing a marrow cavity. These foetal mouse bones were particularly suitable for our purpose,

because their extremely small size made it possible to cultivate them *in vitro* at an advanced stage of development.

Tissue Culture.—The bones were dissected from the limbs, cleaned of all but a few tags of muscle, and grown by the watch-glass method described by Fell and Robison (1929). The culture medium consisted of a mixture of 6 drops of fowl plasma and 2 drops of a concentrated extract of 12- to 14-day chick embryo; the embryo extract contained about 130 i.u. of vitamin A per 100 ml., so that the concentration of vitamin A in the plasma was thus diluted by from one-fourth to one-sixth in the final medium. The extract was made with Tyrode's solution to which 4% glucose and, to improve the calcification, 0.2% calcium glycerophosphate were added; the addition of the glycerophosphate made it necessary to omit the acid phosphate to avoid precipitation, but the *p*H of the solution remained constant at 7.6. The explants were transferred to fresh medium every two to three days. Fresh embryo extract was made for each subculture and fresh plasma was usually drawn once a week.

For most of the experiments on the effects of "artificial" hypervitaminosis pure vitamin-A acetate in an alcoholic solution was added to normal plasma. In one experiment the physiological activity of vitamin A from "avoleum" (a commercial preparation kindly supplied by British Drug Houses, Ltd.) was compared with that of vitamin-A acetate. In order to study the effects of "natural" hypervitaminosis A, the explants were grown in plasma from fowls suffering from hypervitaminosis produced by a diet very rich in vitamin A.

Methods Used in Collection and Treatment of Bird Plasma.—For tissue-culture work it was necessary to obtain the blood and subsequently the plasma not only sterile but in such a condition that it did not clot until this was required—that is, until the embryo extract was added to make the final culture medium. All the syringes and vessels used were sterilized and coated with peanut oil or paraffin wax. Precautions were also taken to chill the vessels, including the centrifuge tubes, and the blood and plasma at all stages. About 30 ml. of blood was drawn from the wing vein of each bird into a syringe containing 3 ml. of a heparin solution (10 i.u. per ml.), so that the blood contained about 1 i.u. of heparin per ml. It was immediately centrifuged and about 20 ml. of plasma was obtained from 30 ml. of blood.

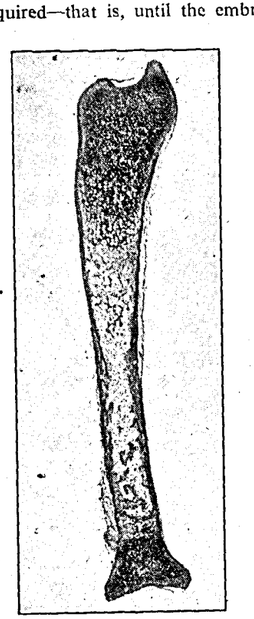

FIG. 1.—Radius from a late mouse foetus, cultivated in normal medium for seven days. The terminal cartilage is strongly basophil. (× 25.)

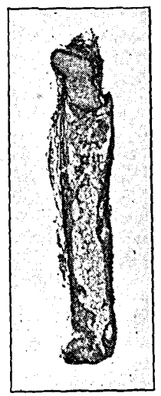

FIG. 2.—Radius from the opposite side of the same foetus as in Fig. 1, after seven days' cultivation in medium containing 1,287–1,490 i.u. of vitamin A per 100 ml. of plasma. The cartilage has nearly disappeared and has completely lost its basophilia; the bone also is being absorbed. (× 25.)

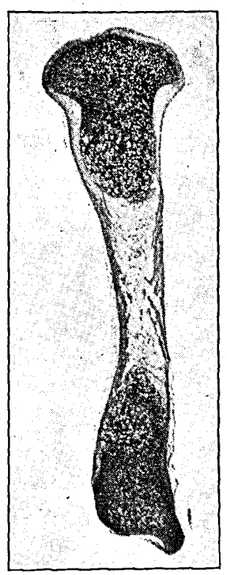

FIG. 3.—Tibia cultivated in normal medium for seven days. (× 25.)

FIG. 4.—Tibia from the opposite side of the same foetus as in Fig. 3, after seven days' cultivation in medium containing about 4,000 i.u. of vitamin A per 100 ml. of plasma. Very little cartilage or bone remains. (× 25.)

Natural Hypervitaminosis-A Plasma.—Cocks were fed on diets very rich in vitamin A. For this purpose avoleum containing 30,000 i.u. of vitamin A per ml. was used: 5 ml. was given each day—2 ml. in the food and 1 ml. by mouth at 9 a.m., 2 p.m., and 5 p.m. Thus each bird received 150,000 i.u. of vitamin A daily. The normal plasma of control untreated birds contained about 300 i.u. of vitamin A and about 300 i.u. of carotene per 100 ml. In the birds fed for about 14 days, as described above, the vitamin-A content rose to 1,400–1,500 i.u. per 100 ml., while the carotene content diminished to about 125 i.u. per 100 ml. Whether the decrease was due to a diminished intake of carotene during the feeding period or to a direct action of the large amount of vitamin A given is not known.

"Artificial" Hypervitaminosis-A Plasma.—This was obtained by adding an alcoholic solution of pure vitamin-A acetate of known strength to the normal bird's plasma. The amount added varied according to the degree of vitamin-A concentration in the plasma required, but the alcohol in the plasma never exceeded 1% and usually it was 0.5%. The same amount of pure alcohol was added to the normal control plasma used in the same experiment. In the earlier experiments vitamin-A acetate in alcohol was added to normal plasma to bring its content up to 4,000 i.u. or more per 100 ml. In all the later experiments, however, the content of vitamin A in this artificially treated plasma was only about 1,400–1,500 i.u. per 100 ml. to make it comparable with the natural hypervitaminosis plasma. In one experiment the vitamin A added to the plasma was obtained from avoleum: 8 ml. of alcohol was shaken up with 2 ml. of avoleum for about 5 minutes, centrifuged, and the clear alcohol, which contained about 6,000 i.u. of vitamin per ml., was withdrawn. A small amount of this solution was added to the normal plasma so as to bring the vitamin-A concentration up to the required amount. Here, again, the same amount of alcohol was added to the control plasma without added vitamin A.

Estimation of Vitamin A and Carotene in Bird Plasma.—These substances were determined in all the plasma specimens even where known amounts of vitamin A had been added to normal plasma. In such cases the calculated and determined results agreed fairly well. The method of estimation used closely followed that described by Yudkin (1941), a modification of Kimble's method (1939), and in detail was similar to that used by the Cambridge team in the investigation of the Medical Research Council (1949) on the vitamin-A requirements of human adults. Two modifications of detail were made: (*a*) a sealed glass tube was used instead of a corked centrifuge tube when the plasma and alcohol mixture was extracted with petroleum ether; and (*b*) acetic anhydride to prevent turbidity in the absorptiometer was not added, as, under the experimental conditions employed, it was not necessary. The standard curves of reference used in the determination of carotene and vitamin A respectively were made from specimens of carotene and vitamin A which had been standardized in terms of international units.

Histological Technique.—Most of the explants were fixed in acetic Zenker's fluid and were serially sectioned. Some were fixed in absolute alcohol and mounted whole in glycerin jelly, a method which gave a very clear general picture of the bones.

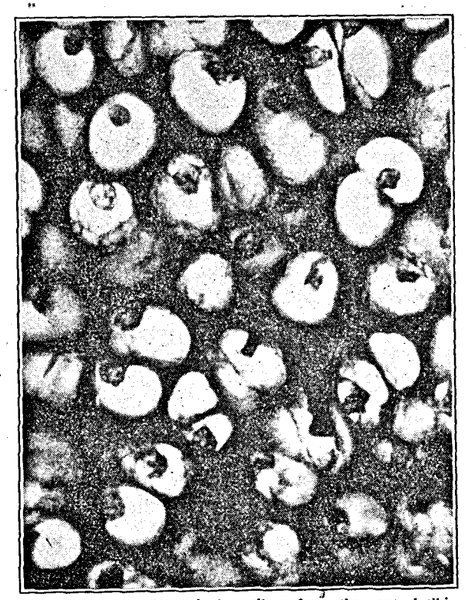

FIG. 5.—Area of terminal cartilage from the control tibia shown in Fig. 3. Note the broad, deep basophil partitions of matrix between the cells. (× 850.)

Effect of Vitamin-A Acetate

In these experiments one of each pair of bones was explanted in medium containing the alcoholic solution of vitamin-A acetate, and the corresponding bone in normal medium containing the same amount of alcohol. The vitamin was added to produce concentrations ranging from 960 to 8,000 i.u. per 100 ml. of plasma. The vitamin-A content of normal bird plasma is about 300 i.u. per 100 ml. Forty-six pairs of bones were cultivated in this way.

The control bones in normal medium did not lengthen much during cultivation, but deposition and absorption of bone continued *in vitro*. During the first three days most of the haemopoietic tissue of the marrow degenerated, but usually the necrotic remains had almost disappeared by the fifth day, and the other tissues remained healthy for the longest period of cultivation (12 days). The soft tissue investing the bone grew profusely and formed a large zone of migrating cells.

The effect of the vitamin-A acetate on the experimental bones was remarkable. In a concentration of 2,000–4,000 i.u. per 100 ml. the soft tissue grew as richly as in the controls, but in three days the bone of the shaft began to be absorbed and the cartilaginous ends to soften and shrink. The process progressed rapidly, and the entire bone rudiment seemed to melt away like a lump of sugar in hot water; in extreme cases, by the tenth day only a few crumbs of bone were left scattered in the sheet of actively growing soft tissue. It was noted that, the more healthy the culture appeared and the more actively it grew, the more dramatic was the effect of the vitamin-A acetate. It was rather toxic at a concentration of 8,000 i.u. per 100 ml., and produced a less striking result than was obtained at 3,000–4,000 i.u. per 100 ml.

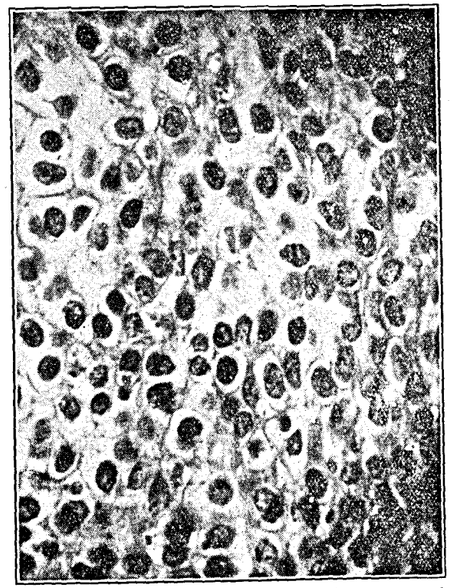

FIG. 6.—Area of terminal cartilage from the experimental tibia shown in Fig. 4. Note the healthy appearance of the cartilage cells, which are much closer together than in Fig. 5, owing to the almost complete disappearance of the cartilage matrix. (× 850.)

Histological sections of the experimental bones (Figs. 1–6), all stained with Delafield's haematoxylin and chromotrope, showed that the cartilage matrix soon lost its basophilia and at the same time shrank, while the cells appeared normal (cf. Figs. 5 and 6). Finally, the matrix of the epiphyses vanished completely, leaving only a compact mass of chondroblasts, while the diaphysial cartilage was rapidly invaded and replaced by the highly cellular connective tissue of the marrow cavity. Exactly how the bone was absorbed was not clear, and although osteoclasts were fairly numerous it was doubtful whether they accounted for all the destruction.

Effect of Vitamin A Prepared from Avoleum

One experiment was made in which "artificial" hypervitaminosis was produced by adding vitamin A in the form of an alcoholic extract of avoleum to the plasma. Six bones were grown in medium containing vitamin A from avoleum (1,558 i.u. per 100 ml. of plasma), six in medium containing vitamin-A acetate (1,538 i.u. per 100 ml. of plasma), and six in normal medium (286 i.u. per 100 ml. of plasma). For purposes of comparison, one bone of each pair was explanted in one of the experimental media and its fellow was grown in either normal or the other experimental medium.

The effect of the avoleum vitamin A seemed identical with that of vitamin-A acetate. By the fifth day the cartilage in both series of explants had begun to shrink and the bone to be absorbed, while the soft tissue grew profusely; after nine days' cultivation the explants were only one-third to one-half the size of the controls, but the soft tissue was still growing actively.

Effect of Plasma from Fowls Suffering from Hypervitaminosis A

Two experiments were made to find how the effect of pure vitamin-A acetate compared with that of the same concentration of vitamin occurring "naturally" in the plasma of birds suffering from hypervitaminosis A. Fowls were maintained on a diet containing large quantities of avoleum. When the vitamin A in the blood had reached a level of 1,200–1,500 i.u. per 100 ml. the plasma was drawn, mixed with embryo extract, and used as a culture medium.

In one experiment eight pairs of bones were explanted. The experimental member of each pair was grown for 12 days in plasma containing 1,435 i.u. of vitamin A per 100 ml. The control bones were cultivated in plasma from normal birds containing 487 i.u. per 100 ml. In the explants grown in the plasma from the birds with hypervitaminosis A the diaphysial bone appeared less dense than in the controls, but the difference was slight. This contrasted strongly with the results obtained in the experiments with pure vitamin-A acetate, in which a concentration in the plasma of only 950 i.u. per 100 ml. produced severe shrinkage of the cartilage and rarefaction of the bone after four to five days' cultivation.

In the second experiment the mouse foetuses were slightly younger than those in the first. Six bones were grown in plasma from fowls with hypervitaminosis A; the plasma used for the first seven days of cultivation contained 1,235 i.u. of vitamin A per 100 ml. and that for the next five days 1,545 i.u. per 100 ml., a rather higher level than was reached in the first experiment. Six bones were grown in normal plasma to which approximately the same concentration of vitamin-A acetate had been added, and six were cultivated in normal medium (320 and 296 i.u. per 100 ml.). All three sets of plasma contained the same amount of alcohol. The experiment was arranged so that one of each pair of bones was explanted in an experimental plasma, and one in either normal plasma or the other experimental plasma.

Apart from a slight rarefaction of the bony shaft, the explants grown in the plasma from birds with hypervitaminosis A showed little change for the first seven days; then the cartilage began slowly to shrink and the bone to be extensively absorbed. The effect, however, was far less drastic than in the corresponding bones cultivated in the same concentration of vitamin-A acetate; after 12 days the changes produced by the "natural" hypervitaminosis were about equivalent to those seen after four to five days' growth in the medium containing the same quantity of the acetate.

Discussion

These results showed that when vitamin A in tissue culture medium is increased from about 300 to 1,200 i.u. per 100 ml. by adding pure vitamin-A acetate to the plasma there is a dramatic effect on foetal bones explanted in such a medium. Plasma drawn from birds with natural hypervitaminosis A of the same order—that is, 1,200–1,500 i.u. per ml.—produced by a diet containing an excess of this vitamin, affects bone explants in a similar way, but its action is much less drastic than that of the artificially enriched plasma. What this quantitative difference in action is due to is not known.

One of the most striking observations described above is the disintegrating effect on the cartilage of foetal mouse bones of vitamin A in abnormally high concentrations. This action is primarily on the matrix, which softens, shrinks, and loses its basophilia, while the cartilage cells remain normal in appearance. In the hypertrophic cartilage at the ends of the diaphysis these changes are associated with a very rapid invasion and replacement of the cartilage by the tissue of the marrow cavity.

This destruction of cartilage *in vitro* is clearly related to the changes produced in cartilage *in vivo* by hypervitaminosis A and described by Strauss (1934), Wolbach and Bessey (1942), and Wolbach (1947). In both conditions there is abnormally rapid excavation of hypertrophic cartilage by the tissues of the marrow, but in the present work the most conspicuous effect is the dissolution of the matrix in the uninvaded cartilage, while in Wolbach's description the chief feature is an acceleration of the normal cartilaginous sequences. Again, in both the *in vivo* and *in vitro* experiments there is destruction of bone, but in the explants nearly all the bone eventually disappears, probably only partly by osteoclasis, whereas Wolbach states that *in vivo* the destruction is limited to osteoclasis in those regions where shaping of the bone normally takes place. Thus, although the effects of hypervitaminosis A are of the same general character *in vivo* and *in vitro*, there are considerable differences in detail. This is probably due to the very different environmental conditions *in vitro* and *in vivo*, and especially to the absence of a blood circulation in the explanted bones.

Summary

Long bones from late mouse foetuses were cultivated by the watch-glass method in medium containing abnormally high concentrations of vitamin A.

When pure vitamin-A acetate was added to the culture medium in concentrations of 1,000–3,000 i.u. per 100 ml. the matrix of the terminal cartilage softened, shrank, and finally almost or completely disappeared, though the cartilage cells appeared normal; in the shaft the cartilage was rapidly replaced by marrow tissue; the bone was resorbed, sometimes completely; the soft tissue surrounding the explant grew as vigorously as in the controls cultivated in normal medium.

The same results were produced by similar concentrations of an alcoholic extract of avoleum, a commercial preparation rich in vitamin A, made from liver.

Similar concentrations of vitamin A obtained by using plasma from fowls fed on a diet rich in the vitamin had a much less drastic effect on the explants.

We are indebted to Mr. L. J. King, technician at the Strangeways Research Laboratory, for his assistance with the tissue culture; to Mr. R. J. C. Stewart, chief technician of the Nutrition Building, National Institute for Medical Research, for his valuable help with the preparation of the birds' plasma; and to Mr. V. C. Norfield for the photographs.

Speaking at the fourth annual conference dinner of the Society of Radiographers, Sir Andrew Davidson, Chief Medical Officer, Department of Health for Scotland, said that the Health Service Acts had made profound changes in the administration of the health services—changes made necessary mainly because of new and progressive trends in medical science and a fuller appreciation of the social, economic, and industrial effects of sickness and disability. There were many gaps to be filled and many deficiencies to be repaired. The new health service claimed to be doing that. Many agreed that the changes had brought real and appreciable public benefits; but they heard less of them than of the weaknesses. The new arrangements had immensely widened the opportunities for the prevention and treatment of ill-health wherever it arose. But could they take advantage of the opportunities? It was of great advantage that Scotland was not too large to prevent personal contacts, yet large enough to be able to maintain a full range of service. Important also was the happy circumstance that they had four flourishing medical university centres, all of the first rank, which together produced about one-third of the new doctors in the United Kingdom. It was fortunate also that the pattern for medical care in rural districts had been set up by the Highlands and Islands Medical Service. Again, Scotland had a well-developed public health service in the counties and burghs. It was too early to make any general assessment of positive achievements, but two facts stood out: (1) The Service has been accepted and indeed welcomed by the public, as 97% of the population are included on doctors' lists; and (2) those who were concerned in operating the Service were making strenuous and helpful efforts to make it a success. The proper balance between the various elements of the Service must be struck. More attention would need to be paid to those working in the homes of the people, whether they were concerned with prevention or cure. The co-operation of the public was needed on how to use the Service. Abuses would destroy it. Doctors had told him that much of the expenditure on expensive drugs was in response to demands by many patients for what they themselves wanted. Surely that was wrong. The public should not regard the Service merely as a machine which would turn out medicine, or spectacles, or dentures, or any other apparatus on demand.

RESPIRATORY STUDIES IN PARALYTIC POLIOMYELITIS

BY

(From the M.R.C. Electro-medical Research Unit, Stoke Mandeville Hospital; the Department of Neurology, Oxford; and the Western Hospital, Fulham)

The following notes are based on studies at the Western Hospital, Fulham, by two of us (L. M. T. and E. D.-J.) during the 1949 epidemic of poliomyelitis, and on laboratory studies at Stoke Mandeville Hospital. While many of the conclusions are tentative, it has become clear that there is much need for improvement in both the design and use of breathing machines. These notes are published in the hope of facilitating such improvement.

The tidal air of a patient in an iron lung can be measured without difficulty by the use of a spirometer of the type commonly employed in hospitals for the measurement of basal metabolism. There are, however, few published measurements of this type in cases of poliomyelitis, and very few detailed measurements taken from patients in tank respirators. Drinker and Shaw (1929) and Shaw and Drinker (1929) showed that in healthy subjects in tank respirators it was easy to produce a large tidal air with minute volumes of over 20 litres a minute at pressures of 20 cm. of water. Elam (1948) showed figures for six cases of poliomyelitis in respirators, but gave few details of the patients' condition. Binet, Bochet, and Bour (1948) gave figures for one patient and four healthy subjects.

Our studies have been concerned chiefly with the effects on tidal air and minute volumes of varying respirator suction pressures and stroke frequency. We have also studied the effects of varying the patient's posture while in a respirator, and the changes occurring in convalescent patients during and after weaning from their respirators. These experiences have indicated a need for a number of alterations in the Both type of respirator, which are discussed later.

Technique

1. *Spirometers.*—A commercial spirometer, using a rubber bellows instead of a float, was found to give too high a resistance to air flow for accurate work. A spirometer of the water-sealed gasometer type was therefore constructed. The counterweight guides and pulley were fitted with ball-races to reduce friction, and thus the pressure required to start the spirometer moving was reduced to only 2 mm. H_2O. As the spirometer was required to measure much smaller tidal airs than normal, the counterweight pulley system was designed to give an optional multiplication ($\times 2$) of the float movement. The sensitivity when this was used was 3.67 in. (9.32 cm.) per litre. The spirometer included an absorbent for CO_2, and was refilled with pure oxygen as and when necessary.

2. *Recording Drum.*—The recording drum used with this spirometer was 12 in. (30 cm.) in diameter and 16 in. (40 cm.) high, and gave paper speeds variable at will from about 2 in. (5 cm.) a minute to 1 in. (2.5 cm.) a second. The highest speed was adequate to display clearly the wave-form of each respiration.

3. *Recording Pressure Gauge.*—A recording pressure gauge was constructed by modifying an ex-R.A.F. air-speed indicator. This gave a pen movement of about 1.75 mm. per cm. water gauge. The time constant of the instrument was less than 1/20 second, so that its response was fast enough to record all details of the pressure wave-form of the respirators. The pressures were recorded on the same drum as the spirometer, so that simultaneous records of respirator pressure and tidal air were obtained.

4. *Alveolar CO_2.*—This was estimated by a Haldane gas analysis apparatus after collection in sampling tubes by the method of Haldane and Priestley (1935).

5. To avoid leakage all measurements of tidal air were made with a nose-clip and a rubber mouthpiece having a flange between the patient's lips and teeth.

Glossary

We use the terms listed below as follows :

Carina. The bifurcation of the trachea.

Hypocapnia. A condition with a subnormal concentration of carbon dioxide in the blood.

Minute volume. The volume of air inhaled or exhaled during one minute.

Regression line (as used in Fig. 2). The calculated straight line for which the sum of the squares of the deviations of volume from the line is a minimum.

Reserve air (="supplemental" air). The volume of air which the subject can expel with an effort after the end of a normal expiration.

Tank respirator. A breathing machine in which the whole of the patient's trunk and limbs are enclosed in a nearly rigid box.

Tidal air. The volume of air inhaled or exhaled during a single respiration.

Vital capacity. The maximal volume of air which a subject can exhale after the fullest possible inspiration.

All volumes quoted in this paper are measured at approximately 18° C. and include water vapour at approximately 15.5 mm. Hg.

Subjects Tested

Among the subjects studied were nine patients for whom respirator treatment was considered essential. Five of these were considered too ill for experimental tests and died without having had any measurements of tidal air. Particulars of the four surviving respirator cases and of the healthy subjects studied are given in Table I (M. C. and D. P. died in June and July, 1950).

Measurements of Tidal Air in Respirators

Effect of Negative Pressures on Tidal Air

About 600 measurements of tidal air were made and correlated with the amount of negative pressure in the Both and Drinker respirators. The results showed wide variations, both between different persons and from day to day in the same person. Fig. 1 shows curves relating negative

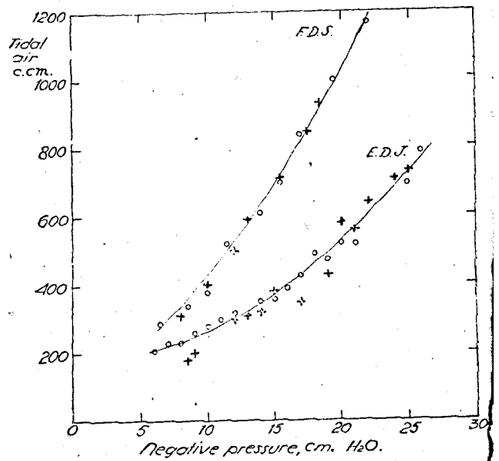

FIG. 1.—Tidal air and respirator suction pressure in two healthy adults. Rate of pressure change approximately 20 cm. H_2O a minute (*too rapid* for equilibrium). Circles show points measured with rising suction pressure, crosses those when pressure was falling. Respirator frequency 20 cycles a minute. Peak positive pressures 2 cm. H_2O.

pressure to tidal air in two healthy subjects. It was found easy to obtain smooth curves of this type by altering the pressure quickly so that unconscious physiological adjustments of the respiration rate did not have time to cause major alterations in the tidal air. In contrast to this, Fig. 2 shows points observed in other tests after the respirator adjusting valves had been left *unaltered for a* time sufficient for the tidal air to appear constant—usually at least one minute after any changes of pressure. These graphs show all tests of this type made at a respirator

TABLE I.—*Particulars of Subjects Studied in Respirators*

Initials	Sex	Age	Height approx.	Weight	Respiratory Muscles Paralysed, and Date of Onset	Total No. of Days in Respirator	Vital Capacity, Supine	
							First Measurement	Last Measurement
					Patients			
A. B.	M.	33	5 ft. 7½ in. (1·71 m.)	9 st. 2 lb. (58·1 kg.)	Intercostals and diaphragm. 16/11/49	65 approx.	180 c.cm. 6/12/49	840 c.cm. 15/3/50
M. C.	F.	20	5 ft. 6 in. (1·68 m.)	7 st. 8 lb. (48·1 kg.)	Intercostals and diaphragm. 10/11/49	More than 125	215 c.cm. 11/1/50	
R. J.	M.	17	5 ft. 6 in. (1·68 m.)	7 st. 7 lb. (47·6 kg.)	Intercostals and abdominal wall, not diaphragm.	31	1,100 c.cm. 30/11/49	1,600 c.cm. 26/1/50
D. P.	F.	26	5 ft. 6½ in. (1·69 m.)	8 st. (50·8 kg.)	Intercostals and diaphragm complete. 30/7/49	150 approx.	450 c.cm. 1/12/49	600 c.cm. 15/3/50
					Healthy Subjects			
D. J. D.	F.	34	5 ft. 2½ in. (1·59 m.)	8 st. (50·8 kg.)			3,200 c.cm.	
E. D. J.	F.	35	5 ft. 9½ in. (1·77 m.)	10 st. 4 lb. (65·3 kg.)			3,000 c.cm.	
F. D. S.	M.	26	5 ft. 7½ in. (1·71 m.)	10 st. 5 lb. (65·8 kg.)			4,400 c.cm.	
L. M. T.	F.	28	5 ft. 4 in. (1·63 m.)	9 st. 5½ lb. (59·6 kg.)			3,100 c.cm.	

The weights given for the patients are those stated by them as observed before their illness. During these studies all patients showed great muscular wasting with consequent loss of weight.

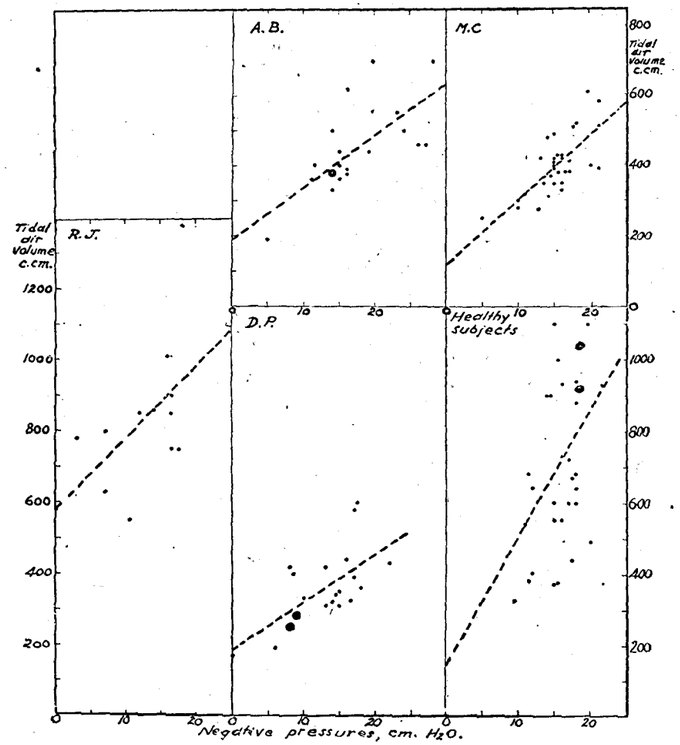

FIG. 2.—Tidal air and respirator suction pressure in four poliomyelitis patients and four healthy adults. All measurements taken at steady valve settings, some time after any change of conditions. The large dots indicate two coincidental observations. Dotted lines show the calculated regression lines.

stroke rate of 20 a minute, and include 86 tests on the patients with poliomyelitis and 33 on healthy subjects. The points show a wide scatter, and even if those measured in fairly quick succession—that is, at a few minutes' interval—are joined by lines to give curves, these show wide variations in slope, especially in the healthy subjects. The causes of the wide scatter shown in these graphs are only partly known. In the patients, some of the higher values of tidal air were due to an irrepressible desire to be "helpful"—that is, to a voluntary effort added to the effect of the respirator. This was especially marked in R. J.

The healthy subjects practised as complete relaxation as possible. The tests were done at varying times after meals, and one subject (E. D. J.) habitually showed unconscious resistance to hyperventilation, presumably by contraction of trunk muscles or of the glottis.

Table II shows certain values calculated from the dotted lines in Fig. 2 and from curves similar to those in Fig. 1. Owing to the wide variations found, the figures in Table II should be taken only as a rough guide. The data for R. J. in particular show the effect of movements of the diaphragm, which remained functional. The healthy subjects all show less resistance to the respirator action than do the patients. This may be due to many causes, such as unconscious co-operation of voluntary muscles in the healthy subjects, the development of chest rigidity in the patients, or possibly to resistance of the laryngeal or other muscles against hyperventilation, which might occur in the patients at unusually low volumes of tidal air owing to their wasted condition.

Optimum Pressures for Tank Respirator

It is obvious that the correct suction pressure for respirator patients can be best judged by studies of blood oxygen and of either blood CO_2 or alveolar CO_2. If reliable measurements of that type are not available, it seems reasonable to assume that, unless fever is high or obstruction by fluid or mucus is present, the normal values of tidal air for healthy subjects should be satisfactory—that is, that for adults lying at rest, with their lungs in a healthy state, the tidal air should not exceed 600 c.cm. and should not be less than 400 c.cm. for a respiration rate of 15 cycles a minute. It should be measured if possible, but if this is impracticable the above data suggest that for adolescents or adults a suction pressure of −12 to −15 cm., according to the freedom of chest movement, is likely to be of the right order, and should be tried as a starting point. This agrees closely with the conclusions of Wilson (1947).

Effect of Positive Pressure on Tank Respirators

In some tests (not quoted above) positive pressures of 9 to 10 cm. H_2O were used with negative pressures of from 10 to 19 cm. Over this range such increase in tidal air as may have occurred with the change from 2 to 10 cm. of positive pressure was too small to be detected in our tests.

TABLE II.—*Relation Between Tidal Air and Respirator Pressure*

	Patients				Healthy Subjects		
	D. P.	A. B.	M. C.	R. J.			
Negative pressure (cm. H_2O) giving tidal air of 400 c.cm.	−16·0	−14	−15·3	No mechanical aid needed	−7·15		
Ditto for 500 c.cm.	−23·5	−21	−20·7	"	−10·0		
C.cm. increase in tidal air for each cm. increase in negative pressure, for "equilibrium" data	13·1	14·5	18·2	19·9	35·4		
					E. D. J.	D. J. D.	F. D. S.
Ditto for points taken during rapid changes of pressure					19·4 and 17·4	39	51·5 and 64

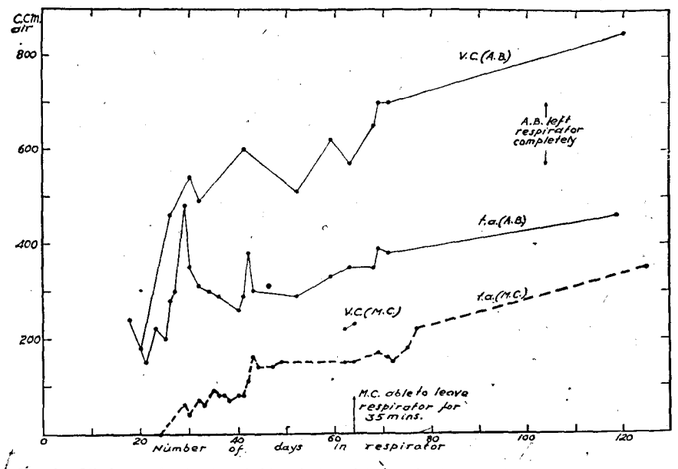

FIG. 3.—Vital capacity (v.c.) and tidal air (t.a.) with unaided respiration for two convalescent poliomyelitis cases.

This agrees with the results of other workers—for example, Wilson (1947). While suggesting that positive pressures of this order are not of much value in increasing tidal air, these tests do not warrant the conclusion that they are useless, since it seems possible that they help to maintain flexibility of the chest and to assist circulation in the lungs, liver, etc. Such observations as were made tended to confirm the belief that positive pressure at part of each stroke does help patients to cough. Both A. B. and D. P. developed atelectasis at one time, and this aid to coughing was then thought to be of definite value, especially if combined with a tilt of 15 degrees head downwards.

Pressure Selected by Patients

In Fig. 2 the graphs for M.C., A.B., and D.P. all show a concentration of points at about −15 cm. pressure. This represents the smallest suction with which these patients felt comfortable during the later portion of their stay in respirators. In the first weeks M. C. became very uncomfortable at pressures less than −22 cm. (at which her tidal air varied from 250 to 590 c.cm.). At −16 cm. she felt "unable to breathe from the bottom." Even at −22 cm. (and +2 cm.) she showed signs of anoxia at this period. R. J., with a milder extent of paralysis and a relatively flexible chest, also appeared to like −15 cm. pressure, though this gave him a tidal air of over 800 c.cm. and a minute volume of 13 to 14 litres.

From these four cases it would seem that the patients' desires may be a useful guide to correct respirator pressures in the absence of all measurements of tidal air or of alveolar or blood gases. Owing, however, to the ease with which the respiratory centre becomes adapted to abnormal concentrations of CO_2, the patient may in time come to prefer a pressure which causes either alkalosis or acidosis (Brown *et al.*, 1948 ; Elam, 1948).

Effect of Stroke Frequency on Tidal Air

The patients concerned were not well enough to tolerate tests of varying respirator frequency over an extensive range. Tests on three healthy adults showed in each case a gradual fall with increasing frequency, the tidal air at 30 cycles a minute being approximately half that at 12 cycles a minute. In contrast to this Shaw and Drinker (1929) reported that in anaesthetized cats treated with curare the tidal air was practically identical at 22 and 37 cycles a minute for all pressures from ±6 to ±20 cm. H_2O. This difference may be due to narrowing of the bronchi during expiration in our healthy subjects (who reported feeling unable to finish expiration at the higher speeds), or to unconscious resistance to over-ventilation. We think the latter explanation improbable.

All healthy subjects found 20 cycles a minute, which is the minimum frequency of the normal Both respirator, uncomfortably fast. They preferred speeds of 12 to 16 cycles a minute, more nearly resembling those of normal respiration when lying down. We see no reason to think that adult patients without fever need higher frequencies than this in most cases. The obvious advantage of using a relatively low frequency is that it facilitates a tidal air large enough to make atelectasis unlikely, and gives less risk of hyperventilation. In the presence of active infection other considerations may become dominant and make higher frequencies preferable.

Tidal Air in Patients Removed from Respirators

Measurements of tidal air and vital capacity form a useful aid in judging the rate at which patients can be weaned from respirators. Fig. 3 shows such measurements for two patients who showed both diaphragmatic and intercostal paralysis. In each case the patient was supine either on a bed or on the respirator mattress with the box front open and no pump running.

The lowest curve (for M. C.) is of interest in showing what low values of tidal air can be tolerated in a wasted convalescent patient. By the 63rd day, with a tidal air of 150 c.cm., she could tolerate periods of 35 minutes without mechanical aids to respiration. At the 125th day she was able to stay out for periods of six hours daily, and showed an unaided tidal air of 350 c.cm., with an alveolar CO_2 of 5.9%. The two higher curves in Fig. 3 show tidal air and vital capacity for A. B., again when unaided by the respirator. On the 20th day he showed collapse of the lower lobe of the right lung, with a tidal air of 150 to 180 c.cm. By the 49th day he was out of the respirator all day and night, with a tidal air of 290 c.cm. A few days later return to the respirator seemed advisable, and he finally left it on the 101st day. On the 119th day he showed the tolerable figures of 460 c.cm. for tidal air and 850 c.cm. for vital capacity. He was fortunate in regaining at least partial control of the upper intercostal muscles, although the diaphragm and lower intercostals remained wholly paralysed.

Fig. 4 shows spirometer curves for tidal air and vital capacity tests for one healthy subject (F. D. S.) and three convalescent patients drawn to the same scale. It shows graphically how great the damage to respiratory muscles may be in cases which survive. The reserve air is shown approximately in each case by the depth to which the curve falls below the dotted line. The vital capacities of the patients are so low as to leave little or no margin for emergencies such as an acute respiratory infection.

Posture in Respirators

It is customary in most hospitals to nurse respirator cases in the supine position, tilting the head downwards only when fluid collects in some part of the respiratory tract. While convenient for both nurses and patients, any constant posture is dangerous, and the supine position is exceptionally dangerous owing to the difficulty of draining the pharynx without excessive tilt and the increased danger of inhalation of gastric contents if vomiting occurs. This applies to all cases needing respirators, and especially to bulbar cases whether in respirators or not.

Statistics of deaths from poliomyelitis show that a large majority of respirator patients die —for example 86% of 834 cases (Bergman and Huldt, 1948), 82% of 98 cases (Edwards, 1948), 57% of 63 cases (Brahdy, 1936), 80% of 76 cases (Nielsen, 1946). Useful data for earlier epidemics are given in the Medical Research Council's Special Report on Breathing Machines (1939). A large number of these patients die with atelectasis and pneumonia, probably accentuated, if not chiefly caused by, accumulation of mucus and fluid in the respiratory tract. While making due allowance for the cases in which death is due to overwhelming invasion of the central nervous system it seems reasonable to suspect that a good many such deaths could be averted if continuous drainage of the main bronchi were assured. Postural drainage is therefore of very great importance in many cases. It is well known as a life-saving measure in bulbar poliomyelitis, but its possibilities during respirator treatment have been little explored.

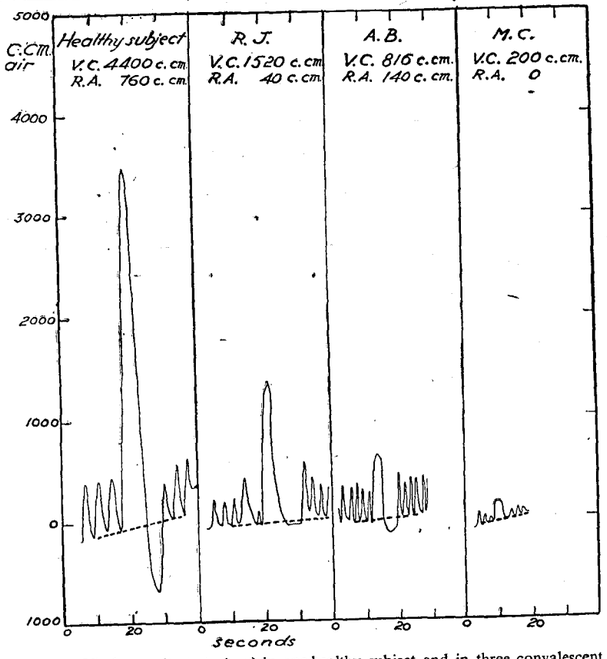

FIG. 4.—Vital capacity tests (v.c.) in one healthy subject and in three convalescent respirator patients. R.A. = Reserve air.

The great advantage of the prone position over the supine in facilitating drainage is not always appreciated. In the supine position, lying flat on a hard surface, there is an upward slope from the carina to the lower corner of the mouth (with the head turned sideways) of approximately 15 degrees. Hence a downward tilt of over 15 degrees is necessary before drainage can even begin, and about 20 degrees is necessary for a useful effect. (These figures are only approximate, since the exact angle of slope is affected by the shape of the chest, the yield of the mattress, and especially by the position of the head at rest.) The reverse holds in the prone position. With the body lying on a horizontal surface, and with the chin in a comfortable position about 1½ in. (3.75 cm.) below the surface supporting the trunk, there is a downward slope of about 15 degrees from the carina to the mouth, so that rapid drainage can occur without any tilting of the patient. The difference between the prone and the supine position thus corresponds to a tilt of about 30 degrees when considering the respiratory tract from carina to mouth. For drainage of all the bronchi distal to the carina no single position can be satisfactory, and changes of posture are indispensable.

Side-effects of Tilting.—The drawbacks to lying with the head tilted downwards deserve consideration. In our tests, two healthy subjects lying prone in an open Drinker respirator tilted head down at 20 degrees for one hour showed oedema of the face, congestion of the nasal mucosa, and alterations in the pitch of the voice. This suggests that even this moderate angle may cause appreciable cerebral oedema, and provides a further reason for using the prone position, where a small angle of tilt may suffice. The drastic procedure of tilting to 30 or 35 degrees is, however, advised by Galloway and Seifert (1949), who report successful results in 15 consecutive bulbar cases.

Posture in Both and Drinker Respirators.—These respirators have sloping fronts, which are advantageous to patients when supine, but tend to interfere with the shoulders in the lateral position and with the chin in the prone position. In this respect the Both with the wooden front 7/8 in. (2.2 cm.) thick, sloping at 20 degrees, is worse than the Drinker with a metal front 3/32 in. (0.24 cm.) thick, sloping at 15 degrees. However, changes of posture were studied in two patients. The prone position was found practicable for A. B. in a Drinker respirator for periods up to two hours at a time. The left lateral position was also found useful in this patient, following collapse of the right lower lobe, but this position was tolerated only for periods of two hours at a time, since his left hip became tender. A boy of 3 was also nursed in a Drinker for long periods in the right and left lateral positions.

When in the prone position the patient needs one or two pillows under the chest and thighs to allow of free abdominal movement in respiration, and two pillows under the shins to protect the knees and feet from pressure. We have found it easy to construct a chest and shoulder support from one of the wedge-shaped cushions of foam rubber sold commercially for upholstery. The removal of the central part of the thin end of the wedge facilitates abdominal movement, and the addition of two pads of foam rubber projecting above the thick end of the wedge effectively protects the shoulders when the respirator is tilted head downwards.

Effect of Posture on Tidal Air in Respirators.—A series of tests on A. B. at different dates showed no decrease in tidal air on changing from the supine to the prone or lateral positions, at the same respirator pressure. In many tests an increase occurred, but it is uncertain if this was due to conscious or unconscious use of the accessory respiratory muscles or to decreased mechanical resistance. When nursing in the prone or lateral positions no increase in respirator pressures seemed necessary to secure comfort. In two healthy subjects tests showed no regular change in tidal air on changing from the supine to the prone position.

Respirator Mattresses.—In wasted patients the properties of the mattress become of great importance. It is customary to use foam-rubber mattresses in respirators, but these are often covered with a thick waterproof covering of red rubberized fabric. A series of tests made on the yield and elasticity of mattresses (to be published later) have shown that the use of covers of this type greatly increases the local pressure on bony points and removes many of the great advantages of the foam-rubber mattress. The patient A. B. when in the lateral position on a mattress covered in this way soon complained of sore hips. Since "dunlopillo" material is easily washed, and since we are informed by the makers that it can be steamed at 100° C. (but not 110° C.) without appreciable damage, we would strongly advocate the use for all respirator patients of foam-rubber mattresses with thin porous cotton fabric covers only.

Conclusions on Posture.—The advantages of the prone position with slightly lowered head seem to need the greatest emphasis, above all in bulbar cases, whether these are treated out of respirators, as is common in this country, or in them, as strongly recommended by Galloway and Seifert (1949). Improvements in the design of tank respirator fronts to facilitate changes of posture are badly needed. Training of the nursing staff in team-work when changing the posture of respirator patients is also important.

Hyperventilation

The ease with which hyperventilation can be produced in tank respirators was noted by Drinker and Shaw (1929) and should not be forgotten. In healthy subjects considerable hyperventilation can be continued for 24 hours or more as shown by Brown *et al.* (1948), though during sleep some mechanism (possibly closure of the glottis) reduced the ventilation in at least one of their subjects. In this respect tank respirators are in striking contrast to manual methods of artificial respiration in which hyperventilation is usually impossible, owing to an ensuing rigidity of the chest sufficient to overcome its natural elasticity (Henderson and Turner, 1941).

The possible dangers of hyperventilation in respirator cases of poliomyelitis need consideration. They are difficult to assess not merely because the conclusions of workers who have studied hypocapnia vary considerably but also because different persons vary greatly in their response to hyperventilation. Some of these dangers have been described by a number of workers, including the following.

Henderson (1910) and Henderson and Haggard (1918) described some very severe tests on anaesthetized dogs, in which three dogs died. In human beings with less severe hyperventilation Hinshaw, Rushmer, and Boothby (1943) found that in tests in which "the rate and amplitude of respiration were merely doubled" two out of ten aeroplane pilots collapsed in 20 minutes, with partial or total unconsciousness, and four others developed troublesome symptoms. The authors refer to this as "such moderate hyperventilation," but, since the alveolar CO_2 was in all cases reduced to half the normal figure within five minutes of starting, we infer that the minute volume was four times the normal figure, a rate which we should regard as giving considerable hyperventilation.

Rahn *et al.* (1946) give quantitative data on the effect of hypocapnia on manual steadiness, mental arithmetic, and other faculties, and find a slight drop in efficiency as the alveolar CO_2 pressure falls to 30 mm. Hg and a rapid fall when this pressure sinks below 25 mm., corresponding to a concentration at normal pressures of approximately 3%. (The partial pressure of alveolar CO_2 with normal ventilation is usually taken as 40 mm.)

Carryer (1947) stresses the dangers of respiratory alkalosis and describes it as causing anxiety, confusion, and often a sense of suffocation tending to cause yet further hyperpnoea; sensations of tingling or numbness in the extremities, muscle tetany (especially carpopedal spasm) follow. He attributes some of these symptoms to tissue anoxia. This can be caused by hyperventilation, because the readiness of oxyhaemoglobin to give up oxygen is lessened by a reduction in the CO_2 content of the blood stream. This has long been recognized as the "Bohr" effect.

A further possible cause of tissue anoxia from hyperventilation is suggested by the studies of Gibbs *et al.* (1942), who conclude that a reduction in the arterial CO_2 content of arterial blood causes constriction of the cerebral arterioles. While these authors hold that such constriction will not be sufficient to cause anoxia, others such as Davis and Wallace (1942) believe that at least sufficient anoxia to produce delta waves is easily caused in this way.

The tetany produced by hyperventilation in man has been recorded by many workers, including Grant and Goldman (1920) and Schneider (1930). The latter observed great spasticity of the chest or shoulder muscles in some of his subjects after about 22 minutes of voluntary forced breathing. This seems of possible interest in considering the "rigid chests" of some respirator cases. The effects of hyperventilation during anaesthesia are discussed by Seevers *et al.* (1939, 1940). If hyperventilation is prolonged a rapid adjustment of the blood alkali occurs, tending to restore the *p*H of the blood to its normal value. The kidneys aid in this process by secreting a more alkaline urine. As a result of these adjustments, overbreathing is not known to cause death in healthy unanaesthetized human beings or dogs. It is, however, uncertain whether hyperventilation in respirators has often proved lethal in the acute stage of poliomyelitis.

Practical Tests on Hyperventilation in Drinker or Both Respirators.—Table III gives the results of a few of our tests on healthy subjects, and is intended to show at what pressures appreciable hyperventilation occurred. In three out of four healthy adults suction pressures of -13 to -16 cm. H_2O at respirator rates of 14 to 20 a minute caused pronounced symptoms of respiratory alkalosis in less than 90 minutes from the start, with a reduction of alveolar CO_2 to less than 3%—that is, to less than 25 mm. Hg pressure. These findings agree well with those of Rahn *et al.* (1946) quoted above.

Hyperventilation in Patients.—With patients the respirator pressures were generally adjusted to the lowest value at which the occupants felt comfortable, and no signs of overventilation were detected. In three of the patients this was only to be expected, since their tidal air was small. With R. J., however, a tidal air of about 800 c.cm. and a minute volume of 16 litres or more was common, as is seen in Fig. 2. Even on the first morning after entry into the respirator a minute volume of 17 litres was observed (at pressures of -17 cm. and $+2$ cm. H_2O). It seems certain that some hyperventilation occurred, though conceivably only during spirometer measurements. No symptoms or signs of overventilation were detected.

TABLE III.—*Respirator Pressures Causing Hyperventilation in Healthy Subjects*

Subject	Negative Pressure (cm.H_2O)	Stroke Frequency	Tidal Air (c.cm.)	Minute Volume (litres)	Duration Since Start of Pump (min.)	Alveolar CO_2%	Symptoms of Alkalosis
L. M. T.	−15	19·5	1,000	19·5	0 15 30 40	4·46 2·45 2·25 1·95	Tingling + Chvostek's sign at 12 min. Carpal spasm at 38 min.
L. M. T.	−16	16	900	14·4	0 25 38 50	4·4 3·94 2·74 2·45	Tingling in arm and bilateral Chvostek's sign at 42 min. Carpal spasm at 48 min.
L. M. T.	−13	14–16	900	13·5			Tingling, carpal spasm, and Chvostek's sign at 3 min. Brief loss of consciousness and sweating hands at 45 min.
F. D. S.	−15·5	16	980	15·6	0 16 30	5·5 3·1 3·45	Tingling at 13 min. Chvostek's sign at 23 min.

E. D. J.	−16	14·5	575	8·2	0 32 69	5·85 4·75 4·1	No symptoms.
E. D. J.	Voluntary hyperventilation		2,066	31·0	19·5	Not measured	No symptoms after 19¼ min.

Note: Positive pressures used varied from 0 to 1 cm.H_2O.

Indications for Respirator Treatment

The high percentage of deaths observed in cases of poliomyelitis treated in respirators has led many physicians to postpone respirator treatment until the patient is obviously struggling for breath. Thus Stimson (1949) remarks: "The contraindications to the use of the respirator, however, are so definite that a number of us feel that a patient should not be put in until you really have to." While realizing that the dangers of respirator treatment may be appreciable, especially when there is a shortage of nurses, we would like to emphasize the physiological grounds for thinking it important to use respirators at the earliest detectable signs of involvement of the respiratory motor neurones.

Ritchie Russell (1949) has pointed out the close correlation between muscular paralysis and exercise in the 72 hours preceding the onset of paresis. He remarks: "Severe physical activity at this stage is almost suicidal." This seems to be especially true in the last 24 hours of the pre-paralytic stage. Now the vital capacity of most people is about eight times as great as their tidal air when at rest. Hence a patient at rest will not show distress from failure of respiratory muscles until a very large fraction of their power is lost. It seems probable that by that time many of their neurones are already out of action, and that the remaining ones are being grossly overstimulated by hypercapnia or hypoxia. It therefore seems most important to rest these muscles before this stage is reached. A further reason for prompt respirator treatment is summarized in the well-known adage "Anoxia breeds anoxia." It therefore seems important that respirator treatment should not be postponed until gross signs of underventilation such as cyanosis, difficulty in answering questions, or twitching of the alae nasi have developed.

In the four surviving respirator cases discussed in this paper the procedure customary in most hospitals was followed, in that the patients were kept under close clinical observation but respirator treatment was not begun until respiratory difficulties were obvious. The time intervals between the first symptoms of respiratory insufficiency and the use of a respirator were as follows: D. P., 26 hours 50 minutes; M. C., 24 hours approximately; R. J., 5 hours 30 minutes; A. B., 4 hours 30 minutes. It is of interest that of these patients the least recovery of respiratory power was shown by D. P. and M. C., who had the longest intervals before respirator treatment. Both these patients died within a year with acute dilatation of the stomach and, in one or both cases, pneumonia.

In determining the first onset of respiratory weakness a rough estimate can be formed by finding how many numbers the patients can count out verbally in one expiration. But if the apparatus is available, some kind of spirometer is much more accurate. In our opinion a spirometer of the type commonly supplied for estimating the basal metabolic rate should be kept as an accessory in every ward where an appreciable number of respirator cases are expected. In the absence of a spirometer of this type, simple apparatus can be constructed for measuring "vital capacity," using either an expanding bellows of paper or cloth, or a metal float chamber as in spirometers. It is even possible to measure vital capacity by using an anaesthetist's rubber bag (the 2-gallon (9.1-litre) size may be needed for adult males), by tying up the orifice and noting the volume of water displaced on immersing the bag in a large vessel. By taking measurements of this sort at suitable intervals it should be possible to detect a weakening of respiratory muscles in the earliest stages, and to justify beginning respirator treatment much sooner than is now customary, at least in hospitals where the staff are fully trained in the management of respirators.

As this conclusion was reached only in the later part of our studies, we have not yet had practical experience of the difficulties which might ensue from this procedure. We do not know if the net result would be to increase or decrease the number of respirators needed, since a shorter period of stay might outweigh an increase in the number

of patients given the treatment. It would of course be important to avoid respirator treatment in bulbar cases, unless they were efficiently drained by tilting or other methods.

Matching of Respirator Frequency to Patient

The normal respiration frequency of an adult lying down is said to be 14 to 16 a minute, falling to about one-quarter of this rate during sleep (Sunderman and Boerner, 1949). All our healthy subjects when first put in a Both respirator found it difficult to adjust to the frequency of 19–20 a minute, which is the lowest that the belt of the A.C. power unit supplied with the Both outfits can give. These subjects felt as if they were not allowed time to breathe out properly, and it was difficult at first to adjust their muscles to the unduly early onset of inspiration. On the other hand, with the D.C. motor of the Drinker outfit, giving speeds down to about 10 strokes a minute, no such difficulty was noticed.

The logical procedure for matching respirator to patient would consist in noting the unaided frequency of the patient's respiration and, when this was not excessive, adjusting the respirator stroke frequency to the same rate. This should give least fatigue to the muscles concerned. It seems important to avoid hyperventilation, since this is normally resisted (at least in healthy subjects) by contraction of respiratory or laryngeal muscles which presumably need rest.

Hypoxia

It seems clear from the observations of Elam *et al.* (1948) that the use of an oximeter may be of great value in the respirator treatment of poliomyelitis. This would make the detection of underventilation easy but would give no guide to hyperventilation. For the detection of this, measurements of alveolar CO_2 would be of great value, and the combined procedure would make it possible to determine the best value of the minute volume for a patient in any particular phase of his illness. In the absence of such facilities it seems wisest to assume that hypoxia is more dangerous than hypocapnia, especially when the latter is of gradual onset so that the acid-base balance can be adjusted by the kidneys. It is therefore reasonable to choose a minute volume rather greater than the optimum theoretical value for a patient at rest. As is well known, many cases require, or at least benefit from, the use of oxygen for a considerable period after treatment has begun. Further, in order to avoid hypoxia when the tank respirator is opened for nursing attention, it is very important to have some auxiliary apparatus available, such as an Oxford inflator or a McKesson or E. & J. resuscitator.

Suggested Alterations to the Both Respirator

Experience has led us to think the following alterations desirable. The first two seem of considerable importance.

1. Provision for running at lower speeds than the present minimum of 20 strokes a minute. We suggest that if, for economic reasons, an A.C. motor and stepped pulley is retained, ratios should be provided giving 12, 15, 18, 21, and 24 cycles a minute. This would make it possible to give patients rather deeper breaths without so much overventilation, and would, we think, often make it easier to match the respirator speed to the natural rate of the patient.

2. Alterations to the front of the tank to make the prone or lateral positions less uncomfortable. A reduction of slope to 10 degrees or even less is suggested, and the replacement of the thick wood by light alloy 3/32 in. (0.24 cm.) thick. If the front were made in an upper and a lower half, with the upper half easily removable, it would be much less difficult to change the patient's posture.*

3. The valve flaps giving control of pressure are at present too easily misplaced or obstructed—for example, by a pillow placed on top of the respirator.

4. The provision of an alarm signal to call attention if undue leakage or other causes produce a cessation of adequate pressure changes.

5. The addition of a metal pressure gauge in addition to the existing water gauge. A note on the errors found in the water gauges of existing Both and Drinker respirators is added as an appendix.

6. The tilting mechanism is unsatisfactory and should be made easier to operate quickly.

7. A series of minor details could be improved: softer sponge-rubber collars, more side openings, castor wheels, and an internal low-temperature heater could make the machine safer for the patient and easier for the nursing staff.

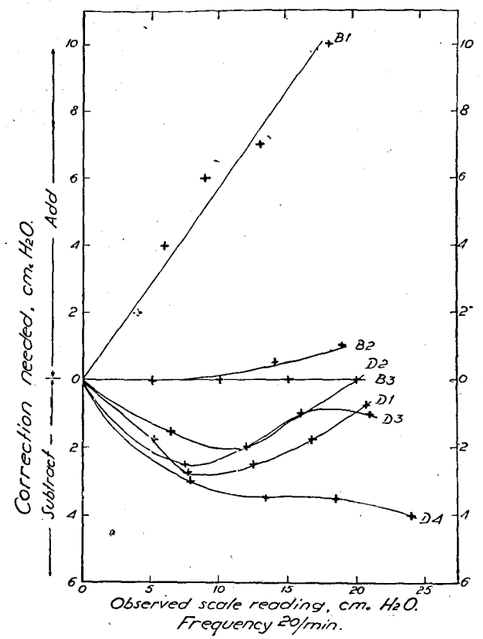

FIG. 5.—Correction curves for water manometers at 20 cycles a minute. These curves and those in Fig. 6 show the amount to be added to or subtracted from the observed reading in order to obtain the correct pressure. They were obtained by comparing the water manometers with a critically damped diaphragm type of pressure gauge. B1, B2, B3 = three different Both respirators. D1, D2, D3, D4 = four different Drinker respirators.

Summary

Numerous measurements of tidal air have been made with a spirometer on patients and on healthy subjects in Both and Drinker respirators, and on patients after respirator treatment for poliomyelitis. These measurements show a wide range of variation from day to day in most cases.

It is considered that in the treatment of poliomyelitis with respiratory involvement there is much need for measurements of vital capacity and tidal air, unless frequent measurements of blood O_2 and CO_2 are practicable.

Early measurements of vital capacity are suggested in order to detect the first signs of respiratory involvement, with a view to resting the muscles concerned by the prompt use of a respirator. The tidal air measurements are indicated as a rough guide to the correct setting of respirator pressures so as to avoid under- or over-ventilation.

The potential dangers of hyperventilation are discussed, and measurements are given showing the ease with which this is produced in respirators.

Tests on the use of the prone position in respirators are described. The importance of using this position is emphasized, especially in bulbar cases.

Some possible improvements in the Both respirator are discussed, in particular provision for slower speeds and a reduction in the angle of slope and in the thickness of the front panel.

*We have to thank Dr. Ritchie Russell for this suggestion.

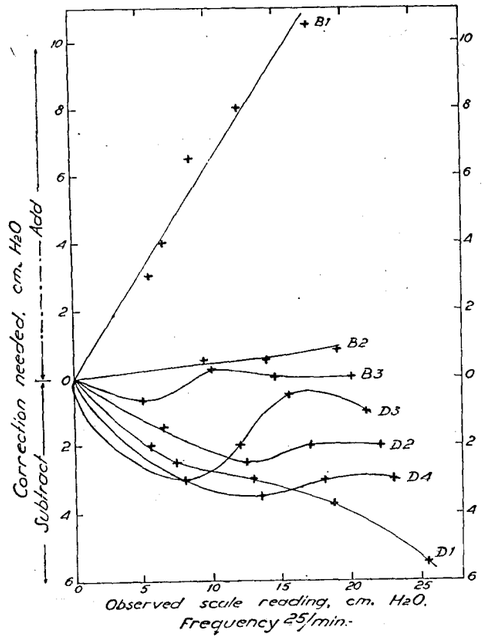

FIG. 6.—Correction curves for water manometers at 25 cycles a minute.

We wish to acknowledge our thanks to Dr. Ritchie Russell, who initiated this work and who has given constant advice throughout it, and to Dr. W. Howlett Kelleher, physician-superintendent of the Western Hospital, for allowing us free use of clinical material and facilities in the hospital, and for his continued co-operation.

APPENDIX

Note on Water Manometers in Both and Drinker Respirators

The water manometers normally fitted to the Both and Siebe Gorman Drinker respirators have the great merit of simplicity; they may, however, give very misleading readings because of (*a*) zero error caused by evaporation of the water; (*b*) overswing due to the momentum of the water column, causing too high readings; and (*c*) overdamping by viscosity, causing too low readings. Of these (*a*) is not serious provided the level is adjusted at regular intervals; (*b*) and (*c*) may compensate each other to a considerable extent, but as these two effects depend on both the amplitude and the frequency of the motion of the water column they cannot generally be made to cancel each other at all pressures and rates.

Figs. 5 and 6 show correction curves plotted for seven different respirators. In two of the Boths, the cancellation of errors (*b*) and (*c*) above is good, but the remaining Both, reading low by about 40%, demonstrates one of the special dangers inherent in the design of the pressure gauge; this large error was apparently due to an accumulation of foreign matter in the manometer and shows the need for a drainage plug at the bottom of all water manometers on respirators. The existing Both gauge cannot be cleaned out without unscrewing it from the respirator, which has to be done from the inside. The Drinker gauges show clearly the variation of the error with different rates and pressures. As gauges differ in diameter, these errors vary considerably from one gauge to another.

Since it does not seem possible to eliminate these errors over the whole range of pressures and rates required, the provision of an additional dial-type gauge has much to recommend it. A pressure gauge of this type can be made critically damped and still rapid enough in response to give true readings at the highest rates and pressures ever required. It has the advantage that it provides an indication of the correct functioning of the respirator which is visible from a much greater distance than the water manometer.

Before the last war the General Nursing Council for England and Wales required candidates for entry into the nursing profession to hold certain minimum standard qualifications. Among these was the passing of the school certificate or matriculation examination. Since these are soon to be replaced by the general certificate of education, the G.N.C. has discussed what subjects of this certificate will be acceptable and what the minimum standard should be. It has decided that, when it can once again require a minimum standard of education for entry into the nursing profession, it will accept a pass at ordinary level in two of the following subjects, of which one must be English language or English literature: English language, English literature, history, geography, and religious knowledge. The G.N.C. cannot at present require these qualifications.

POISONING BY ORGANIC PHOSPHORUS INSECTICIDES*

BY

P. LESLEY BIDSTRUP, M.B., M.R.C.P.

(From the Department for Research in Industrial Medicine (Medical Research Council), London Hospital)

The need to increase food production in all parts of the world has led to the use of many potentially dangerous substances for the control of weeds and insect pests. The value of D.D.T. in the control of mosquitoes, flies, and certain insects is undisputed, and many other chlorinated hydrocarbons have found a special use in pest control. Some of these substances are extremely toxic to man. Control of weeds with sprays containing dinitro-*ortho*-cresol (D.N.O.C.) has increased the yield in cereal crops, but in Great Britain alone seven agricultural workers have died from D.N.O.C. poisoning in the past five years. The average period during which D.N.O.C. is used is only six weeks in each year.

The organic compounds of phosphorus have been most recently introduced into the group of potent agricultural chemicals. These are effective insecticides but extremely dangerous to man unless they are handled with extraordinary care. There has been a tendency to release agricultural chemicals for use by workers of varying experience before the toxic properties have been adequately studied. We know little enough about the acute toxicity of some of these substances, and almost nothing about the long-term effects of repeated small doses.

Substances Now Used

During the 1939–45 war organic compounds of phosphorus possessing a nicotine-like action were described by Schrader, in Germany, and recommended for use as insecticides. It was recognized, also, that these substances might prove effective agents in chemical warfare. At the end of the war the formulae and methods of synthesis of these substances were made available simultaneously to scientists in Great Britain and the United States of America, and in both countries many of them have been developed and tested for use in the control of insect pests. Hexaethyl-tetraphosphate (H.E.T.P.), tetraethyl-pyrophosphate (T.E.P.P.), and diethyl-*para*-nitrophenyl-thiophosphate ("parathion") are now used in many countries throughout the world. They are effective in the control of a wide variety of pests such as aphides and red spider, and are of particular value against insects which may be resistant to D.D.T. and the older insecticides (Porter, 1948). More recently octa-methyl-pyrophosphoramide (O.M.P.A.) has been studied, but its use is not recommended on crops which will be used for food.

These substances are alkylpolyphosphates and potent cholinesterase inhibitors resembling in their effects upon man di-*iso*propyl fluorophosphate (D.F.P.). O.M.P.A. does not inhibit cholinesterase *in vitro* but becomes converted *in vivo*, probably by the liver, to an active anticholinesterase substance (DuBois *et al.*, 1950). H.E.T.P. owes its action as an insecticide to the presence in the manufactured product of T.E.P.P. These substances are heavy syrupy liquids which hydrolyse readily in the presence of moisture or alkali and lose their toxicity. Pure parathion is a clear, colourless, and odourless oily liquid, but the commercial product contains amine impurities which give it a brownish coloration and a distinctive unpleasant odour. Parathion is only slightly soluble in water and hydrolyses slowly. At 25° C. and *p*H 7 only 50% hydrolysis occurs in 120 days (Grob, 1950). Moreover, it is more soluble in lipoids than in aqueous media. These properties enhance greatly its efficiency as an insecticide, and also its action as a poison to man and domestic animals. In a single dose both T.E.P.P. and nicotine are more toxic than parathion, but experience and experiment have demonstrated that the effects of parathion are more insidious and more deadly, especially if exposure is repeated day after day.

Cases of Poisoning

H.E.T.P. and T.E.P.P. are mixed with a suitable wetting agent to prevent hydrolysis of the concentrated material, which is diluted with water immediately before use. Sixteen cases of poisoning with these substances have been recognized in the United States of America since 1947. Although moderately severe symptoms occurred in persons affected, there were no deaths. By contrast more than 100 cases of poisoning and at least six deaths have been reported among persons handling parathion in one spraying season. Towards the end of 1948 the use of parathion increased and in many cases replaced H.E.T.P. and T.E.P.P. because of its more prolonged insecticidal action.

In the United States of America concentrated parathion is adsorbed on to attapulgus or bentonite clay to form wettable powders containing 15 or 25% of the active ester. These may be blended with inert materials to form 1 to 2% dusts or diluted with water for use as aqueous sprays. Methods of applying dusts and sprays vary considerably and include dusting from aeroplanes, mechanical spraying from tractors, and hand spraying. In greenhouses, aerosols or smoke canisters containing parathion are used. In Great Britain parathion is supplied to the user as a concentrated liquid for dilution and use as an aqueous spray. Until 1950 relatively small quantities of parathion had been applied and only four cases of poisoning have been recognized up to the time of writing.

Poisoning has occurred in agricultural workers such as field-workers, entomologists, dusting pilots, fruit pickers, and nurserymen, and in industrial workers, including chemists, formulators, packers, and men employed on maintenance in manufacturing plants.

A welder accidentally cut into a pipe containing parathion. Within ten minutes he experienced nausea, vomiting, vertigo, and headache. He recovered completely in twenty-four hours.

A pilot employed in dusting crops from aeroplanes had been up twice in one day and crashed into a row of trees on his third flight. The man who assisted in loading for the last flight said that the pilot had remarked about his eyesight diminishing, but passed it off as a minor matter. The investigation in this case revealed little, as both the aeroplane and the pilot were destroyed by fire (Abrams and Leonard, 1950).

A plant foreman and a fellow worker were splashed with parathion. The foreman made his assistant wash with soap and water and change his clothing at once, but neglected to do so himself. Eight hours later nausea, vomiting, abdominal cramps, diarrhoea, and constriction of the pupils developed. These symptoms persisted and he was admitted to hospital nine hours after the onset of his illness. At this time there was fibrillary twitching of voluntary muscles and signs of pulmonary oedema. Treatment with atropine produced a temporary improvement, but death occurred in coma twenty-one hours after exposure to parathion.

*Read in opening a discussion at a meeting of the Section of Occupational Health at the Annual Meeting of the British Medical Association, Liverpool, 1950.

Signs and Symptoms

The symptoms and signs of parathion poisoning are similar to those produced by D.F.P. and T.E.P.P. They are due to inhibition of both pseudo- and specific cholinesterase. It is possible that other factors, such as accessibility to the central nervous system, may operate in altering the clinical manifestations produced by different cholinesterase inhibitors. It has been suggested that an additional mechanism of toxic action is responsible for some of the symptoms of parathion poisoning which have not been observed with D.F.P. or T.E.P.P. *In vitro* the depression of cholinesterase activity by parathion is 1/30 of that caused by D.F.P. or neostigmine and 1/300 of that caused by T.E.P.P. All four substances affect plasma cholinesterase more than that of red blood cells, brain, and muscle. The rate of inhibition by parathion is slower, but this does not result in lessened toxicity. In experimental animals the toxicity of parathion equals that of D.F.P. and is one-tenth that of T.E.P.P. Both in animals and in man symptoms of poisoning with T.E.P.P. are more transient (Grob, 1950).

Inhibition of cholinesterase occurs as the result of the combination of the inhibitor with cholinesterase. In the case of D.F.P. irreversible combination occurs almost immediately and recovery depends upon regeneration of cholinesterase. This takes several weeks in the case of plasma cholinesterase and several months for red blood cell and tissue cholinesterase. Although no symptoms may be present until the cholinesterase activity of the effector organs is reduced to between 25 and 50% of normal, an individual is unduly susceptible to the effects of any cholinesterase inhibitor until normal cholinesterase activity of the enzyme is restored. The combination of cholinesterase with T.E.P.P. or parathion is reversible for several hours after combination occurs, but subsequently becomes irreversible (Grob, 1950). It is therefore important that atropine should be given promptly and in adequate doses.

Parathion is lipoid-soluble and readily penetrates the skin. Absorption may also occur through the conjunctiva or by inhalation or ingestion. It causes no local symptoms or signs in the skin, so that absorption by this route may pass unrecognized until the characteristic symptoms begin. Grob, Garlick, and Harvey (1950) report the toxic effects of exposure to parathion in 32 men and 8 women. Death occurred in 6 men, severe symptoms in 2 men and 2 women, and mild to moderate symptoms in 24 men and 6 women. In most of these cases exposure occurred in mixing liquid parathion with attapulgus clay, but included among the fatal cases are field workers and others reported from several sources.

Length of Exposure to Parathion

The length of exposure to parathion before the occurrence of symptoms varied from several days to several weeks. In the fatal cases and in most of the others exposure averaging twelve days had occurred during the month preceding the onset of symptoms, but in five persons with symptoms of mild to moderate severity no exposure is known to have occurred prior to the day on which illness developed. Warning symptoms, including intermittent nausea, vomiting, giddiness, weakness, drowsiness, and fasciculation of the eyelids, were noticed by five persons before more serious manifestations of poisoning appeared. These symptoms were present at intervals for one week, but were ignored by the workers. The concentration of parathion in the working atmosphere at the time that this incident occurred is not known.

Half of the patients studied by Grob, Garlick, and Harvey (1950) began to have symptoms while still exposed to parathion. In other cases the illness began from one to eight hours after the last exposure. The first symptoms are usually anorexia and nausea characteristically increased by smoking or taking food and followed within half to two hours by vomiting, intense abdominal cramps, excessive sweating, and salivation. Giddiness, apprehension, and restlessness usually follow the onset of anorexia, but occasionally these may be the initial symptoms of intoxication.

Constriction of the pupils is found in all patients with moderately severe symptoms, but may be minimal or absent in mild cases. Where parathion has been conveyed direct to the eye pin-point constriction of the pupil occurs and may be unilateral. It is resistant to dilatation with atropine, and may take several weeks to return to normal size. Muscular twitchings beginning in the eyelids and tongue follow shortly after the occurrence of nausea and vomiting. In severely poisoned persons the twitching spreads to the muscles of the face and neck and involves the extraocular muscles, causing jerking movements of the eyes suggestive of nystagmus. Generalized muscular twitching and extreme weakness may develop in spite of adequate doses of atropine, and death can occur from this neuromuscular paralysis.

In addition, diarrhoea, tenesmus, involuntary defaecation and micturition, and signs of pulmonary oedema with broncho-constriction occur in acutely ill persons. A raised blood pressure, returning to normal as symptoms subside, is a constant finding in parathion poisoning. This is unusual, since most directly acting cholinergic drugs cause the blood pressure to fall (Grob, Garlick, and Harvey, 1950). Symptoms and signs of effects upon the central nervous system develop *pari passu* with the muscarine-like and nicotine-like effects. Giddiness and apprehension are accompanied or followed soon by intense headache, and in mild cases insomnia or unusual dreaming may be noticed. In more severe cases ataxia, tremor, drowsiness, diminished concentration, mental confusion, and sometimes disorientation and slurring of speech occur. Multiple repetition of the last syllable of a word is characteristic.

Coma develops gradually, and occurs from one to nine hours after the onset of symptoms. All the patients who died and two who recovered were deeply comatose, with absence of all peripheral reflexes. Coma lasted on an average for three hours. Generalized convulsions almost invariably occur in comatose patients. Three people who subsequently died regained consciousness for several hours following the administration of atropine. Examination of the fundus in one patient revealed two dioptres of papilloedema, and the cerebrospinal fluid was found to be under pressure but otherwise normal.

In fatal cases death has occurred from one to twenty-one hours after the last exposure to parathion, and, on an average, nine hours after the onset of symptoms. The immediate cause is not known, but may be due to the combined effects of neuromuscular paralysis and direct depression by parathion of respiratory and circulatory centres in the medulla.

Cholinesterase Activity

Except for a moderate leucocytosis of 12,000 to 20,000 white blood cells, there were no abnormal findings in ancillary investigations. The urine was normal. Cholinesterase activity of plasma and red blood cells was determined. In four persons severely poisoned, two of whom

died, plasma cholinesterase activity was less than 5% of normal, and that of the red blood cells 14% of normal. In six less severe cases the enzyme activity was reduced to 10% and 22% respectively. The rate of return to normal activity was determined in eighteen cases and found to be for plasma cholinesterase 27% for the first three days, 5% on the fourth day, and only 3% by the tenth day. The enzyme in the red blood cells returned at the rate of 10% for the first three days and subsequently at the rate of 1 to 2% daily. The rate of recovery of cholinesterase activity of both plasma and red blood cells seems to be independent of the degree of exposure or the initial depression. At necropsy, which was performed in five cases, capillary dilatation hyperaemia and oedema of the lungs is described in four cases, oedema of the brain in addition in two cases, and in one there was some pneumonitis present, which was not considered sufficient to cause death (Grob, Garlick, and Harvey, 1950).

Death has occurred after absorption of parathion through the skin and in other instances where the main portal of entry seems to have been the respiratory tract. It has not been possible to determine the exact dosage of parathion which has proved fatal in any single case, either on the day on which symptoms appeared or as a result of previous exposures. On the basis of animal experiments the acute lethal dose has been estimated at 12–20 mg. (1/5–1/3 gr.). Gilman (1950—personal communication) considers that this calculated lethal dose is too high and suggests that the fatal dose is probably a fraction of a milligram per kilogram, a total dose of less than 10 mg. There is no indication at present that any permanent disability results from poisoning by parathion. Acute symptoms last from eighteen to thirty hours in severe cases, and from six to twenty-four hours in patients less severely affected. Mild anorexia, giddiness, and anxiety, with headache and insomnia, may persist for several days, and in a few cases for several weeks. Persons of all ages and of either sex appear to be equally susceptible to the effects of parathion (Grob, Garlick, and Harvey, 1950).

Too little is known about the possible effects of long-term exposure to small amounts of parathion. Provided that the recommendations on the interval between spraying and harvesting of edible crops are rigidly observed it is unlikely that residues on food sprayed with the stable compounds—parathion and O.M.P.A.—will be sufficient to cause symptoms in persons eating such foods. It is less certain that workers harvesting crops or loading and unloading market trucks are not at risk. Twenty-two men developed symptoms of parathion poisoning while picking pears in an orchard which had been sprayed ten days previously. In handling large quantities of materials even slightly contaminated with parathion the risks of absorption through the skin and respiratory tract should be considered and the safety of workers ensured by suitable protective clothing and alternation of work.

Treatment

Symptoms due to overstimulation of the autonomic nervous system and those due to the action of parathion on the central nervous system will respond to the administration of atropine in adequate doses : 1 to 2 mg. (1/60 to 1/30 gr.) should be given at the onset of symptoms and repeated at hourly intervals until the pupils are dilated or the symptoms and signs of pulmonary oedema and excessive salivation and sweating have subsided. Atropine does not protect against the effects at the neuromuscular junction, and artificial respiration may be necessary if neuromuscular paralysis develops. Facilities for prolonged artificial respiration must be available for immediate use in all cases of parathion poisoning.

Where exposure has occurred from splashing of the skin, the clothing should be removed immediately and the patient bathed with soap and water. Since hydrolysis of parathion occurs more rapidly in the presence of alkali, the addition of a mild alkali to the water assists in removing it from the skin. It is important that the person who removes contaminated clothing should be protected against absorption of parathion through the skin by wearing natural rubber gloves. If parathion has been ingested, vomiting should be induced, and this is probably advisable in all cases, since it is likely to be swallowed with nasal mucus. Postural drainage may be necessary when fluid has accumulated in the lungs before atropine has become effective.

The onset of neuromuscular paralysis may occur suddenly and without warning. The patient must be under constant observation so that artificial respiration may be started immediately if this complication develops. It is suggested that equipment for carrying on artificial respiration should be placed at the patient's bedside as soon as he is admitted to hospital. Where muscular weakness results in difficulty in swallowing, tracheotomy should be performed without delay. Relapse has occurred following apparent recovery after the administration of atropine, so that the patient must be kept under observation for at least twenty-four hours after symptoms have subsided. Since susceptibility to small doses of any cholinesterase inhibitor persists until cholinesterase activity of plasma and tissues is restored to normal, persons who have been affected should not return to work with organic phosphates until cholinesterase activity has been shown to be normal. The treatment of poisoning by H.E.T.P. or T.E.P.P. is the same as that of parathion poisoning.

Experience in the United States of America in the 1949 spraying season has demonstrated that, unless all the recommendations made for the safe handling of organic phosphorus insecticides are carried out in detail, serious illness and even death will occur. The stability of parathion and its ready solubility in lipoids may account for the fact that most recorded cases have been observed from the use of either H.E.T.P. or T.E.P.P. Moreover, exposure to minute amounts of H.E.T.P. or T.E.P.P. in spray mist or drift causes immediate constriction of the pupils. The interference with vision is so great that a man is obliged to give up work at once and so avoids any further exposure (W. E. Ripper, 1950—personal communication).

Preventive Measures

Preventive measures both in the factory and in the field should be directed against the risks of absorption by any route. The skin must be protected by overalls which fasten tightly at the neck and at the wrists. Natural rubber gloves, apron, and boots are essential in handling concentrated materials, and sprayers should wear waterproof clothing, including a hat which protects the head and the back of the neck. Complete protection from inhalation can be achieved only by means of a full-face gas-mask with canister designed for protection against organic vapours, acid gases, and smokes (R. A. Fulton, 1950—personal communication).

Chemical cartridge respirators with a facepiece of the half-mask type may reduce the inhalation hazard considerably, but such respirators must be tested and approved for use. The cartridge must be changed at least twice daily, and the facepiece washed in warm water and soap after use. This type of respirator does not give adequate protection for aeroplane pilots, greenhouse sprayers, or those handling concentrated parathion in enclosed spaces. Moreover, up to 16 mg. of parathion may filter through in an eight-hour period, and this together with absorption through the skin around the mask may constitute a fatal dose. Several accidents, some fatal, have occurred where faulty or untested respirators have been used.

Protective clothing, including socks and underclothing, must be laundered each day. Adequate facilities for washing must be available and persons exposed to parathion are advised to remove all working clothes and take a bath at the end of each day's work. If parathion is splashed on to clothing this must be changed completely, and all areas of the skin which have been in contact with the soiled clothing must be washed immediately. The hands and face should be washed thoroughly in hot water and soap before eating and smoking. Whereas these precautions may be enforced in factories it is almost impossible to ensure that they are carried out in the field.

Routine estimations of cholinesterase activity of plasma and red blood cells should be made at weekly intervals in all persons exposed to parathion, H.E.T.P. and T.E.P.P. Davies and Rutland (1950) have investigated the variation in cholinesterase activity of plasma and red blood cells in 200 healthy adults of both sexes. Normal activity may vary from the mean by as much as 40% (see Table). Moreover,

Plasma and Red Blood Cell Cholinesterase: Normal Limits of Variation in Healthy Adults (Mean = 100)

Group	Coefficient of Variation	Mean Normal Limits %
Plasma cholinesterase:		
Service	19·9	60·2–139·8
Males (G.P.)	19·1	61·8–138·2
Females (G.P.)	23·7	52·6–147·4
All Groups	21·2	57·6–142·4
R.B.C. cholinesterase:		
Service	11·8	77·2–122·8
Males (G.P.)	14·4	71·2–128·8
Females (G.P.)	12·1	75·8–124·2
All Groups	15·7	68·6–131·4

After Davies and Rutland (1950).

there is an individual variation of up to 26% for red blood cell cholinesterase and 37% for the plasma enzyme. There may also be a seasonal difference. It is therefore obvious that the significance of reduced cholinesterase activity in random samples of blood is difficult to assess. Every effort should be made to estimate cholinesterase activity in each individual before exposure to organic phosphorus insecticides occurs, and subsequently at weekly intervals. Clearly a more decisive and a more simple test of exposure to these substances is urgently required. Organic phosphorus insecticides should be used only by experienced operators who fully understand the hazards and who are adequately protected and constantly supervised in their work.

I am indebted to the Medical Research Council and particularly to Dr. Donald Hunter for the opportunity to study the toxicity to man of the new insecticides. Special acknowledgment is due to Dr. A. McGhee Harvey and Dr. David Grob, Department of Medicine, Johns Hopkins Hospital, Baltimore, and to Dr. D. R. Davies, Chemical Defence Experimental Establishment, in the United Kingdom.

FOOD-POISONING IN SHEFFIELD IN 1949

BY

E. L. M. MILLAR, M.D., M.Sc., D.P.H.
Deputy M.O.H., Sheffield

AND

MARGARET POWNALL, M.B., Ch.B., D.P.H., Dipl.Bact.
Bacteriologist, Public Health Laboratory, Sheffield
(From the Public Health Department, Sheffield)

During the long hot summer of 1949 seven small outbreaks of food-poisoning in Sheffield produced 36, 4, 20, 37, 9, 1, and 1 cases of illness respectively. Of these 108 cases only 13 were notified by general practitioners and three by hospitals. The remainder came to light through a few of the victims contacting the public health department direct and by the staff of the department making inquiries among other persons likely to be affected.

A food preparer with a septic hand was found to be associated with each of the four outbreaks described below, but the association was not necessarily the cause of the third and fourth outbreaks.

First Outbreak

At 10 p.m. on Wednesday, July 27, 1949, the superintendent of the Infectious Diseases Hospital informed the medical officer of health that he had admitted two patients who were very ill with food-poisoning. A visit was paid immediately to their home and the possible cause of the trouble was ascertained to be a chicken-and-rabbit preparation bought from a near-by shop the previous day.

The shop was visited the following morning and the source of the meat product was traced to a small local food factory which was very clean and well equipped. The chicken and rabbit had been prepared the previous Saturday by two men who boiled the carcasses in a large cauldron, removed the flesh from the bones by hand, and immediately reheated the flesh before packing it into moulds, adding melted gelatin, and then pressing. After cooling, the preparation was stored in a refrigerator until the Monday evening, when it was distributed to five shops where it was kept in refrigerators until sold on the Tuesday and Wednesday. The manufacturer estimated that between 500 and 700 persons would eat the meat.

Although food-poisoning is notifiable in accordance with the Food and Drugs Act, 1938, the great importance of *immediate* notification seemed not to be generally realized. Inquiry was therefore made at the shops, and lists of customers were obtained. When these were visited, a total of 36 persons who had been supplied from one or other of four of the five shops were found to have been affected. Of these, 35 had eaten the chicken and rabbit, and one had eaten black-pudding from the same food factory. Of other persons who had eaten the chicken and rabbit in company with those who were later affected, only three groups (comprising one, two, and three persons respectively) remained unaffected. Two dogs in different households fed on the leavings of the victims remained well.

Of those persons affected, 13 had consumed the meat on the day of purchase and 23 on the following day. One man was unaffected after eating the product on the

day of purchase but had a moderately severe attack of illness when he ate a further portion 20 hours later. There were no complaints regarding taste or appearance. In every case between 1 and 4 oz. (28 and 113 mg.) of meat was eaten.

On the whole the symptoms were severe, five persons being admitted to hospital and several others being in bed at home for some days, with the doctor in attendance. The seven most severely affected persons had all consumed the food about 24 hours after purchase.

Every case suffered from diarrhoea or vomiting, or both. Only five cases did not vomit and in these the illness began 5, 7½, 8½, 10, and 22 hours after eating the food. All but four cases had diarrhoea, and in these four the illness began ½, 2, 5½, and 5½ hours after the food was eaten.

Of the 36 persons affected, five had symptoms beginning within an hour, 21 in one to five hours, and nine in five to ten hours after eating, the longest period between eating the food and the onset of symptoms being 22 hours. This victim was the only one in whom the period was over 10 hours. In the worst cases the period between eating the food and the onset of symptoms was less than 2½ hours and there was pyrexia, dizziness, collapse, abdominal pain, and muscular cramp. One woman was affected even though she had cooked her meat by making "hash."

A total of 13 unaffected households were visited. In 10 of these families the meat had been eaten on the day of purchase, and in three on the following day. In no case had a domestic refrigerator been used.

The weather was exceptionally hot at the time of this outbreak, the maximum and minimum shade temperatures on the Tuesday and Wednesday being 76 and 61° F. (24.4 and 16.1° C.) and 76 and 64° F. (24.4 and 17.8° C.) respectively.

One of the two men who made the galantine was found to have a mild dermatitis of the hands and wrists. The condition had been present since infancy, and he had been employed in his trade for over 30 years. His hands and nose were swabbed at the time of investigation, though an interval of five days had elapsed since he helped to make the galantine. A heavy growth of *Staphylococcus aureus*, coagulase-positive, phage type 6/47/53/54 (that is, the strain was attacked by phages Nos. 6, 47, 53, and 54) was obtained from the hands, but *Staph. aureus* was not isolated from the nose.

Hand and nose swabs were also taken from the four remaining persons employed in the factory. *Staph. aureus* was isolated from the nose and hands of one of these and from the nose of another. Their strains proved untypable, but neither of them had had any contact with the food in question.

Staph. aureus of the same phage type was isolated from portions of galantine removed from the homes of the victims. The number of bacteria per gramme exceeded 20 million, staphylococci predominating. An untypable strain was isolated from a paper bag in which one of those affected had taken the meat in sandwiches for lunch.

From one specimen of vomit and six specimens of faeces, *Staph. aureus*, coagulase-positive, was isolated. Some of these proved untypable, but the following were typed: vomit: phage type 6/47/53/54 (staphylococci numerous on primary plates); faeces: 6/42E/47/53/54 (staphylococci numerous on primary plates); faeces: 6/47/53 and 53/54 (staphylococci isolated only after cultivation in 10% salt broth).

The staphylococci isolated from the faeces were considered by the Central Public Health Laboratory to be probably of the same type as that in the food and as that from the hands of the food preparer. After a week's treatment with penicillin ointment the staphylococci were still present on his hands, but none were isolated after a second week's treatment, though the clinical appearance had altered very little.

Second Outbreak

The second outbreak, on Tuesday, August 23, was associated with an ox tongue brought home from his shop by a butcher on the previous Saturday evening. It was partially cooked the same evening in a domestic pressure-cooker, and cooking was completed the next morning (Sunday) in the same vessel. The butcher's wife then skinned the tongue, and the family of three, consisting of the butcher, his wife, and their adult son, had meals of tongue on the Sunday and Monday, and the wife also had some for Tuesday's lunch, all without ill effect.

On the Tuesday afternoon about ¼ lb. (113 g.) of the cooked tongue was given to a neighbouring family of three persons who ate it between them for tea at 5.15 p.m. The butcher and his wife also had some of the remainder at about the same time. Between 9 and 10 p.m. that evening the butcher's wife and her three neighbours were all seized with severe diarrhoea and vomiting, but the butcher himself escaped. Two of the victims were admitted to hospital and *Staph. aureus*, coagulase-positive, was isolated from the faeces of one of them but unfortunately was not phage typed.

Apart from some weakness, the four victims had recovered by the Thursday morning, when the butcher and his wife and son (who also worked at the shop) were examined. The butcher had a cut on his left thumb which was covered with adhesive plaster; it was very soddened and would not heal. The wife had a slowly healing shallow ulcer the size of a lentil on one of her knuckles. It had been caused by a burn. There were also a few papules on her face. The son appeared healthy.

The bacteriological results were as follows:

Tongue.—Approximately 2,520 million organisms per g. were found, rather more than half of the colonies being *Staph. aureus* coagulase-positive. Three strains were all of phage type 53.

Butcher's Wife.—*Staph. aureus* of phage type 53 was isolated in large numbers from swabs of her hands and nostrils and in smaller numbers from her face. *Staph. aureus* was not isolated from her faeces. She was in fact quite well again by the time a faeces specimen was obtainable.

Butcher.—*Staph. aureus* phage type 53 was obtained in small numbers from swabs of his hands, including the cut, but there was a heavy contamination of faecal organisms which he alleged arose through handling offal. His nose and faeces were negative.

Butcher's Son.—*Staph. aureus* phage type 53 was found on his hands but was not numerous, and *Staph. aureus* of phage type 52A was present in fair numbers in the nostrils.

Staph. aureus could not be isolated from the brine in which the tongue had been salted.

One suspects, therefore, that the butcher's wife was probably the source of the staphylococcal infection which, on the one hand, contaminated the tongue and produced toxin from which the food-poisoning arose, and, on the other hand, infected her husband and son. We particularly noted that this home was exceptionally clean. There was no domestic refrigerator and the weather at the time was very hot.

Third Outbreak

A third outbreak of food-poisoning occurred among a group of 80 probationer nurses who on September 14 consumed a lunch between 12 noon and 1.15 p.m. consisting of braised mutton, gravy, creamed potatoes, boiled dried peas, and sponge pudding with custard. Between 1 and 5 a.m. the next day 20 of them were seized with diarrhoea, colic, vomiting, and dizziness, and a further 40 had mild abdominal pain with no other symptom.

The whole of the food had been prepared by five people on the morning of consumption and it was found that the only items which all the victims had eaten were the meat and gravy and the peas.

When the investigation was made the man who prepared the meat and gravy was not at work; it was later found that he had septic fingers. Apparently he had sustained a small burn on a finger a month previously. This had healed but still remained somewhat inflamed. In addition, two days before the food-poisoning outbreak he had again burned his fingers, and septic blisters had developed, which resulted in his absence from work. A fairly heavy growth of *Staph. aureus*, coagulase-positive, was isolated from each hand.

Unfortunately none of the suspected food remained for examination, and it is unlikely in any case that many organisms would have been found in it as it was eaten hot almost immediately after cooking. The stool specimens from the affected nurses were also negative.

Fourth Outbreak

The fourth outbreak of food-poisoning followed an evening dinner at a café on October 15. The menu comprised soup, roast chicken, stuffing and bread sauce, potatoes, cauliflower, carrots, apple tart with synthetic cream, and coffee. There were 55 diners, of whom 37 were taken ill during the early hours of the following morning, the symptoms being diarrhoea and vomiting. Owing to a delay of almost three days in the notification of this outbreak, nearly a week elapsed before faeces specimens could be obtained from all those persons affected. No *Staph. aureus* or pathogens of the coli-typhoid-dysentery group were isolated from any of the 35 specimens submitted.

None of the food suspected could be obtained, but it was ascertained by interviewing all the diners that only the soup and chicken had been eaten in common by all the victims. The soup had been made entirely from a powder immediately before the meal. A sample of this powder gave a satisfactory bacteriological result.

The chickens were all prepared by one woman who received, cleaned, cooked, and sliced them on the afternoon before the meal. The slices were distributed on plates and remained in a hot chamber for two hours until they were served at about 7.45 p.m. The woman who prepared the chickens was constantly sustaining cuts and scratches from the chicken bones. All swabs of her hands and nostrils taken five days after the dinner gave a fairly heavy growth of *Staph. aureus*, and when one of us examined her nine days after the dinner she was found to have a deep septic puncture wound in the web between two fingers. This she had had for 10 days.

Conclusions

Four outbreaks of food-poisoning in Sheffield during 1949 were associated with *Staph. aureus* infection of the hands of the food preparer. In one outbreak we traced the organism through the food and through the victims. In another we traced the organism to the food, but in the last two outbreaks the specimens required for bacteriological proof of the cause were not available. *Staph. aureus* strains are very common in the nose and septic lesions of people who have never given rise to food-poisoning, and indeed they are not very uncommonly found in the faeces of normal persons. For this reason cultures for phage typing should be made from separate staphylococcal colonies, and more than one colony from each specimen should be examined. From our own cases staphylococci of phage types other than the one incriminated were also obtained. Before concluding that an outbreak of food-poisoning is due to *Staph. aureus*, a strain of a type generally associated with food-poisoning should have been isolated from a number of victims or from one or more victims and food. This evidence was forthcoming only in the first two outbreaks here described.

It is evident that the immediate notification of an outbreak, together with speedy investigation, in which attention is paid to the hands which prepared the food, is important for successful elucidation.

Summary

Four outbreaks of food-poisoning are described, all associated with *Staph. aureus* infection of the hands of the food preparers.

Our thanks are due to Dr. R. E. O. Williams and Miss J. E. Rippon, of the Central Public Health Laboratory, who phage typed the staphylococcal cultures and from whom we obtained most valuable advice. We thank also the sanitary inspectors of the Sheffield Public Health Department for their team-work in obtaining information and specimens for examination.

THROMBOCYTOPENIC PURPURA DUE TO QUINIDINE

BY

G. MOODIE, M.B., B.S.

Although there is a recognized association between quinine and purpura (Wintrobe, 1946), it is very rare for a haemorrhagic state to result from quinidine therapy. In fact, so far as can be ascertained, this is the first case to be reported in England, though five cases have been published in foreign journals.

Case Report

A married woman aged 48 was admitted to hospital on December 28, 1949, in early congestive failure following the onset of auricular fibrillation. She was found to have mitral stenosis, and gave a history of paroxysms of regular tachycardia and paroxysms of auricular fibrillation. There was no past or family history of allergic diseases or of any haemorrhagic diathesis. She asserted that she had not previously received quinidine, and this was checked with other hospitals that she had attended. The auricular fibrillation was confirmed by electrocardiograms and the patient rapidly responded to "digoxin."

Quinidine sulphate, 3 gr. (0.2 g.), was given on December 30 and 31 and regular sinus rhythm resulted. Ten days later (see Chart) a daily maintenance dose of 3 gr. of quinidine sulphate was started after three attacks of paroxysmal regular tachycardia. A slight epistaxis began on January 12, 1950, before the third dose was given, and continued all day. In the evening the patient had a slight vaginal haemorrhage and developed purpura; quinidine was then discontinued, after 9 gr. (0.6 g.) had been given. At first numerous petechiae were present on the legs and the mucous membranes of the lips and gums, with isolated ones on the face, trunk, upper arms, and thighs. During the next twelve hours the rash became more profuse and several ecchymoses developed.

On January 13 a blood smear showed: platelets greatly reduced (fewer than 20,000 per c.mm.); white cells, 5,100 per

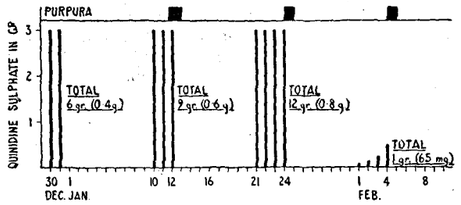

Chart showing the amount of quinidine sulphate given and the time relation between its administration and purpura.

c.mm. (neutrophils 56%, eosinophils 6% (360 per c.mm.), lymphocytes 22%, monocytes 16%). On January 16 the bleeding and clotting times were normal. On January 19 a blood smear showed platelets present in normal numbers; white cells, 7,100.

After nine days' rest quinidine, 3 gr. (0.2 g.) daily, was again started. After the second dose the patient complained of a headache, but this was possibly related to a commencing menstrual period. On January 24 the fourth dose was given in the morning, and that evening the patient developed purpura in a similar distribution.

At 10 a.m. on January 25 Hess's test was normal; a blood smear showed: platelets greatly reduced (fewer than 20,000 per c.mm.); white cells, 4,600 per c.mm. (neutrophils, 60%, eosinophils 12% (552 per c.mm.), lymphocytes 27%, monocytes 1%). No fresh purpura developed, and next day Hess's test was again normal, the platelet count at 3 p.m. was 135,000 per c.mm., but blood taken at this time showed no retraction after 18 hours.

An attempt at desensitization was started on February 1. Quinidine was given in the following very small daily doses—1/12 gr. (5.4 mg.), 1/6 gr. (11 mg.), ¼ gr. (16 mg.), ½ gr. (32 mg.)—but two to three hours after the ½-gr. dose (total 1 gr. (65 mg.) in four days) the patient again developed purpura. This was quite as severe as in the previous episodes, but four days later a blood smear showed platelets present in normal numbers.

Summary of Six Cases of Purpura Due to Quinidine Sulphate

	No. of Times Purpura Occurred	Quantity of Quinidine Sulphate Given Before Purpura	Smallest Dose of Quinidine Sulphate Evoking Thrombocytopenia	Degree of Thrombocytopenia in Each Episode	Platelet Count: Rate of Fall	Platelet Count: Rate of Rise	Eosinophilia
Brock (1941)	2	252–315 gr. (16·4–20·5 g.) 8–6 months before, also 252 gr. (16·4 g.) in previous 14 days	6 gr. (0·4 g.)	23,000 and 24,000/c.mm.	345,000 to 24,000/c.mm. in 6 hours	24,000 to 105,000/c.mm. in 6 hours	—
Burstein and Lamberg (1948)	1 (also thrombocytopenia once without purpura)	66 gr. (4·3 g.) in previous 10 days	15 gr. (1 g.) (i.e., 5 gr. (0·3 g.) 3-hourly for 3 doses)	1,200 and 9,360/c.mm.	Normal to 42,000/c.mm. in 12 hours from start of 3 × 3-hourly quinidine	1,200 to 130,680/c.mm. in 1 day; 9,360 to 65,940/c.mm. in 6 days	—
Larimer (1949)	2	3 gr. (0·2 g.) 3-hourly for previous 4 days	½ gr. (16 mg.)	2 occasions zero	240,000 to 5,000/c.mm. in 4 hours	5,000 to 170,000/c.mm. in 1 day; Zero to 140,000/c.mm. in 4 days	—
Nudelman, Leff, and Howe (1948)	2	9 gr. (0·6 g.) a day for previous 10 days	1½ gr. (0·1 g.)	4,000/c.mm. and zero	Normal to 17,000/c.mm. in 1 hour	4,000 to 152,000/c.mm. in 7 days; Zero to normal in 7 days	—
Soisalo (1947)	1	60 gr. (3·9 g.) 12–6 months before: also 135 gr. (8·8 g.) in previous 28 days	135 gr. (8·8 g.) in previous 1 month	22,000/c.mm.	Not known	22,000 to 94,000/c.mm. in 2 days	480/c.mm.
Present case	3	3 gr. (0·2 g.) a day for 2 days 10 days before	¼ gr. (30 mg.) (1 gr. (65 mg.) in previous 4 days	2 occasions fewer than 20,000/c.mm.	,, ,,	Less than 20,000 to 135,000/c.mm. in 17 hours	360 and 552/c.mm.

Discussion

The time relation between the appearance of purpura and the administration of quinidine sulphate leaves no doubt that the purpura can be attributed to the drug. Brock (1941) published a similar case of thrombocytopenic purpura following quinidine sulphate and also mentioned an oral report of a case observed by Seyderhelm in 1927. Subsequently four other cases have been reported (Soisalo, 1947; Burstein and Lamberg, 1948; Nudelman, Leff, and Howe, 1948; and Larimer, 1949).

It is interesting to compare the findings in the six case reports available. They show several points of similarity; these are summarized in the Table. There are several facts which support the view of Brock (1941) and Soisalo (1947) that this is an allergic type of reaction. In all but one case quinidine is known to have been given over a long enough period for allergy to have developed. In the present case it is interesting to notice that the time relation between the first two courses of quinidine was highly suitable for the development of hypersensitivity. The very small doses required to cause purpura and the eosinophilia in two cases (see Table) also favour the idea of an allergic basis. There is other suggestive evidence, in that a very rapid fall in platelets occurred, and this was usually followed by a rapid remission.

Although it is known that purpura and thrombocytopenia can occur independently of one another (MacKay, 1931), in the cases under discussion marked thrombocytopenia was a constant finding and, when looked for, preceded the appearance of purpura. Thus it seems that a fall in platelets is at least a factor in the production of purpura in these cases, and it is possible that they must fall below a critical level before it occurs. In one case (see Table) thrombocytopenia occurred once without any purpura, which makes it unlikely that the fall in platelets is due to an increased rate of removal to repair capillary damage. Ackroyd (1949) has made an interesting study of "sedormid" purpura, and has produced experimental evidence of both allergic capillary injury and a platelet deficiency. The general features of purpura due to sedormid and that due to quinidine are very similar, and it seems probable that they have a similar pathogenesis.

I am grateful to Dr. H. E. S. Pearson for permission to publish this case, and I wish to acknowledge his help, and the help of Dr. A. L. Jacobs.

OLLIER'S DISEASE: DYSCHONDROPLASIA

BY

SYDNEY G. NARDELL, B.Sc., F.R.C.S.
Surgeon, Whipps Cross Hospital, London, E.11

The introduction of Roentgen rays enabled Ollier in 1899 to describe the disease now generally known by his name. He summarized it as "an affection characterized by irregularity in development, evolution, and distribution of cartilaginous tissue in the bones in process of development, the cartilage seeming to be of normal structure and changing more or less in the direction of ossification." Put more clearly, we may say that Ollier's disease, dyschondroplasia, is characterized by the presence of persistent areas of cartilage in the diaphyses of long bones and short long bones as a result of the failure of normal ossification of cartilage to take place.

Ollier's dyschondroplasia is now clearly differentiated from Keith's diaphysial aclasis, a disease having as its main features multiple exostoses with a strong hereditary factor. Sir Arthur Keith (1920) showed that the so-called exostoses in diaphysial aclasis were in reality bony outgrowths due to defective tubulation in the remodelling process of the long bones during growth. In Ollier's disease there are gradations from persistent islands of cartilage in the metaphysis and diaphysis seen only in the radiographs (and here the importance of radiographs of the whole skeleton is emphasized) to large palpable masses of cartilage. In addition there are small exostoses of irregular formation, not pedunculated and not characteristically pointing away from the end of the bone as are those in diaphysial aclasis. It was partly the presence of these exostoses which has caused confusion in the literature between Ollier's disease and Keith's diaphysial aclasis, but, in addition, it is evident that there are cases occupying an intermediate position.

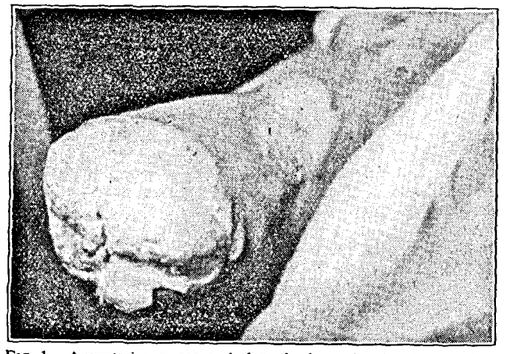

FIG. 1.—Amputation stump and ulcers in the groin, showing the thick everted edges.

The failure of normal ossification of cartilage to take place in the growing ends of bone has as its result that there remain behind in the diaphysis areas of cartilage which do not ossify. These may not be discernible clinically or there may be palpable masses of cartilage to which the term "tumour" in the broadest sense of a lump may be applied. This abnormal growth is not, then, primarily one of true tumour formation, but it is evident that the distinction between a mass of cartilage due to abnormal growth and a true chondroma or neoplasm of cartilage will be a narrow one. The fact that these masses are actually cartilage has been well established by biopsy.

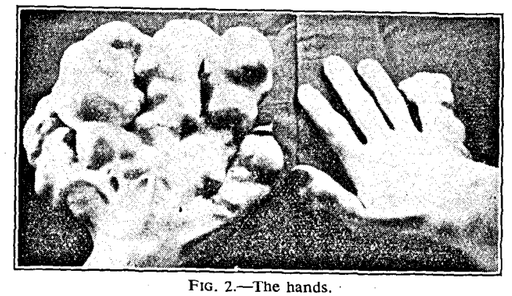

FIG. 2.—The hands.

Certain additional features in the case here reported clearly identify it as belonging to the Maffucci syndrome. This consists of the characteristic features of dyschondroplasia, mostly on one side of the body, with haemangiomata more or less confined to the opposite side. Malignant changes have been observed in some cases in the literature, and they also supervened in the following case.

Case Report

The patient, a man aged 34, was admitted to Whipps Cross Hospital on January 14, 1948. He was apparently normal at birth. Swellings of the left hand were first observed at the age of 5, after his hand had been caught in a door. Later on a nodule came up on the right hand, after it had been struck by a cricket ball. He said he had fractured his left leg eight times while playing football, the last time being in 1930. There was no family history of similar disease.

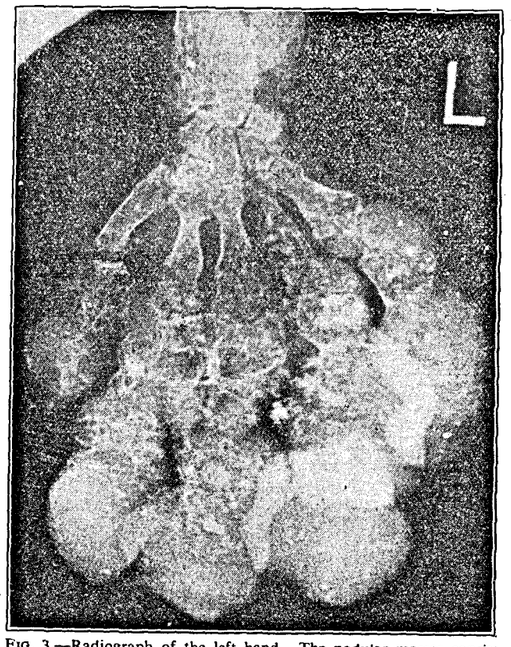

FIG. 3.—Radiograph of the left hand. The nodular masses consist of cartilage with areas of calcification.

FIG. 4.—The left foot, showing multiple hard nodules of the phalanges.

I am much indebted to Dr. H. G. Close and Dr. Malcolm Pearson for the following notes taken after his admission to the Southern Hospital, Dartford, Kent, on February 12, 1945. He was then complaining of pain and a swelling of the right ankle and foot. The right leg was found to be 1 ft. (30 cm.) longer than the left. On the outer side of the right foot was a hard spherical mass with ulceration of the skin below. Biopsy showed this to be a lymphangioma without definite evidence of malignancy. On September 4, 1945, a right below-knee amputation was performed. The skin flaps did not heal satisfactorily, and in January, 1946, enlarged glands were palpable in the right groin. On June 5, 1946, a mid-thigh amputation was performed with the flaps left open, with subsequent secondary suture. On August 14, 1946, inguinal lymph nodes were removed and reported on by Dr. A. H. T. Robb Smith as a "malignant lymphangioma." He subsequently returned home and worked on a barge until Christmas, 1947. The amputation stump then broke down and he developed an ulcer of the right groin.

On admission to Whipps Cross Hospital his condition was as follows. The amputation stump of the right thigh was the seat of a malignant ulcer some 6 in. (15 cm.) in diameter with a thick everted edge and a sloughing floor. There was profuse foul-smelling discharge. In the groin were two ulcers with similar thick everted edges (Fig. 1): a large lower one 4 in. (10 cm.) in diameter over Scarpa's triangle and an upper smaller ulcer near the symphysis pubis. The healed biopsy incision can be seen in the photograph, the ulcers evidently being due to fungation of further malignant glands in the groin.

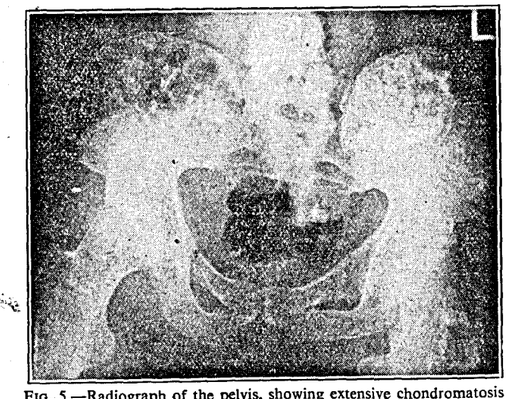

FIG. 5.—Radiograph of the pelvis, showing extensive chondromatosis of both wings of the ilia.

The hands are seen in Fig. 2. The fingers and thumb of the left hand show hard, irregular, but fairly smooth masses over which the skin is tightly stretched. Blue veins course over the cartilaginous masses. He was able to move his fingers a little and some nails were still present. Sensation was present. The right hand showed chondromata of the thumb and little finger only, and was a useful member.

The radiograph of the left hand (Fig. 3) shows the nodular masses on the fingers to be cartilage with areas of spotty calcification. The phalanges and the interphalangeal joints have almost disappeared, but a thin layer of cortical bone remains in some places. The metacarpals approach more nearly to normal, but they are shortened and there are obvious areas of cartilage with spotty calcification in the epiphyses, metaphyses, and diaphyses. The carpus is practically normal. The lower ends of the radius and ulna are broadened and somewhat striated, and there are areas of cartilage and spots of calcification. No Madelung's deformity is present.

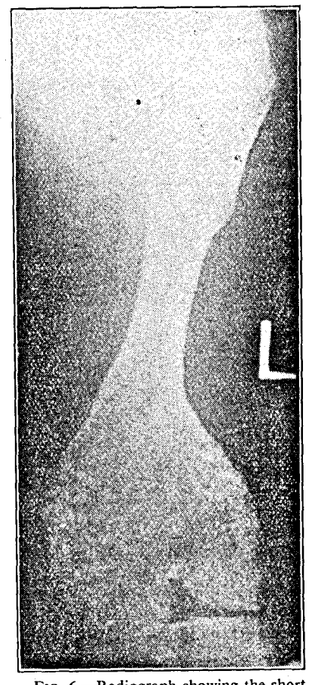

FIG. 6.—Radiograph showing the short left femur, the lower end of which is seen to be greatly broadened.

Fig. 2 shows the Madelung deformity of the right hand, and a radiograph showed the shortened broad radius with some persistent cartilaginous areas, although the lower end of the ulna is not much affected and does not illustrate the bayonet shape mentioned in the literature. There are irregular cartilaginous and bony outgrowths of both phalanges of the right thumb, and a nodule of cartilage in the head of the metacarpal. Two areas of calcification are seen in the head of the second metacarpal, but otherwise the metacarpals and phalanges of the index, middle, and ring fingers are normal. The little finger shows areas of cartilage and bony outgrowths in the distal end of the metacarpal and all phalanges. The carpus is normal.

The left foot (Fig. 4) showed multiple hard nodules of the phalanges, especially of the second, third, and fourth toes, with the remainder of the foot normal. A radiograph showed the tarsus to be more or less normal, though the astragalus has some deformity of its articular surface. There is a clear area in the os calcis near the calcaneo-cuboid joint. Broadening and striation of the lower end of the tibia and short irregular bony outgrowths are present. The masses in the toes are translucent and largely cartilaginous.

The face and skull were normal and showed no asymmetry. The sclerotics were of normal colour. The patient was of good intelligence and stated that he had been getting around on crutches and working on barges until shortly before admission to hospital. A radiograph of the skull was normal. There were no patches of pigmentation on the skin. The cardiovascular system and lungs were normal clinically. The urine was normal—no Bence-Jones proteose was present.

The abdomen was normal to palpation, but a radiograph of the pelvis (Fig. 5) showed extensive chondromatosis of both wings of the ilia. These were not abnormal to palpation. The absence of dense radiating lines in the ilia (raies sombres of Voorhoeve) is noteworthy. As pointed out by Hunter and Wiles (1935), this is probably due to the age of the patient, the radiating lines appearing in the pelvis and other parts of the skeleton in children only.

An *x*-ray film showed a little broadening of some ribs, but no evidence at that time of metastases in the lungs.

The left thigh was short for the patient's general build, and hard masses were felt at the lower end of the femur and upper end of the left tibia and fibula. He had a good range of movement in the knee-joint. Fig. 6 shows the rather short left thigh, but the lower end of the femur is particularly interesting. The lower end broadens in the trumpet-like fashion of diaphysial aclasis, with a broad metaphysis, its sides being approximately parallel. There are extensive areas of cartilage persisting in the metaphysis and epiphysis, and some deformity is evident in the lateral view (Fig. 7). The areas of cartilage in the tibia and the irregular small exostoses, not pointing towards the ends of the bone, are seen.

The angular bends of dyschondroplasia described by Jansen are well seen in the radiograph of the humerus (Fig. 8). The shoulder- and elbow-joints are normal, though the upper ends of the humerus are somewhat broadened. There is a spindle-shaped swelling of well-calcified bone in the middle of each humerus with angulation. There has evidently been dysplasia earlier in growth, with "healing" as Ollier described. Little persistent cartilage is here seen in the shafts.

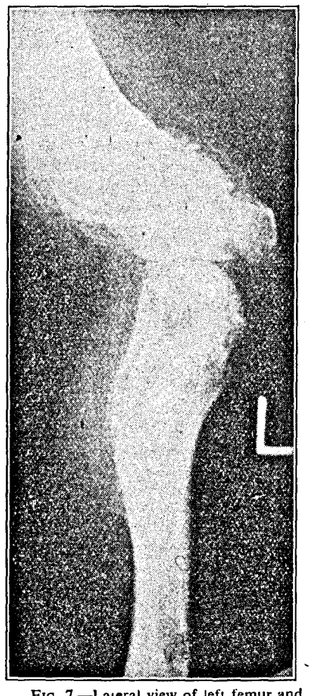

FIG. 7.—Lateral view of left femur and tibia, showing areas of cartilage in the tibia and irregular small exostoses.

A blood count showed: haemoglobin, 76%; red cells, 5,100,000; colour index, 0.74; mean diameter of red cells, 7.3 μ; white cells, 13,500 c.mm. (polymorphs 79%, lymphocytes 10%, monocytes 5%, eosinophils 6%). Serum calcium was 10 mg. per 100 ml.; plasma phosphate 2.3 mg. per 100 ml.; serum acid phosphatase 3.2 units; serum alkaline phosphatase 5.5 units. The Wassermann and Kahn reactions were negative. Biopsy of the amputation stump showed malignant lymphangioma.

Course. — Deep *x*-ray therapy at the London Hospital under Dr. Frank Ellis caused considerable improvement in the fungating ulcers of the amputation stump and groin. The ulcers cleaned up, the thick everted edge became flat, and some epithelization from the edges took place. Subsequently, however, his condition deteriorated and metastases appeared in the lungs. He died in November, 1949, and permission for necropsy was not obtained.

Comment

This case illustrates the essential features of Ollier's disease recorded in the considerable literature on the subject, and the history and appearances may be regarded as typical. The prognosis as regards life appears fairly good, considering that the Maffucci syndrome must be regarded as a mesodermic dysplasia beginning in foetal life. Our patient was 35 years of age at death, and of the 20 cases traced by Carleton *et al.* (1942) the average age was 33. The high proportion of cases (25%) which became malignant is noteworthy.

I am indebted to Mr. B. Cook, of Messrs. Cook and Perkins, Tottenham, London, for the photographs of this case and for the reproduction of the radiographs.

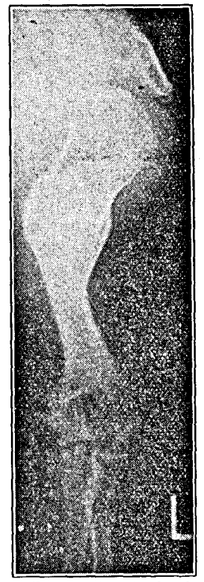

FIG. 8.—Angular bends of dyschondroplasia in the humerus.

Sports facilities for hospital patients and staff are among the amenities on which Exchequer money may properly be spent, according to a circular sent by the Ministry of Health to hospital boards and committees. Free moneys should be used to the maximum extent compatible with other claims on them, but, where there is not enough, reasonable expenditure may be met out of Exchequer funds if the necessary provision has been made in the estimates as approved. Wireless may be provided at Exchequer cost, as may a film projector when considered necessary on therapeutic grounds—for example, in mental hospitals. Concerts, dances, and parties should be regarded as a proper charge on free moneys, but newspapers and magazines in the wards may be provided out of Exchequer money. Amenities provided exclusively for the benefit of the staff should normally be paid for from free moneys and only exceptionally by the Exchequer.

LYSIVANE THERAPY FOR PARKINSONISM

BY

HAROLD PALMER, M.D., M.R.C.P., D.P.M.

AND

D. J. A. GALLAGHER, M.B., Ch.B., M.Med.Sc.

(From the Department of Psychiatry, Dunedin Public Hospital, N.Z.)

The claims made by French workers (Bovet *et al.*, 1947; Sigwald, 1947, 1949; Sigwald *et al.*, 1947) for "diparcol" in the symptomatic treatment of parkinsonism have been confirmed by Duff (1949), Gray (1949, 1950), and Palmer and Black (1949), but the mortality may be in the region of 5%. This paper reports our findings with "lysivane" (N-(2-diethylamino-n-propyl)phenothiazine hydrochloride), a member of the same series of drugs as diparcol.

Both lysivane and diparcol are substituted phenothiazines (the substitution group being the active principle) which have been evolved by Bovet *et al.*, followed by Sigwald *et al.*, whose interest seems to have been derived from the observation that certain drugs of the antihistamine series were capable of benefiting patients suffering from parkinsonism. This benefit they thought was due to the relatively specific action of this series of drugs on the extrapyramidal centres. In addition to this selective action, these drugs (which include such members as "benadryl," "phenergan," diparcol, and lysivane) have a general pharmacological action on the central nervous system, promoting drowsiness, and have other more specific actions, including parasympathicolytic (ganglioplegic) properties. They also have sympathicolytic activity and an anti-acetylcholine and spasmolytic action.

The Parkinson syndrome comprises two main varieties—that which is associated with old age (paralysis agitans), and that which follows encephalitis lethargica. Both varieties have in common a tendency towards muscular tremor which can be coarse or fine (noted in this study to be fairly constant at 5 a second), rigidity and weakness, and an alteration in the psyche. No adequate descriptive term can be given for the change in the mental attitude of these patients, but it includes some apathy, depression, and peevishness, and a paucity of interest, all of which in combination place a peculiar burden on those relatives who are called upon to look after the patients. In many cases this change constitutes the major incapacitating symptom. Parkinsonism following encephalitis lethargica has, in addition, its own peculiar mode of expression, both in the psychical and in the somatic sphere, and in this type oculogyric crises (not encountered in paralysis agitans) are amongst the more troublesome symptoms. In both conditions orthopaedic deformities are apt to develop. Anything one can do to help these patients relieves in turn the despondency which so often descends upon their relatives. In the more practical realm of everyday life a return of the ability to perform the finer movements involved in dressing, writing, feeding themselves, and attending to their toilet is a tremendous contribution to their own and their family's welfare.

This paper reports our experience with 16 patients treated with lysivane, the general purpose of the research having been promoted by the Otago Old People's Welfare Council.

Dosage

The drug is supplied in 0.05-g. tablets. All patients, in the course of one week, were placed on their characteristic effective dose, which varied from 4 to 10 tablets a day. At first we confined our maximum to five tablets daily, but it seems that this leaves a very large margin of safety and some patients did not achieve maximum benefit on this dosage. Up to 20 tablets a day have been used by Sigwald. In view of the fatality encountered with the use of diparcol we have been cautious. We believe that, as further experience is gained and more is known about the clinical toxicity of these drugs, a higher dose may be permissible and better results than those we are recording will be achieved.

The accompanying Table records the effects of our treatment on individual symptoms, as well as the general effect on the patient.

Analysis of Cases

Case No.	Age and Sex	Aetiology	Major Cause of Disability	Disablement	Rehabilitation
1	52 M	Post-encephalitic	Tremor, rigidity, weakness, depression, festination	Walks with aid; fed, shaved, dressed. Partial invalid	Walks, feeds, shaves, dresses unaided. 5 tabs./day for 3 m. (2) Stramonium 15 gr. daily
2	62 M	Senile	Rigidity, weakness, depression, festination	Total invalid	Walks, feeds, shaves, dresses unaided. 10 tabs./day for 3 m.
3	36 F	Unknown	Unilateral tremor	Writing difficult; patient a teacher	Writes normally; tremor absent. 4 tabs./day for 3 m.
4	37 M	Post-encephalitic	Oculogyric crises daily; rigidity, tremor, depression	Crises confine patient to house	Crises 2 a week on diparcol; 1 a week on lysivane 6 tabs./day for 3 m.
5	46 M	Senile	Tremor (arms)	Tremor interferes with fine movements	Can roll cigarette; tremor absent. 6 tabs./day for 2 m.
6	73 F	,,	Tremor, rigidity, weakness, festination, retropulsion, extreme retardation	Total invalid; appearance of senile dementia	Walks, feeds unaided. Mental activity restored. 6 tabs./day for 2 m.
7	59 M	,,	Tremor, depression, slow indistinct speech	Socially incapacitated	Tremor absent, speech clearer. 4 tabs./day for 1 m.
8	60 F	,,	Tremor, rigidity, weakness, depression, retropulsion	Total invalid	Walks, dresses unaided; tremor absent. 6 tabs./day for 2 m.
9	59 F	,,	Tremor, rigidity, weakness, depression, deformity	,, ,,	Walks with aid, dresses; deformities reducing; tremor reduced. 8 tabs./day for 2 m. (2) Stramonium 30 gr. daily
10	53 M	,,	Tremor, weakness, depression	Difficulty in dressing and writing	Writing and ability to dress regained; tremor absent. 6 tabs./day for 1 m.
11	72 F	,,	Tremor, weakness, slow speech, depression, festination	Walks with aid; cannot dress or feed unaided; given up social life. Partial invalid	Walks, dresses, feeds unaided. Loss of depression. 4 tabs./day for 1 m.
12	63 M	,,	Tremor (unilateral)	Socially incapacitated	Tremor controlled. 4 tabs./day for 2 w.
13	68 M	,,	Tremor, rigidity, weakness, depression, festination	Walks with aid; fed and dressed. Partial invalid	Walks unaided; stronger. 4 tabs./day for 2 w.
14	62 F	,,	Tremor, weakness, depression	Foot drags; difficult to manage housework. Given up social life	Improving. 4 tabs./day for 1 w.
15	49 M	Post-encephalitic	Tremor, oculogyric crises, slow speech, festination. Focal epilepsy	Surgical treatment left slowness of speech (and focal epilepsy)	No further improvement on 4 tabs. daily
16	65 F	Senile	Tremor, rigidity, festination, retropulsion, depression	Difficulty with walking and fine movements	Improved on 4 tabs. daily. Treatment not continued owing to isolated home conditions

Results

Rigidity responds better than tremor when the two occur in combination. Tremor alone responds best of all.

We believe that restoration of that controlled background of muscular tone upon which all voluntary movement is based determines the favourable response to lysivane, though some degree of tremor may persist. Festination and retropulsion disappear, the patient ceases to be the important claimant on his relatives' attention, and the tremor becomes a matter of the transient emotional tension to which even normal individuals are prone.

In our opinion the most striking case, and one which illustrates the importance of viewing a patient as a whole as opposed to estimating the effect of the treatment on symptoms, is Case 6. On admission to hospital this patient resembled a senile dement. She was confined to bed in a rigid, hopeless state, with little contact with the outside world, and with all the implications which this state of affairs had for the nursing staff of the home for the aged where she was being nursed. She walked out of hospital unaided, had assumed quite a charming personality, and returned to the home to gladden the hearts of her fellow patients and to encourage the staff in their humanitarian care of the ageing and chronic sick. In a case like this we do not feel disposed too narrowly to estimate benefit in terms of isolated symptoms alone.

Of our 16 cases 12 were treated as out-patients, receiving no other form of therapy. We mention this fact since the remainder whilst in hospital may have derived benefit from rest in bed and the physiotherapy which was given. One patient (Case 15) suffering from post-encephalitic parkinsonism and showing tremor, oculogyric crises, and festination, who had received surgical treatment in the U.S.A. which relieved all symptoms, except bradyphasia and depression (partly due to a post-operative complication of focal epilepsy), obtained no benefit from lysivane.

Toxicity

The laboratory findings of the French workers place the available drugs in the following descending order of toxicity (in rats): phenergan, diparcol, lysivane.

As we have had no deaths with lysivane in spite of one patient stopping the treatment suddenly, and in view of our one fatality with diparcol, we infer that our experience bears out the laboratory findings.

Clinical toxic events are as follows: (1) Drowsiness and lassitude, with or without vertigo, appearing half an hour after dosage and lasting one to two hours, most apparent early in treatment. These effects eventually disappear and are countered effectively by strong coffee or by amphetamine sulphate. (2) Formication, irritation, and cramps are paraesthesiae related to parkinsonism rather than to drug therapy. These are perhaps, strictly speaking, not toxic effects so much as release phenomena consequent upon the treatment of the basic condition. They are relieved by aspirin and disappear in some weeks. (3) Dryness of the mouth, transient diplopia, vasomotor reactions; these are rarely found, and disappear spontaneously.

In the present study only the first group of toxic symptoms was observed and in no case was it necessary to discontinue treatment. In Sigwald's series six out of 106 patients treated suffered vertigo or cramps, necessitating discontinuation of treatment.

An interesting feature was the tendency for patients to show a marked initial improvement followed by some relapse and then a final upward movement until stability had been reached. This probably refers to the placebo effect of encouragement which operates at a maximum initially.

One case (No. 4) previously treated with diparcol gave an improved response to lysivane.

Sigwald has recorded, however, that lysivane was greatly superior to all other forms of treatment in 46 out of 106 cases, identical in 29, and inferior in 4.

Relation to Other Forms of Treatment

One of the advantages of lysivane therapy is that the drug can be combined with other forms of treatment—for example, stramonium. Indeed, in two of our cases which had previously derived benefit from stramonium, lysivane alone was to some extent disappointing, though improvement undoubtedly occurred. When, however, the two drugs were given in combination the final effect was far superior to that achieved by stramonium, or, indeed, by either one separately. It would seem, therefore, that patients suffering from parkinsonism should also be tried with lysivane in combination with stramonium.

With lysivane alone one patient who suffered from oculogyric crises, and who formerly had had attacks daily, had the attacks reduced to one or two a week.

All the remarks concerning withdrawal which apply to diparcol apply by inference to lysivane, but one old lady stopped her treatment while having five tablets a day, with no untoward result. For the time being, however, it would seem to be mandatory that all patients should be carefully instructed never to withdraw the drug suddenly.

Conclusion

Lysivane is capable of affecting beneficially any symptom or complex of symptoms from which the parkinsonian patient is suffering—notably his mentality. We would estimate our findings in general as follows: complete alleviation, 1; good result, 10; improved, 4; and no change, 1 (patient and relatives concurred in cessation of further treatment).

We wish, however, once more to reiterate the dangers of attempting to evaluate results on too narrow a symptomatic basis and are content to assert that in our opinion lysivane does all that is claimed for it in a manner which is safe for the patient. It may confidently be recommended, therefore, as a valuable remedy in the treatment of this condition.

We propose to extend our work to the other drugs for which claims have been made, and this will be reported in a subsequent paper.

We wish to thank Messrs. May and Baker Ltd. for a very generous supply of lysivane, and those practitioners of Dunedin who have so kindly sent patients for clinical treatment.

A booklet on the *Superannuation Scheme for Those Engaged in the National Health Service* has been prepared by the Ministry of Health. It will be issued to new entrants to the Health Service free of charge, and is also obtainable from H.M. Stationery Office for 3d. The scheme is described in plain language, and specific examples are given on how it works.

RELATIVE INCIDENCE OF GASTRIC AND DUODENAL ULCERS

BY

EILEEN M. BROOKE, M.Sc.

General Register Office

The relative incidence of gastric and duodenal ulcers is a subject about which there is some divergence of opinion. Before the war, owing to the absence of any national morbidity statistics, the only sources of information were records of individual hospitals and the Registrar-General's returns of deaths. During the war a study was made of the causes of admission to E.M.S. hospitals, thus providing a rather larger and more uniform, though admittedly biased, set of data. The Survey of Sickness was also begun, involving sampling over the national field, though the data may be open to question as depending on the memory of the person interviewed and his statement of diagnosis. Both death returns and hospital studies showed a preponderance of gastric over duodenal ulcers, yet it was a commonly held opinion that the proportion of duodenal to gastric ulcers was five to one or possibly higher.

The Registrar-General's returns distinguish duodenal ulcer from ulcer of the stomach. The latter term includes, in the *International List of Causes of Death*, the somewhat vague term "peptic ulcer," but where a certificate bears this term inquiry is made regarding the exact site, so that only those ulcers whose site is not known are left in this group. The numbers of deaths in England and Wales for the periods 1929–38 and 1939–47 are shown in Table I.

TABLE I.—*Deaths from Ulcers of Stomach and Duodenum, 1929–47*

	No. of Deaths				Average Annual Deaths†			
	1929–38		1939–47*		1929–38		1939–47	
	M.	F.	M.	F.	M.	F.	M.	F.

Ulcer of stomach ..	21,109	8,391	22,080	7,398	2,111	839	2,413	822
Ratio D.U./G.U. ..	0·55	0·24	0·64	0·30				

* Including non-civilians. † Non-civilians only.

In the earlier period duodenal ulcers formed 36% of all ulcer deaths among males, and in the latter period, 39%. There is a significant difference between these percentages (difference = 3.47 ; 2 S.E. = 0.74). In the case of female deaths, duodenal ulcers accounted for 20% and 23% of all ulcer deaths, showing also significant difference between the two periods (difference = 3.76 ; 2 S.E. = 1.16). Among non-civilian males there were 361 deaths from gastric ulcer and 292 from duodenal ulcer during 1939–47. Excluding non-civilians on the grounds that Service men may be subject to conditions of strain which would tend to produce a high incidence rate of duodenal ulcer, and comparing the average annual deaths in the two periods, duodenal ulcers showed an increase of 32% compared with 14% for gastric ulcers among males, while female deaths showed corresponding changes of + 23% and −2%. New rules for assignment in cases of death from joint causes were in force from 1939 onwards. If correction factors be applied to the death figures for 1929–38 to make them comparable with those for 1939–47, the corresponding increases or decreases in the average annual deaths would be: males, duodenal ulcer +30%, gastric ulcer +12% ; females, duodenal ulcer +20%, gastric ulcer −5%.

The percentage increases or decreases in male deaths from ulcers in various age groups are shown in Table II.

TABLE II.—*Average Annual Deaths from Gastric and Duodenal Ulcers, 1929–38 and 1939–47. Males*

,, 55 up ..	562	896	897	+59·4	+56·4	+59·6	+56·5

* Based on figures for 1929–38 to which correction factors have been applied.

Whether all males are considered, or only civilians, the average annual deaths from gastric ulcer in 1939–47 were fewer than in 1929–38 in all the five-yearly age groups from 15 to 54, the overall decrease for these ages being more than 10%. From 55 upwards each quinquennial age group showed an excess in the second period, the increase at ages 55–64 being 34%, and at 65 and over 56%. The average annual deaths from duodenal ulcer were fewer in each five-yearly age group from 15 to 34, the decrease being 31% in the case of civilians only and 18% if non-civilian deaths are included. At ages 35–54 the rate was 18% higher in the second period, and at ages 55 and upwards 60%. The striking increase in deaths from both types of ulcer in the higher age groups is out of all proportion to the alteration in the age structure of the population. The effect of applying conversion ratios to the figures for 1929–38 is to reduce the increases by 2 or 3%.

In a one-fifth sample of male Service patients admitted to E.M.S. hospitals as in-patients during 1940–7 there were 1,395 cases of gastric, 5,199 of duodenal, and 387 of peptic ulcer. Hence there were 3.7 times as many admissions for duodenal as for gastric ulcer, while the ratio of duodenal to gastric and peptic ulcers was 2.9. Whereas in civilian life it may be possible for patients with duodenal ulcers to carry on with the aid of treatment from their family doctors, while those with stomach ulcers would more often have to go to hospital, it seems probable that most Service men with duodenal ulcers would be sent to hospital, owing to the difficulties of treatment and diet. It may well be, therefore, that the E.M.S. figures give a truer picture of the relative incidence of duodenal and gastric ulcers than other sources. Table III shows the age distribution and the ratio of duodenal to other ulcers of the stomach among male Service patients admitted to E.M.S. hospitals.

The ratio of duodenal to gastric ulcers for all ages rose from 2.9 in 1940 to 4.7 in 1942 and then declined to 4.1 in 1946–7. This may reflect not so much a change in relative incidence as the fact that in the later war years, when owing to the increase in battle casualties there was more demand for hospital beds, it was no longer policy to send so many cases of duodenal ulcer to hospital. For the whole period 1940–7 there were 4.3 times as many men admitted with duodenal as with gastric ulcers in the age group 15–34 and three times as many at ages 35–44. The proportion of duodenal to gastric ulcers was generally greater in the age groups under 34. Although the ratio in these age groups declined in 1943 and 1944, it was rising again by 1947.

TABLE III.—*E.M.S. Hospitals. Men admitted for Gastric, Duodenal, and Peptic Ulcers, 1940–7. (One-fifth sample)*

1946 and 1947	Gastric ulcer	19	32	23	74	—	74
	Duodenal ulcer	98	147	53	298	6	304
	Ratio D.U./G.U.	5·2	4·6	2·3	4·0	—	4·1
	Peptic ulcer	5	8	6	19	4	23
	Ratio D.U./(G.U. and P.U.)	4·1	3·7	1·8	3·2	1·5	3·1
Total 1940–7	Gastric ulcer	220	579	509	1,308	87	1,395
	Duodenal ulcer	940	2,528	1,524	4,992	207	5,199
	Ratio D.U./G.U.	4·3	4·4	3·0	3·8	2·4	3·7
	Peptic ulcer	54	164	133	351	36	387
	Ratio D.U./(G.U. and P.U.)	3·4	3·4	2·4	3·0	1·7	2·9

Comparison of the E.M.S. admissions may be made with those for the New York Hospitals, 1933, and Cardiff Royal Infirmary, 1946, which are shown in Table IV.

TABLE IV

	E.M.S. Hospitals (Males), 1940–7	New York Hospitals, 1933	Cardiff Royal Infirmary, 1946
Ulcer of stomach ..	1,782	1,783	67
Duodenal ulcer ..	5,199	2,248	58
Total ..	6,981	4,031	125
U. of S. as percentage of total	25·53	44·23	53·60

The differences between the percentages of stomach ulcers and those of all ulcers in these three groups are:

E.M.S. and New York ..	Difference, 18·70	..	Standard error,	1·88
E.M.S. and Cardiff ..	,, 28·07	..	,, ,,	8·98
New York and Cardiff ..	,, 9·37	..	,, ,,	4·52

The differences between the E.M.S. figures and those for Cardiff and New York are therefore highly significant ; that between New York and Cardiff is barely so. It seems reasonable to infer from this, either that E.M.S. patients were drawn from a population more subject to duodenal ulcers than the general one, or else that, while they showed the same proportion of duodenal to gastric ulcers as the general population, more cases of duodenal ulcer came into hospital.

TABLE V.—*Social Survey, 1947. Total Illnesses—New, Recurrent, and Continuous*

Diagnosis	Males				Females			
	16–44	45–64	65 Up	All	16–44	45–64	65 Up	All
Gastric ulcer ..	77	81	23	181	18	39	21	78
Duodenal ulcer ..	128	126	19	273	27	28	6	61
Peptic ulcer ..	21	12	4	37	—	6	4	10
D.U./G.U.	1·7	1·6	0·8	1·5	1·5	0·7	0·3	0·8
D.U./(G.U. and P.U.)	1·3	1·4	0·7	1·5	1·5	0·6	0·2	0·7

Table V shows the number of people recorded by the Survey of Sickness as reporting ulcers during 1947. The figures given are for all illnesses reported, whether new, recurrent, or continuing from a month prior to that of interview. Those who were in hospital at the time were not included in the inquiry. For men of working age these figures again show a preponderance of duodenal over gastric ulcers. The same is roughly true of women, since relatively few are in gainful occupations after they reach the age of 45. The proportion of duodenal to all ulcers differs significantly between the sexes (difference, 11·20 ; S.E., 4.59), but not between men aged 16–44 and 45–64 (difference, 0.29 ; S.E., 4.69).

Statistics of cause of death do not distinguish cases of haemorrhage and perforation. The relative proportions in the E.M.S. sample and the Cardiff Royal Infirmary discharges are shown in Table VI.

TABLE VI

	E.M.S. Hospitals, Males, 1940–7		Cardiff Royal Infirmary, 1946	
	Proportion %	Case Fatality Rate (%)	Proportion (%)	Case Fatality Rate (%)
Gastric ulcer:				
Perforation ..	24·9	6·1	40·4	26·1
Haemorrhage ..	4·6	3·1	17·5	10·0
Unqualified ..	70·5	0·2	42·1	4·2
Duodenal ulcer:				
Perforation ..	10·6	4·7	13·8	12·5
Haemorrhage ..	2·2	3·5	12·1	28·6
Unqualified ..	87·2	0·2	74·1	4·7

Tidy (1944) has stated that the case fatality rate taken over a long period at St. Thomas's was 12.5% for gastric and 10% for duodenal ulcers. This may be compared with 13% for gastric and 7.6% for duodenal ulcers in the New York Hospitals in 1933, and with 11.9% for gastric and 8.6% for duodenal ulcers at Cardiff Royal Infirmary in 1946. The experience in the New York Hospitals in 1933 showed 2,248 duodenal ulcers with 172 deaths and 1,783 gastric ulcers with 225 deaths. On this basis the expected deaths from 1,782 cases of gastric ulcer in the E.M.S. sample would be 225, compared with 21 actual deaths, while from 5,199 cases of duodenal ulcer 398 deaths would be expected, compared with 37 actual. This strengthens the impression that cases were admitted to E.M.S. hospitals which would not normally be treated in hospital. It may be hoped that when statistics become available from the Ministry of National Insurance and from the Registrar-General's National Morbidity Inquiry, fresh light will be shed on the relative incidence of duodenal and gastric ulcer.

Medical Memorandum

Chronic Subdural Haemorrhage Associated with Schizophrenic Reaction

Subdural haematoma has been described as "an entity which despite its comparative frequency still remains, on occasion, a neglected or unsuspected lesion for the general practitioner, and one that is difficult of diagnosis for the neurologist or neurosurgical specialist" (Oldberg, 1945). An early diagnosis makes all the difference in prognosis, as timely surgical intervention yields favourable results. The following case was, unfortunately, diagnosed only at necropsy.

CASE REPORT

A Gurkha soldier aged 20 was admitted to a military hospital in August, 1946, in a state of excitement, mumbling some unintelligible phrases. He had been sleeping poorly and been dirty in his habits. The duration of these symptoms was two days. A careful physical examination was negative and he was afebrile. There was no history of a similar illness in the past or of an accident or other trauma. Two days later he was transferred to the psychiatric centre of a larger military hospital, where he was found to be dull, apathetic, self-absorbed, and withdrawn. He had no impairment of orientation or memory, but there was definite evidence of visual hallucinations associated with abnormal conduct. A detailed physical examination, including the cerebrospinal fluid and the fundi, made at this stage was again negative.

As the symptoms were typical of a schizophrenic reaction type clinically, a course of "phrenazol" shock therapy was prescribed. Three injections of 10% solution, 7 ml. each, were given at two-day intervals, and each resulted in a good convulsion. There was a slight improvement, but the treatment had to be discontinued because the stock of the drug was exhausted. About six weeks later (50th day of the illness) another phrenazol injection was given, but this produced no change in the patient's condition, so convulsive therapy was discontinued. He remained the same until nineteen days later (69th day), when he refused food and drink and vomited frequently. He was still afebrile; there was no neck rigidity and Kernig's sign was negative. Systemic examination did not reveal any abnormality. Next day the vomiting stopped and he started taking fluids. On the 79th day of illness his condition became worse and he suddenly went into coma with a temperature of 100° F. (37.8° C.), and dilated and inactive pupils. His breathing became stertorous and he died a few hours later. He had a neutrophil leucocytosis (14,200 per c.mm.) a few hours before death, the differential count being polymorphs 86% and lymphocytes 14%. The cerebrospinal fluid was clear and transparent; a manometer was not available, but the pressure seemed appreciably increased. The specimen revealed: cells, 2 per c.mm.; proteins, 30 mg. per 100 ml.; globulin, not increased: chlorides, 740 mg. per 100 ml.; sugar, normal. The Wassermann reaction was negative. Urine showed no abnormal ingredient. Examination of the nervous system did not reveal any localizing signs even a few hours before death, and the fundi appeared normal.

Post-mortem examination showed that the scalp was free of any evidence of old haematoma and no skull fracture was found in any part; the meninges were not under pressure. On the left side overlying the entire cerebral hemisphere and filling the upper fossa, with replacement pressure on the brain tissue, was a huge subdural haematoma which showed evidence of long standing. No tear of venous sinuses or aneurysm of vessels could be found, and the source of bleeding remained obscure. The haemorrhage itself was becoming liquefied and not organized; much of it, however, was still a spongy gelatinous clot with formation of a kind of false membrane about it but no definite attempt at localization, except that it seemed to be most closely associated with the dura itself and limited by its boundaries. No leak had occurred into the subarachnoid space, and the cerebrospinal fluid in the ventricles was clear without even discoloration. Gross softening of the brain tissue itself was not evident in any part, but in the substance of the pons small centrally placed haemorrhages had occurred apparently as a terminal effect of stem pressure. In the opinion of the pathologist conducting the necropsy (Major Elkarton) the most reasonable explanation of the collection of this large chronic subdural haemorrhage was a minute venous leak over a prolonged period, most probably due to unrecognized trauma.

COMMENT

The possibilities in this case are: (1) That the patient's original mental symptoms eleven weeks before death were due to a subdural haemorrhage following a minor injury which he had forgotten, and that the convulsive therapy possibly aggravated the condition. The last phrenazol injection was, however, given a month before the patient's death, and no worsening in his condition was noticed until 19 days later. (2) That the patient's original symptoms were due to a true schizophrenic illness, and that he sustained a minor trauma, which was unnoticed, while under treatment in hospital for his mental condition, resulting in a subdural haemorrhage which proved fatal. (3) That the subdural haemorrhage was a complication of the convulsive therapy.

The first appears to be the most plausible explanation, though the others cannot be conclusively ruled out.

Subdural haemorrhage is not known to have been reported as a complication of convulsive therapy or of epilepsy, and authorities like Henderson and Gillespie (1944), Curran and Guttmann (1945), Sargant and Slater (1948), and Price (1946) do not mention it at all. It is possible, however, that such treatment may initiate a subdural haemorrhage, for the trauma required to produce it is very trivial. An already existing haemorrhage may of course be aggravated by convulsive therapy.

My thanks are due to Major Elkarton for the post-mortem report and to the D.G.A.F.M.S. for permission to publish this paper.

The Minister of Health and the Secretary of State for Scotland have notified hospitals of changes in the arrangements for the payment of travelling expenses of patients attending hospital. Hitherto the patient's claim for his fare has depended solely on the length or frequency of his journey. But a number of patients have claimed and been paid their fares when they could themselves have met the cost without financial hardship. From September 1, therefore, payment will be made only where the National Assistance Board is satisfied that the patient would suffer financial hardship by reference to the general standard of the regulations, and hospitals will pay travelling expenses only to patients authorized by the National Assistance Board to receive them. Patients whose condition makes it impossible for them to use public transport will be able, as before, to be carried free of charge by ambulance or sitting-case car when this is authorized by a medical practitioner or other appropriate person.

Reviews

TEXTBOOK OF ELECTROENCEPHALOGRAPHY

Electroencephalography. A Symposium on its Various Aspects. Edited by Denis Hill, M.B., F.R.C.P., and Geoffrey Parr, M.I.E.E. (Pp. 438; illustrated. £3 18s.) London: Macdonald and Co. 1950.

This is the first comprehensive textbook to be written on electroencephalography. It is edited by Dr. Hill and Dr. Parr, the first a clinician, the second an electrical engineer, but chapters have been written by a number of different workers in the subject whose combined interests embrace its whole field. Appropriately, a principal contributor is Dr. Grey Walter, who has written five of the eleven chapters. He has covered the physical and technical background, the interpretation of records, and also given an account of the normal electroencephalogram and that of epileptic subjects. In the latter sections he may have emphasized his own techniques of electrical wave-band analysis rather to the simple reader's confusion, but the earlier chapters on method are excellent. Professor Whitteridge has contributed a long account of the physiological basis of electroencephalography, and in other chapters Dr. Heppenstall discusses biochemistry and Dr. Grevile pharmacology. Dr. Cobb and Dr. Hill describe the electroencephalography of organic lesions and of psychiatry. A series of appendices include nearly all the information that anyone might need to start a department of electroencephalography, although the very information might prove a healthy deterrent.

This is a very specialized book, to be used by those actively concerned with the subject. Clinical neurologists will be discouraged by the mass of technical description which necessarily abounds even in the clinical chapters, and they will be confused by the reservations in description entailed by the tenuous relation so often present between clinical and electroencephalographic phenomena. How can the neurologist looking for guidance on cerebral tumours possibly feel at home with "The alpha rhythm is an almost constant example, a bilateral 4–7 a second rhythm is common, and slower rhythms are not rare"; or with "Rhythmic quasi-sine-waves, having much in common with the spike and wave complex, are not so easily dismissed; they certainly occur significantly in epilepsy, and equally certainly are sometimes associated with tumours."

It must be accepted that the application of electrophysiology to clinical problems is a whole-time job which does not attract the clinician and that this text is intended for those to whom the subject appeals. There will be further editions, for the bibliography of the first is already old, and by then new knowledge may have limited academic compromise and so have given the same clarity to the clinical sections as that of the technical one.

DENIS WILLIAMS.

NEUROPHYSIOLOGY

Physiology of the Nervous System. By John Farquhar Fulton, O.B.E., M.D., D.Sc., LL.D. Third edition, revised. Oxford Medical Publications. (Pp. 667; illustrated. £3 15s.) New York: Oxford University Press. London: Geoffrey Cumberlege. 1949.

This work established for itself a front place in the literature of physiology and neurology immediately on the appearance of the first edition. The third edition maintains that position. The book is up to date and written in an interesting manner, and the contents are well classified. Neurophysiology has made such rapid strides during the past few decades, and especially in the last, and so much of the progress has been made in the United States, that a presentation of the subject as it now stands represents no small task. With confidence it can be said that the task has been well done.

The fashionable obsession of synaptic transmission naturally occupies an important position in the earlier chapters, with the increasingly complex relations of acetylcholine and cholinesterase in dominant roles. Acetylcholine is considered to play an essential part in conduction, not only across junctional structures but along nerve fibres, too, an opinion from which the views of some British physiologists 'would differ'. The difficulties are explained away by the observation, made with isotope studies, that the neuronal surface membranes are impermeable to acetylcholine, whereas synaptic structures are permeable.

Recent study of the cerebral cortex has brought to light many important new facts, and viewpoints have changed. Thus the relation between the suppressor areas of the cortex and anterior cerebellum and the facilitatory and inhibitory regions of the reticular formation is of first importance. So also is the fact that definite areas of the forebrain have close connexion with the hypothalamus and thus have functions in autonomic control. In the anterior lobe of the cerebellum it is claimed that precise functional localization has been demonstrated, cortically induced movements being facilitated or inhibited according to whether the rate of stimulation is high or low.

These are only instances taken at random from among the many new features with which the author's tireless pen —or dictaphone—has enlivened a book which is fascinating throughout. The bibliography, as would be expected, is full and valuable, and the illustrations are well and clearly reproduced.

C. LOVATT EVANS.

GYNAECOLOGICAL OPERATIONS

Die Gynäkologischen Operationen und Ihre Topographisch-Anatomischen Grundlagen. By Heinrich Martius. 6th edition. (Pp. 436; 422 illustrations. M. 60.) Stuttgart: Georg Thieme. 1950.

The sixth edition of Martius's textbook of gynaecological operations has appeared relatively soon after the last edition was published. The script has been altered only slightly and most of the diagrams are the same. A few additional pictures have been incorporated, but they are not quite of the high standard of those in previous editions. The success of the book is remarkable, even for a classical German textbook. The publishers have provided excellent paper and print and they have been generous with illustrations.

Martius's pictures are widely known, partly because of their high quality, but mainly because of his exceptional ingenuity and judgment in picking out the salient features of gynaecological operations. Most of the illustrations are coloured. The book can be easily read even by those who have only a superficial knowledge of German. The approach to gynaecological surgery is often quite different from what is found in such American and British textbooks as those of Te Linde and Bonney. It is perhaps natural for the German school to emphasize the work of such masters as Wertheim, Schauta, Stoeckel, and Wagner, but the contributions of other nations are worthy of more mention. Nevertheless, all gynaecological surgeons should study the book very closely.

WILFRED SHAW.

EFFECTS OF NEPHRITIS

The Natural History of Bright's Disease. A Study from the Standpoint of Paediatrics. By G. E. M. Scott, M.B.(Melb.), L.R.C.P.Ed., L.R.F.P.S.(Glasg.). (Pp. 62. 15s.). Melbourne: W. Ramsay (Surgical) Pty. 1950.

Perhaps a more appropriate title for this little book would be "A Study of the After-results of Nephritis in Children," for that is what it is about.

After a brief but adequate survey of the literature on the classification of nephritis since that of Volhard and Fahr, the author gives details of the follow-up of 68 patients who were discharged from hospital with some urinary abnormalities from five to eight years previously. Except in one particular, the results do not differ materially from those published in many similar series. The exception is the very high proportion of patients (49.3%) who were subsequently found to have arterial hypertension.

Since age of onset is known to be an important factor in the development of post-nephritic hypertension, and the mean age at onset in the author's series was only 7.4 years, it must be presumed that the residual hypertension was largely due to nervousness when being re-examined. This is further suggested by the author's statement that in no case was a raised diastolic pressure recorded or cardiac enlargement observed. An analysis of the causes of death in a further 36 patients is also made, but again no new facts are recorded.

The book is well written and well produced, and should serve to accomplish the author's purpose of encouraging practitioners and students of medicine to cultivate the habit of carefully recording their clinical observations.

A. A. OSMAN

RECOLLECTIONS OF A GENERAL PRACTITIONER

My Life in Three Counties. By H. W. Pooler, M.B., B.Ch., M.R.C.S., L.R.C.P., L.S.A. (Pp. 247; illustrated. 15s.) London: Christopher Johnson.

The publisher of this book (a "truant" doctor, by the way) did well when he induced Dr. Pooler to follow up *My Life in General Practice* with this sequel. The author has gone one better in his second essay. It ought to have an even wider appeal than his first. Its outstanding merit in my eyes is the gusto with which it is written and successfully imparted to the reader.

Dr. Pooler is an enthusiastic Salopian, and gives good reasons for his pride in his native county. To a keen eye for scenery he adds an attractive curiosity about the historical events in which Shropshire took part and the many interesting and sometimes famous characters it produced. When, after a memorable career as a general practitioner in Birmingham, he adopts Derbyshire as his future sphere of action, he does so with the same infectious enthusiasm. A good deal of attention is given to local medical celebrities, and the author has many good stories about Birmingham doctors which will be welcomed by old students. He dives into the history of Birmingham, and rescues from oblivion many who well deserve remembrance. I was surprised that among these he did not mention Mr. Hector, the surgeon and lifelong friend of Samuel Johnson, who lived with him for some time and found his wife there. But one can't have everything, and this is indeed a full and joyous book. It is very well illustrated and produced with the good taste one associates with the publishers. I would, however, suggest that it ought to have had an index.

ALFRED COX.

BOOKS RECEIVED

Review is not precluded by notice here of books recently received

Biological Standardization. By J. H. Burn and others. 2nd ed. (Pp. 440. 35s.) London: Geoffrey Cumberlege. 1950.

A Primer of Venous Pressure. By G. E. Burch, M.D. (Pp. 174. 28s.) London: Henry Kimpton. 1950.

Coronary Circulation in Health and Disease. By D. E. Gregg, M.S., Ph.D., M.D. (Pp. 227. 31s. 6d.) London: Henry Kimpton. 1950.

British Journal of Radiology. Supplement No. 2. Some Applications of Nuclear Physics to Medicine. By W. V. Mayneord, D.Sc., F.Inst.P. (Pp. 290. No price.) London: British Institute of Radiology. 1950.

The Future in Medicine. (Pp. 160. 16s.) London: Geoffrey Cumberlege. 1950.

The Harvard List of Books in Psychology. (Pp. 77. 6s. 6d.) London: Geoffrey Cumberlege. Oxford University Press. 1949.

Light Therapy. By R. Kovacs, M.D. (Pp. 112. 16s. 6d.) Oxford: Blackwell Scientific Publications. 1950.

S. Weir Mitchell: Novelist and Physician. By E. Earnest. (Pp. 279. 28s.) London: Geoffrey Cumberlege. Oxford University Press. 1950.

Pre-frontal Leucotomy. By M. Partridge, M.A., D.M., D.P.M. (Pp. 496. 42s.) Oxford: Blackwell Scientific Publications. 1950.

Exhibitionism. By N. K. Rickles, B.S., M.D. (Pp. 198. 40s) London: Lippincott. 1950.

The Results of Radium and X-ray Therapy in Malignant Disease. Compiled by R. Paterson and others. (Pp. 167. 10s. 6d. Postage 7d.) Edinburgh: Livingstone. 1950.

Psychiatry and the General Practitioner. The Medical Clinics of North America. Mayo Clinic Number. (Pp. 1,251. No price.) London and Philadelphia: Saunders. 1950.

Annual Review of Biochemistry. By J. M. Luck and others. Vol. 19. (Pp. 596. $6.) Stanford, California: Annual Reviews, Inc. 1950.

Manual of Rheumatic Diseases. By W. P. Holbrook, M.D., and D. F. Hill, M.D. (Pp. 182. $4.25.) Chicago: Year Book Publishers. 1950.

Recherches Expérimentales sur l'Asthme. By R. Benda and D. A. Urquia. (Pp. 83. 450 francs.) Paris: Librairie Maloine. 1950.

Dermatologie. By H. and L. Gougerot. 7th ed. (Pp. 730. 3,200 francs.) Paris: Librairie Maloine. 1950.

Pathogénie de la Tuberculose, Oxyaminothérapie, Allergie et B.C.G. By D. Hervouet. (Pp. 155. 240 francs.) Paris: Maloine. 1950.

VITAMIN A AND THE SKELETON

Bone growth is affected in a number of nutritional disorders, but at least three vitamins influence it specifically. In scurvy vitamin-C deficiency affects bone through a failure of synthesis of intercellular collagenous material. In rickets and osteomalacia the deposition of minerals in bone—a mechanism in which vitamin D has a specific action—is disturbed. The relation between vitamin A and bone tissue is not so generally known as these two familiar examples, though both clinically and experimentally there is good evidence that vitamin A has an important place in controlling the growth and development of the tissues of the skeleton. Clinicians have paid some attention to hypervitaminosis. Fried and Grant[1] suggest that the scarcity of reports about it is probably due to unfamiliarity with the syndrome. In children hypervitaminosis A is marked by anorexia, loss of weight, fever, pruritus, and pain in the bones. Skeletal disturbances can be demonstrated radiologically by signs of abnormal periosteal bone formation. Bone growth is also affected if the diet does not contain enough vitamin A, for it has been shown that growth at the epiphyses cannot proceed normally in young animals reared on deficient diets. Bone development is selectively retarded, and the disproportion between the rates of growth of bone and of the nervous system results in overcrowding of the spinal canal and cranial cavity. Mechanical pressure on the brain, spinal cord, and nerve roots causes paralysis. It is of interest that developmental abnormalities of bone have been observed in the offspring of rats reared on diets deficient in vitamin A.[2] One of the effects of giving excessive amounts of vitamin A to an experimental animal is an exaggerated degree of osteoclastic "remodelling" of bone, with resulting fragility and fracture. In 1946 Wolbach[3] reviewed the many experimental studies of bone growth in conditions of excess and deficiency of vitamin A.

About six years ago Mellanby[4] showed that the bony changes in experimental vitamin-A deficiency are the result of interference with the distribution and intensity of osteoblastic and osteoclastic activity. There has been some uncertainty whether vitamin A brings about bony changes directly or through some indirect mechanism, but the consensus of opinion has favoured a direct interference with normal cellular processes. Barnicot,[5] for instance, was able to show that vitamin A caused intense destruction of bone—apparently due to local osteoclastic activity—when crystals were attached to implanted bone fragments. In an outstanding paper appearing in the opening pages of this issue Dr. H. B. Fell and Sir Edward Mellanby establish the fact that the effect of a high concentration of vitamin A on developing bone tissue is a direct one. These workers (one of whom has been associated for many years with studies of explanted tissues at the Strangeways Research Laboratories) grew the bones of foetal mice in tissue culture and studied the effects of altering the concentrations of vitamin A in the media. They observed a remarkable interference with the development of the bones at concentrations of 2,000–4,000 i.u. per 100 ml., though the growth of soft tissues was not affected. How this rapid destruction of developing cartilage matrix and bone tissue takes place has not yet been found out, but Fell and Mellanby suggest that, particularly in the case of cartilage, it is independent of ordinarily understood cell processes and that the intercellular material is directly concerned. This work provides another important link between the mechanism of bone growth and the now numerous chemical factors known to control it. It remains to be seen how the selective effect of vitamin A on bone in tissue culture can be related with observations on the more mature tissues of intact animals which are fed on diets containing either too much or too little of this substance.

RADIATION IN THE SHOE SHOP

Of workers exposed to radiation hazards those at the Atomic Energy Research Station at Harwell are probably safer than most. Very elaborate precautions are taken to ensure that the accepted tolerance dose of radiation is not exceeded, and the measurements made indicate that they succeed in their object. In view of this and of the similar precautions taken in *x*-ray departments in hospitals throughout the world it is disturbing that any man, woman, or child can subject his or her own feet to unknown doses of radiation in a shoe shop. Attention has been drawn to this method of salesmanship during the last two years in several articles in American medical journals,[1-4] and our comment here is based on work done in the U.S.A. and not in this country. Nevertheless, although shoe-fitting fluoroscopes are less commonly used here, there is little doubt that more machines will be installed in shops if they improve sales.

The customer who wishes to use the shoe-fitting fluoroscope places his or her foot over an *x*-ray tube from

1 Williams, C. R., *New Engl. J. Med.*, 1949, **241**, 333.
2 Hempelmann, L. H., ibid., 1949, **241**, 335.
3 Frederick, W. G., and Smith, R. G., *Amer. industr. Hyg. Ass. Quart.*, 1948, **9**, 89.
4 Lewis, L., and Caplan, P. E., *Calif. Med.*, 1950, **72**, 26.

which a beam of *x* rays passes through the foot and casts an image on a fluorescent screen. Reflections from the screen can be seen at three openings in the top of the apparatus—by the customer, the salesman, and a third party. The *x*-ray beam is made to pass for a set time by pressing a button, and during this time radiation will be absorbed by the foot being examined, by the group of three at the apparatus, and by others in the shop or room. It must be accepted that the absorption of such radiation is harmful, but so is ultra-violet light in sunlight, and the degree of danger obviously depends on the amount of radiation absorbed. The apparatus usually works at 50 kV. It is mounted in a lead housing on a steel cabinet. Pressing the button will produce an *x*-ray beam lasting for 5–30 seconds, during which time a dose of 10–120 r could be given to the foot (the distance between the target and the skin being 7.5–20 cm.). There is nothing to prevent the button from being pressed repeatedly, and of course the customer can go from one shoe shop to another, undergoing the same experience in each.

To the customer the dangers of the apparatus are through direct radiation and to the salesman through scattered radiation from the foot-opening of the apparatus. At a distance of about 3 ft. (90 cm.) the dose received in one day might be approximately 1 r—about five times the recommended British and 10 times the American tolerance dose which should not be exceeded by those working with radiation. In practice, of course, apart from the salesman using the apparatus, the staff will usually be further away than 3 ft., and it is unlikely that one salesman would be concerned with as many as 150 exposures, which would be the number required, at 20 seconds each, to give this dose. Williams[1] considered that the fluoroscopes he examined were efficiently protected everywhere except at the bottom and back. Often there was a table just behind the apparatus, and salesmen working at it were thus in danger. Lewis and Caplan[4] measured the amount of radiation received by 77 shoe salesmen in California by issuing "film badges" to be carried when at work: two-thirds received no detectable amount of radiation, and of the rest only two received a dose in the neighbourhood of the tolerance dose, and that at foot level (one of the film badges being carried in the trouser cuff). Generally speaking the customer appears in greater danger than the salesman. In one shoe-fitting of 20 seconds—a common length of exposure—doses ranging from 12.8 r to 116 r have been recorded. It is possible that the exposure may be repeated at once in the same shop and again in other shops, and it is clear that large doses might be given. A growing child may receive unknown doses of radiation several times at different ages. An erythema can result from 250 r, and 300 r is considered capable of causing epiphysial growth disturbance in children. Apart from these dangers there is the possible risk of cancer many years later.

Is the shoe-fitting fluoroscope really necessary? Points of pressure on the fleshy parts probably escape detection in any case. According to Lewis and Caplan half of nearly 80 salesmen said that it was not of great practical use in shoe fitting: most considered its chief value was in sales promotion. It would seem desirable that this question should be considered by an appropriate panel of experts, who should decide first whether or not the use of the apparatus should be discontinued—a step which would probably result in no hardship to the customers' feet. If such fluoroscopes are to be used, however, they should be efficiently serviced, they should meet standard requirements of protection, including the bottom and the back of the case, and they should be kept in a separate room used for no other purpose. This room should be dimly lighted to improve the view of the image. The dangers of giving a large dose of radiation to the customer's foot or of demonstrating with his own hand or foot should be made clear to every salesman. A short limit to the exposure time is a suggestion made by health authorities in the U.S.A.—2 seconds in New York and 5 seconds in Detroit. A device to ensure this can be incorporated in the apparatus. It should also be possible to prevent repeated exposures at the same fitting. In addition, customers could be given a card recommending not more than a certain number of such exposures—the New York City Health Department, for instance, specifies not more than three per day and 12 per year. It should be made an offence to tamper with the screen or filter so as to give a brighter image.

It is easy to make regulations to control the shops, but no control of customers is possible, and subsequent disability or disease may arise without apparent cause. In view of the doubtful value of the apparatus and the uncontrollable danger to health, it might be wiser to discontinue its use altogether.

DANGERS OF BREATHING-MACHINES

When poliomyelitis is epidemic physicians and nurses in fever hospitals must come to dread the appearance of "yet another" patient with respiratory paralysis. There can be few methods of treatment which are more trying for the patient to endure or for the physician and nurse to direct than that of respiratory failure, especially with the inadequate facilities generally available in this country. Even the most important fever hospitals are short of staff, and the highly trained nurses who are required to "special" patients in respirators cannot be found. A mobile group of specially trained volunteers is probably what is needed to help with local outbreaks of the disease. An added difficulty is the fact that most

of the box respirators in this country are of the Both type and lack many features now considered desirable in respirator design. On another page Drs. R. B. Bourdillon, E. Davies-Jones, F. D. Stott, and L. M. Taylor record many observations on respiratory physiology, the subjects being patients with respiratory paralysis and healthy volunteers. They point out that measurements of the patient's tidal air may be of great value, and can be made with a spirometer such as is used in measuring basal metabolism. This can indicate, first the degree of respiratory failure, and secondly whether ventilation in the respirator is correct. Later it is most helpful to observe the gradual recovery of respiratory power with the object of judging the right time for the patient to be weaned from the respirator. The use of the spirometer in this way is an obvious advance and should be widely adopted.

The observations of this group of workers about the possible dangers of hyperventilation—especially with the Both machine, which will not run at less than 20 cycles per minute—are also very important. The symptoms and disturbance of consciousness which may be caused by prolonged hyperventilation have been studied by several workers.[1] In respirator-treated patients the symptoms may be mistaken for those of hypoxia, with the disastrous consequence that the negative suction of the machine will be increased further. It may be that hyperventilation contributes to the high rate of death in these cases. Certainly a good rule in practice is to keep trying to use the least necessary pressure, though periods of high pressure are often appreciated by the patient and can do no harm if maintained for only a few minutes: indeed one modern American respirator periodically gives an extra deep breath. The Both type of respirator has so many faults that a policy of improvement or replacement should be devised forthwith. The breathing machine should and could be made safe and comfortable, so that patients can be put in it early in the disease to obtain rest and sleep. There is in fact reason to think that early rest for the respiratory muscles will reduce the extent of respiratory paralysis. It should be possible to give nursing attention to the patient without causing respiratory distress, and without having to hear a terrified plea not to be taken out again. For even simple nursing attention the patient in the Both machine has to be taken out of the respirator, and therefore an efficient lung inflator should be available to maintain respiration.

There is still too much in the treatment of poliomyelitis which is unscientific, but it will be a great advance if rules of respirator treatment can be drawn up on a sound basis. Important studies on respiration and poliomyelitis have been and are being made in the U.S.A., and these should hasten understanding of the many problems yet unsolved.

PHONOCARDIOGRAPHY

Graphic recording of heart sounds and murmurs, first practised at about the same time as electrocardiography, has failed to make similar progress. Owing to technical difficulties the early results were neither consistent nor comparable, but during the last decade the application of new physical methods has revived interest in the subject. An instrument which served as a model for subsequent workers was built by Rappaport and Sprague[1 2]; it consisted of crystal microphones, improved electrical amplifiers, and recording apparatus. They stressed the need to take three records in every case, and called them linear, stethoscopic, and logarithmic.

The linear phonocardiogram represents graphically the vibrations set up by cardiac action at the surface of the chest. This bears only distant relation to clinical auscultation, for as Leatham[3] has emphasized, if the low-frequency vibrations are to appear on a record of ordinary dimensions the higher frequency murmurs will not be seen. The stethoscopic record is modified by the same attenuation of low-frequency components as is caused by the average acoustic stethoscope. The logarithmic record is modified further, according to the practically logarithmic attenuation of low-frequencies exerted by the human ear, and is therefore an actual representation of what should be heard clinically. Murmurs are seen clearly in logarithmic records, while heart sounds will dominate linear records. Both sounds and murmurs will usually be seen reasonably distinctly in the stethoscopic record. Since some standardization of phonocardiographic records is long overdue this method seems practical. A reference tracing of some kind is necessary for the interpretation of the sound record. A simultaneously recorded electrocardiogram is the most usual, but is of value only as an indication of the beginning of ventricular systole and therefore of the ventricular part of the first sound. For the important problem of identification of events in diastole it may be necessary to record the jugular venous pulse, though the linear phonocardiogram usually gives a clear indication of the second and third heart sounds. The application of phonocardiography is particularly helpful in the analysis of triple heart rhythm. Evans[4] has shown that the placing and identification of additional sounds, often a difficult problem clinically, may be a simple matter graphically. Studies of the first heart sound have shown a wide range of normal variation. In eight cases reported by Alimurung, Rappaport, and Sprague[5] a diagnosis of mitral stenosis had been made on hearing a typical presystolic murmur at the apex. Phonocardiography proved this to be an auditory illusion due to several forms of variation of the first heart sound, in all of which the whole sound complex assumed a crescendo configuration.

Much of the evidence about phonocardiography of heart murmurs is conflicting, and serves to emphasize the fact that meticulous technique with good instruments in a quiet room is essential to avoid misleading results. Cowen[6]

[1] *Amer. Heart J.*, 1941, **21**, 257.
[2] Ibid., 1942, **23**, 591.
[3] *Post-Grad. med. J.*, 1949, **25**, 568.

[8] Ibid., 1947, **9**, 225.
[9] *Clinical Auscultation of the Heart*, 1949, London.

was unable to substantiate some of Evans's[7 8] earlier observations, particularly those on the important apical systolic murmur. In his series Cowen found that, while all the "innocent" murmurs started later than the S-wave of a simultaneous electrocardiogram, so also did many of the "systolic murmurs associated with definite valvular heart disease." In addition Levine and Harvey[9] have been unable to demonstrate a mid-diastolic murmur in all cases of mitral stenosis. Leatham[3] found that aortic systolic murmurs have a characteristic shape on sound records which distinguishes them from those of mitral origin: this should assist recognition of those cases of aortic disease with loud apical systolic murmurs. In theory, clinical auscultation should be more sensitive at the higher frequencies associated with the murmur of aortic incompetence. For murmurs of comparable intensity this is certainly true in practice, particularly when the diaphragm chest-piece is used. Conversely, the low-pitched murmurs associated with mitral stenosis can be more easily detected by phonocardiography than by clinical auscultation. The graphic method should prove most useful in confirming the diagnosis of mitral stenosis, or in providing evidence for its exclusion. It may be particularly helpful in the assessment of apical systolic murmurs in children with loud third heart sounds which may be confused with mid-diastolic murmurs.

For teaching purposes a loudspeaker may replace the recording apparatus of the phonocardiograph, the result being an amplifying stethoscope. It is very difficult to obtain faithful reproduction by this or other mechanical devices, and indeed, however faithful the reproduction, the method seems to be of very limited value. There can be no effective substitute for the practice of the close personal application of the acoustic stethoscope.

OPTIMISM IN MENTAL HOSPITALS

All psychiatrists are aware that mental-hospital practice is an entirely different thing now from what it was 20 or even 15 years ago. The extent of the revolution is made clearly evident by some recent statistics given in the annual report of the Crichton Royal Hospital, Dumfries. Twenty years ago most well-managed hospitals were able to secure a discharge rate of 30%, but much higher figures are now being recorded. During the three years 1945–7 the general discharge rate at the Crichton Royal has been 74%, 81%, and 85%. The change is very largely due to the widespread adoption of physical methods of treatment—electroshock, insulin coma, and leucotomy. At the Crichton Royal rather more than half the patients admitted have been subjected to one or more of these treatments, and among them the discharge rate has gone up from 88% in 1945 to 95% in 1947. But the advance is by no means confined to patients treated in this way: the discharge rate among the others is also very high, and has risen from 63% in 1945 to 73% in 1947. It is not to be supposed that the Crichton Royal is very exceptional among mental hospitals, and no doubt there are others which could publish figures nearly as satisfactory. In fact there is probably not a mental hospital in the country where the discharge rate has not taken a sharp upwards slant during the past 15 years. These bare figures reveal in cold statistical form a radical change in the atmosphere of the hospitals. Where there was once hopelessness, lethargy, and cynicism, there is now hopefulness, even confidence, and a willingness to undertake trying duties in the certainty that many of the patients will benefit. The improved results obtained even with patients not submitted to physical treatments shows how much can be done by other methods, by personal interest in the patients, simple psychotherapy adjusted to their needs, and efforts at rehabilitation. There are now very few patients for whom all efforts at treatment can be foreseen as hopeless: much improvement can often be obtained even in those most intractable cases where leucotomy is eventually thought necessary, as is shown by the fact that in different years the Crichton Royal could discharge 73–83% of these patients.

Therapeutic success is attended by a greatly increased interest in clinical problems. At many mental hospitals the medical staff forms itself into a society with regular meetings, which are also often attended by other members of the hospital team, including nurses, psychiatric social workers, and occupational therapists. At some hospitals this society is a centre at which medical men from the neighbourhood also forgather to hear guest lecturers and take part in discussions. Perhaps the most important change of all is shown in a different attitude on the part of patients and their relatives: a nervous or mental illness is now at least beginning to lose its stigma, and patients willingly seek admission for treatment. Thus the mental hospital is showing signs of at last becoming integrated into local society. So much gain could hardly have been made without loss. The debit side is seen in the greater demand for beds. Hospitals are overcrowded and often have long waiting-lists. Their administrators may refuse admission to any patient from outside the hospital area. Worst of all, admission is sometimes denied to patients who are willing to come voluntarily unless their relatives will permit them to be certified. If this tendency is allowed to progress it will cancel much of the gains that have been made. The present difficulty can be surmounted only by increasing the facilities for mental treatment; but in the meanwhile it should be possible to arrange priorities so that the mournful need for certification is not extended beyond its proper boundary.

SKIN CANCER AND CUTTING OILS

Study of malignant tumours of the skin yields an increasing fund of knowledge that should ultimately assist in the elucidation of the problem of cancer, for the pathology of disease in one organ does not differ materially from that in other organs. Since Percivall Pott described scrotal cancer as an occupational hazard in chimney-sweeps careful clinical observation backed by statistical analysis has established the carcinogenic role of many irritants, external and internal, in skin cancer. Oils and tar products, *x* rays and radium emanations, chronic infective diseases—such as lupus—ulcers, and scars are well-recognized causes of cancer. Much has been written about ultra-violet light and cancer of the exposed skin, and Neubauer's review[1] of arsenical cancer suggests that a number of patients with multiple carcinomata of the skin and trunk and limbs suffer in consequence of the ingestion of arsenic many years

[1] *Brit. J. Cancer*, 1947, **1**, 192.

previously. Heredity, race, age, sex, hormonal and other influences, and obscure individual factors may play their part, but it is nevertheless true that in many cases the agent causing cancer of the skin can be recognized. It is possible to cure almost all skin growths, and great advances have been made in prophylaxis. Such successes are of course partly due to the ease with which the skin can be examined and treated.

Many of these points about skin cancer are brought out by Cruickshank and Squire,[2] who have recently investigated the effects of skin contamination with mineral oils among workers in the engineering industry in Birmingham. Cutting oils used with the automatic machine tool contaminate the skin of the worker, and this is not effectively controlled by splash guards and other devices, though improvements in such measures are suggested. Oil acne and folliculitis are seen in 80% of the workers, and over half of those who have been exposed for fifteen years or more develop "shark skin" or "shagreen skin"—a condition recognized as predisposing to cancerous change. One man with scrotal cancer was found among 138 patients examined, but a review of the cases of scrotal cancer observed in hospitals in the region during the previous ten years showed that about half of the patients concerned had worked with oil in the engineering industry. The skin changes observed by Cruickshank and Squire were related to the duration of exposure and not to the age of the patient. They draw attention to the fact that the light engineering industry is comparatively young and that the evidences of damage they present should be regarded as a warning of more serious trouble ahead unless effective prophylaxis is established. The question of the identity or the relationship of those factors in oil which provoke folliculitis and dermatitis to the carcinogenic properties of oil demands careful study. If "eczematogens" may, as suggested by some American workers, be carcinogenic, it would seem that the worker who reacts by dermatitis is fortunate in that he cannot tolerate the duration of exposure necessary for carcinomatous changes to develop.[3]

DRUG TREATMENT OF PARKINSONISM

We have recently referred[1] to some of the new synthetic compounds used in the treatment of parkinsonism, and in this issue of the *Journal* Drs. H. Palmer and D. J. A. Gallagher describe the encouraging results they have obtained with "lysivane"—a member of the same group of drugs as "diparcol." They believe that the results obtained with lysivane are better than those obtained with diparcol or "artane,"[2] but they are careful to state that it is dangerous to draw conclusions about the drug treatment of parkinsonism on too narrow a symptomatic basis. The history of "parpanit," for example, shows how the first enthusiasm for a new drug may have to be modified later. Parpanit, which is a di-ethylaminoethyl ester, was first investigated by Domenjoz[3] in 1946. He found it to have properties which are now recognized to be common to many substances, such as atropine, procaine, or papaverine—that is to say, parpanit relaxes smooth muscle, being a spasmolytic, paralyses the action of the vagus like atropine, and has a local anaesthetic action like procaine. It was, however, the observations of Grünthal[4] which led to its wider therapeutic use. He found that when it was given to normal subjects it produced a sensation of "rubber knees." They walked with uncertainty, as if on cotton-wool, and with freer, though less-controlled, movement: it was difficult to be sure of the position of the limbs; the body seemed lighter, and fatigue disappeared. The subjects complained of dizziness and were obliged to remain still. There was, however, no muscular weakness. In larger doses than 60 mg. there was a disagreeable alteration of personality.

Because of these findings parpanit was applied to the treatment of post-encephalitic parkinsonism, in which muscular rigidity is so marked, and great success was claimed.[5 6] Patients who for years had been reduced to complete immobility and required permanent nursing were able to look after themselves once more and even to resume their professional work. The effect of the drug was to reduce rigidity and improve mobility. Other symptoms such as tremor, the slowness of speech, and the typical parkinsonian posture were modified irregularly or perhaps not at all. Fleisch and Baud[7] provided objective evidence that parpanit does in fact reduce muscle tone. They were able to measure this effect in rabbits as the dose was raised from 8 to 40 mg. per kg. (These amounts are far greater than those given to man, which are about 1 mg. per kg.) They found that in man doses of 100 mg. of parpanit caused a drop in the tonus of the quadriceps, greatest after 90 minutes. This dose also caused a rise in the threshold stimulus for the patellar reflex and a diminished appreciation of a change in a weight supported by the hand. They concluded that the action of parpanit was on the sensory nerve endings for deep sensibility, which were depressed.

Clinical trials with parpanit have been reported by Schwab and Leigh[8] in the U.S.A. and by Dunham and Edwards[9] in this country. The latter gave some of their patients who were receiving the usual treatment with solanaceous drugs increasing doses of parpanit until side-effects appeared. Other patients were given optimal doses of parpanit as well as solanaceous drugs, and the latter were then gradually withdrawn. In a third group of patients a sudden change was made from solanaceous drugs to parpanit. The authors concluded that parpanit was certainly a useful drug in Parkinson's disease but that it had no clear advantage over solanaceous drugs. Some patients were better when taking parpanit, others when taking solanaceous drugs. When parpanit was effective it was equally so whether given alone or together with solanaceous drugs. The side-effects—dizziness, sensation of weakness, dryness of the mouth, and blurring of vision—were similar with both forms of treatment, but the first two were commoner with parpanit and the last two with the solanaceous drugs. Dunham and Edwards found no criteria by which they could forecast the effect of either treatment in any patient, except that patients who responded well to one also responded well to the other. It will be wise to suspend final judgment on the new drugs used in the treatment of parkinsonism until publication of the results of controlled tests.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

POLIOMYELITIS

BY

W. HOWLETT KELLEHER, M.D., D.P.H.

Physician Superintendent, Western Hospital, London

The current outbreak of this baffling disease should soon be reaching its peak, July, August, and September being almost invariably the months of greatest prevalence. In Britain the latter part of September may confidently be expected to show a decline in case incidence, although cases will continue to crop up sporadically during the winter months. Winter epidemics, however, have been encountered in some countries, although rarely. An instance of this was a recent severe outbreak in an Eskimo village during an exceptionally hard winter.

It is likely that the disease has been with us for thousands of years, though its ravages have not been apparent until comparatively recent times. Scandinavia had the unenviable distinction of providing the first real outbreaks, and the disease still remains a serious problem in Northern Europe. Somewhat later the United States suffered from serious outbreaks, notably that in New York in 1907, with more than 2,000 cases. But it was nine years before that city had its most serious outbreak, with over 9,000 cases and a mortality of more than 20%.

It is not within the scope of this article to discuss the theories held to account for the epidemic conflagration of poliomyelitis after it has been known to smoulder for many years. What we must accept as ominous is the expectation, borne out by the experience of other countries, that it will remain with us as a serious menace until more is known about its source and methods of control.

Causal Agent: Prophylaxis

A filterable virus, one of the smallest known, is the cause. There are several groups of poliomyelitis virus, the great majority of human infections being due to one group only, which can be transmitted to monkeys and contains several antigenic strains. The virus is inactivated by a temperature of 55° C. for 30 minutes, and by a 1 : 5,000 solution of potassium permanganate in normal saline. The virus in infected spinal cord can be inactivated by 0.3% formalin in 3½ days. Virus in suspensions of cord in acid solution is inactivated in 10 minutes in the presence of 0.05 p.p.m. of free chlorine. The usually adopted water-chlorination methods are believed to be ineffective in practice, especially in the presence of organic matter: if there is none, however, 0.2 p.p.m. of chlorine should be effective.

The virus has been isolated from sewage and sewage-contaminated water, and from flies, and may occur on unwashed fruit and vegetables. It can be recovered from the patient's oropharynx in the first week or so of the clinical disease and from the faeces in at least the first month or two. Healthy carriers are also known, while some people have been found to excrete the virus for some weeks before the onset of symptoms. These facts help in planning prophylaxis.

During the incubation period (see below) contacts should be kept under close observation and visits to infected households forbidden. During epidemic periods in localities where cases have occurred all unnecessary gatherings, especially of children, should be avoided. Exhausting physical exercise by children or young adults may facilitate infection or lead to more extensive paralysis if undertaken when the disease is beginning.

Some authorities have expressed the view that during a poliomyelitis outbreak inoculations which are not urgently required should be postponed. Operations such as tonsillectomy, adenoidectomy, and dental extraction should also be held over. A damaged mucous membrane may facilitate the entrance of infection.

Age Incidence and Immunity

Although the earlier epidemics in Britain showed up to a 90% attack rate in infants and young children, this group now accounts for little more than one-third of the cases, the other two-thirds being in children of school age and in the adolescent and adult population. Infants under 1 year old enjoy a relative immunity or may suffer a mild attack only. An example of this is the experience on more than one occasion in the Western Hospital that young nursing trainees in infant nurseries have suffered from non-paralytic or from severe paralytic attacks while their protégés appeared to escape entirely.

The mechanism of immunity is as yet unexplained. Plenty of evidence exists of the presence of a neutralizing antibody in the blood of both convalescents and infected adults in communities frequently affected by epidemics, but its presence does not guarantee immunity from attack. Second attacks of poliomyelitis can occur, although the risk of a second attack may be somewhat less for a year or two. Some, if not all, of the recorded cases may have been instances of infections with strains differing from the original infection. It is said that immunity is strain-specific. Serum therapy and prophylaxis have proved a failure.

Incubation Period

This has been variously estimated as between a few days and four or five weeks, but is commonly believed to be between 7 and 14 days. The disease experimentally produced or following injury or operation generally shows itself after 7 to 10 days. Where it has followed local tissue damage from inoculation, it may be noted in from two to four weeks.

Clinical Manifestations

The majority of clinical attacks show two phases. In the first, a stage of general systemic disturbance, it will be impossible in the majority of instances, particularly in the absence of an outbreak, to do more than keep the possibility of poliomyelitis virus infection in mind.

First Phase

The initial constitutional symptoms may closely simulate a virus respiratory tract infection. Cough, however, is only infrequently met with, but pharyngitis is common. Temperature varies within wide limits and no positive conclusions may be drawn from it. More significant may be severe headache, particularly frontal, and vomiting, probably of nervous rather than toxic origin. General muscular pains and lethargy are more noticeable than irritability at this stage. This phase of the disease is most variable in duration, and although it may occupy several days it is important to emphasize now that the briefest and slightest disturbance, a mild malaise and a temperature of 98.8° to 99.6° F. (37.1° to 37.6° C.), may be the only manifestation of poliomyelitis. That, of course, is the true abortive type. It is obvious that its identity, apart from laboratory assistance, can only be inferred—particularly if previous contact is known.

Second Phase

This may be separated from the initial phase by several days of comparative well-being, but in many cases it either merges into it or it may predominate from the start. Where the phases are clearly separated the temperature chart will characteristically show a "camel" (dromedary) curve. It is obvious both clinically and from histological studies that the second phase represents the inflammatory reaction due to viral attack on the central nervous system. It is a true meningo-encephalomyelitis, and the clinical signs vary little from those of any other infective or post-infective viral meningo-encephalitis. This true meningeal phase is almost invariably present in some degree before paralysis, but the paralysis may come on very rapidly, especially in infants, even within a few hours of onset of the first general symptoms. This is particularly so in those cases in which a monoplegia has been suspected to have been influenced by inoculation reaction.

Except in the rare encephalitic types, one of the most striking objective signs in the majority of patients, particularly in the presence of considerable pyrexia and other discomforts, is alertness merging into irritability, at least in young children (the adult is usually more apprehensive than irritable). Frontal headache is often very severe, and vomiting may recur. Generalized hyperaesthesia or pain and tenderness may be complained of, but, apart from that evoked through movement of muscles, painful spasm is not generally a common feature of cases in the pre-paralytic stage seen in the Western Hospital, however troublesome this may be at the onset or after the paralysis has become evident. Tendon and superficial reflexes may be temporarily exaggerated, and there may be fibrillary twitching of muscles.

It is obvious that where, as quite commonly happens, an inflammatory reaction in the mid-brain is marked, any degree of objective signs indicative of encephalitis may be encountered. Nystagmus is quite common and should always be looked for. Complaint is often made of insomnia, even in young persons, and when this is obviously not due to pain it should excite suspicion of early irritative encephalitic involvement.

Almost invariably present at this stage is some spasm of muscles with stiffness of posterior cervical and spinal groups and of the hamstrings, but it is a very variable sign. The elicitation and significance of this sign are amplified below. Retention of urine due to temporary bladder dysfunction is common, particularly where the lumbar cord is heavily damaged. Constipation may also be troublesome.

Methods of Examination and Assessment

For practical purposes and simplicity the following broad classification of cases may be adopted:

I. *Non-paralytic:* Abortive, meningeal, peripheral neuritic, cortical.

II. *Paralytic:* Bulbar, spinal, or combinations of both (bulbospinal).

The term "bulbar" is rather loosely used for any clinical type resulting from inflammation in any part of the brain-stem, although only applicable directly to the much more limited area of the medulla oblongata.

Abortive and Non-paralytic Poliomyelitis

"Abortive" is the name generally given to cases which have not shown signs of inflammation of the central nervous system, whereas non-paralytic cases have progressed to that stage but show no muscle weakness. It is obvious that the abortive case is normally diagnosed only by inference as a contact or with laboratory help. The only symptom may be a slight pyrexia of brief duration, and an abnormal cerebrospinal fluid (a protein level of more than 55 mg. per 100 ml.) alone aids the diagnosis. The real importance of diagnosis lies only in the potential infectivity of the abortive case, which is often a carrier. There is certainly no danger to life or health. Since abortive and non-paralytic infections are said to be 100 times more frequent than paralysed cases, the impracticability of hospital isolation of every abortive case is clear. A very large proportion of cases admitted to our special hospitals to-day on suspicion of poliomyelitis cannot be confirmed as even abortive attacks. Hospitalization is therefore not justified where definite neurological signs are absent. The practitioner's difficulties in face of the possibilities and of family apprehension can be understood, but both the patient and his family may best be served by allowing him to remain under daily supervision at home, and the burden on the hospitals will be considerably lightened, often by more than 50%.

Non-paralytic poliomyelitis includes all cases with the subjective and objective disturbances of the central nervous system known as meningeal irritation. This also is a large group. The hospitalization of such cases is fully justified and indeed important unless their removal creates physical or mental trauma with subsequent worsening of paralysis. Strict rest can be prescribed and a look-out maintained for the earliest signs of dangerous complications. If paralysis ensues it is often evident within a day or two of the onset of meningeal signs, but it may be delayed for many days. Although paralysis becomes maximal within 48 hours of its appearance, instances not infrequently occur where fresh lesions may continue to crop up for as long as seven days after the initial paralysis. For example, respiratory muscle involvement often takes some days to become apparent, a further reason for the hospitalization of the suspected case with meningeal signs.

Paralytic Poliomyelitis

As stated above, this may be spinal, bulbar (brain-stem), or combinations of both. As it still accounts for the largest number of paralytic cases, the spinal will be considered first.

It must be remembered that spinal paralysis includes not only cases of limb paralysis but trunk muscle lesions, including diaphragmatic and intercostal. Constipation and retention of urine probably come into a different category: function generally recovers in a few days.

The symptoms which usher in an attack differ in no respect from those enumerated above in relation to non-paralytic and abortive poliomyelitis. An amplification of the indications of muscle spasm is, however, called for.

(1) *Neck Rigidity.*—This is rarely so marked as in acute suppurative meningitis, but the differentiation from that seen in early tuberculous meningitis may be difficult. Only very rarely is true head retraction noted. Infants and young children

will often naturally resist any attempt at flexion, simulating a true rigidity. By attracting their attention so as to cause neck flexion or by raising them by the shoulders from the supine position (when they should normally flex the head) it is possible to remove the doubt.

(2) *Back Rigidity.*—This varies greatly. In some cases the condition may be so extremely painful as to make it impossible to get even slight flexion, and in others it may be so slight as only to be elicited by asking the sitting-up patient to kiss his knees, which are fully flexed, the thighs also being fully flexed and in the adducted position. Intermediate degrees are often seen, as where the patient can get himself into the sitting posture but because of rigidity or shortening cannot sustain it without using his extended arms placed behind him as in a tripod (Amoss's sign). Very often the difficulty in maintaining the sitting position is not due to stiffness of the spinal muscles but to hamstring muscles in spasm or shortened, and this can readily be demonstrated by sitting him on the edge of the bed with flexed knees, when he is found to be able to straighten his back fully. Incidentally this is an excellent position in which to make tests of the serratus and rhomboid muscles. Spasm of the neck and back muscles may, if prolonged and severe in a patient who is allowed to assume any comfortable position, result in considerable shortening with marked opisthotonus.

(3) *Kernig's Sign.*—This is frequently very marked in poliomyelitis, but it may be absent, especially in infants. Indeed, any or all of the muscular rigidities described above may be absent.

It should be emphasized that all these signs commonly occur in non-paralytic poliomyelitis as well as in all degrees of the paralytic disease. No information regarding the paralysis may be deduced from their intensity.

Paralysis or weakness when it occurs may be so slight as to require the finest tests for its detection, or it may be extreme. It is of lower motor neurone type with diminished or absent tendon reflexes. Even in the most extensively paralysed cases the asymmetry which is typical of poliomyelitis may be detected. Sensory loss should not be encountered, but there may be subjective disturbances—i.e., a feeling of numbness—and in later stages poor circulation and trophic changes may give rise to local sensory disturbances.

The commonest sites of paralysis are the lower limbs and the shoulder girdle, in that order. In the leg the quadriceps, the anterior tibial, and the peroneal groups are most commonly affected, in the arm the deltoid and triceps muscles. When a whole limb is involved the lesion is, except possibly in infants, easily recognized, and one will be concerned merely with making a differential diagnosis. It is, however, with the lesser degrees of dysfunction that detection is difficult, and this makes a meticulous examination necessary. A suggested scheme of examination has been set out in detail by the present author.*

Useful Clinical Points

The examination should be systematic, commencing with the head and neck and proceeding to the upper extremities and shoulder girdle, the trunk muscles and the lower extremities. Certain points must be noted:

(1) With shoulder-girdle involvement look out for diaphragmatic and/or intercostal weakness.

(2) With lower extremity weakness watch for retention.

(3) Immobilization due to pain may give rise to an erroneous impression of the severity of the paralysis.

(4) The abdominal recti are often asymmetrically attacked.

(5) Even in very young children substitute movements to correct the defect of paralysis can very quickly be learned. A frequent example of this is rotation of the scapula to produce abduction of the arm, and tilting the pelvis to help the dorsiflexion of the foot.

(6) In examination of infants accurate estimates of power may be made by the active resistance of the infant to handling. The more annoyed he is the better for one's purpose. Tempting with a toy or a sweet, or stimuli such as plantar tickling, will help greatly. Even assessment of minor weakness may quite accurately be made in this way.

(7) No single examination in a suspected case will suffice. Quite apart from the possibility of an extension of the paralysis or weakness, there are the factors of uncooperativeness and pain which may distort the picture. Continued raised temperature in the pre-paralytic phase or an unsettled one after the onset of the paralysis should make one alert to the possibility of extension. Following such stages a settled temperature for several days almost invariably denotes quiescence, with little further risk.

(8) Paresis when slight may often be detected only when the suspected muscle or group is compared with the opposing limb.

(9) Wasting may be hidden, in babies particularly, by fat. It is usually evident after about a fortnight.

(10) Absent or sluggish reflexes do not necessarily denote the presence of paralysis or even of paresis, but where an asymmetry of response is undoubted it is rarely misleading. The triceps and ankle jerks of normal infants are often difficult to elicit.

(11) Rapid deformity—e.g., foot-drop—may develop through spasm and shortening of opposing muscle groups; hence early diagnosis is of importance in prevention. Over-stretching of paretic muscles may seriously limit their recovery.

(12) Early recognition of respiratory muscle damage is necessary in order to avoid fatigue and further, perhaps irreversible, neurone damage through anoxia.

In any event an early consultation with a specialist colleague will help to avoid occasional pitfalls. Even those with extensive experience are not infrequently humiliated.

Prognosis in Spinal Paralysis

A flail limb in which no partial recovery has occurred in a few weeks is unlikely eventually to show even reasonable recovery. If there is no sign of return of power after four or five months the prognosis is almost negative. Where some recovery is evident early one may expect that with proper supervision the recovery will continue up to 18 months after onset. If neuronal recovery is to take place it does so within a few weeks.

The prognosis in recovery of movement is naturally greatly influenced by physical and orthopaedic treatment; full mobility of joints must be present before any power which remains can be utilized.

Bulbar (Brain-stem) Lesions

This is a most important group, to which full justice cannot be done in this necessarily condensed review. The 1947 admissions to the Western Hospital showed cranial nerve lesions in about one-third of all cases, which was considerably more than previously recorded. As in the spinal group, asymmetry and variability in symptomatology are the rule, ranging from the slightest of attacks to the most virulent. Rarely severe encephalitic symptoms are seen, but in the great majority of bulbar cases paralysis or weakness of certain cranial nerves is the only manifestation. Lesions of the upper group of cranial nerves (third to eighth) must be carefully looked for. For the detection of fifth-nerve involvement it may be necessary to make tests against resistance. Seventh-nerve lesions are relatively common and may occur alone. They are almost always of lower motor neurone type. Eighth-nerve (vestibular) disturbance is not uncommon, but frequently of brief duration.

*Kelleher, W. H., *Med. Pr.*, 1947, **218**, 452.

The lower group of cranial nerves is far more important because of the threat to life which extensive lesions involve. The ninth, if affected alone, and especially if unilateral, may cause little inconvenience. The more extensive combinations of the ninth, tenth, and twelfth cause great inconvenience and danger, due to obstruction of the airway by unswallowed buccal secretions. Another serious threat to life arises from complete laryngeal abductor paralysis, the approximation of the vocal cords causing great difficulty in inspiration. The difficulty is increased with spasm of the adductors. A common enough occurrence is eleventh-nerve paralysis, often detected only by muscle resistance tests.

By far the most fatal of all complications arises from inflammation of the respiratory centre in the medulla, giving rise to variations in depth, rate, and rhythm of breathing, or from defects of the vasomotor centre in the same area leading to circulatory failure.

No examination of a poliomyelitis patient is complete, therefore, until a careful test of the cranial nerves has been made. The pharynx should always be carefully inspected, as prompt treatment (e.g., postural drainage) may avert disaster.

Respiratory Failure

In addition to the commonly fatal type of respiratory failure arising from bulbar damage, it is most important to be able to make an early diagnosis of the more treatable muscle (spinal) paralysis or weakness. Careful and repeated inspection is necessary, particularly where shoulder-girdle paralysis is present. Serious anoxaemia may have occurred long before mechanical defect is obvious. When dyspnoea is present the patient is in urgent need of artificial respiration. Among the earlier signs are an increasing restlessness, anxiety, sweating, dilatation of pupils, and an increasing pulse rate. Later, accessory muscles may be brought into play. Dilatation of alae nasi may be noted, and speech tends to become staccato or jerky. Stethoscopic examination should reveal poor air entry to the lungs, especially at the bases. Defective epigastric excursion may be seen or such excursion may be entirely absent. Often only the upper intercostals may be found active, aided by accessory muscles. Attempts at coughing will be noted as extremely ineffectual.

Unfortunately, a not uncommon combination is that of pharyngeal or laryngeal dysfunction with a blocked airway and a respiratory (spinal) failure. The prognosis here is extremely serious. Central (medullary) respiratory failure is almost invariably fatal.

Differential Diagnosis

This bristles with difficulties as judged by hospital admissions of suspects. In the initial stages with general systemic disturbance many cases of tonsillitis, otitis media, rheumatism, and catarrhal respiratory infections arrive in hospital. There is also an increasing number of cases of pyrexia of unknown origin. Admittedly, many of these could be abortive poliomyelitis and justify diagnostic lumbar puncture, but in inter-epidemic periods or where there is no question of contact it can be justified only on academic grounds.

In the meningeal stage and in the absence of paralysis the examination of the cerebrospinal fluid is fully justified, particularly where tuberculous meningitis must be excluded, since early treatment of that condition is now imperative; this is true also of pyogenic meningeal infections and cerebral abscess. Subarachnoid haemorrhage can be a cause of confusion, in the author's experience.

When paralysis develops the toxic neuropathies must be excluded, rarely with difficulty. Cerebral vascular lesions even in children (thrombosis) are not rare. Trauma of nerve tissue, myelitis, and tumours have all caused confusion. Acute toxic polyneuritis (Guillain-Barré syndrome) is often difficult to differentiate from severe forms. Pseudoparalysis may simulate poliomyelitis, and here mistakes are less excusable.

Pain fixation from any cause (rheumatism, arthritis, or injury) must be excluded. Spasm of muscles due to pelvic inflammation may immobilize the hip. Erythema nodosum and acute osteomyelitis occasionally cause confusion. Again, less excusable are fractures and dislocations.

Treatment

There is no specific for this disease. None of the newly developed antibiotics appear to have any activity against the virus. There is almost universal agreement that the claims for serum (convalescent or gamma-globulin fraction) cannot be supported, even if administered in the pre-paralytic stage. The value of any method is most difficult to assess owing to the very large number of abortive and non-paralytic cases, and also because spontaneous recovery may occur in paralytic cases.

Physical and Orthopaedic Treatment.—Strict rest is necessary for pre-paralytic and early paralytic cases, both for avoidance of discomfort and for the prevention of the spread of paralysis as a result of fatigue. Sedatives and analgesics have their uses in diminishing pain and irritability, but must be cautiously used in the presence of respiratory paralysis. Apart from dealing with mechanical defects (e.g., respiratory dysfunction) and the correction of physiological upset, treatment will be directed to the prevention of deformity in paralysed limbs and the encouragement by various physical methods of the action of muscles or parts.

In former days the idea of treatment by strict immobilization held the field. This is now regarded by many orthopaedists as harmful and by others as certainly no better than methods involving freedom of movement of limbs. The important thing is to transfer responsibility for the treatment of the paralysed condition very early to the physical-medicine department of a hospital where the advice of an orthopaedic surgeon can be obtained. The majority of the authorities believe that passive movement with or without hot moist packs is ultimately of the greatest benefit in preventing deformities, wasting, and trophic changes. Gradually introduced and carefully graded active exercises are commenced quite early. These measures are greatly assisted when carried out in a warm bath or with the aid of supportive slings.

The Kenny Treatment.—The principles of treatment advocated by Miss Elizabeth Kenny make a heavy demand on staff and time. A modified technique is in use in many orthopaedic departments in this country. Few, however, can afford to omit splinting entirely. The majority combine a modified splinting technique with passive and active movements assisted by hot packs in the earlier stages. If no splints are employed the part must be frequently examined and the position corrected, measures hardly obtainable in the comparatively sparsely staffed physiotherapy departments of to-day.

Respiratory Failure.—This can be treated only in hospital, spinal paralysis cases being placed in a respirator, while postural drainage and aspiration, perhaps combined with tracheotomy, may help the bulbar group.

PORPHYRIN METABOLISM AND PORPHYRIA

A University of London lecture was recently given at the London School of Hygiene and Tropical Medicine by Professor C. J. Watson, who holds the chair of medicine in the University of Minnesota. Professor Claude Rimington presided.

Professor Watson said that the first published work on the subject of porphyrin metabolism was Sir Archibald Garrod's Bradshaw Lecture in 1900. Much work had been done since then, and in his own studies he had received a great deal of stimulus and pleasure from contemporary British workers on the porphyrin problem, particularly Rimington and Gray. It was not surprising that the earlier investigations in this field were confused, and that there was difficulty in recognizing the porphyrins. Fisher was the first to differentiate natural and artificial porphyrins, and he gave them the classification which was generally in use to-day and was being amplified as the work proceeded. With regard to uroporphyrin, until two or three years ago it was not possible to determine which isomeric type was preponderant in any sample of urine except by very costly and time-consuming methods, but Schmidt had now worked out a method of analysing the isomer ratio with small amounts of urine, such as 50 ml., although sometimes 200 ml. had to be used. During the past two years also a good deal of interest had been taken in the precursors or chromogens of the porphyrins, and it had become clear that not enough attention had been given to the chromogen of coproporphyrin. It had been generally accepted that the chromogen was converted quickly to a porphyrin, and that its quantitative determination was of no concern. The problem in this field was not quite so simple. When urine was extracted with ethyl acetate a certain extraction of porphyrin was obtained, but if the solution were exposed to violet light or iodine a considerable additional amount of porphyrin, which had been left behind by the ethyl acetate and overlooked because it neither fluoresced nor had colour, was forthcoming. It had been calculated that the chromogens in the urine constituted 75% of the total porphyrin excreted. In the faeces the proportion was from 5% to 20%, but this amount might be larger, since the extraction method used might serve to convert chromogen to porphyrin.

With the congenital type of porphyria, known as the photosensitive type, the patient developed skin lesions over the years, exhibited haemolytic anaemia and hepato-splenomegaly, and had an excess of uro- and coproporphyrins in the urine. The patient with the intermittent or acute type of disease might go on for years in good health, and then develop severe symptoms, with a fatal result. This disease was more common in females, whereas the photosensitive type was more often seen in males, although this difference had been over-emphasized in previous literature. In this type the nervous manifestations were striking, and it was characterized also by severe abdominal pain, which might imitate that attending any abdominal condition. Pigmentation of the skin of a dark brown or blackish colour, which might be confused with Addison's disease, was noted. Often there was impairment of hepatic function and sometimes a development of cirrhosis. Waldenström's porphyrins were excreted. Waldenström was the first to isolate the porphyrins in crystalline form and work with them in considerable detail. There was also a third type of the disease which might be described as mixed, the patients showing some photo-sensitivity and some nervous and abdominal manifestations. In the photosensitive type there was an absence of what Waldenström called porphobilinogen, but in the intermittent acute type this substance was found.

The lecturer said that he and his associates were inclined to the view that coproporphyrin was the precursor of uroporphyrin, but the question was still open and must be left for future discussion. Coproporphyrin did not occur in the red blood cells of patients with porphyria. Schmidt produced acute lead poisoning in rabbits, killed them, and analysed the bone marrow, finding protoporphyrin in considerable amount, but no higher coproporphyrin than in the circulating red cells.

Putting these various findings together, said Professor Watson in conclusion, a rather significant observation had recently been made by one of the workers in his laboratory. He had set out to study photo-dynamic activity in porphyrin metabolism because he had found large amounts of one type of coproporphyrin extracted in patients with pemphigus foliaceus. Finding an enhanced photo-dynamic reaction, he had tried out various substances to determine whether any of them would inhibit or prevent such reaction. Nicotinic acid in large amount appeared to have a mild but definite moderating effect, and folic acid almost completely prevented the excretion of coproporphyrin. The significance of this in relation to other disturbances of porphyrin metabolism remained to be determined.

Correspondence

The G.P.'s Clinical Training

SIR,—Dr. D. McI. Johnson's article (*Journal*, August 26, p. 493) on his clinical training of twenty-five years ago makes strange reading. He has not a good thing to say of his medical school. It is incredible. Should he be allowed to get away with this murder? We have often read the boast—a corollary to the other one about the G.P. being the backbone of the profession—that the British medical student is taught to use his eyes, ears, and hands rather than gobble up the output of a machine. A quarter of a century has redeemed Dr. Johnson, but is there not evidence in his account that a major defect in his student experience was his own lack of interest? Dumped unasked into the profession by a professional father, did he have any sense of the importance of what was going on? What would a Martin Arrowsmith have done with his chances?

Someone may rise to the challenge on behalf of the Bart's of that time; my purpose is to counter with the good things in another medical school (Belfast) of a little over twenty-five years ago.

In your first clinical year you were placed, one of a small class, in charge of a tutor who was willing to discuss, and sometimes had to argue. During your second clinical year you could be selected for six months' residence. You really "dressed." You did side-room pathology. You did jobs in the extern and took charge of it at night. You spent Sunday morning dilating strictures for old gonorrhoeal heroes. You anaesthetized for cold lists and emergencies. By the end of the second clinical year you could, if diligent, be in possession of all your class certificates. That meant that in your final hospital year you could direct your own activities; pick the teachers from whom you learned best or, if you preferred it, immure yourself with the patient in the ward and see if you really could detect the presence and nature of valvular and other cardiac lesions by studying the behaviour of the pulse before resorting to your stethoscope. Or you could take a trip to the poor-law hospital and expand or fill-in amongst an astounding wealth of long-stay clinical material.

It would be impossible nowadays to shake hands over your qualifying script with fifty or sixty anaesthetics for major operations behind you—such lushness would be frowned on; but what the medical student in the crowded teaching hospital needs is the liberty of the large non-teaching hospital. The bugbear of the snob teacher is bad teaching, and he is loth to let the fledgling out of his sight. Bad teaching, however, means often enough somebody else's, as a good shoot-up at the Royal Society of Medicine will reveal. The country is full of good clinical material going to waste. Properly used, it would thin out the ranks around the ward beds; pupilships would bring students into intimate clinical medicine, the daily following of the morbid process that Sydenham taught us, as a refreshing change from watching the pointing finger of an academic Cratylus.—I am, etc.,

London, E.7. ROBERT POOTS.

SIR,—I rejoice at Dr. D. McI. Johnson's article (August 26, p. 493). I would like to add a point, and I consider it as important as all that he has written. I desire to protest against the system of student "ragging." It was the etiquette *not* to

ask questions of qualified students, and to ask questions on cases of the students, even those just up from their second examination (I speak of 30 years ago). The exact reverse should be the case. The student should not be expected to know anything. He should be told the diagnosis, etc., and given the opportunity to examine, it being explained what to look for. It is recorded of even Faraday, among the greatest of observers, that he expressed appreciation when, before an experiment was demonstrated to him by another physicist, he was told what to look for.

Personally I used to blush with confusion and went through untold suffering. It was perfectly unreasonable to expect me to know anything about it. Also I venture to say that, owing to this system, fully half of the clinical teaching time was completely wasted. "Teaching" as such—i.e., "drumming in"—was not called for at all. Most of us were highly intelligent, and it would have been better etiquette and kinder to have assumed that we all were. All that was necessary was to pass on the clinical knowledge; association of ideas, judgment, and differential diagnosis would all come from its accumulation. I may mention that I also was an entrance scholar.

I am not sure that I entirely agree with Dr. McI. Johnson's concluding sentences. Teachers in general are born, not made. It is, however, essential for our teachers to be told what a G.P. should be expected to know. They just do not know. At the date that I started in general practice as an assistant I had never seen a piece of wax in any ear.

This idea of a year extra at hospital as intern is perfectly ridiculous. Hospital practice and general practice are mutually exclusive. It is the function of general practice to treat minor or moderately important cases and to sort out major cases for hospital or specialist (of course bearing in mind that the former may later become the latter). Also, in general practice we have to treat the patient as well as the disease. At hospital really only the disease is thought of. The psychology of the patient, what his own ideas may be and what he (or she) comes to the doctor expecting; to what extent he is influenced by advertisements and newspapers and how to deal with this psychology for his or her benefit *and keep the patient*: all this can only come from actual general practice—half a century of hospital practice would be useless.—I am, etc.,

Dagenham, Essex. M. MELGRAVE.

SIR,—I have read with interest the article by "A London Medical Student" (*Journal*, August 26, p. 496), as, having myself qualified but a few years ago, I realize how well he has summed up the problem of medical education from the students' point of view.

I find, however, that I disagree with his recommendation that "it should be part of the registrar's very limited duties to teach junior students in the wards." Looking back on my time in the wards I remember that the teaching done by a registrar was too often most unsuitable for students—especially junior ones. There were, I think, several reasons for this.

First, the registrar has had little or no experience of teaching, and to put him before a group of students at their most impressionable time when they are newly thrust into the wards from the altogether different atmosphere of their preclinical studies is unfair to both parties.

Secondly, the registrar is himself working for a higher examination and his mind tends to be full of abstruse facts, which are precisely what a junior student does not need or want.

Thirdly, the registrar has had but a small experience of medical practice, whether in hospital or "outside," and so has not the wider knowledge necessary to be able to put across to his pupils in an interesting manner the *centre d'intérêt* of his teaching.

This last is, I feel, the most important point. A student must be interested in his subject, and a lot can be done towards this end by a man with many years in practice who is liked and respected and who can make the student interested by drawing on his experiences of people and patients to illustrate and italicize his teaching.—I am, etc.,

Swindon. DAVID F. ALEXANDER.

Pernicious Anaemia and Gastric Carcinoma

SIR,—I like to argue that pernicious anaemia and gastric carcinoma arise together more often than they should by chance; but that there is no evidence that gastric carcinoma has an excessive incidence in the long-standing P.A. patient. Your annotation (August 12, p. 405) states that Mosbech and Videbaek's data fail to support me and that the increased risk of gastric carcinoma is spread out throughout life. If this is so, the risk at any one moment must be approximately trebled. The risk of a P.A. patient aged 50 developing a carcinoma of the stomach would be about the same as the risk in a man aged 60 without P.A.; and the risk in a P.A. patient aged 60 would be about the same as in a healthy man of 70 (Jennings, 1947). The patient with P.A. behaves as if his stomach is ten years older than he is. The additional risk is small and insufficient to justify annual barium meals, or gastroscopies as Schindler recommends.

The facts as stated can, however, be interpreted differently. Mosbech and Videbaek have not as yet published detailed figures, but the following calculation, based on their paper (August 12, p. 390), is quite accurate enough. Since 219 women are followed up for an average period of 10.7 years, there are 2,343.3 female patient-years (10.7 × 219); and there are eight female deaths from gastric carcinoma instead of the 3.5 which we are told would be expected in a similar population without P.A. The 2,343.3 patient-years can be divided into 982.5 patient-years within five years of the onset of P.A. and 1,360.8 patient-years during the period 5–25 years from the onset.

The figure 982.5 is calculated as follows. The 174 women who were followed up for more than five years—i.e., throughout the first five years—give 870 patient-years (5 × 174). The 32 women who die in the first five years can be assumed without substantial inaccuracy to average two and a half years each and give 80 patient-years (2½ × 32); and the 13 patients who have been followed up for less than five years can also be assumed to average two and a half years each, giving 32.5 patient-years (2½ × 13).

If the risk per 1,000 patient-years was the same in the two periods, the 982.5 patient-years within five years of diagnosis would give an expected figure of 1.5 deaths; and the 1,360.8 patient-years during the subsequent 20 years would give two deaths. Actually, however, the patients during the second period must on an average be about 10 years older, and hence the risk per 1,000 years in the second period must be about three times higher. We are thus justified in constructing our table as follows:

Incidence of Gastric Carcinoma in 219 Female P.A. Patients

	Number of Deaths	
	Actual	Expected
Within 5 years of onset of P.A.	5	<1
From 5–25 years after onset of P.A.	3	>2.5
Total	8	3.5

A less than 1 in 1,000 chance should not turn up five times in 982.5 patient-years, and the increased incidence in the first five years after diagnosis is significant. Many of us now believe that latent slow-growing gastric carcinomata are not uncommon. If this is true, full investigation of these 219 women when their P.A. was first diagnosed might have led to the discovery of four or five neoplasms in a relatively hopeful stage.

It is difficult to offer any explanation for Mosbech and Videbaek's male group, but a number of points suggest that there is a sampling fallacy. Could something like this have happened and led to the inclusion of two or three patients who should have been omitted? A patient is treated by his own doctor for pernicious anaemia for a number of years and then something happens. Either he or his doctor becomes dissatisfied. He is sent to a first-class hospital with a P.A. clinic and with special diagnostic facilities. Nothing is found. Two years later he develops carcinoma of the stomach and he is classified as one of the hospital P.A. series who develops carcinoma. In reality he only went to the hospital because his carcinoma was developing; and his neighbour across the street with P.A. who develops a coronary thrombosis or obstruction from a colonic cancer continues to be treated by the general practitioner until he has to be admitted to the little local hospital. In a small series this only needs to happen in 5–10% of cases and

most misleading figures will result. Ordinary hospital records are almost useless for statistical purposes because one can never feel confident that one knows exactly how and why the patient came to the hospital in the first place.—I am, etc.,

London, E.1. DENYS JENNINGS.

REFERENCE

Jennings, D. (1947). *Brit. J. Radiol.*, **20**, 522.

SIR,—In their paper on gastric carcinoma in pernicious anaemia Drs. J. Mosbech and A. Videbaek (*Journal*, August 12, p. 390) refer to other series of cases in addition to their small series, but they make no reference to the large series reported from my clinic at intervals in the past years. As recently as 1948 I reported[1] perhaps the largest series of patients personally observed in the course of 20 years—my present number being 1,820 patients. The causes of death during this period of 301 patients (20%) out of 1,480 who had been treated with liver and/or stomach preparations showed only 1.1% (17) had died of pernicious anaemia, owing to refusal or discontinuance of treatment; the commonest killing diseases in my observed and adequately treated pernicious anaemias were non-gastric cancers (42), cerebral haemorrhage (38), gastric cancer (28), pneumonia (26), and cardiac diseases (18). I have referred in the past to the probability of an increased frequency of carcinoma in these cases in consequence of their much greater expectations of life on modern treatments. This is now being borne out, as time goes on, for, of 1,820 patients with pernicious anaemia seen and treated by me during the last 21 years, 81 have already developed malignant disease; of these, only 34 had gastric carcinomata (19 males, 15 females), the remaining 47 being affected in the caecum, colon, and rectum (5 male, 6 female), oral, pharyngeal, and oesophageal tissues (6 male, 5 female), breast (6), cervix and vagina (5), epithelial tissues (3 male, 1 female), pancreas (1 male, 2 female), bones (1 male, 1 female), prostate (2), and one each liver, bladder, lung. Their sex distribution was 42 females and 39 males.

These are in contrast with the much smaller numbers of Drs. Mosbech and Videbaek, who had 115 deaths (a mortality of 38%) in 301 cases, finding 14 gastric carcinomata and only seven other neoplastic conditions (13 females, 8 males). Apart from the mortality rate in Drs. Mosbech and Videbaek's series, which is almost double that seen in my own group, the sex frequencies are different, for they had 219 females and 82 males (2.67:1), whereas my patients were divided into 1,097 females and 723 males (1.51:1). The familial occurrence of achlorhydria and of pernicious anaemia is well known, as well as in other conditions such as, among others, hypochromic anaemia, diabetes, and perhaps gastric carcinoma. I would refer to previous papers in which these have been very fully considered.[1 2 3] Of course, achlorhydria can hardly be expected to play much part in the greater occurrence of non-gastric neoplasms in pernicious anaemia. I propose to report further on my results at an early date.—I am, etc.,

Psychological Polemics

SIR,—In his review of my book *Freud or Jung* (August 19, p. 446), Dr. Eliot Slater breaks an antique lance in support of eclecticism in matters concerning the psychology of the unconscious. "It is perfectly possible," he says, "to build new theories from fragments taken from Freud and Jung." This is a truism which no one who has followed the development of clinical psychology in this and other countries would dream of disputing. Nor would anyone dispute Dr. Slater's right to engage in this popular pursuit.

His further contention cannot, however, be allowed to pass unchallenged. In my final chapter I maintained that since Jungian theory is completely incompatible with Freudian theory, a fact which Jung himself would not be inclined to deny, the psychological eclectic, however well-intentioned, cannot have it both ways. "This," says Dr. Slater, "is not the way in which science has progressed." But surely this is precisely one of the ways in which science has progressed. No doubt in their time there were astronomers to spare who favoured a compromise between the Ptolemaic and the Copernican systems. There may even have been flat-earthers who gained a passing reputation for scientific detachment by their readiness to agree that the world was also round. But, however much they may have supported their "new" theories by a "capacity for making predictions which prove true when subjected to the test of experience," it may be doubted whether their efforts to get the "best" out of opposing theories contributed any more to the progress of science than does Dr. Slater's naive incursion into the polemics of unconscious psychology.—I am, etc.,

London, W.1. EDWARD GLOVER.

Foetal Pathology and Vitamin A

SIR,—In your leading article on foetal pathology (August 12, p. 404) you mentioned the effect of maternal German measles in producing congenital abnormalities of the eyes and heart, but you did not mention that lack of vitamin A in the maternal diet produces congenital abnormalities in the eyes of piglets[1] and in the eyes[2] and hearts of rats.[3] The latter "are of particular interest because they show remarkable similarity to many congenital cardiovascular conditions that occur in man."[3] As even trivial infections or fever greatly reduce the level of vitamin A in the blood, the foetus must be exposed to a sudden severe deficiency of vitamin A whenever the mother develops an infection. It is therefore tempting to suggest that German measles acts on the foetus indirectly, by its effect on the level of vitamin A in the maternal blood. If this is indeed so, then in those cases of mothers with German measles where the termination of the pregnancy is not considered wise vitamin A should be given. Since during fever the level of vitamin A in the blood cannot be raised by giving it orally, the active vitamin A alcohol should be injected as an aqueous dispersion.—I am, etc.,

Chemotherapy in Tuberculosis

SIR,—The value of any treatment in tuberculosis needs critical assessment, and conditions of therapeutic trial of a new drug or procedure to be controlled. In assessment of results, one must recognize that bed-rest regimen by itself will improve many cases of pulmonary tuberculosis or bring about clinical recovery. The results of treatment by the newer drugs—antibiotic or other—can sometimes better be judged when treatment is begun after some months of strict bed rest. Only then are we entitled to impute beneficial results entirely to chemotherapy, when we have carefully watched progress under conservative treatment alone and judged thereby of the degree of native resistance possessed by patients. Too often such an expectant attitude is overruled both in regard to treatment by pneumothorax or other collapse measure and to chemotherapy, the consequence being that treatment is inaugurated occasionally without a preliminary trial of bed rest and relaxation.

From the practical viewpoint of wishing to do quickly all possible to promote recovery in tuberculosis, it is understandable that specific treatment by drugs may be commenced sometimes precipitately. From the scientific aspect we think it injudicious that papers should be published, cases demonstrated at clinical meetings, etc., purporting to show the efficacy of chemotherapy in tuberculosis either without an adequately controlled series or without taking into account the effects of an initial period of solely conservative treatment.

At a time when the use of the new drugs has advanced little beyond the stage of clinical trial it seems opportune to draw attention again to types of pulmonary tuberculosis prone to heal spontaneously. Chronic and subacute generalized miliary tuberculosis of lungs and also miliary infiltration localized in one lobe or segment ("localized miliary tuberculosis"[1]) are among the categories in which healing tends to occur, unaided by collapse or drug therapy. Where miliary infiltrates are accompanied by thin-walled cavities seen radiologically ("cavitation complex"[2 3]) it is our experience that spontaneous healing and cavity-closure are particularly liable to take place, given sufficient time. Strict and prolonged bed rest and supportive treatment can heal or cause to become quiescent other types of disease which cannot be fitted into any of the above groups. Numerous phthisical persons have been regularly followed-up over a period of years and their lung condition observed by serial radiography during the same period.

The plea in this letter is not to decry the great benefits now afforded by chemotherapy, of which the value in selected cases is beyond dispute and is often outstanding. Our purpose is to induce others, in recording results of treatment, to weigh in the balance the results obtainable by bed rest alone for a preliminary period of months.

One may question, for instance, the validity of conclusions reached where chemotherapy has been begun without delay in those who have had a recent haemoptysis. Cases have been put on record in which rapid clearing of *x*-ray shadows in the lungs has been attributed to chemotherapy. In "post-haemoptysis" patients it has long been recognized that abnormal *x*-ray appearances may be due to numerous small atelectases, or to non-specific lesions, as well as to spread of tuberculous disease. It is indispensable to show by serial radiography during the ensuing weeks or months whether or not these *x*-ray manifestations after haemoptysis are specific tuberculous lesions. If they are non-specific, they will usually resolve without chemotherapy. If they are tuberculous they, too, may clear in time under bed rest and conservative measures. When antibiotics or other drugs are given in these cases without preliminary observation and assessment of the results of bed rest, then one is not justified in attributing success solely to the drug or combination of drugs that is being used. There are types of tuberculosis in which one should not deprive the patient of chemotherapy instituted at the earliest moment—toxic, exudative, or acute miliary disease, cases of advancing early or intermediate disease, painful ulcerative lesions of larynx or pharynx, etc. One does not blame, either, the doctor who gives an immediate trial of specific therapy to those in whom alternative treatment is not feasible and the prognosis appears grave.

Nevertheless we feel that, as has happened to some extent in the use of sulphonamides and penicillin in certain non-tuberculous conditions, misuse of chemotherapy in tuberculosis may soon arise, if it has not already, unless the considerations mentioned in this letter and others are constantly borne in mind by doctors, both in and outside institutions, who are called upon to treat the disease.—We are, etc.,

Crisis in Tuberculosis

SIR,—Dr. W. H. Tattersall (*Journal*, August 12, p. 416) made a plea for the necessary facilities for the chest physicians to do their job. This relates in particular to the provision of beds under the control of the chest physician in local hospitals. Speaking as one who has no beds, I must agree wholeheartedly, but I cannot share his implied optimism that Ministry of Health memorandum R.H.B. (50) 64 (see *Journal*, July 15, p. 162) will quickly improve the bed position. There is far too much deep-rooted opposition to the provision of beds for pulmonary tuberculosis in general hospitals. With regard to the question of central control of beds, it is obvious that a proportion of any such beds must be under the control of the local chest physician if the Central Middlesex scheme (to which the Minister has given his blessing) is to be duplicated in other areas.

In the meantime the responsibility for treatment of the tuberculous patient during the first 6–12 months after diagnosis falls on the local chest physician. While domiciliary treatment of tuberculosis is no new thing (tuberculous patients spend a large proportion of their lives outside sanatoria), an organized attempt to treat all classes of pulmonary tuberculosis in the patient's home from the time of diagnosis is something which has never been a necessary part of the tuberculosis service. It is at least gratifying that the Minister has given his approval to the efforts of some chest physicians to offset the breakdown of the tuberculosis service by instituting active domiciliary treatment of the tuberculous.

In the Borough of Southwark such a scheme has been in operation for over four years. We try to bring a sanatorium regime into the patient's home, and no treatment is begun until it has been proved that the patient understands and obeys the fundamental principle of bed rest. At the end of the first month the patient is brought to the chest clinic by ambulance for a further *x* ray, B.S.R., etc., and the case is then reviewed and subsequent treatment is planned. This treatment may include artificial pneumothorax, pneumoperitoneum, phrenic crush (done at local hospitals), or chemotherapy. A further period of bed rest may often be necessary before collapse therapy is considered safe. The induction of a P.P. or A.P. is done in the patient's home, followed by two refills at two- and five-day intervals. The patient is brought to the clinic by ambulance 13 days after induction for radiography and refill, and subsequently every week until fit enough to attend by public transport. Owing to the difficulty of getting a thoracoscopy, pneumothorax is not attempted if there appears to be any risk of complications. In a case needing thoracoscopy urgently, I am able to arrange for this to be done only through the personal courtesy of a thoracic surgeon and a physician. The regional hospital board can give me no assistance in this direction. As a result of this a P.P. is much more often found to be the safer operation, and with the increasing use of chemotherapy the time between diagnosis and the induction of collapse therapy is becoming longer.

This scheme has proved remarkably satisfactory, but it has of course involved considerable extra work not only for the medical staff but also for the health visitors and clerical staff. There is no doubt that the psychological effect on the patient who knows that something is being done for him must be considered, as well as the institution of sound treatment at the time it is required rather than when the impersonal central waiting-list permits.

The Ministry memorandum also refers to the desirability of early diagnosis and to the necessity for co-operation with general practitioners. In my view the general practitioners will co-operate only if the chest clinic gives them a good service. In 1942 in Southwark I instituted a scheme for radiography of the chest of all cases with minor symptoms of respiratory disease. The response to this has progressively increased. In 1949 nearly 3,000 films were taken. During the past eight years between 2% and 3% of hitherto undiagnosed tuberculosis in need of treatment has been found, besides many other interesting non-tuberculous conditions.—I am, etc.,

London, S.E.17. E. K. PRITCHARD.

Bact. coli and Infantile Gastro-enteritis

SIR,—Your recent editorial comment (*Journal*, July 22, p. 205; see also August 19, p. 460) on the confused terminology of those members of the *Bact. coli* group which are now being studied in association with infantile gastro-enteritis was not undeserved. The terms "alpha" and "beta" types, which were applied by us[1] to organisms isolated in Aberdeen during the 1947 epidemic of gastro-enteritis, were only labels which seemed useful at the time to identify certain serological types. Bray[2] used the term *Bact. coli neapolitanum* for organisms with which our alpha type was serologically identical. However, this term suggests a uniformity of biochemical properties, which is far from being the case. The alpha type, which has since been antigenically classified by Kauffmann as O:111; B3; H −, shows several biochemical variants and has in fact been isolated as a non-lactose fermenter. Taylor[3] in her original paper called the organism D 433, and Rogers[4] named it the B.G.T. strain of *Bact. coli*. In view of the fact, however, that there is at least one more distinct serological type of *Bact. coli* which is frequently found in cases of infantile gastro-enteritis—namely, the beta type (in Kauffmann's classification, O:55; B4, H −)—it might be advantageous to group both organisms together under a common name.

When Kauffmann's serological classification of the coli group is complete we may find that all potentially pathogenic strains associated with gastro-enteritis have certain antigenic properties in common, and it may then be possible to devise a more rational nomenclature. Until such time and in view of their clinical association with gastro-enteritis, I suggest that the two types be labelled *Bact. coli* G.E., types a and b respectively.

Should further serological types of organisms in this group be found in association with gastro-enteritis in infants, or even in adults, they could then simply be styled *Bact. coli* G.E., types c, d, . . . , etc. I hope that this will meet widespread criticism of ambiguous terms originally introduced by us.—I am, etc.,

Stoke-on-Trent. C. GILES.

Training in Preventive Medicine

SIR,—In his presidential address reported in the *Journal* of August 12 (*Supplement*, p. 85) Dr. Gray performs a service in drawing attention to the fact that the main qualification for the practice of preventive medicine is an attitude of mind rather than special experience, and that teaching arrangements as we know them to-day are in many ways ill suited to the task of developing this approach in the future doctor. The student learns from, and has before him as examples, men who have spent the bulk of their professional lives—and that is usually synonymous with their working lives—in the specialized atmosphere of hospitals and in addition, generally speaking, whose daily work is confined to a relatively small section of medicine. Furthermore, the private practice of the hospital consultant has its own peculiar characteristics.

Throughout his three clinical years and during his resident post—the formative years as far as medical education is concerned—the student is in contact with his patients in circumstances divorced from the daily life of the latter. The patient is away from his family, friends, and work, and is quite outside his normal environment. In professional life, however, most doctors meet their patients in their home or working surroundings, and on leaving hospital find they have to see health and sickness in relation to other characteristics of society in quite different perspective—a re-orientation which would be at least minimized if the student were given a broader basis of training during his clinical years.

The medical curriculum has been subject to much criticism and some revision, but I am stimulated by Dr. Gray's address to suggest that some profit might accrue from the institution of ward rounds primarily intended for the purpose of teaching and discussing the social, industrial, and legal aspects of disease. These rounds would best be taken by industrial medical officers, public health medical officers, and some general practitioners who have the background best suited for the task. It seems to me that such rounds could also be integrated with a very much modified course of lectures on public health (I am of course referring only to undergraduate education).—I am, etc.,

Long Stratton. A. E. BROWN.

Antenatal Separation of Umbilical Cord

SIR,—I was much interested in Dr. Annie Sydenham's case of antenatal separation of the umbilical cord (*Journal*, July 1, p. 50), for I had a similar experience about 18 months ago.

The patient, a European primigravida aged 23, had a perfectly normal pregnancy until the 37th week, when she reported that, after some excessive foetal activity, movements ceased and had not reappeared during three days. On examination everything appeared normal except that no movements could be detected, nor could the foetal heart be heard. A radiograph showed overlapping of the cranial bones. Labour not having supervened in a week, an artificial rupture of the membranes was done, and the liquor was found to be heavily coloured with old blood. Owing to the softness of the head the subsequent labour had to be assisted by forceps, but was otherwise normal, and on the birth of the child the cord was observed to be detached at the umbilicus. The placenta was normal. The severed end of the cord was sealed over by membrane over retracted tissue, and the vessels were full of blood clot. The baby weighed 7 lb. 2 oz. (3.2 kg.), and the cord was 28 in. (70 cm.) in length.

The possibilities are extreme torsion of the cord, or several turns round the foetal body or limbs, and a sudden foetal movement causing avulsion. No other explanation could be found, and she has recently had a normal delivery of a full-term baby.—I am, etc.,

Nairobi. KEITH DUFF.

Obituary

SIR JOHN STRATHEARN, C.B.E., M.D.

Sir John Strathearn, who was warden and chief surgeon of the Ophthalmic Hospital of St. John in Jerusalem for the greater part of his professional life, died in Wimborne on August 14 at the age of 71.

John Calderwood Strathearn was educated at the Glasgow High School and at the Universities of Glasgow, Edinburgh, and Berlin. He graduated M.B., Ch.B. in 1901, and proceeded M.D. in 1905. He became a Fellow of the Royal College of Surgeons of Edinburgh in 1911. After holding a number of resident appointments in hospitals in Glasgow he decided to specialize in ophthalmic surgery. In 1908 he was appointed assistant surgeon at the British Ophthalmic Hospital in Jerusalem, but he returned to Scotland in 1911 and set up in practice as an ophthalmic surgeon in Dundee. He was appointed ophthalmic surgeon to the Dundee school board and to the education committee of the Fife County Council.

During the first world war his work in Egypt and Palestine was recognized by the award of the O.B.E. After the war he returned to Palestine, where he remained until his retirement in 1940. During this period his work at the Ophthalmic Hospital of St. John in Jerusalem earned him fame and honour. His advice on ophthalmic problems was often sought by the Government of Palestine, to which he was appointed consultant ophthalmic surgeon. In a country where trachoma is rife and the percentage of blindness as great as, if not greater than, anywhere in the world, his work was of unfailing value. He was promoted C.B.E. in 1928 and was knighted in 1936. He published a number of papers, the best known of which was on the subject of blindness in Palestine. When he returned to England in 1940 his health was not good, but after he had recovered from a serious illness he worked as a surgeon in the E.M.S. In 1946 he finally retired to his house in Dorset.

Dr. Norman Wren writes: The Ophthalmic Hospital of the Order of St. John of Jerusalem has behind it a long tradition of service. It traces its descent from "a little hospital for Christian pilgrims dedicated to St. John the Baptist under the rule of a certain brother Gerard" which the crusaders found in existence when they captured the city of Jerusalem in 1099. Many men have carried on this tradition since then, but John Strathearn did more, he raised it so that the name of the hospital became a household word throughout the scattered towns and small villages of Palestine, Syria, and Transjordan. Even in more distant Arabia his name was known among the wandering Bedouins. I was privileged to work as his sub-warden in the troublous years between 1933 and the early days of the last war. His never flagging patience, his calm unassuming manner, his keen sense of humour, and his great skill as a surgeon were both an education and an inspiration which members of his staff cannot easily forget. The patients at his hospital were his guests, and were treated with the same unfailing courtesy which he accorded in his own home. He spoke Arabic fluently, and had a deep understanding of the ways and customs of those among whom he worked, so that in his contact with them proverb met with proverb, and their difficulties were often solved by the kindly advice he was ever ready to give. Throughout his busy life in Palestine he received untiring help from his wife, who survives him. Such men as John Strathearn need no memorial. It is for ever written in the minds of those among whom they have worked.

E. D. F. writes: In Palestine there is a high incidence of diseases of the eye, and the Ophthalmic Hospital of St. John in Jerusalem is correspondingly hard pressed. To picture a session in such a hospital—a crowded English "out-patients" transposed into an Oriental key—is an exercise for the imagination. Heat and smell and colour contribute generously to tumult. But where Strathearn was working there was quiet, and he was able to exhort and to encourage, to treat and to teach, without raising his voice. For many years he worked with a complete lack of ostentation, and his personality made an imprint on the whole country. Townsfolk, villagers, and nomads all knew, even if they could not pronounce, his name. Doctors and nurses came to St. John's to learn from his deep experience, and his friends came to enjoy his hospitality, and, if he might be persuaded, to hear him play the piano. He slept but ill, and during the night would plan his complicated time-table and gather reserves of quietude for the noisy daylight. Quietude was his genius. Clinical insight, surgical skill, musical talent, patience, wisdom, and humour seemed only secondary attributes of a quiet and modest man.

W. J. DILLING, M.B.

Professor W. J. Dilling, holder of the chair of pharmacology in the University of Liverpool since 1930, died suddenly at his country home in Coniston on August 18 at the age of 64.

Walter James Dilling was educated at Robert Gordon's College and Aberdeen University. He graduated M.B., Ch.B. with honours in 1907. Shortly afterwards he was appointed second assistant in the department of physiology under Professor MacWilliam and became Carnegie research scholar in physiology. Two years later as Carnegie research fellow in pharmacology he went to Rostock University to work under Professor Rudolf Kobert, to whom he became first assistant. He returned to Aberdeen as lecturer in pharmacology, organizing there the first student course in experimental pharmacology in Great Britain. In 1914 he was appointed Robert Pollok Lecturer in materia medica and pharmacology at Glasgow, a post which he held till 1920, when he went to Liverpool as lecturer in pharmacology. His pre-eminence in his own subject and his talents in the larger sphere of academic statesmanship were speedily recognized. He was accorded the title of associate professor in 1926, and in 1930 became the first holder of the chair of pharmacology. His help was sought by most of the universities in the British Isles as external examiner. He was an honorary member of the Pharmaceutical Society. His gifts as an administrator found an outlet in his appointment as Dean of the Faculty of Medicine of Liverpool University in 1924, a position which he held for the next 11 years and again throughout the strenuous war years. On the national level he was a member of the General Medical Council and a Privy Council representative on the Council of the Pharmaceutical Society.

Dilling was the author of many papers on pharmacological subjects, and his best-known work was the *Pharmacology and Therapeutics of the Materia Medica*, which he had just revised for the nineteenth edition at the time of his death. His erudition and his immense capacity for work were seen to advantage in the zeal and thoroughness with which he carried through the task of revision at frequent intervals over a long period of years. He was also the joint author of *Dental Materia Medica, Pharmacology and Therapeutics*.

He served with the R.A.M.C. in both world wars. From 1915 to 1919 he was attached to the Royal Herbert Hospital at Woolwich. During the second world war he added to the duties of professor and dean the arduous task of commanding the medical company of the University Senior Training Corps, holding the rank of major. Long hours superintending the reception of convoys of sick and wounded, often by night, took heavy toll of health and vigour, but the sacrifice was cheerfully made. Dilling took an active part at several of the Annual Meetings of the B.M.A., and was vice-president of the Section of Therapeutics and Pharmacology in 1928 and 1932. He was a member of the Medical Planning Commission set up in 1940.

Professor Dilling was a man of exceptionally varied interests, and he had many friends. He never failed a colleague, and his staff were devoted to him. Harsh criticism was completely foreign to his nature, and his tolerence and understanding were an encouragement to many who sought his help. An easy and friendly manner coupled with a shrewd tongue endeared him not only to his own students but to the Students' Union as a whole, to which he was for years senior treasurer. His name is honoured in the city of Liverpool because of his services to music. His enthusiasm for opera dated back to early days in Germany, and of his many recreational interests music always held pride of place. As its president he was a tower of strength to the University Musical Society. He was a member of the committee of the Liverpool Philharmonic Society for 20 years. He was elected chairman in 1936 and was again chairman when the new Philharmonic Hall, of which the city is justly proud, was opened in 1939.

He leaves a widow and two daughters, one a doctor and the other a senior medical student. A host of friends share their sorrow.—R. W. B.

G. DRUMMOND ROBINSON, M.D., F.R.C.P.

Dr. G. Drummond Robinson, Consultant Obstetric Surgeon to the Westminster and West London Hospitals, died at Royston on August 19 at the age of 85.

George Drummond Robinson, the son of a doctor, was born in Jamaica, and was educated at Bedford School and St. Bartholomew's Hospital. He graduated M.B. in 1889 and proceeded M.D. in 1891. He took the M.R.C.P. in 1893 and became a Fellow of the Royal College of Physicians in 1906. After qualification he held a number of appointments at St. Bartholomew's Hospital, including that of tutor in obstetrics and gynaecology, and he was appointed assistant obstetric physician at the West London Hospital in 1896. He joined the staff of the Westminster Hospital in 1900 and became obstetric and gynaecological surgeon there in 1908; he was also on the staffs at the British Lying-in Hospital, the Western Dispensary, and the West End Hospital for Nervous Diseases. He was examiner in obstetrics and gynaecology for the Conjoint Board and for the Universities of Cambridge, London, and Wales, and published a number of papers on subjects connected with his specialty. Robinson married in 1906 and is survived by his widow and two daughters.

Mr. A. Goodwin writes: Drummond Robinson belonged to a generation in which clinical teaching was regarded as the very essence of medicine. Those were the days when the patient was everything; her look, her own description of her symptoms, her own history (however trivial the details might appear) were all important in trying to find out why she felt ill. In those days the students were taught by him to use their eyes, their hands, their ears, and even their

noses in striving to arrive at a diagnosis. 'Charts, graphs, x-ray photographs, and laboratory reports were regarded as assets to drive home the findings at the bedside and not as a means of making a diagnosis fit someone who had hardly been looked at. There must be many like myself who met him in the later years of his active hospital service who will ever remember his teaching as a classical example of how to approach a patient.

In his earlier days gynaecology was only slowly being recognized as one of the important branches of general surgery, and gynaecologists were apt to be regarded as rather doubtful hybrids of physicians and surgeons. Perhaps because of this his interests were centred more upon the diagnosis than upon the surgical treatment of women's diseases, but he had a progressive mind that was always open to suggestions. He was quick to recognize the great value of cinematography in teaching, his film of normal labour being one of the first of such teaching films to be produced in this country. He remains in the memory of those of us who had the privilege of walking round the wards and working with him as a great teacher of clinical medicine and a most gracious, kindly, and gentle man who never forgot those who had worked for him; indeed, his wonderful letters spurred them on to yet greater efforts.

Dr. FLORENCE LOUIS died on August 16 in London at the age of 46. She studied medicine at the Royal Free Hospital and graduated M.B., B.S. in 1927. She proceeded M.D. in 1932, and took the M.R.C.P. in 1930. She won a number of distinctions at the London School of Medicine for Women, including the Julia Cock postgraduate scholarship and the Gant Medal. She was in turn house-physician, resident pathologist, medical registrar, and curator of the museum at the Royal Free Hospital, and at the time of her death she was physician to the South London Hospital for Women. While she was still a young resident in hospital she discovered that she had diabetes, and with characteristic courage decided that this should not influence her way of life. She married during her appointment as medical registrar and had two sons. During the war she lost her much-loved doctor brother at Arnhem and her younger son, and from that time she drove herself hard, seeing patients, performing post-mortem examinations, and teaching students. During the last year she suffered a succession of illnesses so severe that those who saw her marvelled at her recovery. Her amazing courage and tenacity enabled her to surmount each crushing blow, for she knew too much to be in any doubt of their significance. She was a lovable and lovely person, relentless in her pursuit of knowledge and in her efforts to help her patients. She was a woman of great integrity who had suffered all her life from "the slings and arrows of outrageous fortune" and had not become embittered in the process. Her husband and son have the sympathy of all her friends in the departure of so rare a person.—D. J. K. B.

The Need for Emotional Adjustments in the Elderly, by Dr. L. Cosin, is a pamphlet published by the National Council of Social Service, Inc. (price 1s., from 26, Bedford Square, London, W.C.1), which, though primarily addressed to the wardens of old people's hostels, should prove useful to all who care for the elderly. He tells the story of an old lady who became quarrelsome and suspicious after a few months in a well-organized and economically run hostel, and shows the importance of taking a careful social history in such a case. It emerged that the warden had no knowledge of the emotional attitudes and medical condition of her old people, and when she began to run the hostel like a family instead of like a hotel things improved. Incontinence in the elderly may sometimes be an expression of an unbearable feeling of loneliness. Old people need plenty of encouragement, and work, however simple, which can give them self-confidence and a social position, and the author outlines how this can be done.

No. 32

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended August 12.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1950 (a)	(b)	(c)	(d)	(e)	1949 (Corresponding Week) (a)	(b)	(c)	(d)	(e)

Rate per 1,000 total births (including stillborn)			22					23		

* Measles is not notifiable in Scotland and the returns are therefore an approximation only.

† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

‖ Includes puerperal fever for England and Wales and Eire.

¶ Primary pneumonia no longer notifiable in Eire.

EPIDEMIOLOGICAL NOTES

Poliomyelitis

Notifications of poliomyelitis in the week ended August 19 were: paralytic, 375 (275); non-paralytic, 175 (117); total, 550 (392). The figures for the previous week are shown in parentheses. The increase in total notifications compared with the preceding week was 158, and of these the bulk was due to more numerous notifications in the county areas indicated below:

	Week Ending Aug. 12	Week Ending Aug. 19	Increase
Yorks (W.R.)	21	45	24
London	25	38	13
Warwick	34	47	13
Yorks (N.R.)	4	15	11
Essex	12	23	11
Gloucester	15	26	11
Worcester	16	26	10
Devon	4	14	10
Middlesex	14	23	9
Bucks	—	6	6
Cornwall	—	6	6
	145	269	124

The proportion of non-paralytic cases in the week under review was approximately 32%. The only county areas with no notifications in the two-week period ending August 19 were Huntingdon, Suffolk (West), and the Welsh counties Cardigan, Merioneth, and Radnor. The following counties contributed only 1 notification in these two weeks: Suffolk (East), Anglesey, Brecknock, Caernarvon, Pembroke, and Soke of Peterborough.

The uncorrected notifications in 1947, 1948, and 1949 for the week corresponding to that under review were 691, 78, and 296, respectively.

Discussion of Table

In *England and Wales* decreases were recorded in the number of notifications of measles 1,553, whooping-cough 265, and scarlet fever 261, while the only rises were dysentery 32 and acute poliomyelitis 25.

The largest decreases in the number of notifications of measles were London 190, Gloucestershire 183, Warwickshire 159, Lancashire 112, and the largest rise in incidence was Shropshire 67. No changes were reported in the local trends of diphtheria. Only small variations occurred in the trends of scarlet fever; the largest were decreases in Nottinghamshire 24 and Southampton 23. The only fluctuations of note in the trends of whooping-cough were a fall of 72 in Nottinghamshire and a rise of 42 in Lancashire.

A further rise in the outbreak of dysentery in Leicestershire was reported, 46 cases being notified during the week (Leicester C.B. 43). The other large returns were: Lancashire 52 (Oldham C.B. 14), Yorkshire West Riding 49 (Morley M.B. 24), Durham 10.

The largest returns of acute poliomyelitis were: Lancashire, 36 (Liverpool C.B. 12, Blackpool C.B. 5, Manchester C.B. 5); Warwickshire, 34 (Birmingham C.B. 23, Sutton Coldfield M.B. 5); London, 25 (distributed over 14 boroughs); Lincolnshire, 25 (East Kesteven R.D. 13); Staffordshire, 22 (Wolverhampton C.B. 5); Yorkshire West Riding, 21 (York C.B. 5); Worcestershire, 16 (Dudley C.B. 5, Halesowen M.B. 5); Surrey, 15 (Godstone R.D. 6); Isle of Wight, 15 (rural district 9); Gloucestershire, 15 (Bristol C.B. 7); Glamorganshire, 13; Essex, 12.

In *Scotland* an increase of 45 was reported in the number of notifications of whooping-cough, and decreases were recorded for scarlet fever 19 and dysentery 7. The notifications of acute poliomyelitis were 5 more than in the preceding week. The largest returns were Glasgow 17, Dundee 9, and Fife county 4. The largest centres of dysentery were Glasgow 47, Edinburgh 11, Dundee 7, Lanark county 5. Three cases of typhoid fever were notified in Glasgow.

In *Eire* decreases occurred in the number of notifications of measles 23 and whooping-cough 15, and an increase for scarlet fever 15. The trend of scarlet fever and whooping-cough was mainly due to the experience of Dublin C.B.

In *Northern Ireland* the number of notifications of measles increased by 18 and those of whooping-cough decreased by 16. Sixteen cases of acute poliomyelitis were notified, the largest number during the present outbreak. The returns for acute poliomyelitis were Belfast C.B. 5, Down county 5, Antrim county 4, and Armagh county 2.

Returns for Week Ending August 19

The notifications of infectious diseases during the week in England and Wales included: scarlet fever 614, whooping-cough 3,939, diphtheria 31, measles 5,529, acute pneumonia 233, acute poliomyelitis 550, dysentery 141, paratyphoid fever 9, typhoid fever 9.

Medical News

W.H.O. Appointment

Dr. Pierre Dorolle has been appointed Deputy Director-General of the World Health Organization. Born in 1899, Dr. Dorolle completed his medical studies in Paris and Bordeaux and specialized in tropical medicine. He has had a wide experience of the control of epidemic diseases in the East.

Poland Withdraws from W.H.O.

Poland has withdrawn from the World Health Organization. The nine other countries which have done so are Albania, Bulgaria, Byelorussia, China, Czechoslovakia, Hungary, Rumania, the Soviet Union, and the Ukraine.

Price of Cortisone Reduced

The price of cortisone has been reduced from $95 to $50 per gramme by the manufacturers, Messrs. Merck and Co. The initial price was $200 per gramme.

Control of Smallpox

In the light of experience during the outbreak of smallpox in the West of Scotland in the spring of this year the Minister of Health has reviewed the arrangements for co-operation between hospitals and medical officers of health in regard to the control of epidemic disease and for the protection of hospital staffs who are liable to be brought into contact with such disease. A circular from the Ministry to hospital boards and committees states that boards should now examine the existing arrangements for co-operation between hospitals and medical officers of health to ensure that they are comprehensive, fully worked out, and generally understood. There should be standing arrangements to provide for the prompt transmission to the M.O.H. of the area, by channels which should be precisely defined in agreement with him, of information concerning any actual or suspected case of smallpox or other epidemic disease which may arise in or be admitted to the hospital. The M.O.H. should be consulted on preventive measures within the hospital to combat the spread of infection. The M.O.H. should send the hospital authorities information on the incidence of epidemic disease, since it may assist in early diagnosis. Nurses and other members of the hospital staffs who are liable to be exposed to risk of infection should be adequately protected against smallpox. Special arrangements should be made in those hospitals where the staff are specially at risk—e.g., in general, children's, and infectious-diseases hospitals. Staff should be offered vaccination or revaccination at least once in every three years. If a case or contact of smallpox arrives at the hospital or is likely to be admitted, vaccination should immediately be offered to all staff and their vaccinal state should be carefully checked. No general rule can be laid down making vaccination compulsory or requiring its acceptance as a condition of employment. In hospitals designated for the reception of smallpox cases special care must be taken to ensure that all members of the staff are adequately protected at all times. In offering vaccination to unvaccinated adolescents or adults the remote chance of complications should be explained.

International Congress of Haematology

On August 23 a dinner in honour of the International Congress of Haematology was held in the Guildhall, Cambridge. Delegates from all over the world were present. In proposing the toast to the Congress, Sir Lionel Whitby, the president, greeted in particular those who had come from distant parts, and said how grateful he was that so many representatives had come from North and from South America. One of the objects of the Congress was discussion on a friendly and personal level of the problems that interested them all. Here they had the opportunity of meeting face to face those whose writings they had read and perhaps criticized or admired.

The size of the Congress (more than 400 sat down to dinner) bore witness to the world-wide interest in haematology. Sir Lionel ended by paying a tribute to those responsible for the organization of the Congress, especially the secretary, Dr. Martin Hynes. Spurning the microphone, Dr. Chevallier, president of the European Society—and perhaps the only professor of haematology—responded eloquently to the toast, observing that the publication of Sir Lionel's book had shown him that Cambridge was not merely a place where young men rowed for exercise.

British Pharmacopoeia Commission

Mr. T. C. Denston, F.R.I.C., has been appointed secretary to the British Pharmacopoeia Commission in succession to Dr. C. H. Hampshire, who will retire on October 4.

Birmingham Medical Library

Birmingham University Medical School has been offered a donation sufficient to provide a new medical library. Plans for the library and a lecture theatre to accommodate 600 people have already been approved at an estimated cost of £100,000. The anonymous donor has been associated with the medical school all his life. During the past 12 years the annual intake at the school has risen from 60 to 110 students, and the library and lecture theatre will ease the difficulties of accommodation which have arisen during that period.

Prize for Investigation into Chest Disease

The American College of Chest Physicians offers a cash prize award of $250 for the best original contribution, preferably by a young investigator, on chest disease. The prize is open to contestants of other countries as well as those residing in the United States. The paper must be submitted to the executive office of the college, from which full particulars may be obtained, at 500, North Dearborn Street, Chicago 10, Illinois, not later than April 1, 1951.

Brussels Treaty Powers Health Committee

The sixth session of the Health Committee of the Brussels Treaty Powers is to be held in St. Andrew's House, Edinburgh, on September 7–9, under the chairmanship of Sir Andrew Davidson, chief medical officer of the Department of Health for Scotland. The committee was set up by the Governments of the Brussels Treaty countries—Belgium, France, Luxembourg, the Netherlands, and the United Kingdom—to consider the development on corresponding lines of health services in these countries. Some of the subjects to be considered at this session are the comparison of medical education, the exchange of medical and auxiliary medical personnel, the protection in wartime of the health of the civil population, and the standardization of blood transfusion apparatus.

Westminster Medical School

The inaugural address of the Westminster Medical School will be delivered by Sir Cecil P. G. Wakeley, President of the Royal College of Surgeons of England, at Church House, Great Smith Street, London, S.W.1, on Monday, October 2, at 3 p.m.

Film Congress

The Fourth Congress of the International Scientific Film Association will be held in Florence on October 14 to 22. There will be a Festival of Scientific Films during the congress. A special committee of the British Scientific Film Association has been formed to recommend films for submission to this festival, and the committee would be glad to have information as soon as possible about recent films. Full details about films for submission should be sent, including running time, gauge, date of production, brief synopsis, etc. Particulars may be obtained from the Scientific Film Association, 4, Great Russell Street, London, W.C.1.

Broncho-oesophagology

A theoretical and practical course in broncho-oesophagology will be held in the Amphithéâtre d'Anatomie des Hôpitaux de Paris on October 19–28. The number participating is limited to 24. Particulars may be obtained before September 30 from Dr. Jean Braine, l'Amphithéâtre d'Anatomie des Hôpitaux, 17, Rue du Fer à Moulin, Paris, 5e.

Courses in Psychiatry

A prospectus of training courses to be held in 1950–1 for psychiatrists, psychologists, and ancillary workers by the Tavistock Clinic may be obtained from the clinic at 2, Beaumont Street, London, W.1.

COMING EVENTS

Digestive Tract

A course on the pathology of the digestive tract will be held at the Hospital de la Santa Cruz y San Pablo, Barcelona, from October 5 to December 16. Particulars may be obtained from the director, Dr. F. Gallart Monés, Escuela de Patología Digestiva, Hospital de la Santa Cruz y San Pablo, Barcelona.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday

CAMBRIDGE UNIVERSITY.—At Biochemical Laboratory, Cambridge, September 4, 3 p.m., "*Hormones and the Anterior Pituitary Gland*," by Dr. H. M. Evans (University of California). Free to all members of the University.

Friday

EDINBURGH POSTGRADUATE BOARD FOR MEDICINE.—At University New Buildings (Anatomy Lecture Theatre), Edinburgh, September 8, 4.30 p.m., "*The Paralysis of Autonomic Ganglia*," by Dr. W. D. M. Paton.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Craib.—On August 20, 1950, at Devonshire Lodge, Eastbourne, to Ann (formerly Neely), wife of Dr. David Craib, a daughter.

Darke.—On August 17, 1950, at Shearwood Road Nursing Home, Sheffield, to Margaret (formerly Wild), wife of Dr. Christopher Darke, a sister for Jonathan and Christopher—Elizabeth Margaret.

Evershed.—On August 8, 1950, at the British Military Hospital, Nairobi, Kenya, to Elizabeth, wife of Squadron Leader T. A. Evershed, M.B., B.Chir., R.A.F., a daughter—Jennifer Margaret.

Lund.—On July 5, 1950, to Dr. Elizabeth Lund, wife of Dr. Maxwell Lund, F.R.C.S.Ed., of 65, Hosking Road, Pietermaritzburg, Natal, a son—Charles Robert.

Peach.—On August 13, 1950, at Colchester, to Pauline (formerly Ward), wife of A. N. Hamilton Peach, F.R.C.S., a daughter—Caroline Hamilton.

MARRIAGE

Molloy—Millett.—On August 5, 1950, at Canterbury, John Molloy to Joan Millett, M.B., B.S.

DEATHS

Bates.—On August 15, 1950, John Vincent Bates, *M.C.*, M.B., B.Ch., of West Malling, Kent.

Dodd.—On August 17, 1950, at 222, Woodstock Road, Oxford, Frederick Henry Dodd, M.R.C.S., L.R.C.P.

Foreman.—On January 15, 1950, Joseph Foreman, M.R.C.S., L.R.C.P., of 125, Macquarie Street, Sydney, Australia.

Glover.—On August 12, 1950, at Brailsford House, near Derby, Norman Glover, B.M., B.Ch.

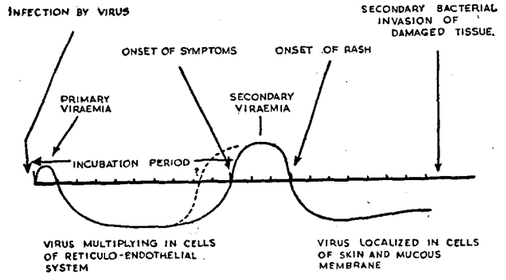
Heard.—On August 16, 1950, at 7, Crossland Crescent, Peebles, Richard Heard, C.I.E., M.D., Major-General I.M.S., retired, aged 80.

Kerr.—On August 14, 1950, at the Royal West Sussex Hospital, Chichester, Arthur Edgar Kerr, M.B., B.Ch., of Tripp Hill House, Fittleworth, Sussex.

Ranken.—On August 7, 1950, at Royal Infirmary, Sunderland, Margaret Ranken, M.B., B.S., of St. George's Square, Sunderland.

Robinson.—On August 19, 1950, at Ivy Court, Royston, Herts, George Henkell Drummond Robinson, M.D., F.R.C.P., aged 85.

Any Questions?



Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Treatment of Smallpox

Q.—*(a) Has chloromycetin any effect on smallpox? During a recent epidemic in India I had a patient with a continued rising pyrexia of six days' duration; she was delirious and seriously ill. Thinking that she was suffering from enteric fever, and without waiting for blood reports, on the sixth day I gave her chloromycetin, 3 g. immediately and 0.25 g. two-hourly. On the seventh day she had large areas of purpura and haematuria. On the eighth day there was no increase in the purpura and a rash very like the smallpox prodromal rash appeared. On the ninth day the typical smallpox rash began to appear, and the chloromycetin was discontinued. Her temperature gradually fell from 104.4° F. (40.2° C.) on the sixth day to normal on the ninth day. The smallpox rash was confluent, the entire dorsum of each of the hands and fingers and feet and toes being covered with one large vesicle. In spite of the severity of the disease, this patient showed no marked secondary rise of temperature. As soon as smallpox was diagnosed she was given sulphonamides and daily injections of liver extract, with the local application of concentrated solution of potassium permanganate. This case was by far the most serious that I treated in this epidemic, but with the exception of very mild cases was the only one in which there was no secondary rise in temperature. The only difference between the treatment of this case and the others was the chloromycetin. In spite of the severity of the rash she had practically no pitting—much less than the other cases—though there was much residual pigmentation of the skin, which now (six weeks after discharge from hospital) is gradually fading. I cannot help but feel that the chloromycetin had a marked effect on the outcome of this case. Is there any other evidence of its having a beneficial effect in the treatment of smallpox?*

(b) I have recently been treating cases of confluent smallpox with intravenous injections of potassium permanganate. I believe that this treatment lessens the risk of septic complications. It was noticed that the lesions remained dry, that irritation was diminished, and that the characteristic smell of confluent smallpox was hardly noticeable. Is the permanganate reduced by the haemoglobin in the blood and is there any risk in treating patients with an intravenous injection of 10 ml. of 1/1,000 potassium permanganate daily for several days?

A.—As a background to the treatment of smallpox the following diagram may be of value. Like all rationalizations it may tend to over-simplify, but, so far as our present knowledge goes,

it gives a fair picture of what is happening during the different stages of the infection.

The purpose of the diagram is really to make two points. First, the virus, which probably multiplies only intracellularly, is free in the blood stream—and therefore susceptible to antiviral substances—at only two periods in the disease—namely, at the primary infection and again just before and during the initial stages of the onset. During most of the incubation period and after the true rash has made its appearance the virus is probably to a large extent beyond the reach of therapeutic substances by reason of its intracellular position. Secondly, the effect of virus damage to the cells of the skin is to encourage bacterial invasion with the formation of the characteristic pustules. Such a picture of the infection permits certain broad generalizations about treatment, which may be listed as follows:

(i) Direct attack upon the virus (as is suggested in the use of potassium permanganate) is likely to be effective only if used either at the moment of initial infection—which is usually impossible to time accurately—or at the end of the incubation period when the virus is again released into the blood stream. The timing of the latter event would also present obvious difficulties. The use of some of the newer antibiotics, say "aureomycin", or chloramphenicol, at this stage might be worthy of trial, however, in view of the suggestion that they may have anti-viral properties. During the remaining period of the illness it is unlikely that any medicament at present known is capable of reaching and neutralizing the virus.

(ii) Chemotherapy, however, has a place in the management of smallpox in inhibiting the secondary bacterial invasion which is a part of every attack. It should be appreciated that the character of such invasion varies from case to case, so that the substance to be used should be aimed at the organism. Sulphonamide will not always be effective, and penicillin may well fail because the responsible bacteria are insusceptible. Chloramphenicol and aureomycin, because of their wider range of action, will therefore suggest themselves.

(iii) Despite the successful use of antibacterial chemotherapy, the patient with severe confluent smallpox may still die from the effects of virus damage and virus toxaemia.

As to the questions themselves, the first raises the interesting point whether this case was in fact treated during the period of the secondary viraemia and should encourage further attempts to repeat the experiment. Of the value of chloramphenicol in reducing the secondary infection there is no doubt, but in the confluent case the patient may die (even when the "pustules" have been rendered bacteriologically sterile) from the gravity of the virus toxaemia. In regard to the second question it seems unlikely that potassium permanganate could have any useful effect in the dosage suggested, and so far as virucidal properties are concerned its value would be subject to the conditions outlined above.

Tuberculous Cervical Adenitis

Q.—*Is P.A.S. a suitable preparation for the treatment of tuberculous cervical adenitis? Would a clinical response be expected in this form of tuberculosis? Would P.A.S. in combination with streptomycin be better? Is there any evidence that this type of treatment with P.A.S. alone, or combined with streptomycin, should be undertaken in this intractable disease?*

A.—The treatment of cervical adenitis with P.A.S., with or without streptomycin, is still very much in the experimental stage. So far the results have not been encouraging. In view of the lymphatic character of the lesion it is hardly to be expected that the drugs in question would have much effect. The administration of streptomycin in these cases is a useful prophylactic measure before operative procedures, but it is doubtful if much benefit can be expected from its use as a routine treatment for this condition.

Chronic Bact. coli Pyelitis

Q.—*How should one treat a chronic Bact. coli pyelitis? Would streptomycin or any other antibiotic be worth a trial?*

A.—Provided that pyelography has excluded any underlying lesion, this remains simply a problem of finding a drug to which this organism is sufficiently sensitive, and the help of the bacteriologist must first be enlisted for this purpose. *Bact. coli*, properly so-called, is usually sensitive to sulphonamides, but more so to some than to others, and if tests show, for instance, that it is more sensitive to sulphathiazole than to other sulphonamides, and this drug has not yet been given, it might

be tried with advantage. If the organism is sensitive to streptomycin, this offers the best chance of a rapid cure. Before this drug is administered the urine must be rendered consistently alkaline, as indicated by a test of the first morning specimen, and the administration of alkali should be continued throughout treatment. It may be necessary to prescribe as much as 2 g. sodium bicarbonate four times a day. Streptomycin is given by intramuscular injection, and in order to keep its concentration in the urine continuously high it is advisable to give three daily doses, which should be of 0.5 g. each. Fluids should not be forced, but if anything restricted. This treatment is usually effective within three days or less. "Aureomycin" is also an excellent urinary antiseptic, and one which might be considered in this type of case.

Stilboestrol and Prostatic Enlargement

Q.—*A 78-year-old man suffering from prostatic enlargement had on several occasions passed urine containing a great deal of blood. On administering 1 mg. of stilboestrol t.d.s. the urine became free from blood after two days. The patient spent the next few weeks in an institution where he had no stilboestrol. Two days after returning home he complained of pain in the pubic region and inability to pass urine except for a few drops now and then. Pending admission to hospital, I ordered stilboestrol again, and the next morning was surprised to find the bladder—which had been up to the umbilicus—empty and the pain gone. If this is a malignant case can the improvement be attributed to stilboestrol? Can a good response to stilboestrol in any case of prostatic enlargement of unknown pathology be interpreted as an indication of malignancy, and does the converse hold good? What are the ill-effects of stilboestrol in cases of benign prostatic enlargement? Is mastitis one of them?*

A.—The ups and downs of a patient suffering from enlargement of the prostate are in any case so great that it is important to be very careful before attributing a temporary improvement to a remedy. Most surgeons would hesitate to attribute the sudden relief of this patient's bladder distension to the stilboestrol, but at the same time the possibility of its being so cannot be denied. Nothing has been stated about the feel of the prostate per rectum, the existence of pain or not, and whether there has been any loss of weight. If anything else suggests the possibility of malignancy it would be worth while continuing with the small doses of stilboestrol already given. Should this lead to still further improvement in the symptoms, then it would not be unreasonable to suspect that there was a malignant focus. Clinically neither stilboestrol nor testosterone have been found to have any effect on the adenomatous prostate. Stilboestrol may produce enlargement and soreness of the nipples, but not a general mastitis.

Neurodermatitis of the Scalp

Q.—*An elderly female patient has suffered from a neurodermatitis of the scalp for a number of years. Clinically there are several "bald" areas where the hairs have broken off; the hairs themselves are split, and the most distressing feature is the formation of a grey crystalline dust which sets up a most intense irritation. Only by constant brushing and combing can some degree of relief be obtained. Is there any line of treatment likely to assist this condition?*

A.—This circumscribed type of neurodermatitis is very persistent and difficult to relieve. It is described by the French as *fausse teigne amiantacée*. Fractional doses of *x* rays carefully administered, tar, as in the following ointment, and such sedatives as phenobarbitone are helpful.

℞ Acid. salicyl. } āā gr. 20 (1.3 g.)
Pic. carb. prep. }
Ung. hydrarg. ammon. aquosum ad 1 oz. (28 g.)
Ft. ung.

The underlying constitutional and psychological factors are naturally of great importance in treatment. The apparent baldness and the broken and split hairs are the result of trauma. Constant brushing and combing, rubbing, and scratching aggravate and perpetuate the affection.

Wart-weed and Spurge for Warts

Q.—*What is the active ingredient in the white juice of the common wart-weed, or spurge, which is sometimes used successfully in the treatment of warts?*

A.—Wart-weed (chelidonium) and spurge (euphorbia) are not synonymous. The juice of chelidonium is yellow rather than white—that of euphorbia is whiter. There are several references in the botanical literature to the destructive effect of both these juices on the vitality of warts, but there is no medical literature on this matter, and it is highly doubtful if they have much effect. As no scientific work has been done on the subject it is sheer speculation to guess at the active ingredients, if indeed they are active. They are possibly euphorbone ($C_{26}H_{44}O_2$), an amorphous resin ($C_{29}H_{32}O_4$), and—it may be—a crystalloid alcohol called euphorbol for which there is apparently no formula.

Iodine, Thyroid, and Aspirin

Q.—*I have recently received samples of a preparation made up as follows: thyroid B.P. ¼ gr. (32 mg.); iodum B.P. ¼ gr. (16 mg.); acid. acetylsalicyl. B.P. 4 gr. (0.25 g.). The powder is in gelatin non-keratinized capsules which smell strongly of iodine. Is it safe to give ¼-gr. doses of metallic iodine? Is there any interaction between the iodine and the other ingredients?*

A.—Chemical interaction between the components of the mixture is not likely to occur. After liberation from the capsule the metallic iodine will be converted to iodide in the intestine. In a dose of ¼ gr. it will have no deleterious effect except on the occasional patient who is sensitive to iodides. The real objection to the preparation is that there seems to be little point in prescribing such a combination of drugs. The only indication for such a dose of iodine is in the pre-operative treatment of thyrotoxicosis, when thyroid should not be used. Similarly, nothing is gained when treating cretinism or myxoedema with thyroid by giving iodine in addition. Finally, there is no evidence that the analgesic effect of acetylsalicylic acid is potentiated by thyroid or iodine.

Nocturnal Cramps

Q.—*A man, aged 60, otherwise in good health, suffers from regular nightly spasm of the adductor muscles of both legs. He is awakened every night by these cramps and has to massage his legs. Mild sedatives have now lost their effect. What do you suggest?*

A.—These nocturnal cramps can be most distressing and are a common cause of sleepless nights in the middle-aged and elderly. The two drugs most effective in their relief are: quinine bihydrochloride gr. 10–15 (0.65–1.0 g.) or nicotinic acid 50 mg. on retiring. It is probably advisable to give a barbiturate as well when starting treatment.

NOTES AND COMMENTS

Methodist Missionary Society.—The Medical Secretary of the Methodist Missionary Society (25, Marylebone Road, London, N.W.1) announces that the Methodist Missionary Hospital at Ilesha, Western Nigeria, is in urgent need of a locum for four to six months. He should have at least two years' postgraduate experience. The society will be responsible for return air passage and for allowances at missionary rates, plus a small outfit allowance. Particulars may be obtained from the society.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology, Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.
Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.
ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Britmedads, Westcent, London.*

STUDIES ON THE NATURE OF THE INTRINSIC FACTOR OF CASTLE*

BY

BYRON E. HALL, M.D.

Division of Medicine, Mayo Clinic, Rochester, Minnesota

In the years immediately following the demonstration by Minot and Murphy (1926) of the therapeutic efficacy of orally administered liver in pernicious anaemia, Castle and his associates (Castle, 1929; Castle and Townsend, 1929; Castle, Townsend, and Heath, 1930a; Castle, Heath, and Strauss, 1931; Castle and Ham, 1936; Castle, Heath, Strauss, and Heinle, 1937), in a series of brilliant investigations, concluded that there was in normal gastric juice from human beings a substance (intrinsic factor) which acted on a dietary substance (extrinsic factor) to produce a material required for the normal maturation of erythrocytes. Patients having pernicious anaemia lacked intrinsic factor.

Since these publications first appeared an intensive search has been made to isolate and to identify substances essential to haematopoiesis and to define the relationships between them. In recent years two pure compounds possessing marked haematopoietic activity have been obtained from liver. The first, pteroylglutamic acid, was isolated in 1943 (Pfiffner *et al.*, 1943) and synthesized in 1945 (Angier *et al.*, 1946). The second, vitamin B_{12}, was isolated in crystalline form in 1948 (Rickes *et al.*, 1948; Smith and Parker, 1948). Both substances possessed the property of converting megaloblastic erythropoiesis to a normoblastic type of regeneration, but only one, vitamin B_{12}, when administered parenterally, was found to be fully as effective as extracts of liver in controlling all manifestations of pernicious anaemia. Pteroylglutamic acid stimulated haematopoiesis, but failed to prevent the development or progression of the neurodegenerative changes characteristic of this disorder.

Vitamin B_{12}, therefore, appeared to be either the anti-pernicious-anaemia component of liver or a substance closely allied to it. However, in contrast to the haematopoietic activity of orally administered extracts of liver, vitamin B_{12}, in doses known to be effective parenterally, failed to produce a haematopoietic response when it was administered by mouth to patients having pernicious anaemia in relapse, unless gastric juice or other known sources of intrinsic factor were given simultaneously with it. Thus it appeared that vitamin B_{12} functioned also as extrinsic factor (Berk *et al.*, 1948; Hall *et al.*, 1949). Confirmation of the extrinsic-factor activity of this substance subsequently was obtained by the demonstration that it was an active haematopoietic component of beef muscle (Gardner *et al.*, 1949; Morgan *et al.*, 1949; Wolf *et al.*, 1950).

Since Minot and Castle (1931) had shown that liver extracts given by intramuscular injection were from thirty to sixty times as active as when administered by the oral route, it appeared to be advisable to determine the therapeutic activity of vitamin B_{12} administered orally in the absence of intrinsic factor, in doses in excess of those known to be effective parenterally. Few data are available in the literature concerning the minimal effective dose of orally administered vitamin B_{12}. In most instances only small quantities have been employed. However, Spies and his associates (1949) presented evidence to show that approximately fifty times the minimal effective parenteral dose is required when vitamin B_{12} is administered by mouth. On the other hand, Meyer and his associates (1950) observed no haematopoietic response to the daily oral administration of 150 μg. to one patient and of 250 μg. to a second patient. These quantities represent doses of from 150 to 250 times the minimal effective parenteral dose.

Oral Administration of Vitamin B_{12} in the Absence of Intrinsic-factor Activity

Nineteen patients having pernicious anaemia in relapse received vitamin B_{12} alone by mouth. Sixteen of the 19 were given the vitamin daily in doses varying from 5 to 100 μg. for periods of from seven to thirteen days (average ten days). The haematopoietic responses elicited are summarized in Table I.** Among 10 of 11 patients who ingested 5 to 10 μg. of vitamin B_{12} daily, haematopoietic

* Sturgis. † Single oral dose. ‡ Vitamin B_{12} concentrate. § Received one meal of cooked liver by error on second day of therapy.

*To be read at the First International Congress of Internal Medicine, Paris, September 11–14, 1950.

**Detailed data concerning the haematopoietic responses noted in these 19 patients have been published elsewhere.

responses either were not observed or they were of such minor degree that they were listed as being insignificant. One patient who received 10 μg. a day showed a significant although suboptimal response. Of the remaining five patients who received daily doses of vitamin B_{12} three were given 100 μg. daily, one 50 μg. daily, and one 25 μg. daily. It is of interest that the patient who ingested 25 μg. a day showed an optimal haematopoietic response, whereas two patients who received 100 μg. daily manifested distinctly suboptimal responses. The patient who was given 50 μg daily and one who was given 100 μg. a day had good but suboptimal responses.

Three of the 19 patients were given single oral doses of vitamin B_{12}, one receiving 25 μg., one 75 μg. on one occasion and 150 μg. seven days later, and one 1,000 μg. No haematopoietic response was observed in the patient ingesting 25 μg. of the vitamin, and the other two patients had suboptimal responses.

Studies on the Nature of Intrinsic Factor

Earlier studies on the nature of intrinsic factor in the gastric juice of human beings have demonstrated that the activity of the material is destroyed by heating to a temperature of 40° C. for three days, of 70° to 80° C. for thirty minutes, and by boiling for five minutes (Castle, Heath, and Strauss, 1931). Intrinsic factor may be separated from the enzymes pepsin and renin by precipitation with casein without losing its activity (Castle, Townsend, and Heath, 1930b; Helmer *et al.*, 1934) and it is not destroyed by a degree of alkalinity (*p*H 9.8 for thirty minutes) which will inactivate pepsin and pepsinogen (Ungley and Moffett, 1936).

Intrinsic factor does not pass through a semi-permeable membrane which permits the passage of extrinsic factor. It is partially soluble in 80% alcohol and 80% acetone and is precipitated on saturation with ammonium sulphate (Helmer and Fouts, 1937; Goldhamer and Kyer, 1938).

The observations of Fouts, Helmer, and Zerfas (1935) on the intrinsic-factor activity of a powdered liver extract are of current interest in view of the isolation of vitamin B_{12} from liver. In 1935 these authors reported that the intrinsic factor contained in from 50 to 100 ml. of normal gastric juice seemed to be the minimal amount necessary to produce an optimal response when incubated with an extract derived from 100 g. of liver and administered by mouth daily to a patient with pernicious anaemia. Some response was obtained from as little as 10 ml. of the juice. The vitamin B_{12} content of the liver extracts employed in these studies is not known, but it seems probable that the daily dose supplied at least 10 μg.

In December, 1948, Berk and his associates demonstrated that vitamin B_{12} functions as food or extrinsic factor when administered by mouth simultaneously with gastric or intrinsic factor to patients having pernicious anaemia in relapse. Normal gastric juice from human beings was used as a source of intrinsic factor. They confirmed the observation of Castle and Ham (1936) that a haematopoietic response was not elicited if an interval of twelve hours elapsed between administrations of sources of extrinsic and intrinsic factors.

The findings of Berk and associates (1948) were confirmed by my associates and me (Hall *et al.*, 1949) in February, 1949. Berkefeld-filtered pooled gastric juice obtained from patients who had either duodenal ulcer or functional disturbances of the gastro-intestinal tract was employed. The haematopoietic activity of the simultaneous oral administration of 5 to 10 μg. of vitamin B_{12} and 100 to 150 ml. of Berkefeld-filtered pooled gastric juice of human beings is shown in Table II.

* Single dose of vitamin B_{12} concentrate.

Since, as has previously been shown by others, intrinsic factor passes readily through a Berkefeld filter, the risk of the transmission of bacterial infections, such as tuberculosis, may be avoided when pooled gastric juice is administered to patients. It also makes possible the collection of relatively large quantities of gastric juice of normal or high acidity in the routine gastric laboratory for the purpose of studying the effects of various physical and chemical agents on intrinsic factor. A preliminary survey of the results of some of these studies has been reported (Campbell *et al.*, 1949).

Some of the earlier observations on the properties of intrinsic factor, derived either from gastric juice of human beings or from the stomach and intestines of swine, have been confirmed in our studies on the effectiveness of orally administered vitamin B_{12} when given in conjunction with various derivatives of gastric juice or gastro-intestinal substances to patients having pernicious anaemia in relapse.

Gastric juice heated to a temperature of 63° C. for thirty minutes was ineffective as an intrinsic factor when given to a patient with pernicious anaemia in a daily dose of 150 ml. together with 5 μg. of vitamin B_{12}. The patient subsequently responded well to 75 ml. of unheated gastric juice daily, with 5 μg. of vitamin B_{12} (Case 2, Table III).

TABLE III.—*Oral Administration of Vitamin B_{12} and Pooled Filtered Gastric Juice of Human Beings: Effect of Heat on Intrinsic Factor*

Case	Period	Daily Oral Therapy*: B_{12} (μg.)	Daily Oral Therapy*: Intrinsic Factor	Days Observed	Erythrocytes (Millions per c.mm.): Onset	Erythrocytes (Millions per c.mm.): End	Maximal Reticulocyte Response: %	Maximal Reticulocyte Response: Day
2	1	5	150 ml. of gastric juice previously heated to 63° C. for 30 min.	12	2·64	2·05	—	—

* Unless otherwise specified.

Since a temperature of 63° C. is required to destroy most viruses, the administration of pooled gastric juice of human beings which possesses intrinsic-factor activity could result in the transmission of a virus infection, such as infectious hepatitis.

Vitamin B_{12}, unlike intrinsic factor, is not destroyed by relatively high temperatures. A thermostable combination of intrinsic factor and vitamin B_{12} was not obtained by allowing a mixture of the vitamin and neutralized gastric juice to stand for twenty-four hours at a temperature of 25° C. before heating to 70° C. for one hour. Such a mixture, containing 100 ml. of gastric juice and 5 μg. of vitamin B_{12}, administered daily to a patient having pernicious anaemia in relapse failed to produce a therapeutic response. During a second period an unheated mixture of the two substances after standing for twenty-four hours at 25° C. was administered orally each day. While the reticulocytosis was suboptimal, there was a significant rise in the erythrocyte count, and the subsequent administration of vitamin B_{12} intramuscularly did not elicit a second reticulocyte response (Case 3, Table III). It was concluded, therefore, that either vitamin B_{12} and intrinsic factor present in human gastric juice did not combine chemically, or if chemical union did occur the product of the interaction was also thermolabile.

Pooled Berkefeld-filtered gastric juice from human beings, collected and stored for three months at a *p*H of 1.7 and a temperature of 5° C., retained intrinsic-factor activity although it appeared to be less active than the fresh material. The results of the daily oral administration of 5 μg. of vitamin B_{12} and 100 ml. of stored gastric juice to two patients having pernicious anaemia in relapse are shown in Table IV. One patient (Case 22, period 2)

TABLE IV.—*Oral Administration of Vitamin B_{12} and Pooled Filtered Human Gastric Juice: Presence of Intrinsic Factor After Storage for Three Months at pH 1.7 and 5°C.*

* Unless otherwise specified.

manifested a reticulocyte peak equal to the estimated maximal response calculated for the initial level of erythrocytes, but there was no rise in the erythrocyte count during administration of the mixture. Since secondary reticulocytosis was demonstrated during period 3, when the patient received vitamin B_{12} and fresh gastric juice, the haematopoietic response to the oral administration of the vitamin and the stored gastric juice probably was suboptimal. The other patient (Case 23), on the other hand, showed a significant haematopoietic response that approached an optimal figure.

At low temperatures the enzymic action of pepsin is largely inhibited, and previously reported observations by Castle and Ham have indicated that loss of the intrinsic-factor activity of gastric juice on standing may be due to inactivation by the native pepsin contained in the juice.

A 95% solution of ethyl alcohol apparently destroys intrinsic factor, inasmuch as no significant haematopoietic activity could be demonstrated in either the precipitate or the soluble fraction of gastric juice when these fractions were administered with vitamin B_{12} successively to a patient having pernicious anaemia in relapse (Case 24, Table V).

TABLE V.—*Oral Administration of Vitamin B_{12} and Precipitates of Gastric Juice of Human Beings*

	3	5	75 ml. of gastric juice	11	2·10	2·87	9·8	8

In November, 1949, Ternberg and Eakin reported that normal gastric juice contained a heat-labile non-dialysable substance which combined with vitamin B_{12} in such a manner as to make the vitamin unavailable for the growth of certain bacteria (*Bacterium coli, Lactobacillus lactis* Dorner, *Lactobacillus leichmannii*). The application of heat to the complex thus formed liberated vitamin B_{12}, whereupon the vitamin again became available for microbial growth. Heated gastric juice did not contain a principle capable of combining with vitamin B_{12}. Ternberg and Eakin (1949) postulated that the heat-labile factor in gastric juice, which they called "apoerythein," either was intrinsic factor itself or an important component of this factor. Commercial preparations of gastric mucosa of swine made for therapeutic use were found to contain a principle which seemed to be analogous to the apoerythein in gastric juice.

Subsequently, Eakin (unpublished data) reported that apoerythein possessed all of the known chemical properties of intrinsic factor. Its concentration was found to be greater in the gastric juice of normal subjects than in that of patients having pernicious anaemia. Eakin estimated that 25 μg. of vitamin B_{12} could be bound by the apoerythein contained in 1.5 litres of gastric juice. This amount of juice is an approximation of the volume secreted by a normal person in twenty-four hours. Apoerythein was found in the lining of the gastro-intestinal tract of all vertebrates studied. Its presence was not demonstrable in other tissues.

In a collaborative study with Dr. Frank Bethell and his associates of the University of Michigan, my associates and I (unpublished data) reported recently the enhancement of haematopoietic activity of orally administered vitamin B_{12} when preparations of stomach and duodenum of swine were given with the vitamin. The results of the simultaneous administration of vitamin B_{12} and extracts of gastric mucosa of swine to two patients with pernicious anaemia in relapse are shown in Table VI. The lyophilized preparation had greater activity than the non-lyophilized material. However, of the extracts employed by us, greatest intrinsic-factor activity was found in the lyophilized non-dialysable fraction of a dilute hydrochloric acid extract of duodenal mucosa. A dilute acid extract of ground whole duodenum, prepared at a *p*H of 3 to 4, was found to be moderately effective when given daily in a dose of 2 g. of desiccated material together with 5 μg. of vitamin B_{12}. Desiccated duodenal mucosa without extraction or fractionation also possessed considerable therapeutic

TABLE VI.—*Oral Administration of Vitamin B_{12} and Extracts of Gastric Mucosa of Swine*

* Unless otherwise specified.

activity when administered by mouth in a dose of 2 to 4 g. together with 5 μg. of vitamin B_{12}.

Bethell and his associates have assayed the vitamin-B_{12}-binding power of these materials and of the gastric juice of normal human beings, according to the method of Ternberg and Eakin, employing the test organism *Lactobacillus leichmannii*. The materials, after sterilization by passage through a Berkefeld filter without heating, were added to the culture medium. The highest binding activity of the duodenal materials tested was shown by the water-soluble non-dialysable fraction of duodenal mucosa. The acid extract of ground whole duodenum possessed about half and the desiccated unfractionated duodenal mucosa about an eighth of the activity of the water-soluble non-dialysable material.

The property of binding vitamin B_{12} shown by derivatives of the lining of the gastro-intestinal tract, which inhibits the characteristic stimulation of microbial growth exerted by the vitamin, should serve as a useful adjunct to the concentration and purification of intrinsic factor. Nevertheless, it seems probable that natural substances other than intrinsic factor may possess the property of combining with vitamin B_{12} in a similar manner. Thus

TABLE VII.—*Oral Administration of Vitamin B_{12} and Egg-white Lysozyme*

* Unless otherwise specified.
† Vitamin B_{12} and egg-white lysozyme administered separately at an interval of twelve hours each day.

C. E. Meyer and his associates (1950) reported that lysozyme derived from egg white formed a complex with vitamin B_{12} which prevented stimulation of the growth of the test organism *Lactobacillus lactis* Dorner by the vitamin. Therapeutic trials on two patients with pernicious anaemia in relapse, employing daily oral doses of a complex of egg lysozyme and amounts of vitamin B_{12} up to 25 μg., have indicated that lysozyme has no significant potentiating effect on orally administered vitamin B_{12}. The results of these observations are shown in Table VII. Recently, two extracts of the gastric mucosa of swine, which showed a strong binding capacity for vitamin B_{12}, as determined by the Ternberg–Eakin method, were found to possess little or no intrinsic-factor activity when tested clinically on patients with pernicious anaemia in relapse (Table VIII).

Comment

Vitamin B_{12}, administered parenterally, is as effective as extracts of liver in the treatment of pernicious anaemia. However, when it is administered by mouth the presence of a potentiating agent is required for its effective utilization. In the absence of such an agent the haematopoietic responses to the oral administration of vitamin B_{12}, in doses up to 100 times the minimal effective parenteral dose, are variable and unpredictable.

Potentiation may be provided by known sources of intrinsic factor, such as the gastric juice of human beings and extracts of the stomach and intestines of swine. Extracts of stomach or duodenum of swine possess intrinsic-factor activity, the activity in duodenal mucosa of swine appearing to be greater than that contained in the entire wall of the stomach or duodenum. However, concentrated preparations that yield consistently effective and reliable therapeutic results when given in relatively small doses have not yet been produced. The barrier to the manufacture of dependable commercial products of this nature has been the destruction of a portion or all of the activity of the intrinsic factor during the process of concentrating gastric or duodenal substances. Until methods for preserving intrinsic-factor activity have been devised, patients with pernicious anaemia who are receiving preparations containing vitamin B_{12} by the oral route must be observed closely, and parenteral therapy substituted if the

haematopoietic and clinical response to oral therapy is not satisfactory.

It would appear that the solution to effective oral therapy is dependent on a clearer understanding of the factors governing absorption in the gastro-intestinal tract. The demonstration by Ternberg and Eakin that vitamin B_{12} may be "bound" by a substance or substances in normal gastric juice of human beings and in the lining of the gastro-intestinal tract of vertebrates, thereby rendering the vitamin no longer available for the growth of certain bacteria, is important, even though present evidence suggests that this method cannot be used, solely as an *in vitro* test for intrinsic-factor activity.

The assumption seems warranted that the role of intrinsic factor must be concerned with absorption of vitamin B_{12} by (1) altering the chemical or physical nature of the compound so that it more readily traverses the intestinal barrier; (2) protecting the vitamin from destruction by secretions of the digestive tract; or (3) preventing the removal of the vitamin from the contents of the upper part of the gastro-intestinal tract by micro-organisms. Little direct evidence has been brought forward in support of any of these hypotheses.

With respect to the possible removal of vitamin B_{12} by bacteria within the gastro-intestinal tract of patients with pernicious anaemia it is pertinent to recall some conclusions to which Davidson (1928) was led by his studies on the gastro-intestinal flora in pernicious anaemia. In 1928 Davidson stated: "A great numerical increase of organisms, normal inhabitants of the bowel—e.g., *Bact. coli*, streptococci, and especially *Cl. welchii*—was found in the gastro-intestinal contents of cases of pernicious anaemia. . . . The great quantitative increase of bacteria, especially at levels of the small intestine which in normal persons are relatively bacteria-free, may be a factor of great aetiological importance." Dick (1941) reported his finding of the almost constant presence of bacteria of the colon and lactis-aerogenes group in the fasting gastric contents of patients with pernicious anaemia, and suggested that there was a profound derangement of the whole gastro-intestinal tract in persons with this disease, which permitted the return of colon bacilli from the colon to the stomach. Recently Davis and Mingoli (personal communication) have shown that *Bact. coli* have an avidity for vitamin B_{12}, and Lichtman, Ginsbert, and Watson (unpublished data) have reported that the daily oral administration of 3 g. of "aureomycin" and 3 μg. of vitamin B_{12} to patients having pernicious anaemia in relapse is followed by haematopoietic responses. Since aureomycin would be expected to reduce greatly the number of coliform organisms in the gastro-intestinal tract, vitamin B_{12} may thereby be made more available for absorption. Studies along this line would appear to be a promising field of investigation.

Summary and Conclusions

In pernicious anaemia, orally administered vitamin B_{12} requires for its effective utilization the presence of a potentiating agent (intrinsic factor of Castle). In the absence of this factor the haematopoietic responses obtained from the oral administration of the vitamin, in doses up to 100 times the minimal effective parenteral dose, are variable and unpredictable. Potentiation may be provided by known sources of intrinsic factor, such as gastric juice of normal or elevated acidity from human beings and extracts of the stomach and intestines of swine. Concentrated preparations that yield consistently effective and reliable therapeutic results, however, have not yet been produced, owing to the ready destructibility of intrinsic factor and the consequent loss of a portion or all of the intrinsic-factor activity during the process of concentrating gastric or duodenal substances. It is believed that the studies herein reported support the concept of the enzymic nature of intrinsic factor.

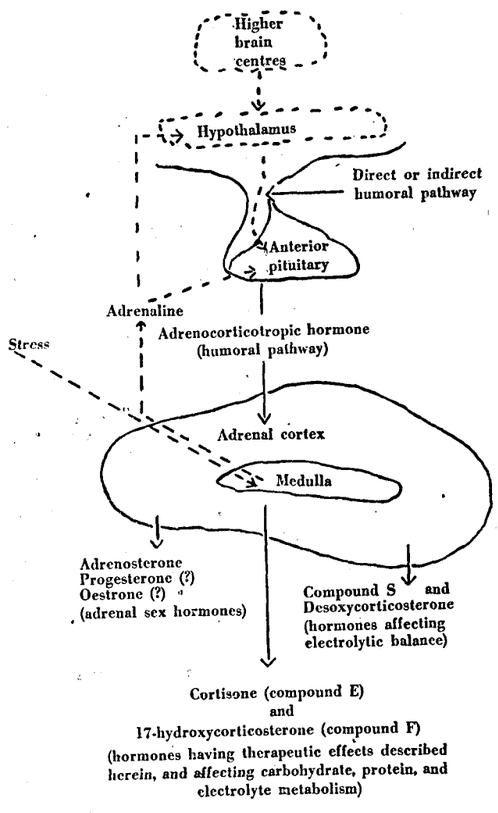
The World Health Organization reports a striking reduction in the malaria rate among the rural population of the Mymensingh District of East Bengal (Pakistan), where a W.H.O. malaria control demonstration team for the past year has been carrying out residual spraying operations with D.D.T. Dr. G. Gramiccia (Italy), the leader of the team, states that not a single case of new infection has been detected in people living in the area which has been covered since this time last year in the spraying operations. There has been a reduction in the rate of enlarged spleen from 74.5% to 21.2% of the children of the area. Incidence of malaria parasites in the blood has been reduced from 22% in May, 1949, to 1.3% in May, 1950. Meanwhile, in the surrounding unsprayed areas the percentages of enlarged spleen and malaria parasites in the blood of children tested have been increasing. In 1949 protection against malaria was provided by this team's operations to about 35,000 people. More than 22,500 separate rooms were sprayed. Dr. Gramiccia added that these encouraging results have had a profound effect on the population, who had taken a rather diffident and sometimes openly hostile attitude at the first. Now they not only are appreciative but earnestly request the continuation of the spraying and the extension of the programme to neighbouring regions.

CORTISONE (COMPOUND E)

SUMMARY OF ITS CLINICAL USES*

BY



J. M. CARLISLE, M.D.

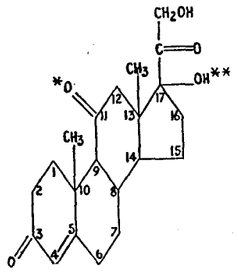
Medical Director, Merck and Co., Inc., Rahway, N.J., U.S.A.

Cortisone is one of the series of crystalline hormonal substances isolated from extracts of the adrenal cortex in the laboratory of Dr. E. C. Kendall, of the Mayo Foundation. This substance, originally named "compound E," was isolated from beef adrenal glands and described by Mason, Myers, and Kendall in 1936. It was also described independently by Reichstein as "substance FA," and by Wintersteiner and Pfiffner as "compound F."

Cortisone was first synthesized from a bile acid in 1946 by Dr. L. H. Sarett, of the Research Laboratories of Merck and Co., Inc. The availability of cortisone in sufficient quantities for clinical use was the result of a practical synthesis developed by the combined efforts of Dr. Kendall and his associates and of Dr. Max Tishler and his associates in the Merck Research Laboratories.

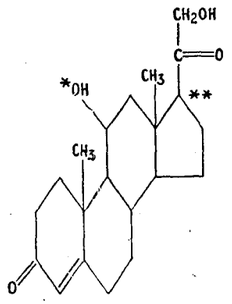
PITUITARY—ADRENAL RELATIONSHIPS

*A paper to be read at the First International Congress of Internal Medicine, Paris, September 11–14, 1950.



Theoretic Mechanism of Adrenal Secretion of Cortisone and Related Adrenal Steroids

The adrenal cortex upon stimulation elaborates (1) the group of hormones producing the therapeutic effects described herein and affecting carbohydrate, protein, and electrolyte metabolism, such as cortisone and compound F; (2) the group affecting electrolyte balance, such as compound S and desoxycorticosterone; and (3) the adrenal sex hormone adrenosterone, and possibly progesterone and oestrone. The present concept is that the secretion of cortical steroid hormones is mainly or entirely mediated through stimulation of the adrenal cortex by the adrenocorticotropic hormone of the anterior pituitary (see Diagram).

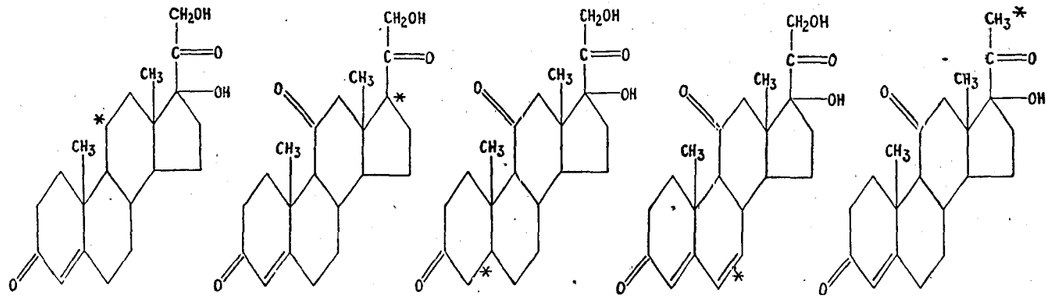


Specificity of the Chemical Structure of Cortisone

From the formula below it will be seen that cortisone has an oxygen atom at position 11* and a hydroxyl group (OH) at position 17**, and that these features differentiate it structurally from the earlier-named corticosterone.

Although the presence of an oxygen atom at position 11 and a hydroxyl group at position 17 are features which are vital to the biological activity of cortisone (and which have required much attention in the synthesis of the hormone),

Cortisone (Kendall's compound E). The chemical name, 17 - hydroxy - 11-dehydrocorticosterone, is based upon points of difference and similarity between the molecular structures of cortisone and corticosterone (Kendall's compound B).



Corticosterone (Kendall's compound B)

it should also be noted that every other atom and configuration of the molecule probably is equally important. This is indicated by the fact that dozens of similar steroids have been prepared and tested for the antirheumatic and other therapeutic activity of cortisone, and that none possesses such activity (with the probable exception of compound F), although chemically each may differ very slightly from cortisone. Examples of a few of these "analogues" are given on the opposite page.

The list could be extended to include many more compounds, now numbering almost fifty, which have been synthesized and tested for cortisone-like activity. As each has been tested and negative results obtained, the remarkable specificity of the cortisone molecule has again been emphasized.

Metabolic Effects

Electrolyte balance is affected in varying degrees in different cases. Retention of sodium and water early in the course of treatment is often observed, especially when high dosage of cortisone has been employed, but is usually followed by spontaneous diuresis on continued

Reichstein's compound S (11-desoxy-17-hydroxycorticosterone, or "desoxycortisone"). *Molecule differs from cortisone only by the absence of an oxygen atom at position 11.

Kendall's compound A (11-dehydrocorticosterone). *Molecule differs from cortisone only by the absence of a hydroxyl group at position 17.

Dihydrocortisone. *Molecule differs from cortisone only by absence of a double bond at position 4, 5 (presence of an extra hydrogen atom).

6, 7 - Dehydrocortisone. *Molecule differs from cortisone only by presence of a double bond at position 6, 7 (absence of a hydrogen atom).

21 - Desoxycortisone. *Molecule differs from cortisone only by the absence of an oxygen atom at position 21.

administration of the hormone or after its discontinuation. In several instances, however, sodium and water retention has been so great as to require lowering the dosage or discontinuing administration of the drug because congestive heart failure with ascites or peripheral or pulmonary oedema developed. Sodium retention can be diminished or avoided by the restriction of sodium intake alone, or together with the use of diuretics during administration of the drug. High dosage of cortisone has caused increased urinary excretion of potassium, with metabolic alkalosis in some cases. In these patients potassium depletion resulting from such loss has produced symptoms of weakness, electrocardiographic changes characteristic of hypopotassaemia (such as lowering of T waves, and depression of the S-T segment and S-T junction), and hypotension. This development can be avoided by carefully following the CO_2-combining power, E.C.G., and chloride depletion. If any changes indicating alkalosis are noted, the dosage of cortisone should be reduced, or potassium administered concomitantly with the hormone. Also, it should be noted that in such cases the use of diuretics may provoke a further dangerous diuresis of potassium.

Carbohydrate metabolism may be affected also, in that blood-sugar levels may be increased and the response to insulin decreased. In patients with diabetes mellitus, insulin requirements are increased during administration of the hormone, but revert to their original levels soon after discontinuation of the drug.

Protein metabolism is affected in many patients, especially those receiving high dosage of cortisone. The continued administration of large doses usually produces a negative nitrogen balance, which may be overcome in certain instances by increased food intake. Where reversed albumin–globulin ratios are present, these tend to revert towards normal. Creatinuria is increased, uric acid excretion increased, and changes in the pattern of amino-acid excretion occur.

Studies in animals suggest that cortisone may inhibit the growth of granulation and fibrous tissues. Clinical studies also have provided evidence which suggests that the hormone may retard wound healing. This must be further evaluated, but these data should be considered when surgical procedures are contemplated in patients receiving cortisone, especially patients with ulcerated or inflamed lesions and those who show evidence of hypoproteinaemia, hypovitaminosis, and general malnutrition.

General Physiological or Hormonal Effects

Cortisone is a potent hormonal substance, and definite physiological effects are to be expected from its administration. With high or prolonged dosage, and in certain patients on the recommended dosage, undesired hormonal effects may occur. However, as with other hormones, such effects are reversible and disappear after administration of the substance is discontinued.

In some patients the drug has produced such evidences of hyperadrenalism as rounding of the face, mild hirsutism, acne, striae of the skin, and, in a few instances, amenorrhoea. All these phenomena disappeared after administration was discontinued.

In animal investigations, prolonged administration of large doses of cortisone may cause reduction in the size of the adrenal cortex. In man, muscular weakness and asthenia have been reported for brief periods after treatment was abruptly withdrawn. This suggests that a transient period of adrenal cortical insufficiency may exist when administration of the drug is stopped. In certain patients a temporary reduction of urinary corticoids and 17-ketosteroids is found; a temporary hypoglycaemia and suppression of eosinophil response occasionally occur.

Electroencephalogram.—In several patients an increase of approximately 10% in the frequency of alpha waves has been observed. This finding is said to indicate increased cerebral activity.

Other Physiological Effects

Cortisone has rarely caused a significant increase of blood pressure, but this possibility exists where sodium and water retention occurs. The resting blood pressure in patients with essential hypertension may be decreased. In some cases decrease in prothrombin time has been noted.

Certain mental effects have been reported. Definite improvement in the mental attitude of patients receiving this drug usually occurs, often with acceleration of the alpha waves of the electroencephalogram. In certain instances the increase in psychomotor activity has temporarily produced an exaggerated sense of well-being and, infrequently, a manic state. Conversely, mental depression has been reported in a few cases. Insomnia has been noted in some individuals. In rare instances pre-existent or latent mental derangement, such as schizophrenia, seems to have been intensified or precipitated. In such cases

premonitory symptoms of the psychotic reaction usually occur, such as pronounced insomnia and exaggerated swings of mood.

Clinical Effects in Rheumatoid Arthritis and its Variants

In rheumatoid arthritis and its variants, such as rheumatoid spondylitis (Marie–Strümpell disease), Still's disease, and psoriatic arthritis, the usual pattern of response is, first, diminution in subjective stiffness, usually within 24 to 48 hours, but sometimes within six hours after the initial dose (Table I) : in many cases this symptom is significantly

TABLE I.—*Response of Various Diseases to Cortisone*

Beneficial Effect Often Dramatic	Results Encouraging But Require Further Evaluation	Transient Beneficial Effects Observed	No Beneficial Effects Established
Rheumatoid arthritis	Various allergies: Hay-fever Angioneurotic oedema Drug sensitization Serum sickness	Acute leukaemia (lymphocytic or granulocytic)	Diabetes mellitus (increases insulin requirement)
Rheumatic fever	Acute gouty arthritis	Multiple myeloma	Myasthenia gravis
Rheumatoid spondylitis	Ulcerative colitis	Lymphosarcoma	Cushing's syndrome
Still's disease	Regional enteritis	Hodgkin's disease	Amyotrophic lateral sclerosis
Psoriatic arthritis	Nephrotic syndrome	Chronic lymphatic leukaemia	Multiple sclerosis
Lupus erythematosus (early)	Scleroderma (early)		Progressive muscular dystrophy
Addison's disease	Dermatomyositis		Progressive muscular atrophy
Asthma (status asthmaticus)	Psoriasis		Congestive heart failure (*may* be detrimental in some cases, but cases secondary to acute carditis may be benefited through effect of *cortisone on* inflammatory lesions)
Inflammatory eye diseases	Periarteritis nodosa (early)		Chronic myelogenous leukaemia
Exfoliative dermatitis	Pulmonary granulomatosis		Acute monocytic leukaemia
Pemphigus	Alcoholism (?)		Glomerulonephritis (exclusive of nephrotic syndrome)
Panhypopituitarism			Poliomyelitis
			Osteoporosis (may be detrimental?)

or completely relieved within a few days. Next, articular tenderness and pain on motion decrease. Finally, swellings of the joints diminish, sometimes fairly rapidly and completely, but occasionally more slowly and incompletely. In many patients mild soft-tissue deformities of the knees or elbows have disappeared within seven to ten days. An increase in muscle strength has been reported. The extent of return to normal has been limited, as must be expected, by the degree of permanent pathological change present.

The appetite usually improves rapidly, and many patients have described a loss of the feeling of malaise associated with the disease and have experienced a sense of well-being, occasionally within several hours after initial administration of the drug.

When cortisone is discontinued signs and symptoms may begin to reappear within 24 to 48 hours, becoming gradually worse during the following two to four weeks. The degree of relapse varies, and is apparently unrelated to the duration of treatment. In some individuals, however, the greater part of the remission of signs and symptoms achieved after use of the drug has persisted for as long as several weeks or months. If the drug is readministered when manifestations of the disease return, prompt remission is again induced.

Laboratory Findings

Erythrocyte Sedimentation Rate.—Elevated sedimentation rates are decreased, sometimes rapidly, during the administration of cortisone, usually becoming normal within 10 to 35 days. Occasionally, however, the rate does not return to normal, but is definitely reduced. In a few instances, persistently high sedimentation rates may be lowered by temporarily increasing the daily dose of the drug.

Haemoglobin.—Low haemoglobin values tend to increase when cortisone is administered. Increases of 2 g. within several weeks have been observed.

Erythrocytes.—Increases of as much as 1,000,000 red cells per c.mm. of blood have been observed in anaemic patients during cortisone therapy of two weeks' duration or longer.

Serum Protein.—Increased serum-globulin levels and low or reversed albumin–globulin ratios usually return towards normal, in most cases promptly, during treatment, but gradually revert to pretreatment levels when the drug is discontinued.

Arterial Synovial Biopsy.—Findings after several weeks of cortisone therapy included almost complete disappearance of lymphocytic reaction, improvement in appearance of collagen, and the presence of many fibroblasts in more adult form. Though not normal, the synoviae revealed definite evidence of healing.

17-Ketosteroids.—During administration of cortisone, urinary 17-ketosteroid values are initially reduced, but they usually rise again, and to a somewhat higher level. When large doses (e.g., 200 mg. daily) are employed the ketosteroids may remain slightly above the pretreatment level throughout the period of administration.

Corticosteroids.—The urinary concentrations of corticosteroids are initially increased by administration of cortisone and may reach a peak of excretion of about 5 mg. per 24 hours soon after treatment is started. The amount excreted then declines gradually to a fairly constant level, ranging from 1 to 2 mg. per 24 hours, on continued administration of the drug. On discontinuing cortisone therapy following prolonged treatment periods or after the injection of large doses of the drug, both 17-ketosteroid and corticosteroid excretion has been observed to diminish temporarily in certain patients.

Clinical Effects in Acute Rheumatic Fever

Within 24 hours after the initial injection of cortisone patients have usually described a sense of well-being and appeared alert instead of ill and "toxic." Temperatures that had been elevated usually became normal within one to four and a half days. Appetites have usually improved, with resultant gains, reaching 5 to 12 lb. (2.3 to 5.4 kg.) in 18 to 28 days in some cases.

Painful, swollen, and inflamed joints have in most instances become symptom-free after three and a half to six days of treatment with cortisone. In most of the patients with acute rheumatic fever improvement has been maintained for periods of three months or longer following treatment. Several patients with acute rheumatic fever who relapsed after the drug was discontinued responded promptly to another series of injections, and have remained apparently well since discontinuation of the drug a second time. While cortisone has demonstrated its value in curtailing the acute manifestations of rheumatic fever, long-term studies will be necessary to evaluate its effects on the development of cardiac lesions.

Effects on Cardiovascular System

Pulse Rate.—Tachycardia, when present, disappeared in three and a half to five days after treatment was started. Bradycardia, ranging from 44 to 60 beats a minute, accompanied the use of the drug in some cases. The bradycardia persisted while

the young adult patients were receiving 200 mg. a day of cortisone, but disappeared shortly after the dose was reduced to 100 mg. daily.

Blood Pressure.—Significant blood-pressure changes have been observed infrequently during or following treatment of acute rheumatic fever with cortisone.

Electrocardiographic Findings.—In patients with prolonged P-R intervals return to normal or nearly normal limits usually occurred within eight days after the beginning of treatment. Electrocardiograms, made daily, showed no evidence of toxic effects on the heart.

Laboratory Findings

Erythrocyte Sedimentation Rate.—Usually the elevated sedimentation rate became normal within 12 to 18 days after injection of cortisone was begun.

Haemoglobin.—Increase in haemoglobin value by as much as 2.4 g. occurred within three weeks in patients in whom the pretreatment levels were low.

Leucocyte Count.—No characteristic effect on the total number of circulating leucocytes was noted during administration of cortisone, despite rapid clinical improvement and reduction of the erythrocyte sedimentation rate.

Serum Proteins.—In almost every instance administration of cortisone caused a slight increase in the values for serum albumin and a reduction in the values for serum globulin.

Response in Other Diseases

Disseminated Lupus Erythematosus.—Cortisone has produced a temporary beneficial effect in most cases in which treatment was started in the early stages of the disease. Elevated temperatures and sedimentation rates have been lowered, joint symptoms improved, and the skin lesions in certain cases alleviated. The general condition of the patient also has been improved. These effects generally last from a few days to a few weeks, and even longer in some patients. Favourable response cannot be expected in late cases with advanced renal involvement, azotaemia, hypoproteinaemia, retinal haemorrhages, and cachexia. Because of the frequent involvement of the heart and kidneys in this disease, the physician should be particularly watchful for evidence of aggravation of salt and water retention and congestive heart failure in response to cortisone.

Bronchial Asthma.—Cortisone administered to patients in status asthmaticus has in most instances produced relief of the symptoms, and in certain patients has increased the vital capacity. The improved state has lasted from several weeks to several months in many of the cases.

Non-specific Iritis, Iridocyclitis, Uveitis, and Sympathetic Ophthalmia.—Striking improvement during the course of cortisone administration has been reported. Congestion has decreased and vision has improved to some extent. In some cases these benefits occur rapidly, but further investigation is necessary before any conclusions can be drawn concerning the efficacy of cortisone in the treatment of these conditions. Recent reports indicate that local ophthalmic instillation of cortisone (as a 1:4 dilution of the standard formulation in physiological saline solution) may also be effective. (Such instillation should be made at intervals of 30 to 60 minutes throughout the waking hours.)

Skin Conditions.—Cortisone has been tried in a variety of severe skin conditions, including pemphigus, angioneurotic oedema, atopic dermatitis, and exfoliative dermatitis, including cases secondary to drug reactions. In general, its use has resulted in improvement, with rapid subsidence of the inflammatory reaction.

Addison's Disease.—Cortisone has been highly effective in controlling Addison's disease, in conjunction with D.C.A. (desoxycorticosterone acetate) and/or supplementary sodium chloride (for special dosage see below).

Leukaemias and Lymphomas.—In some cases of acute leukaemia, especially in children, there is a temporary response to treatment with cortisone, but relapses are to be expected. Even in those cases in which there is an initial response, refractoriness to cortisone develops during repeated courses of the substance. Chronic lymphatic leukaemia, lymphosarcoma, and Hodgkin's disease also have shown transient involution of neoplastic masses. The peripheral blood picture of chronic lymphatic leukaemia apparently is not altered appreciably. Acute monocytic leukaemia and chronic myeloid leukaemia have shown no response to cortisone therapy in several cases treated.

Other Conditions.—Cortisone has been used in investigations of several other conditions, but the data are still very incomplete and inconclusive. From the information available at present, it appears that cortisone does not produce any significant benefit in chronic gout, myasthenia gravis, amyotrophic lateral sclerosis, or congestive heart failure. It has no appreciable effect on the late structural changes of the rheumatic diseases.

Dosage

With high or prolonged dosage, and in certain patients on the recommended dosage (see below), undesired hormonal effects may occur. The physician planning to use cortisone should have received instruction in its use and should familiarize himself with the published literature before attempting treatment.

The treatment should be given only to patients in hospitals which have adequate facilities operated by trained technicians and under the supervision of a qualified physician. Facilities should be available for electrocardiography and for routine blood determinations, such as blood sugar, carbon-dioxide-combining power, and, where possible, for blood electrolytes. Facilities for laboratory studies must be available during the entire course of treatment.

Although cortisone has now been used in over 3,000 individual cases, the duration of clinical study has been less than two years and only a small number of cases have been observed over this entire period. In no instance has continuous treatment been used for a longer period than eight months. Therefore it must be realized that recommendations are limited by the extent of this experience, and that optimal-dosage schedules are still tentative. The administration of cortisone must be carefully adjusted for each patient and regulated according to the effects observed. Failure to obtain an expected therapeutic response suggests, in the absence of any undesirable effects, the possible need for a temporary increase in dosage.

Dosage in Rheumatoid Arthritis

Initial Dosage.—When a maximal response to cortisone is desired in rheumatoid arthritis in adults, the following schedule is strongly recommended : 100 mg. every eight hours for three doses, then 100 mg. every 12 hours for two doses, followed by 100 mg. every 24 hours for 7 to 14 days (the last can be given as a single injection or as a divided dose of 50 mg. every 12 hours. In some cases it seems that the single injection is better). In all cases the injections should be made deeply into the gluteal muscles, at the outer upper quadrant of the buttock. The optimal dosage for children has not been established, but it seems to be more nearly proportional to the severity of the disease than to body size. A comparatively large dose, or the adult dose, may be necessary and is often well tolerated.

Subsequent Dosage.—When the desired response appears to have been obtained the dosage should be lowered gradually in a stepwise manner. The total daily dose should be reduced by 10 or 15 mg. at two- to three-day intervals until the total daily dose is 50 mg. The schedule may then be changed to 100 mg. every other day (or 100 mg. on Monday and Wednesday, and 100 or 200 mg. on Friday). If at any time during the change-over significant relapse occurs, 100 mg.-a-day dosage must be reverted to until the desired response again appears, before lowering the dosage.

Temporary Increases in Dosage.—If the expected response is not obtained within four to five days after initiating cortisone therapy according to the schedule suggested above, the dosage should be increased to 100 mg. every 12 hours for four doses and then again reduced to 100 mg. daily. If inadequate dosage is employed it is likely that the desired beneficial effect will not be obtained. It is essential for many patients that a temporary increase in dosage, as outlined above, be given in order to provide the greatest relief.

Rest Period.—A rest period of not less than three or four weeks should be allowed between courses of treatment with cortisone in order to permit recovery of adrenal activity. A "course" at full therapeutic dosage is generally considered to extend over a period of two to six weeks, and the total dosage per course should not exceed 3 to 4 g.

Dosage in Rheumatic Fever

Optimal dosage for treatment of rheumatic fever has not been established. In the adult cases treated thus far, 200 mg. of cortisone was injected intramuscularly daily for 10 to 19 days, and, following this, 100 mg. daily for 5 to 27 days.

It is suggested that, as a general practice, courses of treatment be extended over a period of 10 to 14 days, with rest periods of varying duration between the courses (see under "Dosage in Rheumatoid Arthritis"), but it is more important that the natural history of the disease be taken into account and that re-treatment be instituted as indicated by recurrence of signs and symptoms of reactivation of the disease, such as return of fever, increase of sedimentation rate, recurrence of arthralgia, and lengthening of the P-R interval.

Dosage in Other Diseases

For eye and skin conditions and the leukaemias and lymphomas the required dosage seems to be comparable to that outlined for rheumatoid arthritis. Somewhat larger doses may be required initially in bronchial asthma, but the duration of treatment necessary is usually not more than five to ten days. In Addison's disease 25 mg. daily, or less, may be adequate, but supplementary salt or desoxycorticosterone should be given concurrently, as indicated, to maintain normal values of blood electrolytes.

Special Precautions

It must be emphasized most strongly that cortisone is an agent with powerful biological actions. The patient receiving cortisone must be closely watched at all times for the development of unfavourable side-reactions. The most important precautions relative to these are :

1. *Evaluation of Relative Contraindications Before Using Cortisone.*—As in the case of other powerful therapeutic agents having potentially harmful effects, the physician must weigh the advantages of treatment with cortisone against the possible deleterious effects. This consideration is crucial where relative contraindications exist, such as diminished cardiac reserve or congestive heart failure, latent or overt psychotic tendencies, diabetes mellitus, and the debility accompanying advanced cachectic states, uraemia, and senescence.

2. *Restriction of Dietary Sodium Chloride.*—Salt and water retention is a common occurrence after several days of full cortisone dosage. Usually there is a gain of only a few pounds in weight and minimal dependent oedema. This may progress, however, and result in pronounced oedema, including pulmonary oedema, or cardiac enlargement and congestive failure, especially in patients with previously diminished cardiac reserve. Occasionally such symptoms may come on quite suddenly. There may be some elevation of arterial blood pressure. Measurement of fluid intake and output and daily weighing of the patient provide the best indices of fluid retention. When salt and fluid retention occurs the simplest treatment is the low-sodium diet. If sodium intake is kept below 1 g. daily for a few days it is usually possible to prevent or correct fluid retention. In some instances it may be necessary to decrease cortisone dosage or even discontinue it.

3. *Correction of Hypopotassaemia.*—When hypopotassaemia develops, supplementary administration of potassium chloride may be required. It is important to note carefully the discussion under "Metabolic Effects," relative to hypochloraemic-hypopotassaemic metabolic alkalosis.

4. *Control of Hyperglycaemia.*—When a patient with diabetes mellitus is treated for a concurrent disease amenable to cortisone the diabetic status must be followed and regulated with great care. It is usually possible to compensate for the anti-insulin effect of cortisone by administering larger doses of insulin—double the usual requirement may be needed. In treating non-diabetic individuals the physician should be aware of the possibility that cortisone may induce renal glycosuria or hyperglycaemia with glycosuria. In all such cases thus far reported these changes have disappeared soon after cortisone administration was discontinued.

5. *Detection of Early Psychic Disturbances.*—Although the usual psychic reaction to cortisone is a desirable increase in the sense of well-being, an occasional individual will develop pronounced psychic derangements, especially where high dosage has been used for protracted periods, but sometimes early during the course of therapy. These reactions include a wide array of phenomena ranging from pronounced euphoria to frank psychoses. Therefore, treatment should be continued with caution when early signs of such reactions appear. The premonitory symptoms are marked swings of mood, severe insomnia, bad dreams, and increased psychomotor activity.

6. *Supervision of Patient Following Cortisone Therapy.*—After discontinuation of cortisone supervision is essential, for this substance may continue to act for some time after the last injection, or there may be a sudden reappearance of severe manifestations of the disease for which the patient was treated. In a few cases following prolonged high dosage, evidence of a temporary hypo-adrenal state may be observed if treatment is withdrawn abruptly. Weakness and hypoglycaemia may occur, but return of adrenal function may be expected within two weeks.

Theories of the Mechanism of Action of Cortisone

It may be said at the outset that the fundamental nature of the action of cortisone against disease processes is unknown. During the past eighteen months, however, much valuable and intensive work has been directed towards the solution of this problem—a widespread research effort which may be expected to bring about a new concept of the nature of disease itself.

It seems likely that cortisone does not act therapeutically through a single circumscribed mechanism, but that this action must involve the many known physiological properties of the hormone as well as various undiscovered effects of this substance on the chemical processes of organs, tissues, and cells of the normal and the diseased organism. At the present time we have information indicating that (1) cortisone and/or compound F is involved in the metabolism of carbohydrate, protein, and fat; (2) it is necessary to the normal function of certain endocrine organs; (3) it exerts profound effects on neuromuscular metabolism; (4) it has distinct immunological effects; (5) it can bring about remarkable cytological changes; and (6) it is involved in several specific enzyme systems (see Table II).

It is for future research to determine which of these effects, or others, are fundamentally associated with the therapeutic activity of cortisone, and which ones are associated only coincidentally. The tendency to oversimplify the problem must be avoided, since it is clear that the hormone is implicated, directly or indirectly, in a large number of the physiochemical processes of the vertebrate organism.

Looking Ahead

The body of knowledge concerning the exact value of cortisone in the treatment of the variety of diseases discussed above is rapidly growing, as is the understanding of its pharmaco-physiological effects. Steadily increasing supplies of cortisone are becoming available, so that clinical and experimental studies are rapidly expanding in number and scope. So, too, the periods of observation on patients already treated are lengthening, and the results are becoming more measurable. Combined, these factors assure that a more exact appraisal of the effects of cortisone will shortly be possible.

TABLE II.—*Certain Known (or Probable) Effects of Cortisone*

Metabolic	Interendocrine	Neuromuscular	Immunological and Serological	Cytological	Enzymological
Increases gluconeogenesis	May either depress thyroid activity (probably via diminished pituitary production of thyrotropic hormone) or *increase sensitivity of tissues* peripherally to thyroid hormone	Restores capacity of muscle for work in adrenalectomized animals	Tends to bring about a restoration of normal A.-G. ratio in disease	Produces lymphopenia (some species) and eosinopenia in peripheral blood	Diminishes hyaluronidase activity
Lowers renal threshold for glucose	Increases insulin requirement. In individuals with normal pancreatic reserve *this requirement is* adequately met, but in latent or overt diabetes additional insulin must be administered	May cause increased activity in electroencephalogram (increase in frequency of alpha waves) or appearance of abnormal slow rhythms	Diminishes antibody response to typhoid antigen in rabbits	May increase tissue eosinophils and metaplasia of fibroblasts into eosinophils	Probably reduces blood glutathione
Opposes the action of insulin	Relative hypoglycaemia may occur after withdrawal of *cortisone*	May restore electroencephalographic pattern to normal in Addison's disease	Diminishes or abolishes tuberculin reaction	Inhibits fibroplasia	May be involved in enzyme systems concerned with pigmentation of skin
Increases mobilization and utilization of fat	Restores normal diuretic response to ingested water in Addison's disease	May induce euphoria and increased psychomotor *activity*	May prevent vascular lesions otherwise resulting from injection of D.C.A. (rats) or heterologous serum (rabbits)	Increases growth of macrophages in tissue culture	Increases arginase in liver and kidney of *mice*
Increases *protein* catabolism, urinary nitrogen, and urinary uric acid	May delay or inhibit menstruation, *probably* via depression of pituitary gonadotropic activity	May precipitate psychotic reaction (probably only in predisposed individuals)	*Prevents or reduces* tissue reaction to chemical irritants (guinea-pigs)	Stimulates reticulocyte production or release	Increases urinary excretion of urodepsin in patients with Addison's disease
Increases deposition of hepatic glycogen		May increase muscle strength (in rheumatoid arthritis) or may cause muscle weakness (probably only in cases of hypopotassaemia)	May inhibit formation of histamine	May bring about polycythaemia	
May bring about retention of sodium				May increase neutrophils in peripheral blood	
Increases urinary excretion of chloride and potassium				Causes involution of lymphoid tissue and of certain neoplastic tissues	
May increase calcium and phosphorus excretion					

A technical committee of the British Standards Institution has devised simple common names for certain pest-control products. A list of 25 names is being circulated for comment among Government departments, manufacturers, and scientific societies before final publication. In order to pre-empt the use of these names as proprietary names, the list has been lodged with, and approved by, H.M. Patent Office.

STREPTOMYCIN AND NEOMYCIN*

AN ANTIBIOTIC APPROACH TO TUBERCULOSIS

BY

SELMAN A. WAKSMAN, Ph.D.

(From the Department of Microbiology, Rutgers University, New Brunswick, N.J., U.S.A.)

"This attempt to place between the covers of a book the record of a drug discovered less than five years ago is a daring and unprecedented one. It suggests a wealth of knowledge, established despite the haste of its gathering. It is particularly daring in the instance of tuberculosis, a disease so chronic in its habit that phthisiologists rarely do more than describe its victims as 'apparently' cured, and so multiple in its manifestations that it required the discovery of the tubercle bacillus to unify its many forms beneath a single name."—Walker, Hinshaw, and Barnwell (Waksman, 1949).

Historical

The history of tuberculosis is as old as that of man himself. It was, however, the discovery of the causative agent of this disease, *Mycobacterium tuberculosis*, by Robert Koch that stimulated the search for "cures" of this "white plague" of man. Most of these, ranging from the tuberculin of Koch himself to the much publicized "gold cure" of recent years, led to serious disappointments. The antibiotics, or those compounds of microbial origin that have the capacity of inhibiting and even of destroying in very dilute solutions the growth of other microbes, especially the causative agents of disease, have given new hope for a final solution of this ancient disease. Although most of the antibiotics are not very effective against the acid-fast bacteria, a few have proved to be highly effective against the mycobacteria, including the tuberculosis organism. Side by side with the discovery of antimycobacterial agents of microbial origin, progress has also been made in the use of synthetic compounds which are non-toxic but still active enough to justify their use in chemotherapy.

*A paper to be read at the First International Congress of Internal Medicine, Paris, September 11–14, 1950

The utilization of micro-organisms as well as their products for the treatment of tuberculosis is not of recent origin. The first attempt at such treatment was made soon after the tuberculosis organism was isolated. Cantani tried in 1885 to utilize living saprophytic bacteria for combating tuberculosis; he was soon followed by Babes, who in 1888 used bacterial products. Later, Rappin and Vaudremer, in 1912–13, treated many patients with products of bacterial metabolism and with metabolic products and cell constituents of fungi, respectively. In general, the history of bacteriotherapy of tuberculosis is a long one (Waksman, 1947). Numerous investigators established beyond question that various saprophytic and pathogenic micro-organisms have the capacity to inhibit the growth of and even to destroy the *M. tuberculosis*. Further studies brought out the fact that this is due primarily to certain well-defined chemical compounds which these micro-organisms are able to produce when grown in artificial culture media and which are now known as antibiotics.

It has been definitely established that the ability to form antibiotics which are active upon the *M. tuberculosis* is widely distributed among various groups of micro-organisms. At least 16 products of fungi, 11 bacterial preparations, and 10 antibiotics of actinomycetes have been isolated and are now well recognized. They are listed in Table I. Most of these compounds or preparations proved

TABLE I.—*Production by Different Micro-organisms of Antibiotics Possessing Antituberculosis Properties*

Fungi	Actinomycetes	Bacteria
Aspergillic acid	Actinomycin	Ayfivin
Aspergillin	Anti-smegmatis factor	*Bacillin*
Biformin	Litmocidin	Endosubtilisin
Clitocybine	Mycomycin	Esperin
Diploicin	Neomycin	Eumycin
Emiatin	Nocardin	Gramicidin
Gliotoxin	Streptin	Licheniformin
Helvolic acid (fumigacin)	Streptothricin	Micrococcin
Javanicin	*Streptomycin*	Nisin
Lactaroviolin	Mannosidostreptomycin	Pyolypic acid
Lateritiin		Subtilin
Mycocidin		
Nebularin		
Polyporin		
Usnic acid		
Ustin		

to be, for one reason or another, quite unsuitable as chemotherapeutic agents. Some were too toxic, others were inactive or insufficiently active in the animal body. Some of them, however, gave definite promise of becoming important tools in combating tuberculosis. Most important of these proved to be streptomycin, an antibiotic produced by an actinomyces, *Streptomyces griseus*, which has already found extensive application in the therapy of tuberculosis.

Antimycobacterial Properties of Streptomycin

Streptomycin is highly active against various strains of *M. tuberculosis* (Waksman, 1949). The degree of sensitivity varies considerably, however, as shown in Table II. Of particular importance is the fact that upon contact with streptomycin, or upon continued administration of this drug to diseased persons, some of the strains tend to develop resistance to the antibiotic. This is shown in Table III, in which the sensitivity of different freshly

TABLE II.—*Comparative Effects of Neomycin and Streptomycin Upon the Growth of Different Mycobacteria (Waksman et al., 1949). Growth Inhibition in Units (for Neomycin) or in Micrograms (for Streptomycin) Per Millilitre of Broth After 14 Days' Incubation*

Organism	Neomycin	Streptomycin
M. avium	0·1–0·3	10·0
M. tuberculosis H37Rv	0·2–1·0	1·0–5·0
M. tuberculosis H37RvR*	0·2–1·0	5,000
Mycobacterium 607	0·1	0·2–0·4
Mycobacterium 607R*	0·25	300

*R = Streptomycin-resistant strain.

TABLE III.—*Comparative Effects of Streptomycin and Neomycin Upon Freshly Isolated Strains of M. tuberculosis (Waksman et al., 1949)*

Strain No.	Source of Culture	Amount of Antibiotic Required to Inhibit Growth in Liquid Medium	
		Streptomycin	Neomycin
		μg./ml.	units/ml.
100	Sinus left hip	1 to 5	<0·5
500	Sinus left flank	1 to 5	<0·5

isolated strains of the pathogen to streptomycin, as compared with neomycin, is presented.

As is shown below, the search for a second antibiotic was stimulated by this limitation of streptomycin—namely, the rapidity with which bacteria develop resistance to it. Both the streptomycin-sensitive and streptomycin-resistant strains of different mycobacteria are sensitive to neomycin. This is true of saprophytic and pathogenic forms, whether the resistance is natural or is acquired by contact with streptomycin.

Search for New Agents

The discovery of streptomycin, and its extensive application in the treatment of various forms of tuberculosis, has aroused great interest on the part of bacteriologists, chemists, and clinicians, and has resulted in further extensive searches for new substances, microbial or synthetic in origin, which would overcome the limitations of streptomycin.

In the search for and selection of new antimicrobial agents, four postulates may be made (Waksman *et al.*, 1949):

1. These substances must be active, not only *in vitro* but also *in vivo*, against the specific micro-organisms. It is desirable that this activity be greater than that of other substances which are now recognized as useful or promising.

2. They must be active against those strains of the disease-producing micro-organisms which are not sensitive or which have become resistant to other chemotherapeutic agents.

3. They should not favour the development of resistance among sensitive bacteria; at least, the new agents should permit lesser emergence of such resistance than existing agents.

4. They should be of low toxicity to animals, or at least they should be no more toxic than agents now used in chemotherapy.

Many organisms have been tested for their capacity to produce such antibiotic agents. Various substances have been isolated in our laboratory since the isolation of streptomycin was reported in 1944, and their activity *in vitro* and *in vivo* has been determined. Of these, only one, neomycin, was found to satisfy the postulates. This conclusion was reached after extensive comparative studies of the effect of streptomycin and neomycin upon various bacteria. These included test-tube studies of both saprophytic and pathogenic mycobacteria and animal studies of both antibiotics against various Gram-positive and Gram-negative bacteria. These studies brought out the following facts:

1. Neomycin is more active than streptomycin against both the saprophytic *Mycobacterium* 607 and the human and animal pathogenic strains of *M. tuberculosis*.

2. Neomycin is as active against the streptomycin-resistant strains of the above organisms as against the sensitive ones.

3. Neomycin favours to a far less degree than does streptomycin the development of resistant strains of mycobacteria; it is true that on prolonged serial transfer of large numbers of cells a considerable increase in resistance may be obtained, but the rate of increase is much slower than in the case of streptomycin.

4. Neomycin is characterized by a relatively low toxicity in animals and has a high therapeutic index.

Before examining the limited experimental and clinical data now available for neomycin, it may be of interest to summarize briefly the very extensive literature on the effect of streptomycin upon tuberculosis. For a detailed review reference can be made to the various works dealing with this subject (Fanconi and Löffler, 1948; Florey *et al.*, 1949; Riggins and Hinshaw, 1949; Waksman, 1949).

Effect of Streptomycin in Experimental and Clinical Tuberculosis

In the first studies on the treatment of experimental tuberculous infections in guinea-pigs with streptomycin the results obtained were strikingly better than those previously reported with the use of various other chemotherapeutic agents. This is brought out in Fig. 1. Feldman and Hinshaw were soon able to state emphatically: "The evidence obtained from the many studies of the effect of streptomycin on the natural course of experimental tuberculosis in animals amply justifies the conclusion that this antibiotic is a highly potent antagonistic agent for tuberculous infections in animals produced by fully virulent tubercle bacilli of human or of bovine type."

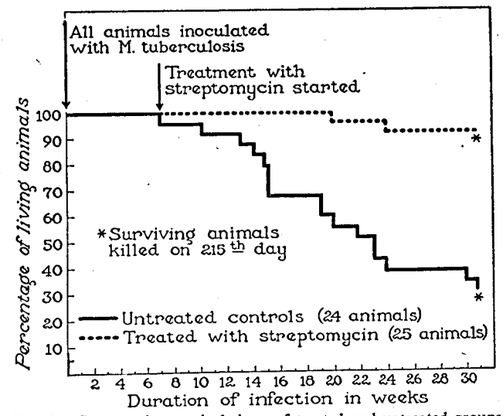

FIG. 1.—Comparative survival times of treated and untreated groups of guinea-pigs (from Feldman, Hinshaw, and Mann, 1945).

Clinical investigations soon followed (Hinshaw and Feldman, 1945; Hinshaw *et al.*, 1946a, 1946b). The first results obtained with streptomycin proved to be encouraging. It is now barely five years since the first clinical cases were reported and since the first attempt was made to manufacture streptomycin in sufficient amounts for large-scale clinical evaluation; a wealth of information which permits certain broad generalizations has already accumulated.

In general, the laboratory demonstrations of the effectiveness of streptomycin *in vitro*, followed by the experimental proof of its usefulness in experimental animals, were fully substantiated by numerous clinical investigations. The large-scale studies conducted in England by the Medical Research Council (1948), and in the United States by the Veterans Administration (Council on Pharmacy and Chemistry, 1950) and the American Trudeau Society (1950), produced adequate evidence that an agent for the treatment of tuberculosis was finally available. Although many hundreds of drugs were previously reported to control the tubercle bacillus in the culture tube, none were able to do so in the animal body. Many drugs that have been effective against the infection in animals were found to be impracticable against the same disease in man. In the case of streptomycin the analogy from laboratory to animal to man held well. It was only in the clinic, however, that investigators finally learned of the potentialities of streptomycin, on the one hand, and of its limitations and dangers on the other.

The clinical usefulness of streptomycin has been carefully summarized by Riggins and Hinshaw (1949) and by Walker, Hinshaw, and Barnwell (Waksman, 1949).

In submitting its report to the Council on Pharmacy and Chemistry (1950), the committee in charge of the work at the Veterans Administration emphasized the importance of combining surgical procedures with chemotherapy. The use of daily doses of 1 g. or less has decidedly reduced the incidence of toxic manifestations. The development of resistant micro-organisms was delayed, especially by the combined administration with para-aminosalicylic acid.

The American Trudeau Society Committee (1950) recommended for adults 1 g. of streptomycin, administered in a single dose intramuscularly, or 1 or 2 g. of dihydrostreptomycin in one or two injections. In miliary tuberculosis and tuberculous meningitis in adults, 2 or 3 g. a day, given intramuscularly in two or three doses of 1 g. each, was recommended. To overcome the emergence of streptomycin-resistant organisms, it has been recommended that streptomycin be administered at greater intervals, as 1 g. every third day or twice a week, or that its daily administration be combined with para-aminosalicylic acid.

It may be of interest to consider in somewhat greater detail certain special forms of tuberculosis.

Meningeal and Acute Miliary Tuberculosis

Since they were first recognized, these two types of tuberculosis have involved a mortality rate of 100%. The time between onset of disease and death was measured in weeks, especially in meningitis. These two forms provided, therefore, an ideal testing ground for the efficacy of streptomycin. It has fully justified itself. Its ability to suppress or destroy the tubercle bacillus was demonstrated. The effectiveness of streptomycin is now generally agreed on by investigators in the U.S.A., in England, and in other European countries. In one series of 100 patients with proved diagnoses, 24 were alive between 14 and 26 months after treatment had been instituted. These results are given in Table IV.

TABLE IV.—*Effect of Streptomycin on Acute Miliary and Meningeal Tuberculosis (From Walker, Hinshaw, and Barnwell—Waksman, 1949)*

Nature of Disease	No. of Patients	No. Living*	No. Dead After Start of Treatment in Months			
			0–1·5	1·5–6	>6	Total
Acute miliary ..	19	12	3	2	2	7

Meningeal developing during or after treatment for miliary ..	13	1	3	4	5	12
Total ..	100	24	36	23	17	76

* All patients still living 14 to 26 months after start of treatment.

Pulmonary Tuberculosis

Pulmonary tuberculosis is commonly considered, both in incidence and in the number of lives it takes, as one of the most serious forms. Since 1900 the mortality rate of tuberculosis has been reduced in the U.S.A. to 20% of its previous rate. In 1942, however, 52,000 deaths were still ascribed to tuberculosis, and of these 92% were due to pulmonary disease. The situation is worse in many European and Asiatic countries, particularly since the recent war. The prolongation of life in patients with meningeal and miliary tuberculosis was ample evidence that streptomycin had a definite effect on tuberculosis. The chronic nature of pulmonary tuberculosis suggests that years will pass before the effectiveness of streptomycin can be evaluated by its effect on the mortality rate.

In the relatively short period since its introduction, however, there has been substantial agreement among investigators that certain immediate results may be expected from its use. The question of toxicity and the development of bacterial resistance were the two controlling factors in establishing the most desirable duration of treatment. Originally a period of 120 days was selected. To lessen the incidence of resistance a decrease in duration of treatment has often been recommended. A reduction in efficacy did not seem to accompany a reduction in duration of treatment to 60 days. A further reduction to 42 days appeared to decrease the efficacy of streptomycin but certainly did not destroy it. The tendency over the last two years has been to reduce the daily dosage of streptomycin from 2 g. to 1 g. or even to 0.5 g. and to reduce the period of treatment from 120 days to 60 days or even less. The first is an attempt to avoid toxicity, and the second to reduce the incidence of resistance.

In a comprehensive study of the effectiveness of streptomycin in tuberculosis carried out under the auspices of the British Medical Research Council (1948), the conclusion was reached that the course of bilateral acute progressive disease can be halted by streptomycin therapy :

"Fifty-one per cent. of the streptomycin-treated patients showed considerable improvement radiologically when comparison was made with their chest radiographs taken on admission. That streptomycin was the agent responsible for this result is attested by the presence in this trial of the control group of patients, among whom considerable improvement was noted in only four (8%), and two of these four patients had improved only after collapse therapy. In other words, streptomycin therapy was effecting what the patient's tissues alone could not do—checking the spread of the tubercle bacillus in one of its most favourable *milieux*."

A summary of these results is presented in Tables V and VI.

TABLE V.—*Assessment of Radiological Appearance at Six Months as Compared with Appearance on Admission (Medical Research Council, 1948)*

Radiological Assessment	Streptomycin Group		Control Group	
	No. of Patients	%	No. of Patients	%
Considerable improvement ..	28	51	4	8

S = Streptomycin treated. C = Control.

Draining Cutaneous Sinuses and Fistulae

The ability of streptomycin to produce healing of tuberculous lesions of mucous and serous membranes, extending to lesions which involve the skin and its underlying tissues, was reported to be most remarkable. Prior to its use, cutaneous sinuses usually continued to drain for years. Their surgical treatment and closure were rarely possible. When treated with even small doses of streptomycin most sinuses were found to heal readily. The effect is so striking that it was not even considered necessary to have untreated controls. In the first clinical report of streptomycin therapy all sinuses in three patients healed during treatment. A much more extensive series of cases is summarized in Table VII.

TABLE VII.—*Effect of Streptomycin Upon 382 Patients with 687 Draining Cutaneous Sinuses and Fistulae (From Walker, Hinshaw, and Barnwell—Waksman, 1949)*

No. of Patients	Treatment: Streptomycin	Treatment: Days	No. of Sinuses and Fistulae	Observations at End of Treatment: Healed (Av. 8 wks.)	Imp.	No Change	Worse	Recurrence After Healing
126	1·8–2 g.	120	257	87·3%	7·8%	4·6%	0·3%	2%
229	1 g.	120	403	69·6%	23·5%	6·9%	0	2·5%
15	0·5 g.	120	15	60%	40%	0	0	0
12	0·2 g.	120	12	83%	17%	0	0	0

On the basis of extensive experience in the use of streptomycin in tuberculosis, Walker, Hinshaw, and Barnwell (Waksman, 1949) concluded :

"The introduction of streptomycin into clinical medicine has been peculiarly exciting to phthisiologists. Not only have they never had an 'antibiotic' which was helpful in the treatment of tuberculosis in man, they have never had a proved effective drug of any sort. So far as chemotherapy is concerned, not only was their situation comparable to that of the syphilologist prior to the discovery of penicillin, it was worse than his position before the appearance of Ehrlich and arsenic. Phthisiologists have been dependent on rest in bed, which finds its climax in the 'lung immobilizer,' and, more recently, on collapse therapy,

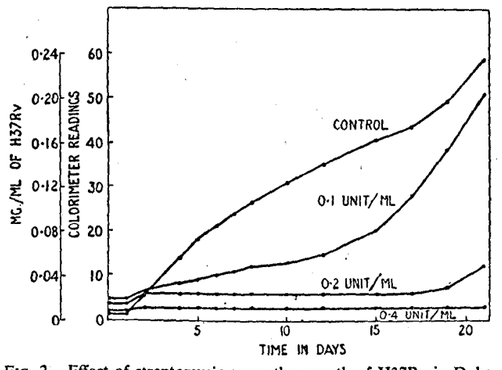

FIG. 2.—Effect of streptomycin upon the growth of H37Rv in Dubo medium (from Steenken and Wolinsky—Waksman, 1949).

which has become most definitive in the form of excisional surgery.

"Chemotherapy is a radical departure from tradition in tuberculosis, and on this account it might have been anticipated that a tuberculostatic drug would be slowly, perhaps inaccurately, evaluated. In the case of streptomycin, this would appear not to have occurred. Within three years after publication of the first clinical paper describing its use, it has been possible to write a chapter of the present sort. This relatively rapid evaluation of a new drug—rapid for tuberculosis if not for pneumococcic pneumonia—is partly the result of experience gained from the investigation of other drugs in other diseases. It is partly a result of the employment, here and in England, of co-operative methods of investigation which have yielded data, reasonably uniform, rapidly, and in large amount; methods which were used, perhaps for the first time, in the beautifully organized study on penicillin and syphilis which was initiated during the recent war."

Development of Resistance to Streptomycin

Attention has already been directed to the fact that among the most important problems involved in the use of streptomycin in tuberculosis is the development of resistance. This is brought out in a study of the effect of different concentrations of streptomycin upon the rate of growth of *M. tuberculosis* (Fig. 2). Steenken and Wolinsky (Waksman, 1949) emphasized that if the obstacle of streptomycin resistance could only be overcome the efficacy of the drug would be greatly increased. Whether by intermittent administration, or by combination of streptomycin with sulphones or para-aminosalicylic acid, or with some other tuberculostatic agent, it was found possible to delay the onset of streptomycin resistance. By shortening the course of therapy for pulmonary tuberculosis to four or six weeks the incidence of resistant strains is diminished. There is considerable variation in the development of drug-resistant strains in the study of a large group of patients. Those who have definite pulmonary cavitation are more likely to produce resistant cultures than are those without cavitation. Patients who start treatment with a high bacillary count in the sputum show a greater tendency to yield drug-resistant cultures during streptomycin therapy than those with few organisms in the sputum. *M. tuberculosis* lodged in the central nervous system becomes resistant less readily than it does in the lungs.

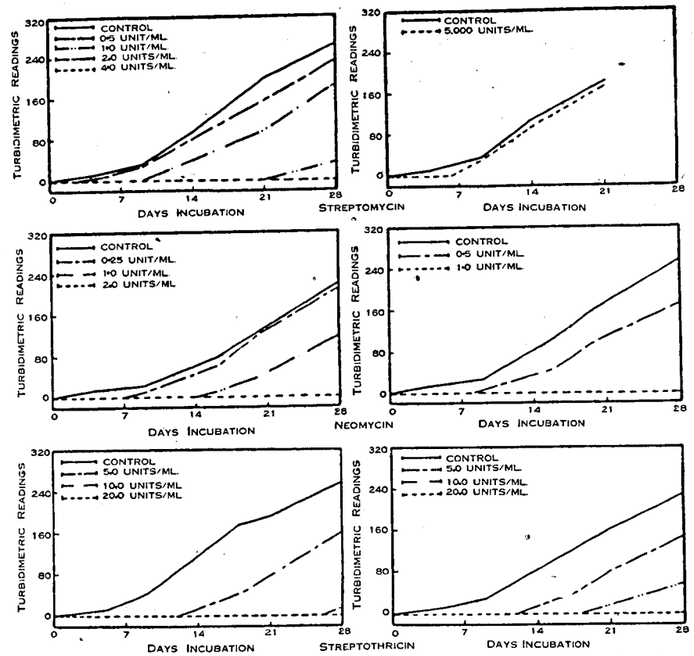

FIG. 4.—Inhibition of growth of streptomycin-sensitive (left) and streptomycin-resistant (right) strains of *M. tuberculosis* H37Rv by three basic antibiotics: upper, streptomycin; middle, neomycin; lower, streptothricin (from Waksman *et al.*, 1949).

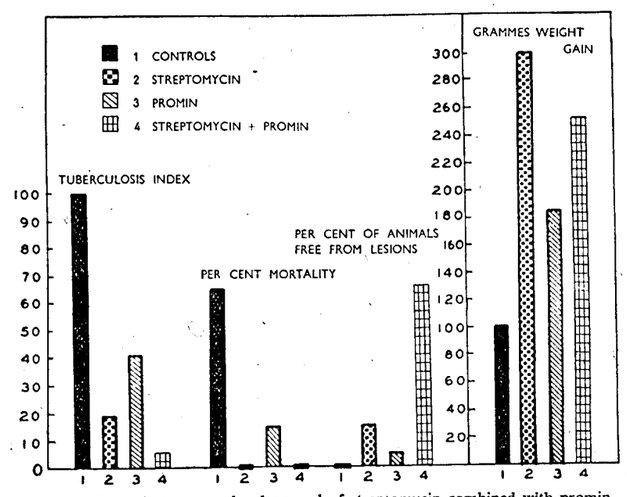

FIG. 3.—Effect of streptomycin alone and of streptomycin combined with promin upon experimental tuberculosis (from Smith and McClosky, 1945).

The possibility of utilizing a combination of two antimycobacterial agents appears, for the present at least, to provide an answer to the problem of development of resistance. This is illustrated in Fig. 3. Another answer may be found in the search for new antibiotics. That this may finally be accomplished is illustrated by the use of neomycin (Fig. 4).

Whether the final solution of the tuberculosis problem will be an antibiotic or a combination of two antibiotics administered together or alternately, such as streptomycin with neomycin, or of an antibiotic and a synthetic compound, only the future can tell. The main conclusion, however, can now be reached: the chemotherapy of tuberculosis is possible. We may only hope that in the near

future this dread disease, the "white plague" of mankind, will become but a memory in the history of man.

Potentialities of Neomycin

Information on the effect of neomycin in experimental and in clinical tuberculosis is still rather scanty. It is difficult to say what this antibiotic will do either in replacing or in supplementing streptomycin. The results presented here are based upon various published and unpublished reports of work done in a number of laboratories in the United States by G. L. Hobby, G. W. Rake, G. Duncan, O. Felsenfeld, and others.

Neomycin possesses a relatively low toxicity for experimental animals, the LD_0 for 20-g. mice being from 750 to 1,500 units. Daily injections of 1,200 to 2,000 units per mouse, administered subcutaneously in divided doses, produced no toxic manifestations. The drug is rapidly absorbed in the body and readily detected in the serum. It is rapidly excreted in the urine. It is highly active in experimental animals, daily dosages of 50 to 110 units per mouse being sufficient to suppress the tuberculous infections. It is just as active against streptomycin-resistant strains as against the sensitive strains.

With regard to the antituberculosis potential of neomycin, it is sufficient to say that in the animals infected with streptomycin-sensitive tubercle bacilli the results of neomycin therapy were, by and large, quite comparable to the results obtained with streptomycin.

One is impressed by the antituberculosis potential of neomycin in experimental tuberculosis against infections induced by either streptomycin-sensitive or streptomycin-resistant tubercle bacilli of the human type, as shown recently by Karlson, Gainer, and Feldman (1950). Until further pharmacological studies exonerate the drug of responsibility for direct or indirect damage to the kidneys, however, its use clinically must be approached with caution.

In human tuberculosis there is an immediate reaction consisting of lowering of the fever and a feeling of well-being. We have not seen toxic reactions with low doses. In two patients there was an increase of the N.P.N. and of the sedimentation rate, which disappeared when the drug was stopped. In some cases, however, definite evidence of a nephrotoxic and ototoxic action was reported.

The results recently published by Karlson, Gainer, and Feldman (1950) brought out the fact that neomycin is capable of producing a reversal of progressive tuberculosis in experimental animals. It is also effective against experimental infections due to streptomycin-resistant tubercle bacilli. A number of clinical cases, representing different forms of tuberculosis, are now being treated with neomycin, and it is expected that before very long a clear picture may be obtained of the potential place that this antibiotic may find in the treatment of tuberculosis. The possibility of combined action of neomycin and streptomycin or another antimicrobial agent is also receiving much consideration.

What of the Future?

The last decade has witnessed considerable progress in the chemotherapy of tuberculosis. From an unknown and questionable possibility, the treatment of this group of diseases by means of chemical agents has become a certainty. The introduction of antibiotics into the field of chemotherapy has opened new potentialities in the eradication of numerous infectious diseases, including tuberculosis. In the case of the latter, streptomycin pointed the way. Announced early in 1944, it has found immediate application in the treatment of various forms of tuberculosis. But streptomycin is not and must not be considered as a cure for tuberculosis.

It has its limitations. Most important of these is its toxic effect upon the eighth nerve and the development of resistance in the infecting agent upon prolonged treatment.

In the search for new antibiotics particular attention has been paid to agents that are more active than streptomycin, that are as active upon the streptomycin-resistant as upon the sensitive strains, and that allow, to a less extent than does streptomycin, the development of resistance. The discovery of neomycin pointed to the possibility of finding such antibiotics. Sooner or later other antibiotics will be found which are more effective than either and less toxic. The fact that in the various surveys on antibiotic production by micro-organisms the acid-fast bacteria are found to be among the most sensitive forms points to the possibility of the existence of such agents. Finding these is merely a matter of further search.

Further possibilities for improving the effect of streptomycin in tuberculosis are found in the combined use of two antibiotics or of an antibiotic and a synthetic compound. We can therefore look forward to a very bright future in the search for chemotherapeutic agents which will prove to be effective in the final eradication of tuberculosis.

As the result of changes made in the National Hospital Service Reserve since recruiting first opened last autumn, the Ministry of Health has now sent an up-to-date outline of the scheme to all hospital authorities. It has come to the Ministry's notice that some of those who served at first-aid posts in the last war—and would be ready to do so again—have held back from joining the National Hospital Service Reserve because they are under the impression that there will be separate recruiting for first-aid-post personnel. This is not the case. Unlike the arrangements in the last war, the first-aid posts will in future be linked directly to hospitals; therefore personnel for all emergency nursing work, whether in hospital wards or first-aid posts, will be recruited and attached to the hospitals themselves. As far as possible those members joining the Reserve who express a preference to serve at first-aid posts will be earmarked for this kind of work. By the end of June membership of the Reserve had risen to 3,225, made up of 266 trained nurses and 2,959 auxiliaries. In supervising the organization of the Reserve, the Ministry has the guidance of a National Advisory Committee of sixteen members which includes representatives of the hospital authorities, St. John Ambulance Brigade, British Red Cross Society, Association of Hospital Matrons, Royal College of Nursing, and other bodies.

CHOICE OF SULPHONAMIDES FOR MIXTURE THERAPY*

BY

DAVID LEHR, M.D.

Associate Professor, Department of Medicine and Pharmacology, New York Medical College; Associate Attending Physician, Flower and Fifth Avenue Hospitals, New York City

Extensive experimental and clinical studies of the last five years have established the advantages of sulphonamide mixture therapy.[1-17]

In brief the rationale for the use of mixtures is as follows: The renal toxicity of most of the newer sulphonamides, if used singly, is due primarily to over-saturation of the tubular urine with a sparingly soluble sulphonamide and/or its metabolic product, resulting in the formation and deposition of drug crystals in the urinary pathways (crystalluria). This event may be followed by haematuria, oliguria, and complete renal shutdown. If instead of a single sulphonamide a combination of partial dosages of several therapeutically equivalent sulphonamides is employed, the danger of crystal formation in the kidney from the drugs comprising the mixture is significantly reduced. In fact, it will be only as great as if each compound had been administered alone and in the partial dosage contained in the mixture, since sulphonamides of different molecular structure, even if closely related, can be dissolved *simultaneously* to the full extent of their individual solubilities. At the same time full therapeutic potency is retained, since the antibacterial effect of such combinations is completely additive and may in many instances even show potentiation of action *in vitro* as well as at the bedside.[1 2 15]

From the standpoint of renal protection, combinations of substantially equal partial dosages of at least *three* sulphonamides were considered adequate in routine therapy in the absence of alkalization.[18] Some objection has been voiced against the use of mixed sulphonamides on theoretical grounds. It was intimated that the concomitant use of several drugs may lead to the simultaneous development of allergy against more than one component of the mixture.[19] Thus the incidence of allergic reactions might be increased and the possibility of "switching" a sensitized patient to another sulphonamide drug might be eliminated.

This thought was based on the concept that the incidence of sensitization to sulphonamides is largely independent of the dosage used. However, this point of view is not borne out by practical experience. Critical evaluation of the vast literature on sulphonamide therapy[12] demonstrated that, in the dosage range employed in human prophylaxis and therapy, the incidence of sensitization increases in direct proportion with the dosage. Table I shows that, for example, at an oral dosage of not more than 2 to 4 g. of sulphanilamide, sulphathiazole, or sulphadiazine in 24 hours, none of these drugs appeared to produce rash or fever in any significant percentage of cases, even if used for prolonged periods and repeatedly in the same individuals. The incidence of allergic reactions assumed significant proportions only when the daily dosage was increased to more than 4 g. and reached even higher percentages with full therapeutic amounts of 6 g. or more, provided medication was maintained for a minimum of three to five days. These observations indicate that the production of sensitization reactions is dependent upon the repeated presence of certain minimal tissue concentrations of a sulphonamide for a minimum period of several days.

TABLE I.—*Relation of Dosage to Incidence of Sulphonamide Allergy*

Drug	Daily Dosage (g.)	Days of Treatment	No. of Cases Treated	Incidence of Rash and Fever
Sulphanilamide ..	1–2	120–240	188	% 1·0
	1·5–4	7–21	1,687	0
	6–9	5–10	1,407	>10·0
	Routine therapy			7·2*
Sulphathiazole ..	2–4	3–15	3,584	0
	6	3–10	2,475	>6·4
	6–10	5–10	529	>10·0
	Routine therapy			11·2*
Sulphadiazine ..	1	12–90	664,840	<0·5
	2–4	3–20	18,185	0·07
	4–6	7–14	500	1·8
	6+	2–31	2,791	2·3
	Routine therapy			2·9*

* These figures are based on a comprehensive compilation of the incidence of rash and fever reported in the literature.

In most patients sensitization is specifically limited to the sulphonamide used. Hence the simultaneous administration of several sulphonamides in *partial* dosage may result in a reduced rather than an increased incidence of sensitization because mixtures permit "dilution" of individual drug concentrations below the level necessary for the production of allergy.

This concept appeared to be substantiated by our experience with more than 700 patients treated with combinations of two or three sulphonamides, including sulphadiazine, sulphamerazine, sulphapyrazine, sulphacetamide, and the "worst offender" sulphathiazole. The incidence of drug rash and fever at the full therapeutic dosage of 6 g. in 24 hours was impressively low and nowhere exceeded 2%.[12]

It has yet to be established whether closely related compounds such as isomers and homologues—e.g., sulphadiazine, sulphapyrazine, sulphamerazine, and sulphamezathine (sulphadimidine)—can be distinguished by the cells of the body as specific haptens. Should they prove indistinguishable, the danger of sensitization from their combined partial dosages could still not be greater than if the equal total amount of any one of these drugs had been employed. Hence no *increased* incidence of allergic reactions should result from any sulphonamide mixture, so long as individual drug concentrations in the tissues are kept well below the level usually necessary for the production of sensitization.

Theoretical Considerations

It seemed of interest to compare some properties of systemic sulphonamides which might help to determine their relative desirability as components of mixtures.

TABLE II.—*Relation of Solubility to Renal Complications*

Drug	Symbol	Solubility in Water 37° C.; pH 5·5 (Mg./100 ml.)		Blockage of Kidneys by Crystalline Deposits
		Free	N, Acetyl	
Sulphadiazine ..	SD	13	20	*Frequent*

Sulphamezathine	SMMD	75	115	Rare ,,
Sulphapyrazine ..	SPZ	5	5	Very frequent
Sulphathiazole ..	ST	98	7	,, ,,
Sulphacetamide ..	SAC	1,100	215	Not encountered
Sulphanilamide ..	SA	1,500	530	,, ,,

*This investigation has been made with the assistance of grants from the Committee on Therapeutic Research, Council on Pharmacy and Chemistry, American Medical Association, and the Schering Corporation, Bloomfield, N.J. A paper to be read at the first International Congress of Internal Medicine, Paris, September 11–14, 1950.

Table II represents an enumeration of systemic sulphonamides which deserve consideration for possible use as combinations. (The symbols for the different drugs shown here will be used in all subsequent graphs and tables.)

It is readily apparent that a definite relationship exists between the solubility of the sulphonamides and their acetylated metabolites and the frequency of renal complications. From this point of view sulphapyrazine would seem to be about the least desirable and sulphacetamide and sulphanilamide the most advantageous compounds. However, the high solubility of sulphanilamide is outweighed by its considerable overall toxicity. For this reason sulphanilamide was not used in our studies.

The behaviour of the other six drugs in the human body, as gleaned from the extensive literature on this subject, is illustrated in Table III. The desirable features of each

drug are there stressed by bold print. Distinct drawbacks are indicated by italics. It can be seen that sulphadiazine is the least plasma-bound, best-diffusing, and least acetylated of the four "diazines." Hence, sulphadiazine rightfully maintains a therapeutic advantage over sulphamerazine and a definite superiority over sulphamezathine and sulphapyrazine. Sulphathiazole shares the disadvantage of excessive plasma-binding with the three last-named drugs and manifests in addition particularly poor diffusion into the cerebrospinal canal. Sulphacetamide, on the other hand, except for low blood levels due to rapid excretion, exceeds even the merits of sulphadiazine with regard to conjugation, diffusion, and plasma-binding.

No substantial differences seem to exist among systemic sulphonamides concerning their antibacterial spectrum. It should be remembered that various sulphonamides possessing a free para-amino group do not display appreciable differences in bacterial affinities. Molecular changes in the N_1 substituent serve to modify quantitative rather than qualitative antibacterial properties.[20]

In the animal experiment sulphathiazole proved the most toxic of the group, closely followed by sulphapyrazine, and then sulphadiazine and its two methyl homologues, which are about equally as toxic, whereas sulphacetamide is about five times less toxic than sulphadiazine.[21]

From a clinical point of view it can be assumed as established that, on the basis of their excellent clinical record, sulphadiazine and sulphamerazine qualify at present for first and second place respectively as components of any mixture. The other four compounds deserve attention as possible *additional* members of a combination.

Experimental Results

With this view in mind, I compared various triple mixtures with regard to antibacterial activity, toxicity, and therapeutic effectiveness in the experimental animal and in man. The majority of the mixtures contained both sulphadiazine and sulphamerazine as constant components, whereas the third component varied between sulphamezathine, sulphapyrazine, sulphathiazole, and sulphacetamide. Most experimental procedures used were closely similar to those outlined previously in detail.[2,7] For the sake of conciseness their description was eliminated from the present report.

No substantial differences were observed with any of the mixtures studied concerning *in vitro* antibacterial activity and efficacy against experimental infections of mice. On the whole the triple mixtures proved about equally as effective as sulphadiazine in identical total concentration or dosage.

Absorption, fate in the body, and excretion of these triple mixtures were investigated in rats, rabbits, and human beings. The results of representative experiments on tissue distribution in groups of albino rats are summarized in Figs. 1 and 2.

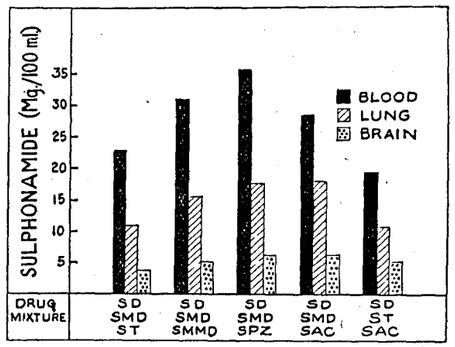

FIG. 1.—Concentrations of sulphonamide mixtures in tissues (single administration in albino rats).

Fig. 1 demonstrates the relationship of the drug concentrations in blood, lungs, and brain three hours after a single oral intubation of five triple mixtures (0.5 g./kg.). Although the sulphapyrazine and sulphamezathine combinations show higher blood levels, the sulphacetamide mixture, which is a close third in this respect, stands out as the one with excellent tissue distribution. In fact, the diffusion of this drug mixture into lungs and brain slightly surpasses that of the sulphapyrazine combination and is distinctly higher than that of the sulphamezathine or sulphathiazole mixture.

Similar results were achieved in 70 rabbits in studies of tissue distribution of sulphonamides from various routes of administration. In addition spinal fluid was obtained in these animals by occipital puncture, so that the blood–spinal-fluid ratio could be calculated. From the oral route of administration the diffusion of the sulphadiazine–sulphamerazine–sulphacetamide mixture through the haematocephalic barrier was as good as that of sulphadiazine, and the absolute concentration in the spinal fluid and blood even somewhat higher than that from sulphadiazine alone.

In the chronic study (Fig. 2), groups of rats were examined in a similar fashion after having been fed a standard diet containing 0.5% of four triple mixtures for 14 days. Here the mixture containing sulphamezathine as third component produced the lowest sulphonamide concentrations in lungs and brain, whereas there was no substantial difference between sulphathiazole, sulphapyrazine, and sulphacetamide in this respect. Since sulphathiazole

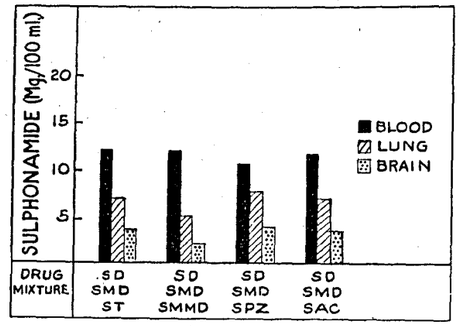

FIG. 2.—Concentrations of sulphonamide mixtures in tissues (chronic administration in albino rats).

has fallen into disfavour[22] and sulphapyrazine possesses a rather high experimental and clinical toxicity,[23] the mixture containing sulphacetamide appeared the most desirable composition for immediate clinical application.

This viewpoint was strengthened in numerous studies of absorption and excretion in 60 human subjects, using single and multiple dosages of separate and mixed sulphonamides. Tables IV and V represent a summary of all single-dose experiments with separate drugs and drug mixtures.

TABLE IV.—*Absorption and Excretion of Single Sulphonamides in Man**

Drug	Blood: Free Drug Mg./100 ml. 1 Hr.	4 Hrs.	8 Hrs.	24 Hrs.	Urine: Total Drug Excreted After 24 Hours Mg.	% of Dose

SAC ..	6·2	6·8	4·5	1·4	2,801	71·0

* Each figure represents the mean of the values of 4 or more male test subjects. The dose was 4 g. sulphonamide orally.

Table IV illustrates on the left the blood levels achieved in groups of four male subjects with five single sulphonamides and on the right the total amount of drug excreted in 24 hours in mg. and as percentages of the 4-g. dose. It is apparent that sulphacetamide and sulphathiazole show the fastest absorption and most complete excretion, and that within the four-hour interval the blood levels of sulphacetamide are better than those of sulphathiazole and not far behind those of sulphamezathine. This is the more significant since sulphamezathine, like sulphamerazine, shows very incomplete urinary excretion, a fact which could be partially accounted for by their greater retention in the blood stream (plasma-binding) and partially by poorer absorption after oral administration. The percentage of acetylation was highest for sulphamethazine (68%), followed by sulphamerazine (46%), sulphadiazine (33%), sulphacetamide (30%), and sulphathiazole (21%). The behaviour of three triple mixtures under identical experimental conditions is depicted in Table V.

It is apparent that the replacement of sulphathiazole by sulphacetamide as the third component tends to raise blood levels slightly within the first four hours and to lower them accordingly thereafter. Sulphamezathine in the same position assists, as expected, in the prolonged maintenance of high levels and greatly retards urinary excretion. Conjugation of all three mixtures within the first 24 hours was

TABLE V.—*Absorption and Excretion of Sulphonamide Mixtures in Man**

around 30–40%, which was less than could be expected on the basis of mathematical computation using the figures of the single drugs. Since, in our hands, a combination of sulphadiazine–sulphamerazine–sulphathiazole had given excellent therapeutic results at the bedside, it was expected that the replacement of sulphathiazole by sulphacetamide would not interfere with the therapeutic efficiency of the triple mixture.

Clinical Application of Triple Mixtures

Clinical trials with a combination of equal partial amounts of sulphadiazine–sulphamerazine–sulphacetamide have been completed. A total of 170 unselected patients of all age groups with serious acute infections have undergone this therapy at the full routine dosage (in children: 0.15 to 0.2 g./kg. body weight daily; in adults: 3–4 g. initially, 4–6 g. daily thereafter; the lower maintenance dose of 4 g. daily proved adequate in most instances). Blood levels were excellent. They ranged as a rule between 10 and 25 mg. of free sulphonamide per 100 ml. Acetylation was low, rarely exceeding 20–25% in the blood and 40% in the urine. Although no alkalizing agents were used, crystalluria of a moderate degree was encountered in only 12 instances, as a rule in connexion with excessive urine concentrations of sulphonamide. There were two cases of drug rash and fever occurring on the tenth and the thirteenth day of therapy, respectively, and two instances of fever alone, possibly due to sulphonamide administration. One patient with acute tonsillitis had severe nausea and vomiting on the third day of drug administration, requiring interruption of therapy, and another patient with pneumonia developed a moderate degree of "cyanosis" apparently due to the drug. No other serious untoward reactions were observed.

Therapeutic results were highly satisfactory, with defervescence usually occurring within the first 24 to 48 hours. The series comprised 55 cases of bacterial pneumonia, 23 of shigellosis (*Shigella sonnei*), six of pyelitis, five of bacterial meningitis, one of penicillin-resistant pneumococcal bacteriaemia, and one of penicillin- and streptomycin-resistant staphylococcal septicaemia.

The experimental and clinical evaluation of other sulphonamide mixtures is continuing at present.

Summary

The simultaneous administration of several sulphonamides in *partial* dosage may result in a reduced rather than an increased incidence of sensitization, because mixtures permit "dilution" of individual drug concentrations below the level necessary for the production of allergy. Hence it is possible to enhance the renal protection afforded by sulphonamide mixtures by using additional components in proportionately smaller amounts, without the danger of increasing the incidence of allergic reactions.

Sulphadiazine and sulphamerazine qualify for first and second place, respectively, as mixture components. Sulphathiazole, sulphapyrazine, sulphamezathine, and sulphacetamide deserve attention as possible third and fourth members of a combination. Although sulphathiazole has fallen into disfavour in the U.S.A. because of its high clinical toxicity, mixtures containing this drug have shown a low overall toxicity. Sulphapyrazine, the most insoluble of these compounds, induces frequent renal and allergic reactions and therefore offers no advantages over sulphathiazole. Sulphamezathine has adequate solubility and low toxicity, but is subject to substantial conjugation and plasma-binding, which diminish its therapeutic efficiency. Sulphacetamide retains the high solubility of sulphanilamide and shares with the parent compound the improbability of renal concretion formation and the ready diffusibility into all tissues. In addition, it shows low figures for conjugation, plasma-binding, and sensitization.

The mixture sulphadiazine–sulphamerazine–sulphacetamide (equal amounts) revealed low toxicity in animals as well as excellent bacteriostatic activity *in vitro* and in experimental infections of mice. After oral administration, blood and spinal-fluid levels were similar to those from equal doses of sulphadiazine or sulphamerazine. Clinical trials of this mixture in 170 patients with acute systemic infections showed a high curative value and low toxicology.

Over 200 Scottish nurses had their names added to the *Register* of the General Nursing Council for Scotland on June 21. New rules made by the Council provide for the transfer of these nurses from the 1943 Nurses' List to the *Register* without application or payment of fee. This allows these nurses, who have hitherto been known as State-listed nurses, to be classified as State-registered in the branch of nursing in which they are qualified. It also grants them the right to vote in the forthcoming elections for the new General Nursing Council. The rules provide that persons who would have been eligible for admission to the 1943 list but who did not apply within the prescribed period may also be admitted to the *Register*. In their case, however, application for admission must be made to the registrar of the council.

MEDICAL TREATMENT OF HYDATID CYSTS OF LUNG*

BY

MARIANO R. CASTEX, M.D.

AND

EDUARDO L. CAPDEHOURAT, M.D.

Pulmonary hydatid cysts, apart from the rare cases which heal spontaneously after a single or repeated expectoration, are exclusively in the domain of surgery, varying only in the details of technique suited to each case.

Encouraged by the good results obtained in severe broncho-pulmonary suppurations, both localized and diffuse, by our method of transthoracic intrapulmonary injections of sulphonamides, antibiotics, and other drugs, we extended this treatment to suppurations due to the retention of hydatid membranes—that is, to suppurating cysts of the lung with incarcerated membranes. A few years later, in view of our favourable experience with infected cysts, we applied the same method of treatment to clean uninfected hydatid cysts.

Without exaggeration, and on the basis of our case records, we can now say that some cases can be treated medically. The importance and scope of this treatment remain to be established by further experience. Whilst the results in cases followed up have so far been successful, their number is too small to warrant definite conclusions. Nevertheless, we are optimistic, since we cannot believe that only the favourable cases came into our hands.

These cases fall into three categories : (1) suppurating pulmonary hydatid cysts, with retained membranes ; (2) ruptured pulmonary hydatid cysts, with loss of fluid content and persistence of the parasitic cavity, whether air-containing or not ; and (3) hyaline hydatid cysts—that is, closed and non-infected. We will outline the therapeutic procedures employed in each category, and give a single example of each kind to show the more salient clinical features.

Suppurating Pulmonary Hydatid Cysts, with Retained Membranes

These cases present two problems : broncho-pulmonary suppuration and the retention or incarceration of the parasitic membranes. The first problem is really a consequence of the second, since the membranes, except in rare instances of clean encystment or of calcification, behave as true foreign bodies, leading sooner or later to pus formation in the surrounding parenchyma.

We treat pulmonary suppuration locally by means of transthoracic injections of sulphonamides and antibiotics, choosing the drug according to the organism isolated, whenever possible, from the material aspirated, and adapting the dosage, interval of administration, etc., to the clinical and radiological progress of the patient.

The complete expulsion of the membranes, which is essential to end the suppuration, is achieved by a purely mechanical effect. The local congestion, partly hydrostatic and partly biochemical, created by the transthoracic injection provokes intense and repeated bouts of coughing, which directs the fluid current towards bronchi already dilated as a result of the suppuration. This flow carries along with it fragments of endocyst which have been

*A paper to be read at the First International Congress of Internal Medicine, Paris, September 11–14, 1950.

detached as much by the intense cough as by the proteolytic ferments of the pyaemic organisms. The insertion of the needle into the parenchyma, as well as the jet of solution, helps to break up the membrane and facilitate its expulsion. It is noteworthy that in most cases cyst remnants thus ejected were expelled during or shortly after injection ; this seems to establish a cause-and-effect relationship between the local influx of the drug and the expulsive action that follows it. In our cases the mechanical action achieved by the intrapulmonary injection has shown itself to be superior to bronchoscopic suction, which proved completely ineffective in all our cases, though performed by an experienced operator several times on one patient.

When all parasitic remains have been expelled and the broncho-pulmonary infection has died down, healing occurs rapidly ; this includes the whole bronchial tree draining the affected area, as demonstrated by clinical and radiographic examination. In some cases a slight increase in pleural opacity remains, with deformity of the diaphragm and obliteration of the costodiaphragmatic recess in the case of basal cysts, sequelae which do not affect the working capacity of the lung or the efficiency of the patient in carrying out normal activities.

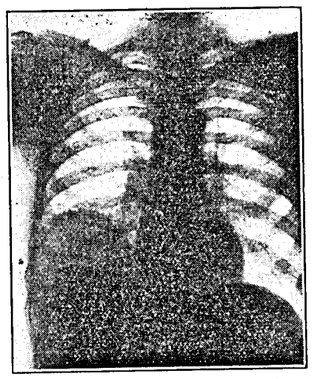

FIG. 1.—Case 1. The opaque cyst occupying the base of the right lung. A slight reaction is present.

FIG. 2.—Case 1. The cystic shadow is in the lowermost segment of the right lower lobe.

Case 1

A single labourer aged 41 was suffering from a suppurating hydatid cyst in the right lower lobe (Figs. 1 and 2). He was treated in the out-patient department and was thus able to remain on light work throughout treatment.

In view of the long history and the size and superficial location of the cyst, it was punctured at once at its most accessible point, which corresponded to the postero-inferior region of the lobe.

Hydatid ocentesis was carried out without the slightest inconvenience, immediate or remote. The first punctures yielded a small quantity of very thick pus and were then followed by 27 intrapulmonary injections. The first contained 200,000 units of crystalline sodium penicillin in 20 ml. of isotonic glucose saline ; most of the others contained 100,000 units in the same volume. Two injections consisted of an ampoule of "prontosil" mixed with an ampoule of "cibazol," and the last two injections consisted of 100,000 units of penicillin and an ampoule of cibazol and an ampoule of prontosil respectively. Treatment began on June 13, 1947, and ended on August 23 of that year, the intervals having varied from one to three days at the beginning and from four to twelve days towards the end. The cyst membrane was expelled in fragments during the course of the treatment. The good result obtained is clearly shown in Figs. 3 and 4.

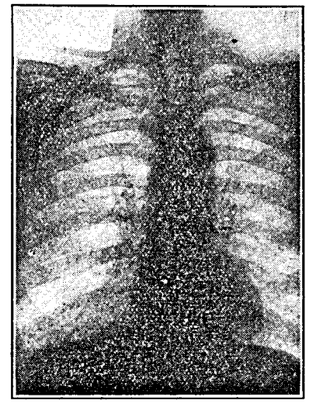

FIG. 3.—Case 1. Disappearance of the cystic shadow, and absence of any remnant of membrane.

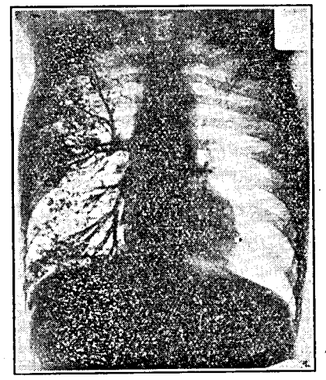

FIG. 4.—Case 1. Bronchogram showing the normal bronchial tree in the area previously occupied by the cyst.

Hydatid Cavities, Whether Air-containing or Not

In these cases, after rupture of some cysts, treatment is aimed essentially at removing the retained parasitic membrane which lines the cavity. This is achieved over a certain time, usually several months, by injection of digesting solutions containing hydrochloric acid and pepsin. Hydatid membrane, when exposed to these substances, becomes appreciably thinned and can then be coughed up without great efforts. This structural change is easily demonstrable by comparing the eliminated fragments with membrane which has not been exposed to digestive action. Patients show complete tolerance to the digestive solution, and this allows the frequent injections rendered necessary by the fact that the solution acts only for a short time because of rapid elimination, reabsorption, or both, and because of its dilution.

Case 2

A single labourer aged 34 had a ruptured hydatid cyst with air in the residual cavity situated in the left postero-inferior lobule. He was given intracystic injections of 10 ml. of a solution of pepsin in hydrochloric acid, the concentration of pepsin varying between 5 and 20%, and the HCl from 0.05 to 0.15%.

After 30 injections over a period of three months, and following complete expulsion of the parasitic membrane and consequent obliteration of the cavity, he was discharged healed. The digestive action had visibly affected the chitinous membrane, the expelled fragments being reduced to thin wafers which had lost their characteristic tendency to form cylinders. Erosion of the membrane facilitated its fragmentation and subsequent expectoration.

Hyaline Hydatid Cysts

These are referred to as clean, because they are closed and non-infected; they require a more complex treatment as follows: (1) Desensitization of the patient by injection in increasing doses of hydatid fluid and of its antigen, along the lines suggested by its discoverer, Dr. B. Calcagno. This is to prevent anaphylactic shock which, as is known, may be severe or even fatal. According to Calcagno this measure brings on death of the hydatid and so deprives it at the time of opening of its toxic properties on absorption of the hydatid fluid. (2) Fixation of the cyst to the chest wall, if this has not already occurred. This requires: (*a*) the induction of a pneumothorax; (*b*) irritation of the pleura by the use of substances such as hypertonic glucose or saline solutions, cibazol, 5% sodium morrhuate or ricinoleate urethane, etc., after previous injection of about 2 ml. of 0.5 to 2% procaine to allay pain and prevent reflex manifestations; (*c*) re-expansion of the lung; and (*d*) confirmation of pleural adhesion over the area by the failure of repeated attempts at fresh pneumothorax. (3) Puncture of the cyst, or hydatidocentesis. (4) Gentle aspiration of part of the hydatid fluid. (5) Chemical sterilization of the cyst by instilling some 10 to 20 ml. of 2% formalin and allowing it to stand for ten minutes. (6) Complete evacuation of the cyst.

There are now two alternative courses. One is similar to the treatment of a hydatid cavity and relies on the use of digesting substances. The other, which is much longer, is to await suppuration as a result of the retained membranes, or to induce it by such means as injection of terebene oil; induction of suppuration, however, is difficult to achieve because of the diffusion and absorption of the injected fluid. When suppuration is established, treatment is carried out as for the first category, in which infection pre-existed.

Expectoration of the intact membrane after emptying the cyst by puncture remains for us only a theoretical possibility, since we have never seen it happen. This could be explained by the disparity between the size of the membrane and that of the bronchial lumen, so that passage of the former is impossible even in the most severe bouts of coughing, whether or not induced by intrapulmonary transthoracic injection.

On the other hand, expectoration of the endocyst occurs reasonably easily and within a relatively short period after intrafocal medication when pulmonary suppuration is present, since the latter dilates the bronchial lumen at the same time as it fragments the parasitic membrane.

Case 3

A married woman aged 30 had a hydatid cyst in the left postero-inferior lobule. Pneumothorax was first induced, later followed by the intrapleural injection of 25 ml. of 50% glucose solution containing one ampoule of cibazol. Another sclerosing solution, "neo-varisclerin," was run in on three subsequent occasions, and the lung was then helped to re-expand by aspiration of the pneumothorax. All this took four months, during which time the patient was also undergoing desensitization with an antigen prepared by Dr. Pirosky, following Dr. Calcagno's method, according to whom this procedure should kill the cestode.

Failure to reinduce pneumothorax having demonstrated the pleural adhesion, the cyst was punctured without mishap. Then 20 ml. of fluid was drawn off and replaced by 10 ml. of 2% formol. Ten minutes later a similar amount was extracted and a further 10 ml. of 2% formalin was run in. As a final step, total evacuation of the cyst was attempted by carrying out injections into the cavity, some of penicillin and some of sulphonamides ("rubiazol" and prontosil), over a period of two months. After an interval of air-distension, the cyst collapsed and incarcerated the membrane.

Months later, since the patient had not managed to cough up the membrane, suppuration of the surrounding lung parenchyma was induced by the injection of terebene oil and the patient was temporarily discharged until the suppuration had become established some six months later. At this stage amounts of 20 to 40 ml. of physiological saline were injected into the area to act purely mechanically by causing coughing and subsequent expectoration. Five injections in six days were enough to achieve the complete expulsion of the parasitic membrane followed by the almost immediate subsidence of the pulmonary infection despite the fact that no active therapeutic substance had been used. This supported the belief that the pulmonary suppuration was caused mainly by the retained endocyst acting as a foreign body.

Conclusion

We consider that this method of bloodless treatment which we have devised is worthy of trial in strictly selected cases of hydatid cyst before deciding in favour of surgical intervention, which should remain a last resort.

The advantages of the method are: (1) It can be completely effective. (2) It does no injury to the body, whether locally or systemically. (3) It does not hinder the recovery of the affected broncho-pulmonary area. (4) It carries less risk than operative methods, which involve loss of blood and some mutilation. (5) It can be carried out on outpatients, to the advantage of either the State or the individual, who is spared the expense, and of the family, whose breadwinner can with care engage in some forms of light work without prejudicing his recovery. This double advantage of ambulant treatment would compensate for the longer time that is sometimes required for medical treatment as compared with surgical methods, particularly since the latter may also occasionally be prolonged by unfortunate complications. (6) It is no bar to subsequent operative treatment, which should be held in reserve in case of failure of this bloodless method.

RECENT ADVANCES IN OUR KNOWLEDGE OF THE MALARIA PARASITE*

BY

H. E. SHORTT, C.I.E., M.D., F.R.S.

Professor of Medical Protozoology, London School of Hygiene and Tropical Medicine

The demonstration by James and Tate (1938) of the essential part played by the exo-erythrocytic forms in the life cycle of *Plasmodium gallinaceum* started an intensive search for similar forms in the case of mammalian and human malaria parasites. The subsequent demonstration of the pre-erythrocytic forms of this parasite (Mudrow, 1940; Shortt, Menon, and Iyer, 1940; Huff and Coulston, 1944) intensified the search for similar pre-erythrocytic forms in simian and human malaria.

The investigation was taken up by malariologists in Europe, America, Asia, and Africa, and various findings were reported, none of which secured general recognition. A critical survey of these results was made by Angelini (1947), who came to the conclusion, subsequently justified, that none of the claims had been substantiated. This was the position when Fairley (1945, 1947) described the results of his classical experiments at Cairns with human volunteers infected with *P. vivax* and *P. falciparum* by the bites of

*To be read at the First International Congress of Internal Medicine, Paris, September 11-14, 1950.

infected mosquitoes. The results of these experiments, which cannot be described in detail, demonstrated the inescapable conclusion that during the incubation period of malaria after infection by mosquitoes the parasites which develop from the sporozoites must undergo some form of development, preliminary to invading the erythrocytes, in a secluded situation outside the circulating blood. This was a sure foundation on which to base the search for pre-erythrocytic forms.

The monkey parasite, *P. cynomolgi*, readily transmissible by *Anopheles maculipennis*, and closely resembling *P. vivax* of man, provided the most convenient material for study. All attempts, however, to demonstrate pre-erythrocytic forms proved abortive, and some observers cast doubts on their existence, while others considered that the methods being used in the search were faulty and that some new approach to the problem was indicated.

I had come to the conclusion, however, that the cause of failure by all workers, including myself, to demonstrate pre-erythrocytic forms of mammalian plasmodia was the use of inadequate numbers of infective mosquitoes in individual experiments. For this reason a crucial experiment was carried out in which 576 infected mosquitoes were fed upon a single rhesus monkey and the entire number of mosquitoes ground up and inoculated into the same animal.

Development of Pre-erythrocytic Forms

The monkey was killed seven days later and material from practically every type of tissue taken for study. The examination of this revealed, in the liver only, the long-sought pre-erythrocytic stage of a mammalian malaria parasite. Following this technique, it has been possible to demonstrate the development of these pre-erythrocytic forms from their early stages to maturity. The details of this development are as follows.

The earliest form so far found is a parasite seen four days after infection of the monkey by mosquitoes. It is situated inside a parenchyma cell of the liver, close to the nucleus. The original nucleus of the parasite has divided to produce 20 or more nuclei, so the parasite may now be called a schizont. From the fourth to the ninth day the parasite increases in size, while the nuclei multiply progressively until by the eighth or ninth day there are certainly over 1,000. The liver cell by this time is a mere bag containing the parasite, which may be 35 to 40 μ in diameter. The nucleus of the liver cell is pushed to the periphery of the body. The general shape of the schizont is ovoid, but lobose arms may be produced, probably due to unequal expansion in the direction of least resistance. In many cases vacuoles, single or multiple, appear in the body of the schizont.

There now follows condensation of the parasitic cytoplasm around the nuclei to form merozoites, which in a mature schizont number well over 1,000. Each is a small ovoid body about 1.1 μ in diameter with a single nucleus often eccentric in position. The containing cell membrane now ruptures and releases the merozoites into the surrounding tissues or into a blood sinusoid. Up to this point there has been no reaction on the part of the liver to the foreign body. On rupture of the latter, however, there is an immediate invasion of the area by phagocytic cells. The majority of the merozoites probably now invade erythrocytes to produce the blood infection, but many are engulfed by the phagocytes and destroyed.

Some of the merozoites almost certainly reinvade other parenchyma cells and recommence the cycle which has been described. This cycle can go on in the liver independently of the blood cycle, and is the probable cause of relapses in malaria. In proof of this a monkey which had been infected three and a half months previously, and in which the primary development from sporozoites must long have been completed, was examined. This monkey had shown no parasites in the peripheral blood for a month, and an early relapse was considered probable. On examination of the liver, exo-erythrocytic forms were found similar to those previously described.

The following interpretation of the cause of relapses is offered for consideration.

When an animal has been infected for some time it acquires an active immunity which is capable of destroying the merozoites produced either in the blood or by the liver schizonts when these enter the circulation, but the latter in their protected position in the parenchyma cells are unaffected. Therefore the merozoites released by the liver schizonts into the circulation are at once destroyed by the immune bodies, humoral or cellular or both, and so cannot attack the erythrocytes, while those which re-enter parenchyma cells are unaffected. If this immunity is lessened from any cause it is no longer effective in destroying the young merozoites escaping from the liver schizonts, and in consequence they succeed in invading the erythrocytes and so produce a parasitic relapse.

I shall now deal with pre-erythrocytic stages in human malaria.

Plasmodium vivax

In this case 2,010 mosquitoes infected with *P. vivax* were fed upon a human volunteer on two successive days. The volunteer was operated upon seven days later and a piece of liver removed. On examination this was found to contain schizonts of *P. vivax* very similar to those of *P. cynomolgi* found in the monkey. These schizonts measured up to 42 μ in diameter, and at 7 days old contained over 1,000 nuclei, so that the eventual number of merozoites produced was probably much greater. The description given of the schizonts of *P. cynomolgi* would apply generally to those of *P. vivax*. This experiment, where previously there had been doubts, proved conclusively the existence in vivax malaria of pre-erythrocytic forms, and there is no reason to doubt that here also there are later exo-erythrocytic forms which could produce relapses after recovery from the original attack of malaria.

Plasmodium falciparum

In this case there was no simian parasite readily available to guide one in devising experimental procedures, and so it was essential, from the beginning, to use a human volunteer in a transmission experiment.

A strain of *P. falciparum* was obtained from Rumania and used to infect *A. maculipennis* and *A. quadrimaculatus* mosquitoes. A total of 770 bites by heavily infected mosquitoes were inflicted on the human volunteer over a period of three successive days. Six days (140 hours) later a piece of liver was removed from the volunteer by open operation. If this should contain the expected pre-erythrocytic forms it would follow that the latter would be of three stages of development separated by 24-hour periods. On examining the biopsy specimen this prediction was proved to be correct and exo-erythrocytic stages were obtained of approximately six, five, and four days' development. Those of six days' development were fully developed schizonts with the merozoites already formed and ready to be released into the surrounding tissues. The forms of five and four days' development were schizonts, smaller in size and with the nuclei still in process of division preparatory to formation of merozoites. In the case of *P. falciparum* the fully developed schizonts were considerably larger than those of *P. cynomolgi*, measuring as they did 60 μ or more in diameter. They were less regular in shape than those of *P. cynomolgi* and tended to be multilobed. The merozoites were smaller and much more numerous.

Summary

It may be claimed that now, for the first time, unequivocal proof has been obtained that in simian and human malaria

pre-erythrocytic development of the parasites takes place in the parenchymal cells of the liver with the production of merozoites which invade the erythrocytes to establish the blood infection. At the same time strong evidence has been adduced to suggest that this developmental cycle in the liver persists after the establishment of the erythrocytic infection, may even exist without the latter, is relatively unaffected by the immunity response of the host, and is the probable source of relapses of the disease.

Medical Memoranda

Death from Atropine Poisoning

The following rare case is interesting enough to be placed on record.

CASE REPORT

A boy aged 2 years 9 months was brought to hospital on May 20, 1950, for the treatment of an alternating convergent squint which his mother had noticed five months previously. Atropine ointment 1% was prescribed and approximately 90 gr. (6 g.) was dispensed. The mother was given a glass rod with printed instructions about the method of administration.

The ointment was first used on May 23, when two applications were given, the first in the afternoon and the second in the evening. The mother stated that the application was made by first dipping the rod into the ointment, and that the amount applied was quite small. Next morning the child was not well and the parents called in their doctor, but a further application of the ointment was given. On the morning of May 25 the child had no breakfast, and at 9.15 a.m. he had a fit (tonic and clonic contractions) and was semiconscious afterwards. At 11 a.m. he had another fit, and was admitted to All Saints' Hospital, Chatham, at 2.20 p.m. under the care of Dr. Sadiq.

On admission his temperature was 97° F. (36.1° C.), pulse 120, and respirations 32. He was a well-nourished child. He had sordes on his lips; petechiae, mainly on the left side of the trunk; dilated pupils, not reacting to light; and slight opisthotonus. The cerebrospinal fluid was normal in every way. There was no growth of organisms from a throat swab. The white blood cells numbered 28,000 per c.mm. (polymorphs 72%, lymphocytes 23%, monocytes 5%). The blood sugar at 4 p.m. on the 25th was 30 mg. per 100 ml. Next day he had petechial haemorrhages on his neck, upper chest, elbows, and forearms, and a papular rash on his legs. His blood pressure was 130/60. His voice was hoarse; he cried without shedding tears and was restless. The blood urea was 60 mg. per 100 ml. He died at 9.45 p.m.

Post-mortem Examination.—This was carried out at 3.30 p.m. on May 27 by Dr. H. G. Close. The body was that of a well-nourished male child of stated age. The eyes were sunken and the pupils dilated. Bruises were found on the tip of the right iliac crest and below the left ankle. The air passages and lungs were dry. Several petechiae were present on the anterior aspect of the heart (weight 3 oz.—85 g.). There was a very small vegetation on the mitral valve. The thymus weighed 1 oz. (28 g.), the spleen 2 oz. (57 g.), and the lungs 9 oz. (255 g.). The liver (18 oz.—510 g.) was very pale, with several petechiae on the surface; microscopically, extensive fatty changes were seen. No gross abnormality was found in the kidneys (3 oz.—85 g.). The brain (44 oz.—1.25 kg.) was mushy, soft, and tore easily, and petechiae were present in the corpus callosum. The clinical story and post-mortem appearances are consistent with the diagnosis of atropine poisoning.

COMMENT

An analysis of the ointment showed that it contained 0.8% of atropine alkaloid, and the analyst stated that at least seven-eighths of the original quantity of the ointment dispensed was sent to him for analysis. Approximately ½ gr. (32 mg.) of ointment was picked up on the glass rod at each application. The total quantity administered, therefore, was approximately 3 gr. (0.2 g.), containing 1.6 mg. of alkaloid. The possibility that the child may have swallowed some of the ointment was considered, but almost all the ointment originally dispensed was accounted for.

Morton (1939) reported nine cases of atropine poisoning, two of which were fatal. In the first case six drops of 1% atropine solution were dropped into an injured eye, and after operation 1.5 g. of 1% atropine ointment was placed on the dressing next to the eye. Death occurred fourteen hours later. The total amount of atropine administered was 18.1 mg. In the second fatal case the pupils of both eyes were dilated with 1% atropine solution. Death occurred in under twenty-four hours and the total amount of atropine administered was 2 mg.

Hughes (1938) recorded a case, not fatal, in which 1% atropine ointment was smeared into both eyes twice daily for three days. On the third day the child was reported to be ill with a temperature, and the skin was flushed and very dry to the touch. Morphine and pilocarpine were given and recovery was uneventful.

My thanks are due to Dr. M. Sadiq for permission to publish this case and to Dr. H. G. Close for the pathological report.

Neurological Complication After Combined Diphtheria and Pertussis Immunization

The occurrence of severe complications after an injection of pertussis vaccine is rare enough to merit record.

CASE REPORT

A girl aged 1 year was admitted to hospital on July 17, 1948, with left hemiplegia. She had been a healthy infant. There was no family or personal history of convulsions or allergy. Injections of diphtheria A.P.T. on May 9 and 19 had caused no apparent untoward effect. An injection of pertussis vaccine on June 17 similarly had caused no ill effect. On July 15 a mixture of alum-precipitated pertussis vaccine and diphtheria A.P.T. had been injected, and a few hours later she is said to have been quieter than usual, but by bedtime (about 17½ hours later) had become her usual self again. Early next morning she had been found in a fit with twitching of the face and both limbs on the left side, and 2½ gr. (0.16 g.) of phenobarbitone had been given. Shortly afterwards a state of semi-coma had ensued, lasting several hours, and later a left hemiplegia had developed.

On admission the child was very irritable, her temperature was 102° F. (38.9° C.). Physically she was well nourished. She had a left hemiplegia with little movement of the upper limb and none of the lower. The reflexes of the upper limb were absent, the knee-jerks were present and equal, but the left ankle-jerk was absent. The right plantar response was flexor but the left was indefinite. The abdominal reflexes were absent. There was no detectable involvement of the cranial nerves and the fundi oculorum were normal. The pyrexia subsided in two days.

On January 17 the spinal fluid was under normal pressure. It contained no excess of cells; 30 mg. of protein per 100 ml.; no excess of globulin; 730 mg. of chlorides per 100 ml. On January 20 a repeat tap showed that the fluid contained no excess of cells; 30 mg. of protein per 100 ml.; no excess of globulin; 720 mg. of chlorides per 100 ml.; 65 mg. of sugar. No organisms were grown. Queckenstedt's test was negative. The Wassermann reaction of the blood and spinal fluid was negative.

The hemiplegia improved rapidly, all the deep reflexes of the limbs and abdominal reflexes appearing within a week. The patient was discharged on July 31, a happy and lively baby with slight weakness of the affected limbs.

When seen again on August 5 there was no apparent weakness of the limbs. Her mother had noticed some clumsiness of the affected limbs in play, but considered that this was improving. There was no evidence of mental deficiency.

COMMENT

Anderson and Morris (1950) have reviewed the literature and reported a case which developed convulsions 36 hours after a first injection of combined diphtheria–pertussis antigen. Their case had had a previous history of convulsions.

The present case is of interest because no apparent ill-effects had been produced by previous injections of A.P.T. and alum-precipitated pertussis vaccine given singly; the convulsion followed the injection of a mixture of these two antigens, made by the same manufacturer. Sensitization as a result of the previous injections cannot be ruled out, but the frequency of allergic states and the rarity of serious neurological complications of this kind suggest that these reactions may have a genetic basis; a previous history of convulsions may therefore, pending further additions to our knowledge, be regarded as a contraindication to the use of pertussis antigens. It should not be forgotten that an attack of whooping-cough may cause encephalopathy with permanent residua, including mental changes (Levy and Perry, 1948).

An Emergency Leucotomy

Prefrontal leucotomy is now an established procedure in psychiatry. The indications for such an operation are usually regarded as certain forms of chronic mental illness which have not responded to more conservative methods. In the following case the operation may be correctly described as life-saving; and it would not be inaccurate to speak here of "an emergency leucotomy."

CASE REPORT

The patient, a woman aged 21, was admitted to hospital on August 6, 1947, with a provisional diagnosis of anorexia nervosa. She was the youngest child of a family of eight, whose father had committed suicide at the age of 54. Her childhood and adolescence had passed without revealing any abnormal personality traits. At 19 she became sensitive about her appearance and fastidious about her food, and developed the delusion that she was unable to swallow and that she might become "filled up with wind" and die. She would pretend to chew her food but secretly spit it out and hide it in odd corners. Her sleep was disturbed and she was losing weight. On admission her weight was 5 st. (31.8 kg.); two years previously it had been 7 st. (44.5 kg.). Apart from this peculiarity about eating, there were no other psychotic symptoms.

A course of modified insulin was given and strict hospital routine and observation were maintained. Her weight gradually returned to normal and she was discharged home on December 13 "happy, sociable, and eating and sleeping well."

After remaining well at home for four months her previous delusions and habits returned, and she was readmitted to hospital on June 30, 1948, in a dangerous state of emaciation. Her urine was loaded with acetone and her appearance was that of a concentration-camp victim. Her weight was 5 st. 5 lb. (34 kg.). She refused all food and required tube-feeding. Later, when her physical health was stronger, a course of E.C.T. was given. This treatment produced only very temporary remission, and within a few days of stopping it the refusal of food began again. Tube-feeding had to be resorted to. This was a painful procedure for all concerned, as the patient did all in her power to resist and to regurgitate the food. She made frequent promises to eat, but was a genius at deception. Food would be found hidden in the strangest places. She showed no insight into the danger she was in and could explain her refusal to eat only by saying "she came of a thin family."

A transorbital leucotomy was performed on December 6, 1948. This produced a temporary remission, but by March 13, 1949, she had returned to her previous state and tube-feeding had again to be resorted to.

It was at this stage that the emergency occurred. She developed a recurrent evening pyrexia. A radiograph of her chest showed "a cavity below the right clavicle with a little surrounding opacity, doubtless tuberculous." Her erythrocyte sedimentation rate at this date was 37 mm. in 1 hour. Further E.C.T. was now out of the question, and the prognosis was indeed grave. Her emaciated state and continued dependence on tube-feeding pointed to a fulminating phthisis soon ending the story.

A full leucotomy seemed now the only possible hope. This was performed on May 4. Convalescence was uneventful and she ate her food satisfactorily from that day forward. Before operation her weight was 5 st. 6 lb. (34.5 kg.) and a week after it was 5 st. 12 lb. (37.2 kg.). On June 27 it was 8 st. (50.8 kg.) and her erythrocyte sedimentation rate was 7 mm. in 1 hour.

In spite of the presence of a tuberculous cavity it was decided not to confine her to bed. The after-treatment of a leucotomized patient should be one of continued occupation, and this was considered a matter of priority in her case. Her activity was gradually increased and no rise of temperature was noticed. As the weeks passed her mental state improved concurrently with her physical condition. She became more interested in other people and in her own appearance, and her work at the occupational therapy class improved. On June 9 a further *x*-ray report read: "Cavity cleared below right clavicle and infection almost gone."

COMMENT

This case seems worthy of record for several reasons. (1) It raises an interesting point in psychiatric diagnosis. The initial symptoms were classically those of an anorexia nervosa, but the long duration of the illness, the temporary response to E.C.T., and the more permanent response to leucotomy suggest that basically the illness was schizophrenic. (2) It shows that when a transorbital leucotomy has proved a failure a full prefrontal operation may yet be a success. (3) The influence of the mental state on a patient suffering from phthisis is well known. In the above case a specifically psychiatric procedure and the ignoring of the physical disease during convalescence led to an eventual healing of a proved tubercular lesion—a healing as rapid as any collapse treatment would have produced.

My thanks are due to Dr. J. N. P. Moore, medical superintendent of St. Patrick's Hospital, Dublin, and to Professor A. McConnell and Mr. J. P. Lanigan, of the Neurosurgical Unit, St. Laurence's Hospital, Dublin, for their assistance with this case.

Deputy Medical Superintendent, St. Patrick's Hospital, Dublin.

Reviews

POSTGRADUATE LECTURES

Postgraduate Obstetrics and Gynaecology. By F. J. Browne, M.D.(Aberd.), D.Sc., F.R.C.S.Ed., F.R.C.O.G. (Pp. 501; 107 figures. £2 10s., postage 1s. 6d. extra.) London: Butterworth and Co. 1950.

Professor F. J. Browne's energy and enthusiasm for teaching at all levels continue unbounded, to the admiration and envy of his friends and colleagues. Even since his nominal retirement a few years ago he has regularly conducted classes in advanced obstetrics and gynaecology for those seeking specialist rank and diplomas, helping by individual initiative to fill one of the gaps in the facilities for the training of such in this country.

The forty-five chapters in this book each represent the basis of one or other of his postgraduate lectures, selected to exclude so far as possible the material in his other book. They are mainly on those topics around which interest has centred in recent years, those which are likely "spots" for any higher examination, and those on which anyone engaged in practice or teaching may wish to have a clear and concise statement of the latest views. The outlook throughout is academic rather than practical, some of the chapters being good, some less good, but all useful. In his introduction Professor Browne writes: "The aim of a teacher should be, I think, to know the literature as far as he can, to filter it through his mind and give his conclusions, right or wrong." Not everyone will agree with this when the result is a predigested meal which satisfies rather than stimulates the appetite and deprives the student of the necessity to think and to browse among journals. Nevertheless, there is no doubt that postgraduate students will welcome it, and in doing so should beware lest it result in a uniformity in replies to examination questions. The examiners also can hardly fail to have read it, and, human nature being as it is, may grow weary of script after script containing thinly veiled chapter "X" of F. J. Browne.

T. N. A. JEFFCOATE.

CLASSIFICATION OF SHIGELLAE

On the Classification of the Shigella Types. With special reference to the Flexner Group. By Sten Madsen. (Pp. 122. No price.) Copenhagen: Ejnar Munksgaard. 1949.

Those bacteriologists working on the identification and the preparation of diagnostic sera for the investigation of organisms of the genus *Shigella* will be grateful to the author for collecting all the more important findings in his book. Madsen obained 230 strains of dysentery bacilli, mainly from British and American sources, but also from Denmark and other parts of the world, including strains used in earlier classifications. Using these, he confirms the use of the biochemical division into mannitol-fermenting and non-fermenting groups. The former group consists of *Sh. flexneri* types 1–6, *Sh. boydii* types 1–7, and *Sh. sonnei*; the latter of *Sh. shigae, Sh. schmitzii,* and *Sh. large-sachsii* types 1–5. He replaces with arabic the roman numerals commonly used in recent classifications. The organisms "alkalescens" and "dispar" are excluded from this genus on serological grounds, which suggest that they are more closely related to the genus *Escherichia.* Many observers will agree with this exclusion, since the organisms do not cause clinical dysentery. Details are given of both the typical and atypical biochemical reactions of all strains studied. In the chapter on serology the author describes the preparation of sera as well as his method of absorption used in the preparation of type-specific sera. His work on the Flexner group shows that he did not find one group antigen common to all types 1–6; in this respect his findings differ from those of some other investigators.

This monograph, the result of much careful work, is another step towards obtaining an internationally acceptable stable scheme for the classification of the shigella group. The descriptions of media, technique, and detailed laboratory findings will be of great assistance in the routine laboratory, but particularly in the specialized laboratory concerned with the full identification of strains.

JOAN TAYLOR.

THE STATISTICIAN'S JOB

Practical Statistics in Health and Medical Work. By Ruth Rice Puffer, Dr.P.H. (Pp. 238. £1 12s.) London: McGraw-Hill Publishing Co. 1950.

This book is an expansion of lectures given by the author to the School of Public Health of the University of Chile in 1946. The subject has been liberally illustrated with examples from the work of the Tennessee Department of Health, where Dr. Puffer has been Director of Statistical Service since 1933. Much of the advice she gives is no wishful idealism but the keynote of her work. She preaches what she practises—that careful planning is the key to the successful solution of any problem in field work, and that the statistician's job is to help design the experiment, not merely to analyse data for which he has not been responsible. She emphasizes that a knowledge of the field of study is more important than elaborate analysis, and that for many problems simple statistical techniques are sufficient.

The first four chapters of the book are on the general principles covering the uses of statistics in public health work, planning of studies, and presentation of data. Much of this could well be condensed, while Chapter 5, "Elementary Statistical Method," is at once too short for beginners and unnecessary for those with any previous knowledge. It is in the succeeding chapters, where she draws on her own experience, that the book is valuable. For the English reader the discussion of secondary attack rates, and the need for defining what Frost called the "index case," is useful. In two chapters she considers person-years as a measure of exposure to risk and life-table techniques in long-term and follow-up studies, uses which in the future will probably be of great importance. The sections on morbidity surveys in the U.S.A. make clear the distinction between prevalence and incidence data. A large part of the chapter on industrial mortality and morbidity is drawn from English data.

There are omissions, among the more important of which are a discussion of the uses and difficulties of sampling in field studies, but the student wishing to solve an epidemiological problem will find useful advice in this book.

J. KNOWELDEN.

OCCUPATIONAL THERAPY

Occupational Therapy; Principles and Practice. Edited by W. R. Dunton, jun., M.D., and S. Licht, M.D. (Pp. 321; 12 illustrations. £2 5s.) Oxford: Blackwell Scientific Publications.

Although occupational therapy has been in use as a form of hospital treatment for nearly forty years, particularly in mental hospitals and tuberculosis sanatoria, little was written on the subject before the second world war. It was then that the value of this type of therapy came to be more fully recognized and understood, not merely for its use in providing a pleasant diversion from brooding over disabilities and apprehensions, but as a positive means of restoring muscular tone, stimulating interest in creative work and providing recuperative activity for both body and mind.

This volume is the work of the associate editors of the useful bi-monthly journal *Occupational Therapy and Rehabilitation,* and, unlike previous treatises on the subject, is primarily intended for physicians. It has been written with the purpose of acquainting them with the varied conditions in which occupational therapy can make a direct contribution to ordinary medical and surgical treatment. That is why it probably includes many details of purely pathological and diagnostic interest which appear somewhat irrelevant in a book of this nature, and which tend to obscure the main object of the work.

Among interesting subjects discussed at length by expert contributors are the various purposes served by occupational therapy in the treatment of psychiatric disorders; kinesiology, and its value in selecting suitable handicrafts for weakened muscles; the place of drama therapy, and its psychotherapeutic function; and the type of occupational methods most suitable in the rehabilitation of cases of pulmonary tuberculosis, heart disease, and cerebral diplegia. Miss Lyttleton (a British occupational therapist) contributes a useful chapter on the treatment of amputees, with valuable hints on the right psychological approach.

The actual technique of occupational therapy is very scantily described, and there is but little reference to the details of application in traumatic and orthopaedic cases, or to the adaptation of machines in industry itself for the rehabilitation of injured workmen—such as is proving so fruitful a development of occupational therapy in Britain. The book will, however, give the general physician a wide view of the varied possibilities of this form of hospital treatment.

HAROLD BALME.

FOOT DISORDERS

The Practice of Chiropody. By Keith Campbell Jones. Foreword by Norman C. Lake, M.D., M.S., D.Sc., F.R.C.S. (Pp. 279; illustrated. £2 2s.) Sydney and London: Angus and Robertson, 48, Bloomsbury Street, W.C.1.

This is an excellent straightforward textbook for the student and practitioner of chiropody. The author is a past president and foundation member of the Australasian Guild of Chiropodists, and for many years has been recognized as one of the foremost teachers in his profession. His experience as editor of a journal devoted to chiropody has enabled him to present the material in a readable yet concise form.

He covers the subject comprehensively and discusses the various problems with admirable common sense. He gives in full the prescriptions of all therapeutic preparations in ordinary use, and includes a useful account of chiropodial physiotherapy. The chapters on the organization and conduct of a modern practice, on military chiropody, and on the problems of post-war chiropody are noteworthy. The only illustrations are of anatomical drawings of the leg and foot. These, though good in themselves, lose much of their value by being scattered haphazardly throughout the book. It is to be hoped that in future editions the illustrations will be grouped together in close relationship to the relevant text. The production is otherwise good, though the price seems rather high for a book so sparsely illustrated and printed on paper of only moderate quality.

J. C. ADAMS.

BRITISH MEDICAL JOURNAL
LONDON
SATURDAY SEPTEMBER 9 1950

INTERNATIONAL CONGRESS OF INTERNAL MEDICINE

Two years ago a group of physicians met in Basle to found the International Society of Internal Medicine. The first Congress of the Society will be held in Paris next week under the presidency of Professor André Lemierre, and it is expected that between 1,000 and 1,500 delegates from all over the world will be present. It is unfortunate that there is no representative of the U.S.S.R. on the International Committee of the Society, the existence of which owes much to the inspiration of Professor A. Gigon, of Switzerland.

As the Congress has limited funds at its disposal those responsible for its organization asked certain internationally known periodicals to publish some of the principal contributions to be read next week. This task has been shared by the *Acta Medica Scandinavica*, the *Schweizerische Medizinische Wochenschrift*, the *Semaine des Hôpitaux*, and the *British Medical Journal*. In the opening pages of this week's issue are printed papers whose excellence is a testimony to the wisdom of those who, under the guidance of the Secretary-General of the Congress, Professor L. Justin-Besançon, of Paris, chose the subjects and speakers for next week's meeting. Copies of the journals participating in this novel method of publishing part of the proceedings of a congress will be in the hands of all those who attend it on Monday, September 11. This *Journal* welcomes the opportunity of making this small contribution to international medicine.

PERNICIOUS ANAEMIA AND THE INTRINSIC FACTOR

An important concomitant of two great chemical discoveries—the isolation[1] and synthesis of pteroylglutamic acid (folic acid) and the isolation[2] of vitamin B_{12}—is the evidence that these substances are factors essential not only for the maintenance of normal haematopoiesis but are also required for the growth of many kinds of living cells and organisms. In the study of pernicious anaemia, however, the nature of the gastric lesion still remains an unsolved problem. It is now apparent that pteroylglutamic acid is not the extrinsic factor of Castle. Though effective in securing normoblastic transformation of the megaloblastic marrow in pernicious anaemia, it does not halt the onset of subacute combined degeneration and may indeed precipitate it. There is some evidence that it may also fail to maintain adequate numbers of erythrocytes in the circulation. On the other hand, the effect of injections of vitamin B_{12} on both the haematopoietic and central nervous systems more closely resembles that of adequate parenteral liver therapy. Pteroylglutamic acid is as effective by the oral as by the parenteral route in procuring haematopoietic response, but vitamin B_{12} is very variable in its effects when given by mouth, and, at best, far larger doses are required than by injection to produce comparable results. All this recent work links up with the fundamental research of Castle and his co-workers on the intrinsic factor, for when vitamin B_{12} together with normal gastric juice is given to patients with pernicious anaemia the haematopoietic response is good.[3,4] In the opening pages of this issue Dr. Byron E. Hall describes experiments which shed light on the probable relationship of vitamin B_{12} to the intrinsic factor.

Both the nature and the mode of action of the intrinsic factor are mysterious. It has been established that in normal gastric juice it is heat labile, it is separable from pepsin, and it will not pass through semipermeable membranes. The effectiveness of dry preparations of hog stomach when given orally in pernicious anaemia may be explained by their content of both vitamin B_{12} and intrinsic factor.[5] Dr. Hall, collaborating with Dr. Bethell and his associates, has found that lyophilized extracts of gastric and duodenal mucosa of swine are particularly effective in promoting response to orally administered vitamin B_{12} in pernicious anaemia. Interaction between vitamin B_{12} and the intrinsic factor appears necessary for the absorption of the former from the human alimentary tract, but the nature of the reaction and its specificity and function are still under investigation. Some workers have suggested that the intrinsic factor has an enzymatic function, possibly acting on peptide linkages. Dr. Hall also supports the concept of an enzymatic action. Simple liberation of vitamin B_{12} from combined forms in the diet appears unlikely from the results obtained by giving the free vitamin and intrinsic factor preparations together by mouth. Although much is now known of the chemistry of the vitamin B_{12} molecule, including evidence for the presence of the

benziminazole nucleus,[6,7] there is no proof that any chemical modification is brought about by the intrinsic factor. The possibility of small structural changes not reflected by such physical properties as the absorption spectrum is admitted by Wolf and his colleagues,[8] but these workers also found no change in the microbiological activity of vitamin B_{12} for *L. lactis* Dorner when added to normal human gastric juice at *p*H 2, 3, and 7 and incubated for periods up to 22 hours at 28–30° C.

Evidence that "binding" of vitamin B_{12} occurs in certain conditions may have an important bearing on the problem of utilization. Ternberg and Eakin[9] have reported that the non-dialysable, heat-labile component of normal gastric juice unites with vitamin B_{12} and renders it non-available to such bacteria as *Bact. coli*, *L. lactis* Dorner, and *L. leichmannii*, and that heating liberates the microbiologically active vitamin B_{12} again from this complex. These authors have named the heat-labile component of the gastric juice "apoerythein." This is less abundant than normal in the gastric juice of patients with pernicious anaemia, and it is suggested that the substance is related to or identical with the intrinsic factor. Dr. Hall reports that the duodenal mucosal extracts of hogs which potentiated the absorption of vitamin B_{12} were also active in rendering vitamin B_{12} non-available to *L. leichmannii*. There is evidence that egg-white lysozyme will unite with vitamin B_{12} to form a complex non-available to *L. lactis* Dorner.[10] This complex is ineffective haematopoietically when given by mouth, and Dr. Hall has also discovered extracts of swine gastric mucosa with strong binding capacity for vitamin B_{12}, but not very effective clinically.

This evidence suggests that, although vitamin B_{12} may interact with several substances and lose microbiological activity, it is only after interaction with the intrinsic factor that increased absorption from the human alimentary tract takes place. How does this tally with the available evidence on the aetiology of pernicious anaemia? The simplest view is that grossly reduced production of intrinsic factor in pernicious anaemia is a consequence of atrophic gastritis and that vitamin B_{12} in food fails to be modified and absorbed. But the question of why absorption fails remains. The intrinsic factor may act in several ways—by aiding the passage of vitamin B_{12} through the intestinal mucosa, by protecting it from destruction within the lumen, or by preventing its assimilation by micro-organisms growing in the intestinal tract—but, as Dr. Hall points out, there is little direct evidence to support any of these theories. The possible role of micro-organisms in the development of the megaloblastic change in pernicious anaemia is interesting, in view of Frazer's[11] remarks about the importance of intestinal bacterial competition in the sprue syndrome and the work of Cameron, Watson, and Witts[12] on macrocytic anaemia occurring in association with anastomoses and strictures of the intestine. A similar anaemia can also be produced experimentally in rats. Davidson[13] showed, over 20 years ago, that the faecal population of micro-organisms may be abnormally large in pernicious anaemia. Gastric atrophy and failure of secretion may be the cause of this, so that the lack of intrinsic factor still remains the central problem. Whether the gastric atrophy is the primary lesion or only part of a widespread tissue defect, and the extent to which the process is genetically conditioned, are questions which cannot yet be answered with assurance.

KITCHEN HYGIENE

Over 6,000 cases of food-poisoning were notified last year, and no doubt a great many more went unrecorded. Slovenly handling of food is not only aesthetically unpleasant: it is a positive danger to health—the more so since eating in canteens and publicly owned restaurants became common. It is surprising that public opinion has not reacted more vigorously to some of the revelations about dirty food which have appeared in the newspapers, but the Ministry of Health and some local authorities are striving to bring the important points home to the professional food-handler and the housewife, and the Ministry of Food has sent to local authorities model by-laws[1] which will enable them to secure "the observance of sanitary and cleanly conditions and practices in connexion with the handling, wrapping, and delivery of food." At the British Food Fair which has been held at Olympia during the last fortnight the Ministry of Health's portable exhibition has been on view. This can be lent to local authorities to support their clean-food campaigns. At the same Fair the Central Council for Health Education convened a conference on the subject of food and drink infections, and it can only be hoped that as a result of all these efforts the public will demand that the high standard set by some food manufacturers and caterers will soon be followed by all.

It is impossible to lay down definite standards to which all kitchens must conform, for conditions differ greatly even among those preparing communal meals. The aim is to ensure that in the storage, preparation, and serving of food no deleterious bacteria are added and no opportunities are allowed for bacterial multiplication to occur. To secure this there must be a high standard of personal hygiene among the staff handling the food,

scrupulous cleanliness of kitchen and dining-room utensils, and adequate cold-storage space. Large numbers of organisms, including potential pathogens, have often been found in bacteriological investigations of kitchen utensils, and Frisby[2] has recently compared the results obtained when washing-up with soda and with a proprietary cleansing agent containing hypochlorite and a detergent. Sinks were redosed every 15 minutes and emptied and refilled every 30 minutes. With soda, bacterial plate counts per utensil were in the hundreds and occasionally in the thousands; bacteria in the washing-up water were uncountable even at a dilution of 10^{-4}; and the sinks even after cleaning yielded very high bacterial counts, faecal coli being among the organisms grown. The temperature of washing-up waters sampled at the height of the lunch-time rush in a busy canteen never exceeded 52° C. When the proprietary cleanser was used the bacterial count was usually below 100 per utensil, and some were sterile. The washing-up water and the sinks were almost sterile. Poor-quality cutlery deteriorated in the presence of hypochlorite and eventually had to be washed in the detergent only. Redosing with detergent had to be accurately timed: if the intervals rose to 20 minutes free chlorine disappeared from the water and the bactericidal power was lost. Higgins and Hobbs[3] inspected the kitchens of 30 catering establishments classified according to the washing and rinsing equipment provided, and investigated the number and type of bacteria remaining on utensils after washing. In one-sink kitchens high bacterial counts were obtained, but these were reduced if utensils were rinsed under running hot water and drained (not wiped) dry. The results obtained in two-sink kitchens (washing and rinsing) were only slightly better, probably owing to the low temperature of the rinse water. The third group—two sinks, one of which was "sterilizing," with the water thermostatically maintained at a constant temperature—was more satisfactory: plates washed by hand in water containing soap, soda, or synthetic detergent and chloramine compound were placed in metal racks and immersed for half a minute in the rinse water maintained at 170°–180° F. (76.6°–82.2° C.), and they were then stood in a hot-plate container without drying. Of articles washed in this way 63% attained the United States Public Health Service standard of fewer than 100 organisms per utensil, and intestinal and respiratory organisms were absent. In a fourth group of kitchens (with mechanical dish-washing machines) bacterial counts were much higher, probably due to lack of care in the supervision of the machine. Rinse waters were generally below the recommended temperature, necessitating hand drying, with the consequent addition of organisms from the cloth.

These investigations suggest that an efficient and simple method of cleansing tableware is washing with a detergent and rinsing at a temperature high enough to sterilize. This obviates the use of dish-cloths, for the utensils will dry in the air. Knox and Walker[4] investigated the washing and sterilization of food containers from a central kitchen supplying 3,000 meals a day, and they found that bacteriologically good results could be obtained with two sinks, one containing plenty of hot soapy water with soda and the other rinsing water at 80° C. After rinsing, the utensils dried in the air without the need for wiping. This method does not need much expert supervision and could be adopted by the least pretentious of feeding-places.

A more difficult problem is the personal hygiene of the food-handler. In larger kitchens, such as those of catering establishments and industrial works, with modern equipment and superintendents alive to the possibility of infection, personal cleanliness and a planned hygienic routine can be enforced and a high standard maintained. Such a routine has been well described in an excellent booklet published by one large company.[5] Food-handlers are medically examined before engagement and are periodically re-examined. Diarrhoea, severe colds, and septic skin infections must be reported, and the affected workers are temporarily withdrawn from their work. The harm which can be done by, say, a cook with a septic hand was well shown by Drs. E. L. M. Millar and M. Pownall in a paper which appeared in last week's *Journal*. It is much more difficult to maintain a high standard of personal hygiene in the small kitchens of private hotels, cafés, and snack-bars. The premises are often antiquated, with insufficient or no wash-basins and water-closets for the staff and equally unsatisfactory washing facilities for the dishes. The staff may be inadequate in number and poor in quality. No two premises are alike and no two sets of problems identical, and local authorities may find it good policy to appoint a keen sanitary inspector as food hygiene officer, with the sole task of improving standards of cleanliness. Such a person, with tact and patience, can suggest the most suitable methods for each kitchen, and by routine visits can keep alight any spark of enthusiasm that the staff may have shown. By regular sampling of utensils and washing-waters he can keep a check on method and supply a standard at which to aim. It is theoretically desirable that catarrhal and intestinal illness in food-handlers should be notified and that nasal and faecal specimens should be bacteriologically examined before the returned worker is allowed to handle food, but at present this is impracticable. A good sanitary inspector, however, can often obtain such specimens voluntarily. Bousfield[5] has suggested that, if we require food-handlers to have higher standards of personal hygiene, then the work of education must be started now in the schools. Perhaps it is too much to hope that education in the home could be equally effective.

NEOMYCIN

The list of antibiotics now known to have an action on the tubercle bacillus and presented by Dr. S. A. Waksman in a paper appearing in this issue is a formidable one: the majority are of course unsuitable for therapeutic use, usually on account of toxicity if for no other reason. It will not be forgotten in Paris, where Dr. Waksman is reading his paper at the First International Congress of Internal Medicine, that the first recorded use of a fungus product for treating tuberculosis was made in that city: Vaudremer treated 200 cases with an extract of *Aspergillus fumigatus* some 40 years ago. Waksman naturally deals mainly with streptomycin, not only giving a concise account of its remarkable achievements based on the well-known findings of American and British studies but emphasizing its two main drawbacks. These are the toxic effects of larger doses on the eighth nerve and the capacity of tubercle bacilli to acquire a high degree of resistance to the drug, which, once acquired, is permanent. These imperfections demand that if possible other antibiotics should be identified which can supplement its action or if necessary replace it, and it is suggested in this paper that such an antibiotic may have been found in neomycin.

The discovery of neomycin was announced by Waksman and Lechevalier[1] little more than a year ago. It is another product of the indefatigable search among the soil actinomycetes for useful producers of antibiotic substances—a search which has given us not only streptomycin but aureomycin, chloromycetin, and terramycin. Its source is *Streptomyces fradiae*, which is also reported by Swart, Romano, and Waksman[2] to form another substance, fradicin, which has no action on bacteria but is highly active against many species of fungi. Neomycin has a wide range of activity, most marked against Gram-negative bacilli and mycobacteriae. In the treatment of infections in mice due to the former, exemplified by *Salm. paratyphi B* and *Salm. pullorum*, Waksman and his colleagues[3] showed it to be more effective than streptomycin, and in another paper they have given particulars of its action on 52 species.[4] Organisms in the genera *Mycobacterium* and *Bacillus* and those of the enteric and dysentery groups are in general very susceptible, as are some other but not all species of Gram-negative bacilli: some streptococci, the pneumococcus, and *Cl. welchii* are much more resistant. Warth, Chandler, and Bliss[5] found it active *in vivo* as well as *in vitro* against *Bact. friedländeri* and *H. influenzae* and without effect on streptococcal and pneumococcal infections. They emphasize its high *in vitro* activity against both *Proteus* and *Pseudomonas* (presumably *Ps. pyocyanea*), characterizing it as the only substance known to them which attacks both of these organisms. This last interesting finding is to a large extent confirmed in the studies of Waisbren and Spink,[6] who nevertheless found that among their numerous strains some showed varying degrees of resistance.

This is the general picture of the potentialities of neomycin, but two important facts remain to be added which are of particular interest if it is to be used in the treatment of tuberculosis. One is that organisms which have become resistant to streptomycin remain sensitive to neomycin. Secondly, although some bacterial resistance to neomycin can be acquired, the process is a slow and gradual one. Waisbren and Spink have induced resistance to neomycin by the usual procedures and point out that it is of the "penicillin" and not the "streptomycin" type. Weiss and Waksman[7] also found that organisms rendered resistant to neomycin had an impaired vitality and growth rate and lost their resistance on transfer to normal medium. All these facts are encouraging, but it still appears uncertain whether neomycin will find a place in the treatment of tuberculosis or indeed of any other condition, because its toxicity has apparently yet to be fully ascertained. The only reports on this, so far as we are aware, refer to acute toxicity tests in mice: it seems that different batches have varied in their effects, some of the latter being lethal in lower doses than the original product.[4] These studies will have to be extended to other animals. Waksman mentions that the drug has actually been given to certain cases of human tuberculosis with good results, and with possible temporary toxic effects, presumably referable to the kidneys in two of the cases. Pending further information on this aspect of the action of neomycin its therapeutic usefulness must evidently remain *sub judice*.

ELECTRON STERILIZATION

The attraction of sterilizing food by electrons or *x* radiation is that penetration is virtually instantaneous up to the limit of depth which can be usefully reached. The possibilities have lately been examined at the Massachusetts Institute of Technology, and Brasch and Huber[1] have described a machine designed for practical use to which the name "capacitron" has been given. The proposed method is similar in conception to the *x*-ray treatment of cancer: the aim in each case is to render the cells irradiated incapable of division. With mammalian cells there is evidence that vulnerability is limited to the division process, and it is supposed that it is because of their greater rate of proliferation that cancer cells suffer the greater damage. With bacterial cells the evidence is that they can be rendered incapable of division at any time; and, provided that the initial count is not too high, it should be possible to achieve a 100% kill in a single short irradiation of high dosage. In their examination of the physical possibilities of this method Trump and Van de Graaff[2] pointed out that electron irradiation is much more efficient than the *x*-ray method. As against this, the penetration depth is less starting with electrons than starting with *x* rays: a fat herring might have to be irradiated from both sides for sterilization to be effective. Dunn and his colleagues[3] have studied the effects of electron sterilization on heat-resistant Gram-positive and Gram-negative bacteria, on

spore-forming and non-spore-forming bacteria, on moulds, and on some foods. Doses of 500,000 roentgens usually destroyed all non-spore-forming bacteria and 99.9% of the spore-formers, while 1,000,000 roentgens rendered apple juice 99.999% sterile. The effect is cumulative: each increment of dose destroys the same proportion of bacteria, and if the dose is big enough in relation to the initial bacterial count not a single cell will survive. In the equipment which has been developed at the Institute irradiation is with 3,000,000 volts electrons, and sterilization is effected in pulses of one-millionth-second duration produced at about one-second intervals. It could therefore be a moving-belt process, but careful design would be needed. Trump and Van de Graaff state that "high energy cathode rays and x rays offer a new and effective means of producing biological, bacteriological, and even chemical changes on a practical scale." Stern and his colleagues suggest on slender evidence that the changes in bacteria which render them incapable of division can be regarded as being of a different kind from the disruption of normal chemical molecules and that effects "on the taste, odour, and appearance" of food need not be feared. On the other hand, Dunn and his colleagues found that the colour of butter was progressively destroyed, and Goldblith and Proctor[4] have shown a reduction in riboflavin and carotene, which in the case of the latter amounted to an 80% loss under some conditions. These aspects of the matter are now being further investigated by the Department of Scientific and Industrial Research at the Low Temperature Research Station, Cambridge: they are the equivalent, in this new method of food treatment, to the effects of x radiation on normal cells in the treatment of cancer.

MEDICAL BIBLIOGRAPHY

The recent decision to discontinue the *Index Catalogue of the Library of the Surgeon-General's Office* (Army Medical Library, Washington) is a serious loss to medical bibliography. Since 1927 the *Index Catalogue* has been supplemented by the more up-to-date *Quarterly Cumulative Index Medicus*, published by the American Medical Association. In its early days the latter made available an author-subject index of books and papers within three months of their publication, but it has for some years become progressively more out of date, and at present is over eighteen months late. Nevertheless it has always been accurately and skilfully edited. During the last war the necessity for a really up-to-date index of medical literature resulted in the publication of the weekly *Current List of Medical Literature*, which, although more difficult to consult and less well produced, provided an index which could properly be called current. Responsibility for its production was soon taken over by the Army Medical Library. It has, however, slowly fallen behind, and in June there was a "back log" of about four months. The decease of the *Index Catalogue* and the lateness of the *Index Medicus* have led to the decision to improve the *Current List* and to publish it monthly.

The first issue of the *Current List* in its new form, dated July, 1950, has now reached this country. It is not yet as up to date as might be hoped; for example, the issues of the *British Medical Journal* and *Lancet* for April 15 appear in it, but no doubt it will eventually absorb the accumulation left by its weekly predecessor. It includes an alphabetical list of over 1,300 journals regularly indexed as received, a list of contents of each journal received during the month (arranged alphabetically by title of journal), and a combined author and subject index. Annual indexes will also be published. The July issue lists 2,992 items. All articles in a given journal are indexed, and titles of articles in foreign languages are followed by an English translation. New titles will be added gradually to the list of journals covered. The *Current List* will not displace the *Quarterly Cumulative Index Medicus*; it will provide a more up-to-date index of current medical literature, although it will not be quite so easy to use as the latter. It is reproduced by photo-offset; subscription outside the U.S.A. is $11.50 per annum. The number of journals indexed by the *Current List* will probably increase rapidly, and it should become one of the most important bibliographical aids in medicine. It might increase the usefulness of the publication if lists of medical books were included.

LINEAR ACCELERATORS

The Ministry of Health with the Department of Health for Scotland have recently placed orders for five new 4,000,000-volt "linear accelerators" for the treatment of malignant disease. One of these is going to Scotland, one to London, and three to the provinces as a first step in the equipment of some of the larger radiotherapy centres with high-voltage apparatus of British design, material, and craftsmanship. Since the war higher voltage apparatus has come steadily into wider use in radiotherapy departments all over the world, and the linear accelerator is one of the major British contributions to this advance. In 1945 experimental work at the Atomic Energy Research Establishment, Malvern, under Mr. D. W. Fry, led to the development of the apparatus which has now been ordered. The first 4,000,000-volt machine of this type was operated successfully in February, 1948. The apparatus employs high-power radio waves generated by magnetrons—the special valves which contributed so much to the pre-eminence of British radar during the war—to accelerate the electron stream until it acquires a velocity equivalent to that produced by a potential of 4,000,000 volts. It will be so mounted that the beam may be directed into the patient at any required angle, and it will have such a high output that the treatment of large numbers of patients will be practicable. Engineers, hospital physicists, and radiotherapists have successfully co-operated in designing this high-voltage apparatus expressly for clinical work. Much of the credit for the way in which advantage has been taken of the work done at Malvern must be given to the staff of the Medical Research Council's Radiotherapy Research Unit at Hammersmith Hospital. While these five linear accelerators are being built and installed a 10,000,000-volt linear accelerator has been constructed for research purposes. It was recently demonstrated to delegates attending the Sixth International Congress of Radiology, and will shortly be installed at Hammersmith Hospital.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

CHEMOTHERAPY*—II. INDICATIONS FOR THE USE OF PENICILLIN

BY

LAWRENCE P. GARROD, M.D., F.R.C.P.

Bacteriologist, St. Bartholomew's Hospital; Professor of Bacteriology, University of London

The indication for using penicillin is not a disease, such as pneumonia or meningitis, but infection, wherever situated, by a sensitive micro-organism. This is now almost a truism, and since the advent of this and other forms of chemotherapy the profession as a whole has learned to think bacteriologically as it never did before. The laboratories are kept busy in providing the information on which rational treatment can be based. For this, it may be mentioned, they prefer a specimen obtained before treatment is begun; a short period of chemotherapy, even if not fully successful, can hopelessly obscure the picture. Naturally there are conditions, such as gonorrhoea and carbuncle, in which the bacteriological as well as the clinical diagnosis is self-evident, but even in some of these—and carbuncle is an example—it may be as well to confirm that the organism is normally penicillin-sensitive: staphylococci sometimes are not.

Sensitivity of Different Bacterial Species

In the past bacteria have been classed as either sensitive or resistant to penicillin. In fact, there is no such thing as complete resistance, but only a wide range of variation in sensitivity, the total compass of which is about 100,000-fold, and in the top ranges of this the bacteria and other organisms concerned are for practical purposes resistant, since the concentrations necessary to inhibit their growth cannot be attained anywhere in the body. At the other extreme are highly sensitive organisms, affected by concentrations easily attained throughout the body by giving moderate doses. Between these extremes there is a ladder of diminishing susceptibility with a species on almost every rung of it, and whether treatment will be of any value depends on how high a concentration can be attained at the site of infection. To maintain high concentrations throughout the body is difficult, arduous for the patient, and expensive; but to maintain them locally may be very much easier. In the central nervous system, and notably in the urinary tract, organisms which are outside the range of susceptibility for systemic effect may be successfully attacked.

If we retain the terms "sensitive" and "resistant" and make two categories of each according to their degree, some of the principal species can be classified as follows:

Fully sensitive (inhibited by 0.005–0.05 unit per ml.).—*Gonococcus; Meningococcus; Str. pyogenes; Str. viridans*†; *Pneumococcus*†; *Staph. aureus*†; *B. anthracis; Actinomyces israeli*†; *Treponema pallidum;* Vincent's organisms; *Erysipelothrix rhusiopathiae.*

Less sensitive (inhibited by 0.1–0.5 unit per ml.).—*Clostridia; C. diphtheriae; L. icterohaemorrhagiae.*

Moderately resistant (inhibited by 1–10 units per ml.).—*H. influenzae; Str. faecalis; Proteus vulgaris; Salm. typhi.*

Highly resistant (inhibited only by >50 units per ml.).—*Myco. tuberculosis; Shig. dysenteriae; Ps. pyocyanea; Bact. friedländeri;* most other Gram-negative bacilli; yeast-like and some other fungi; most viruses.

This list is far from complete, but the first category embraces the vast majority of infections for which penicillin is ordinarily used. It is noteworthy that four species in it have to be classed as variable, and in dealing with them it may be necessary to have a laboratory estimation made of the degree of sensitivity of the patient's own strain.

It is impossible within the compass of a short article to give an account, however brief, of all the possible uses of penicillin in different conditions. Many of these, however, if classified according to their causes, fall into only a few categories, in which the principles of treatment, if not its detail, are the same.

Haemolytic Streptococcal Infections

Streptococcus pyogenes of Lancefield's Group A is remarkably constant in its high degree of sensitivity to penicillin, which cannot be altered to any material degree by habituation either in the body or in the test-tube. Penicillin is therefore a dependable remedy for all infections caused by this organism, and the only serious question affecting its use concerns the merits of the sulphonamides as an alternative. Most strains are also fully sulphonamide-sensitive, and until the advent of penicillin we were perfectly satisfied with these drugs; indeed, they had brought about the greatest therapeutic revolution of modern times, and completely transformed the outlook in conditions which formerly had a high mortality. They are also cheap, easily administered, and reasonably free from risk, except in sensitized patients or those given very large doses.

Wound sepsis, acute throat infections, and puerperal fever, the three principal classes of infection which may be caused by haemolytic streptococci, can or could still be treated with sulphonamides with almost uniform success, although the response may initially be not quite so rapid as that to penicillin. Whether they should be is a matter of opinion, and involves considerations extraneous to the merits of the treatment, such as those of convenience and economy. It is perhaps reasonable to suggest that early and uncomplicated cases, at least of the first two of these classes, especially if undergoing treatment in their own homes, might be treated with sulphonamides only. Penicillin is always there in reserve should it prove to be needed. On the other hand, penicillin should be given from the first in severe wound infections, middle-ear disease, and puerperal fever, since here the inherent dangers are more immediate and less predictable, and a more rapidly acting and slightly more certain remedy is evidently called for.

Owing to its bactericidal action (that of the sulphonamides being merely bacteriostatic) penicillin is more capable of actually eliminating the organism as well as curing the disease. This is one reason for using it in scarlet fever, since it greatly shortens the period of infectivity: to ensure this effect treatment must be continued for seven days. It should not be forgotten that haemolytic streptococcal infection commonly complicates several other specific fevers, including severe diphtheria (for which large doses of penicillin are beneficial in any case) and smallpox.

*Part I appeared in the *Journal* of August 19, p. 453.
†Some strains may be less, or much less, sensitive.

Pneumococcal Infections

Pneumococci are usually fully sensitive to penicillin, but this species can acquire a moderate degree of resistance to the drug, and such strains are sometimes encountered. The same is true of their reaction to the sulphonamides. In general they are fully sensitive to the newer members of this series, but difficulties with resistant strains began to be encountered in the latter part of what may be called the sulphonamide era (1935–45); how often they occur now is unknown. There is this difference, that whereas the dose of penicillin can be multiplied twentyfold if necessary to meet this difficulty, that of a sulphonamide cannot.

The choice between the old and new treatments for the principal disease concerned here, pneumonia, must again remain a matter of opinion. It may perhaps be made on similar lines; that is to say, a mild case with otherwise favourable features may justifiably be given a sulphonamide only, whereas the patient whose condition justifies any serious anxiety should be given penicillin or both. Whenever possible the sputum should be examined, since in bronchopneumonia (and even in rare cases of lobar pneumonia) the infection may not be pneumococcal, and one of the newer antibiotics may be the only useful specific—e.g., streptomycin for *H. influenzae* or *Bact. friedländeri*. There is only one drug effective in all forms of pneumonia, virus as well as bacterial, and unfortunately we cannot afford in this country to give it to every case: this is "aureomycin."

Staphylococcal Infections

The position here is different in two ways: sulphonamides are relatively ineffective, and yet by a strange misfortune this is the one common sensitive species which sometimes possesses a high degree of resistance to penicillin. Staphylococci can in fact be rendered enormously resistant in the test-tube, but this change has nothing to do with the natural resistance which is now presenting a serious therapeutic problem: this has a different mechanism, and there is almost no doubt that selection and not habituation is the cause of its increasing prevalence. The general use of penicillin is steadily eliminating staphylococci sensitive to its action, while those naturally resistant to it survive and spread. At present the proportion of all staphylococcal infections which are due to these resistant strains appears to be only about 5% in the general population, but it often exceeds 50% in institutions such as hospitals and maternity homes: here cross-infection and the nasal carrier-state in nurses enable a resistant strain to become endemic.

There is ample proof that the degree of this natural resistance varies widely in different strains, and unfortunately its degree cannot easily be estimated. There is no general agreement on whether it can be overcome by greatly increased dosage; the truth almost certainly is that it sometimes can and sometimes cannot, depending on the degree of resistance. When it cannot, the best alternative is again aureomycin.

But for this qualification, which recent developments have made necessary, it could well be said that penicillin is more of a godsend for staphylococcal infections than for any other. It is invaluable in osteomyelitis, although here, as in any other lesion causing necrosis or suppuration, it does not remove the need for surgery. It is required for carbuncle, and may be used also in severe furunculosis and in staphylococcal infections of wounds, of the air passages, and of the urinary tract. Either applied locally or, if necessary, given parenterally, it is useful for all skin conditions of which staphylococci are the cause (sycosis, pemphigus, impetigo, blepharitis), and to some extent for any in which these organisms are important secondary invaders.

It is now advisable to consider infection in a few special situations, for which the method of treatment may be different.

The Circulatory System

Endocarditis.—It need scarcely be said that septicaemia of whatever origin, due to any sensitive organism, is the strongest possible indication for penicillin treatment. Equally so is endocarditis, whether acute or in the subacute form also known as endocarditis lenta. The treatment of endocarditis, particularly of the latter type, calls for more vigorous and sustained efforts with penicillin than any other disease. The latest conclusion reached from its study in this country is that a daily dose of two million units is advisable, and that treatment should be continued for at least six weeks. This dose should be so subdivided as to maintain a continuous effect. Among factors affecting the prognosis are the stage of the disease at which treatment is begun. Early recognition is thus vital, with repeated blood cultures for confirmation. Another is the degree of sensitivity of the organism. This is variable in *Str. viridans* and uniformly low in *Str. faecalis* and *Haemophilus parainfluenzae*, which are less common causes of the infection. Some cases will therefore require either very large doses of penicillin, perhaps reinforced with caronamide, or another antibiotic or combination of two, such as penicillin with streptomycin.

The Central Nervous System

Meningitis.—The only form of purulent meningitis which it is still advisable to treat with sulphonamides alone is meningococcal. When streptococci, pneumococci, or staphylococci are concerned penicillin must be used, and because comparatively little reaches the cerebrospinal fluid from the blood, intrathecal injection is necessary. The concentrations which can so be maintained in the cerebrospinal fluid are such that even less sensitive organisms can be attacked in this situation. These include *H. influenzae*, although streptomycin is to be preferred for this infection. Penicillin should be given intramuscularly as well as intrathecally, and when the organism concerned is also sulphonamide-sensitive one of the more potent sulphonamides which attains a good concentration in the cerebrospinal fluid—sulphadiazine being probably the best—should be given in addition.

Urinary-tract Infections

When penicillin is administered by injection some is destroyed in the body, but almost the whole of the remainder, amounting to 60% or more, is excreted in the urine. Thus if a patient is given 250,000 units a day and his urinary output is 1,500 ml., its penicillin content will be 100 units per ml., a far higher concentration than that attained in the blood or tissues. This means that infections of the urinary tract caused even by bacteria in what has been termed earlier the "moderately resistant" class may be successfully treated. The principal species, with the concentrations usually required to inhibit their growth, are:

Staphylococcus aureus and *albus* ...	0.02 unit per ml.
Streptococcus faecalis	2 units per ml.
Proteus vulgaris	8 units per ml.

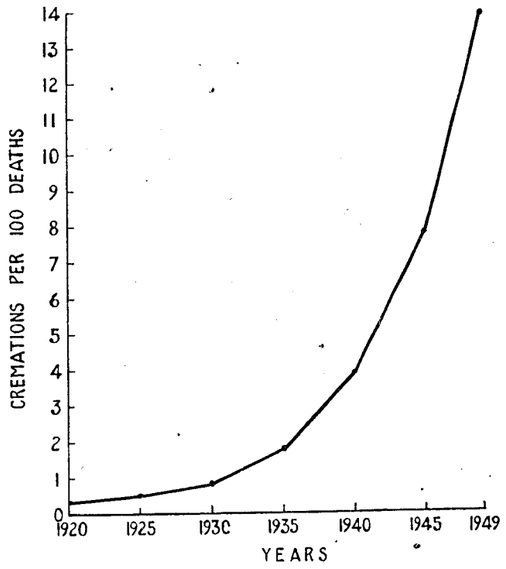
Even some strains of *Bact. coli* are sensitive to about 25 units, although others are more resistant. *Bact. aerogenes, Ps. pyocyanea,* and various paracolon bacilli are highly resistant, and penicillin is useless for them. Penicillin can thus be used for some urinary-tract infections, but only with any expectation of success if the nature of the infection is known and comes within no more unfavourable category than the "moderately resistant." Large doses are not necessary, but they should be given at least four times a day unless in a slowly absorbed form. No attempt need be made to alter the reaction of the urine, but output may with advantage be diminished by restricting fluid intake.

Prophylactic Use

The use of penicillin to prevent infection in very varied circumstances has become common, and a few personal opinions on some of these types of use may perhaps be expressed.

At least three seem fully justified. One is the prevention of infection in extensive and grossly contaminated recent wounds. The effect of the intramuscular penicillin given to casualties with the more dangerous types of wound during the attack on Normandy in 1944 astonished and delighted everyone who saw these men, and there is no doubt that this example should be copied in dealing with all wounds involving serious danger from sepsis generally and gas gangrene in particular. Another imperative indication is dental extraction or tonsillectomy in a rheumatic subject, or indeed in anyone in whom the temporary bacteriaemia now known to be produced by these operations is likely to have any consequences. A third is prolonged labour with much manual interference, or any other circumstances particularly tending to infection of the placental site.

It is more doubtful whether penicillin should be used as a preventive of infection during the course of what should be a clean operation, or of post-operative chest complications. This sort of use is often unnecessary, wasteful, and not always successful, since infections, particularly of the chest, do occur in spite of it, and are then usually due to penicillin-resistant bacteria. It can be said even more emphatically that penicillin given alone is not a reliable preventive of infection in connexion with operations on the urinary tract. The majority of the Gram-negative bacilli apt to cause this are not merely resistant to penicillin: they appear to thrive on it. This is not simply a figure of speech: there are good reasons for believing that *Ps. pyocyanea,* for instance, is actually stimulated by penicillin, and it is not very uncommon for a urinary-tract infection to be produced by this organism *de novo* in a patient having a long course of penicillin treatment, for no other apparent reason than that the drug is being given. If penicillin is considered necessary to prevent tissue sepsis due to cocci, then a sulphonamide should be added to give wider cover for the urinary tract itself.



Reference to the list of the principal sensitive bacteria will serve as a reminder that penicillin can be used in a number of other diseases, for which there is no space for further discussion. On the other hand, it is without action in many other infections, and some of these are susceptible to the newer antibiotics, which are the subject of two articles to follow.

Impact, a quarterly bulletin issued by Unesco, gives reports of addresses and notes on books mainly on the theme of the impact of science on society. The first issue, which is dated April–June, 1950, includes a short introduction on the main theme, to which is attached a bibliography with notes on the books listed. The bulletin is obtainable for 3s. a year from the Unesco Sales Service, Unesco House, 19, Avenue Kléber, Paris, 16e.

CREMATION

COMMITTEE AND CRANK

Disposal of the dead by cremation has become increasingly popular in the last thirty years. According to a recent report of the Cremation Committee[1] there were 1,796 cremations in 1920 and 79,607 in 1949. The following graph shows the number of cremations per 100 deaths in England, Wales, and Scotland in certain years from 1920 to 1949.

The committee was appointed in 1947 to review the regulations made under the Cremation Act of 1902, and to make recommendations. Its members were: Mr. H. A. Strutt (chairman) and Mr. R. S. Wells, of the Home Office, Mr. R. Howat, of the Department of Health for Scotland, Mr. J. M. Ross, of the General Register Office, and Mr. H. F. Summers, of the Ministry of Health.

Medical Certification

The regulations were framed primarily to prevent cremation being used to destroy evidence of crime. The normal medical attendant of the deceased gives a detailed certificate leading up to the opinion that there is no reason to suspect that death was due to other than natural causes (Form B); and an independent medical practitioner gives a shorter confirmatory certificate (Form C). Alternatively, a medical certificate (Form D) may be given by a pathologist who has conducted a necropsy on the case, or by the coroner (Form E). Authority to cremate is given by the medical referee (Form F).

The committee's main recommendations on medical certification are as follows:

The certificate in Form B should require further and more explicit details: (*a*) Where the medical attendant has consulted the coroner, the fact and the result should be stated on the form. (*b*) It should be stated whether or not a post-mortem examination has been made, and, if so, by whom it was made, and the result. (*c*) Particulars should be given of the date of any operation during the final illness or within a year before death. (*d*) The present question No. 13 should make it clear that the reference here is to private nursing. (*e*) The medical attendant giving the certificate should furnish his

[1] Report of the Interdepartmental Committee Appointed by the Secretary of State for the Home Department, 1950. (H.M.S.O., 9d.)
[2] *British Medical Journal*, 1880, **2**, 461.
[3] Ibid., p. 794.
[4] Ibid., 1884, **1**, 123.
[5] Ibid., p. 515.
[6] Ibid., p. 624.

address and telephone number. (*f*) Dual questions should be set forth as separate questions.

The requirement that Form B must be completed by a medical attendant who attended the deceased during his last illness should be varied to permit certification by the doctor "to the best of his knowledge and belief" if he had visited the deceased within 14 days prior to death.

The requirement that the medical practitioner completing Form B must certify definitely the cause of death before cremation may take place should be modified to permit the confirming doctor to authorize cremation where there is no reason to think that death resulted from other than natural causes.

The confirmatory certificate should be retained and serve the dual purpose of confirming the certificate B and authorizing cremation, combining the present functions of Forms C and F.

This combined certificate should be given by the medical officer of health of the county or county borough in which the death occurred, the M.O.H. of a county to have power to delegate in appropriate cases to M.O.H.s of county districts. The medical officer of health should be assisted by a panel of medical practitioners chosen by the local authority.

In the case of a death in a hospital which is not referable to the coroner, the medical superintendent or his deputy should give the combined confirmatory certificate and authority to cremate.

In any case in which there may be conflict of medical opinion as to the cause of death, but in which there is no reason to suppose that the death may have been due to poison, to violence, to any illegal operation or to privation or neglect, the confirming doctor should be empowered to authorize the cremation without requiring any further examination of the body.

Any suspicious case should be reported to the coroner by the doctor giving the confirmatory certificate. If the coroner is satisfied that an inquest or post-mortem examination of the body is unnecessary, he should have power to authorize the cremation to take place. He would do this on Form E. The coroner should be empowered to authorize cremation on Form E in any case of accidental death, without waiting for the termination of the inquest.

In every case in which a coroner issues a certificate on Form E, that document should be the authority to cremate. Where the coroner, after being consulted by the doctor who gives the confirmatory certificate in Form C, does not think it necessary to hold an inquest or to make a post-mortem examination, the doctor who gives the certificate should authorize the cremation to take place. A note should be made on Form C by that doctor that the coroner has been consulted.

The Confirmatory Certificate

Some witnesses before the committee recommended abolition of the confirmatory certificate. Among the reasons for this suggestion were that the certificate was given in a perfunctory manner because the certifying doctor would not be disposed to act inquisitorially in respect of the medical man who gave Form B, and some fatal poisons might escape detection from a superficial examination of the body.

The B.M.A. in its evidence strongly opposed abolition of the confirmatory certificate, which it considered was a public duty that the medical profession should be required to take seriously. The Association emphasized that to place the onus on a medical referee alone would be to burden him with undue responsibility, and would lead inevitably to unnecessary distress to the relatives when he exercised his discretion to direct pathological examinations. The requirement that two medical certificates should be completed by medical practitioners unrelated to one another, either professionally or in law, was considered to be sound and in the public interest.

The committee also makes a number of recommendations to regulate the procedure at crematoria and to ensure that the staff should be suitable.

Sanitary Advantages

An early advocate of cremation in this country was Sir Henry Thompson, a well-known surgeon, who was one of the joint founders of the Cremation Society in 1874, among the other founders being Mr. (later Sir) Spencer Wells and Dr. Ernest Hart, editor of this *Journal*. At the B.M.A. Annual Meeting in 1880 Spencer Wells[3] read a paper on cremation in the Section of Public Health, his theme being that "the sanitary advantages over burial in coffins or in wicker baskets are undeniable and very great." He referred to Darwin's observation that earthworms bring soil to the surface from a considerable depth. He then pointed out that Pasteur had shown how the earth mould brought up by worms in fields where cattle had been buried after dying of "charbon," or splenic fever, contained "the specific germs which propagate the disease." The same germs had been found in the intestines of the worms.

As a result of this paper over 120 members of the B.M.A. sent a memorial[3] to the Home Secretary saying that "we disapprove of the present custom of burying the dead and . . . until some better mode is devised we desire to promote that usually known as cremation."

Four years later public interest was excited by the actions of a surgeon, Mr. William Price, living in Glamorganshire, an eccentric character who claimed that he was a descendant of the ancient Druids.[4] One night "attention was directed to a large fire in the grounds adjoining his house; and he was found to be in the act of cremating, in a barrel containing paraffin oil, the body of the illegitimate child of his housekeeper. He was chanting the supposed Druidical incantations over the body; and threatened to shoot anyone who interfered with him." But he was seized by a constable and conveyed to the police station. The housekeeper was later locked up because she refused to give evidence as to maternity at the inquest. Mr. Price admitted that he was the father of the child, and said that it had died of convulsions. The mother afterwards corroborated Mr. Price's evidence, and was released from custody, a verdict of death from natural causes being returned at the inquest. The body was returned to Mr. Price, who undertook that it would be interred in the ordinary way.

Mr. Price was then charged with misdemeanour, but was acquitted at the Glamorganshire Assizes by Mr. Justice Stephen and a jury, a decision which this *Journal*[5] "hailed with great satisfaction," remarking "that clean ashes are surely less repulsive to contemplate than mouldering carcasses." Mr. Price, unrepentant after all, soon accomplished his object. The body was cremated[6] on a pile consisting of three hurdles, half a ton of coal, and pair of large iron grates, Mr. Price chanting "an ancient sacred song in the presence of a number of spectators."

A Bill to regularize cremation was introduced into Parliament the same year, 1884, but was rejected, and it was not until 1902 that an Act was passed prescribing the conditions under which cremation should take place.

WORLD FEDERATION FOR MENTAL HEALTH

[FROM A CORRESPONDENT IN PARIS]

Psychiatrists, psychologists, sociologists, and psychiatric social workers from 25 countries assembled in Paris from August 31 to September 7 for the third annual meeting of the World Federation for Mental Health. The World Federation "stemmed"—to use a word which is at present in favour in this field—from the memorable London Congress on Mental Health two years ago, and its establishment and survival in face of obvious difficulties, especially financial ones, are due above all else to the driving force of its director, Dr. J. R. Rees.

The Paris meeting, which was held under the presidency of Professor WILLIAM LINE, of Toronto, was on four topics—namely, mental health in education, from the pre-school child to the education of teachers and medical men; occupational and industrial mental health; mental health of transplanted and homeless persons; and leadership and authority in local communities.

Collaboration with W.H.O.

An official welcome was given to the Federation by representatives of the French Ministries of National Education, Labour, and Public Health, and by Professor P. Heuyer and Dr. Xavier Abeley on behalf of French psychologists. Dr. G. R. HARGREAVES, chief of the Mental Health Section of W.H.O., spoke on collaboration between the Federation and his organization, pointing out that governmental and non-governmental agencies were complementary, not overlapping. He answered those who objected that W.H.O., like other instruments of the United Nations, moved slowly. He asked whether it moved more slowly than their own Governments. The time had come to shift the inquiry into the efficiency and speed of the machinery from the international centres at Geneva or elsewhere to the national components. He quoted his chief, Dr. Brock Chisholm, as stating that perhaps the success of W.H.O. should be judged not by the amount of money which it could persuade its member Governments to spend in the international field, but by the amount which it could persuade them to spend on health in their own countries.

In his presidential address to the World Federation, Professor LINE made the point that the man in the street had confidence in the leadership of medicine so far as his physical needs were concerned, and was content that medicine should advise public-health departments in the interests of his own physical and environmental well-being. He had in fact handed over his responsibility in this respect to professional medicine, and medicine was worthy of the trust. But the man in the street must be made to realize that in the field of mental health, involving the effectiveness with which he could live with other people and with himself, he could not afford to delegate his responsibility. This was something that could not be turned over to the expert because it concerned personality development, character formation, and social adaptation, which last was expressed in that loosely used word "democracy."

The Language of Science and of Industry

The discussion on mental health in industry was opened by Dr. R. F. TREDGOLD, who made the point that it was not so much more knowledge on this subject which was required, as the better application of the knowledge already existing. He also said that the results of scientific research were quite frequently made public in a manner as remote as possible from the understanding of the industrialist, who was expected to approve them and incorporate them in his organization. The language of science was as far apart from that of industry as English was from French—indeed, it was farther apart, because when the industrialist came upon scientific language (which he was apt to call "jargon") his inhibitions were at once aroused, and he tried not to understand it, whereas the Englishman, faced with a presentation in French, regarded it as a challenge and did his best to understand it. The psychiatrist, said Dr. Tredgold, should be aware of the suspicion and uncertainty with which the industrialist regarded him. A frank statement of his aims, qualifications, and practices was at least the first step towards a better understanding.

He reminded the assembly of three cross-currents which were now operating: (1) while all were agreed that prevention was better than cure, preventive work was less attractive to the student and to the practitioner; (2) the advance of psychiatric treatment during the last 20 years, and perhaps the next 10, might gradually result in a diminution of the "chronic" population of mental hospitals, and thus release many psychiatrists for fields of work outside the hospitals; (3) in spite of what he had already said about the latent antagonism of the industrialist, it already seemed to be accepted by industrialists, who had the reputation of being hard-headed business people, that in financial terms the value of such mental-health services as had been planned and put into operation in industry had been worthy of their support.

Displaced Persons

The subject of the mental health of homeless and "transplanted" persons was developed by Professor JOHN COHEN, professor of psychology in the Hebrew University, Jerusalem. Human transplantation, he said, was as old as Adam. In fact, Adam was the first transplanted person, and perhaps his transplantation to a less comfortable environment might account for the delinquency of one of his offspring, who slew his brother. Moreover, displaced persons were not only groups vaguely thought of as moving about rather aimlessly in distant parts of the world, but were in our own community—the child taken from home to hospital, the old person removed from domestic independence to a home for the aged, the conscript entering the Army. What was new in the situation, he said, was not the phenomenon itself but the deliberate attempt or intention to reduce its hardship and to dovetail the life of the newcomer into that of the receiving community. The integration was always going on, and there were indices by which its process could be measured—the comparative literacy of the immigrants and the native groups, the extent of inter-marriage, the vital and morbid statistics of each, and the comparative industrial productivity.

One aspect of the problem of integration was the elimination of tensions. Tension, said Professor Cohen, was a central concept in psychology. It was a pity that it had been rather isolated from other concepts such as frustration and conflict, for all three cohered in the same framework. Each type of frustration or conflict produced a different kind of tension, and an analysis of these different forms of tension, above all in the social sphere, should be attempted.

One of the reports presented to the meeting concerned the results of an inquiry into training facilities in psychiatry and allied mental-health disciplines. Replies so far have been received from no more than a dozen countries, not including Great Britain. The replying country in which there is the most abundant provision is the United States. At the present time the approximate annual output of trained psychiatrists from training institutions in the U.S.A. is 500. It is estimated that approximately that number of medical graduates complete each year a comprehensive systematic training course in psychiatry covering a period of three years. There are 253 hospitals, institutions, and other training centres in the U.S.A. which are recognized by the medical profession as providing acceptable training. Three-year advanced training courses are provided by 10 approved psycho-analytic institutes, and an average of 21 psycho-analysts complete this training annually.

Nova et Vetera

GIORDANO BRUNO AND THE CIRCULAR MOTION OF THE BLOOD

So far, Giordano Bruno (1548–1600), the philosopher of pantheism and martyr of science, does not seem to have been cited in connexion with the discovery of blood circulation. I have no intention of claiming a share in this discovery for Bruno. I wish, however, to put on record several passages in which Bruno emphasizes the "circular" pattern of the motion of the blood. He says: "The spiritual life-force is effused from the heart into the whole of the body and (flows back) from the latter to the heart, as it were from the centre to the periphery and from the periphery to the centre, following the pattern of a circle. . . . The material part of all these spirits is a fluid which cannot move on its own account, but by means of its innate spirit. Hence there is no circular or sphaerical motion outside the body, for the *blood, which in the animal moves in a circle* in order to distribute its motor, the spirit, lies immovable outside the body, is inert and decays, no longer deserving the name of blood" (*De Rerum Principiis*. 1590. A certainly genuine though posthumous treatise from the "Noroff Collection," edited by F. Tocco and H. Vitelli. Opp. Latina. Florence, 1891, p. 521.).

He also says that "in us the blood and other fluids are being *moved continually and very rapidly in a circle*, flow and flow back, are diffused from the centre into the extreme periphery and from there return to the centre—a movement for which the followers of Aristotle give far-fetched and confused reasons such as an instinct of nature, the necessity of fate, the providence of God, etc." (The italics are mine.)

There are also allusions to the circular motion of the blood in two of his better-known treatises (*De Immenso*, VI, 8; *De Monade*, 1591, p. 23). The ideological background to this is (*a*) his most probable acquaintance with Caesalpino, the well-known Aristotelian philosopher, naturalist, and precursor of Harvey, the first to use the term "circulatio" (1571), and (*b*) Bruno's belief in the perfection of the circle as the fundamental symbol of all life and action in the cosmos (*De Triplici Minimo*, I, 3; *De Monade*, I, 2). The above passages from Bruno show that Caesalpino's idea of "circulatio" was alive in a general philosophical form towards the end of the sixteenth century.

WALTER PAGEL.

The Difficulty in Medical Education

SIR,—Your educational number was highly entertaining, but the contributors do not appear to have grasped the real difficulty in medical education, which is that people cannot avoid preaching what they practise. The preclinical teacher practises medicine as a branch of inductive science, the hospital consultant practises it as a specialty, and the whole-time clinical professor, restricted to a small unit, practises it as a means to clinical research. None of these practices has much relevance to general practice. The ideal medical school would be different from either a university or a key hospital; I often think it would come better outside and after the university. So long as we go on expecting to prepare students for general practice in institutions which have a different frame of reference we shall continue to be dissatisfied with the results.—I am, etc.,

Oxford. L. J. WITTS.

Training for General Practice

SIR,—In his article, "A G.P. on his Clinical Training," Dr. Donald Johnson writes (*Journal*, August 26, p. 493) of his hospital education in preparation for general practice as having been "wholly bad." He is writing of 25 years ago when he spent two years and six months as a medical student at St. Bartholomew's Hospital. As I am no longer a member of the teaching staff of that hospital, I may perhaps be allowed, without prejudice, to explain to Dr. Johnson how it is that he has become a competent general practitioner in spite of (because of) Bart's. The same post which brought me the *Journal* with his article in it brought me a brochure about the Paget Club, which is one of our institutions at St. Bartholomew's. This brochure opened with the words: "Sir James Paget, 'Nothing appears more certain than that the personal character, the very nature, the will, of each student had far greater force in determining his career than any helps or hindrances whatever'—('What Becomes of Medical Students,' *St. Bartholomew's Hospital Reports*, 1869, 5, 242.)"

St. Bartholomew's Hospital, with its tradition, atmosphere, teachers, nurses, porters, and students, strengthened Mr. Johnson's character and will. *We made the man* and he became a good doctor, partly because we made him, or we left him, hungry for knowledge. He tells us how, after leaving the hospital, he gained valuable clinical experience in the Metropolitan Hospital, Kingsland Road, how he learnt about the treatment of minor complaints from the experienced G.P. from whom he bought his practice, and about skin diseases from his dispenser. His article is that of a man with strong convictions; it is boldly critical, and he tells us that he is a pretty good doctor ("reasonably competent," he says). He is in fact a good Bart's product, and it is doubtful if he would have turned out any better if he had done his clinical training in a tip-top spoon-feeding unit.—I am, etc.,

London, W.1. GEOFFREY EVANS.

SIR,—Despite the publication of enlightened protests, such as that of Dr. Donald Johnson (August 26, p. 493), against the process of standing six months in a theatre catching glimpses of specialized surgical operations or of parking one's posterior on the patient's bed-locker during interminable ward rounds, students still come to be qualified without an adequate idea of how to work in general practice.

It is refreshing to read in an article by Professor W. Hobson and Dr. J. Pemberton in the *Lancet* this week (August 26, p. 324) that at Sheffield:

> "In the final three months of his curriculum each student will be attached to a general practitioner for a fortnight. He will attend the morning surgery and accompany the general practitioner on his daily round. In this way he will see for himself the opportunities open to the doctor for practising social medicine in the community."

These fortunate students should be able to see many other sides of medicine, and particularly those which are neglected in their hospital experience. May I repeat what I said at the meeting of members of the Royal College of Physicians at which Dr. Lawrence spoke? If I had a child who was taking up medicine I should make sure that he or she had at least three months' "apprenticeship" to a good general practitioner. Thinking it over, I am inclined to suggest six months; one period of three months before going to walk the wards and another after that, but before taking finals. Could not this sort of apprenticeship be made compulsory and interchangeable with six months of the new compulsory intern year?

Finally I still have a dream, which is unlikely to come true, of a general practitioner being allowed to attend all lectures and ward rounds where students are instructed, and his being given five minutes at the end to tell them how much they may forget. (Perhaps five minutes would not suffice.) This is obviously impracticable, but might not each teacher carry in his mind a similar imaginary counsellor to stop him from wasting the students' time?—I am, etc.,

Bristol. HUGH R. E. WALLIS.

SIR,—Heavier bludgeons than mine will, I feel sure, be swung at Dr. D. McI. Johnson (*Journal*, August 26, p. 493). I feel compelled, however, to make a pass at him myself. He has put himself, it is true, in a strong strategic position; anyone who blames himself and not his teachers for what he failed to learn 25 or more years ago can easily be disposed of as self-righteous. May I suggest that Dr. Johnson explains nearly the whole of his let-down by Bart's in the words "somewhat unwilling but not entirely uninterested"?—I am, etc.,

Potters Bar. W. E. HAYES.

SIR,—I have read with much interest Dr. Donald Johnson's article in the *Journal* (August 26, p. 493).

I had no idea that, 25 years ago, the clinical teaching at St. Bartholomew's was so primitive. At Edinburgh—but that was 50 years ago—we had the most excellent clinical teaching, which covered the needs of the embryo G.P. or specialist. Ward rounds (I do not remember tired legs); side-room talks; out-patients; evening tutorials; anaesthetic giving, with the not uncommon sequel of instruction in artificial respiration—all gave us the chance of assimilating what was to be of future use: "You mustn't mind seeing these cases frequently. You'll see lots in G.P." (Cotterill). "Handle the patient's body as if it were your own" (Chienne). "This is the sort of puzzle you'll meet in practice" (Bramwell). And so on.

The defects in my methods, which may be so obvious to my colleagues, I can fairly put down, with the modesty so characteristic of the southern Scot, to my own lack of attention, or of the ability to absorb. The material was presented well; it was up to me to digest it. Two or three years later I adopted what I think should be a universal practice (even for medical scientists—it will broaden their minds). I went as assistant to a first-class G.P. In a small country town on the Scottish borders Dr. David Huskie gave me the chance—may I have taken at least some of it—of learning how to approach patients, how to bear adversity, how to give the gentle answer, to see and how to treat the minor and chronic ailments which are inevitably not seen in hospital, how to shoulder responsibility.

I agree wholeheartedly with Dr. Johnson in his condemnation of systematic lectures, a complete waste of time in that we wrote instead of listening, and I thank him for spurring me on to pay a belated tribute to my old hospital and my old chief.—I am, etc.,

Glamorgan. A. W. B. LOUDON.

SIR,—Dr. D. McI. Johnson's diatribe against the clinical teaching he received at Bart's (*Journal*, August 26, p. 493) should, of course, have the heading "Stinking Fish."

As one who must have been a contemporary of Dr. Johnson may I say: (1) I thought then, and still do, 22 years afterwards, that I was made to learn many things that have been no use to me since. (2) This does not alter the fact that the picture he draws of the futility of Bart's teaching then is grossly exaggerated. (3) There must be many old Bart's men who are eternally grateful for the teaching of men like Horder, Gow, Vick, Rawlings, Patterson Ross, Kenneth Walker, Roxborough, Girling Ball, Wilfred Shaw, Langford Moore, and a host of other grand teachers too numerous to mention. (4) Dr. Johnson blames his teaching for not foreseeing early death after a hemiplegia. Why? The best bedside clinician cannot always foretell the outcome of these cases. (5) He complains that he could only write two prescriptions. Why? Had he never read and resorted to the Bart's Pharmacopoeia, or was this included in what he, in his wisdom, "ruthlessly eliminated" from his programme? (6) He could not give "even a hypodermic injection." Why? I seem to remember we all had ample opportunity to learn this simple job. (7) He knew nothing about rashes, infectious or non-infectious. Did he never attend Skins or Fevers? What was he doing all the time? And the final absurdity—of which we have heard *ad nauseam* from other sources—"Society, shocked at the incompetence and inexperience of newly qualified doctors . . ." Let us have evidence of the proof of this statement. What "Society," or branch or faction of it? What "incompetence" has been a nine days' wonder?

I am old-fashioned enough, Sir, to believe in loyalty. Loyalty to one's team, one's crowd, one's Alma Mater. And I for one will always be glad and proud and happy that I went to Bart's and that I have tried to live up to, and profit by, all that Bart's has taught me.—I am, etc.,

Aylesbury. W. A. BELLAMY.

SIR,—I take a hasty pen to protest how very different from the curriculum described by Dr. D. McI. Johnson (August 26, p. 493) was the teaching at Guy's about fifteen years earlier. On reaching the clinical stage a student became a ward-clerk. A firm, maximum six, had about seventy beds between them, and certain hours, extensible to taste, in the "Front Surgery." The clerks were immediately responsible for case-history of all admitted cases, with all signs and symptoms they could detect. Later the registrar took the firm round, with criticism and coaching; and when the consultant had made one more round there would not be very much unelicited about these cases, especially as questions were searching and treatment and progress had to be meticulously noted. There was much rivalry between firms, and efficiency was checked by interim examination.

Work in Casualty or "sorting" department was under supervision by dressers and house-surgeons, and all the way up the scale there was an admirable blend of responsibility with guidance. We were not forced into P.-M. room or museum, but the wisest spent many hours there. For those aspiring to house appointments there was a ward called "Clinical," where one had one's own beds and had first choice of all cases admitted to the hospital.

As regards special departments, we were encouraged to believe that the G.P. was the backbone of the profession, and should know enough of all branches to do some good and no harm. Skin Out-patients in particular was always crowded, and thought to be about the best value per man-hour to be obtained. There was always so much of interest going on in the hospital, including "culture," that there was little temptation to seek it elsewhere; nor, considering all there was to learn in a brief four years, did the less brainy of us find much time to do so, after taking a fair share of athletics.

A graduate trained only in a general hospital must inevitably lack much knowledge of minor ailments and chronics, but how better gain the lacking experience than by six months as assistant to an "old-timer"?

Dr. Donald Johnson seems to have found standing round beds a trial; but we were all young once, and a posse (or is it a fleet?) of bath-chairs would be somewhat of a traffic problem.—I am, etc.,

Kington-on-Arrow, Herefordshire. G. W. DRYLAND.

SIR,—I have only just read Dr. J. H. S. Hopkins's article on Bornholm disease (May 27, p. 1230). It is an extremely common condition. Practitioners should try to get all their cases of this and of atypical pneumonia as fully investigated as laboratory facilities allow. It is a "pushover" as a subject for an M.D. thesis. My experience has been that physical signs are usually present, but I have made embarrassing misdiagnoses.

Early descriptions of outbreaks in nursing staff and failure to instruct students about the disease are related phenomena and the usual hallmarks of impending dissemination of knowledge of common, interesting, and overlooked diseases. All students are well instructed in the pathology, aetiology, and differential diagnosis of the rarer, progressive, serious, and fatal illnesses. These are also in the books, where you can look them up if you did not attend ward rounds. Teachers neglect the common ones because they know nothing about them. Their only contact with everyday disease is in themselves and nursing staff. (Note the reluctance with which some consultants approach the sick nurse or student.) Serious disease eliminated, analytical thought and further investigation are abandoned. For this there is some slight excuse. However, they fail to teach the management of cases. Hence modern insistence on a doctor doing a few house jobs. If he does them in a municipal or non-teaching hospital an intelligent man soon picks up a working knowledge of medicine.

I qualified without having been shown any of the common infectious fevers except chicken-pox. Fortunately I had had the others, but this experience is not universal. However, if I saw a case of aortic stenosis I knew the patient was usually a man; and that a child with chorea is usually a girl (this is more useful).

Any general practitioner of sound intelligence who analyses his cases carefully will cut clean through the mass of inexperienced consultants to the top, as witness Mackenzie—provided he advertises by writing. If he does not do this he is merely a miser deriving pleasure from his hoard of superior knowledge.—I am, etc.,

Co. Derry. D. HAMILTON, Capt., R.A.M.C.

Psychology as Science

SIR,—Dr. F. M. R. Walshe, in his Linacre Lecture (*Journal*, August 12, p. 379), has paid me the compliment of referring to a work which I wrote a quarter of a century ago. In the naturally brief summary which he sets out I do not feel that he has given a correct picture of the position which I adopted in that book, and I am therefore seeking this opportunity to make my position clearer.

He accuses me of claiming that psychological medicine has established itself as a discipline within the field of the natural sciences, that the data of the psychologist in medicine are strictly comparable in character to those of natural science, that—as a scientific concept must be capable of verification by repeated reference to experience and experiment—I clearly believe this postulate to be fulfilled in psychological medicine. There are other accusations which I will refer to later, but may I in the first place be allowed to plead not guilty to these preliminary charges, basing my defence entirely on the statements made in the book in question? To begin with, I did not claim that psychological medicine had established itself as a discipline within the field of the natural sciences. On the contrary, the whole aim of the book was to examine whether and how far psychological medicine could claim a place within the field of *Science*. Science is not here equated with "natural science," and Dr. Walshe would obviously agree with me in this respect, as he uses the term "historical science." The meaning which I attached to "science" was the employment of the method of science as defined by Karl Pearson—viz., a procedure involving three successive steps. First, the observation of phenomena; secondly, the orderly arrangement and classification of the facts which have been observed; and, thirdly, the finding of "laws" which will serve to explain those facts, and enable one to predict and control the occurrence of future phenomena of the same order. The object of my book was, as I have said, to examine to what extent the development of psychological medicine had followed this road. While I found that it had done so in certain respects and at certain stages of its growth, in other respects and particularly in some of its later stages I emphatically stated that the canons of scientific validity were not satisfied. I described my final position with regard to these

later developments as one of "benevolent scepticism." I share the substantive with Dr. Walshe, though hardly the adjective.

Next, so far from claiming that the data of the psychologist are strictly comparable to those of natural science, I have expressly set out their weakness in this respect. Except for the facts of introspection all other psychological facts are inferences, in that they are inferred from behaviour and speech. I quoted Drever's remark that this peculiarity was an inherent weakness, and one which dooms psychology always to occupy an invidious position in the scientific hierarchy. I added that, owing to the nature of its material, psychology can give only an imperfect response to the demand for objective verification which science insistently makes. Nevertheless I did not, and do not, think that this weakness is sufficient to remove psychology altogether from the employment of the method of science. Often the gap that separates the "psychological fact," which forms the material to which psychology applies the method, from the directly observed fact—e.g., speech—is so small that it may safely be neglected. After all, inferences of this degree are commonly accepted in medicine. If a patient tells me that a spot is tender, I include the tenderness without protest among observed facts, though it is actually an inference. I do claim that, by following the method of science, psychological medicine has in its development arrived at conceptions which serve to explain and control our experience to a degree which no other mode of attack has succeeded in achieving. I may cite here the work of Janet on hysteria, which cast a new light on a field illuminated before only by the completely sterile concept of "functional nervous disorder" bequeathed by our neurologist ancestors. Moreover, this work was to a reasonable extent capable of being checked by experience and experiment. I would also add the conception of "purpose" in disorder, which we certainly owe to Freud's earlier work. This conception enabled us to understand the genesis of the psychoneuroses of the first world war, and moreover the knowledge so gained enabled practical and effective steps to be taken in controlling and reducing similar manifestations in the second world war. It is perfectly true, therefore, that in my book I claimed that psychological medicine had, by employing the method of science, succeeded in making considerable advances. But, in estimating that success, the gap between the actual observed fact and the psychological fact behind it must be carefully watched, and the possibility of distortion between the two borne constantly in mind. In the later work of the Freudian school I felt that the gap had been too wide, and I therefore was not prepared to accept it as conforming to the postulates of scientific method.

I may remark here that the context of Dr. Walshe's lecture makes it plain that he is identifying psychological medicine with the doctrines of the orthodox psycho-analytic school. He pays no attention to the very considerable work which has been and is being accomplished altogether outside that school. This point does not directly concern me, however, except in so far as Dr. Walshe has by implication included me with those accepting the Freudian claims.

One further accusation of Dr. Walshe must be mentioned. Commenting on my remark that the introduction of "purpose" removes psychology from the mechanistic sciences, but not from the whole field of science, he says, "Here Hart seems almost trembling on the brink of awareness that psychology does not belong to natural sciences. However, he goes on to place it with biology. Yet the word 'purpose' is not unequivocal, for teleology in biology is not the 'purpose' that determines human action. Such are the pitfalls of linguistics." I understand this quip to mean that I have unwarrantably identified "purpose" in psychology with teleology in biology. If I had done so I should not describe my transgression as having anything to do with linguistics, but should term it a gross confusion of thought. But I perpetrated no such error. The gist of the whole passage in question is as follows. There are two concepts of causality: (1) An unconditional sequence; *a* is inevitably followed by *b*. (2) Not merely inevitable succession but a relation of identity between cause and effect. The effect is regarded as the cause in a new form. In this sense causation is an equation, and a reversible equation. It is the sense in which causality is understood in the mechanistic sciences, and obviously psychology cannot be brought under it, for sequences in which "purpose" is playing a part are clearly not reversible. But this irreversibility does not exclude psychology from the first concept of causality. If it were insisted that the method of science requires the concept of causality in the second sense, biology and even physiology would have also to be excluded, not because teleology and "purpose" are identical, but because both necessarily involve irreversible sequences. They are analogous in this attribute of irreversibility, but that is all.

In my book I pointed out that I held no brief for regarding the method of science as a unique mode of approach to the problems of psychology, and was quite prepared to employ any other method which should prove to be more effective. Dr. Walshe now puts forward the method of historical science as the only sound alternative. He does not give any concrete example of the use of this alternative in the problems of psychological medicine, and we could of course hardly ask for this in the scope of a single lecture, though I hope he will give us further indications of his proposals in this respect. But I must confess that I feel considerable apprehension over his comparison of the historical method of approach with the taking of a clinical history. In the latter, as he rightly says, "From its items we select, discard, and assemble in the light of our previous experience; and the final product of our activity is the sublimation of a certain kind of evidence from one source and of a critical study of it from another," and later he speaks of the ideal medical psychologist dealing with the mental activities he is examining "by rethinking or reliving these activities in his mind, and in the context of his own knowledge." The possible action of bias and distortion here is so great that my feeling of helpless scepticism, in face of the labyrinth of conflicting speculations and methods which Dr. Walshe so eloquently describes, is far from being assuaged. It is very doubtful whether the clinical history obtained by Dr. Walshe in a given case would be identical with that obtained by an enthusiastic psycho-analyst in the same case. I would point out that the advance in historical method which has taken place in the last century is largely due to a better estimation of the part played by bias and emotional distortion in presenting alleged factual records, and this has been achieved by the application of psychology to historical method, rather than vice versa. Some of this knowledge, indeed, has been attained by the use of investigation and experiment—e.g., by Stern and the Breslau school—which needs no apology on the score of scientific method.

Finally I would say that one of the lessons of history is that systems of thought and belief are destroyed, not by attacking them, but either by a process of internal decay or by the appearance of another and more satisfying system which gradually undermines it. I would be content to leave the developments which Dr. Walshe anathematizes to the first process, in the hope that a considerable sediment of solid stuff would be left. But if Dr. Walshe can really provide the second alternative it is cordially to be welcomed. For my own part I felt when I wrote the book, and still feel, that psychology will get along better by pushing the method of science, albeit in an imperfect form, as far as it will prove reasonably sound and effective, than by any other method as yet available.—I am, etc.,

Eastbourne. BERNARD HART.

SIR,—In his most interesting Linacre Lecture (August 12, p. 379) Dr. F. M. R. Walshe writes: "Of its possible relation to historical science we find no word in the superabundant writings on psychological medicine" (p. 382). May I be allowed to point out that in the preface to the fifth edition (1944) of my *Psychology and Psychotherapy* I wrote:

"Psychology as a science is based on the category of historical causation, and the rules of diagnosis and prognosis in medical psychology are based on patients' medical histories supplemented by the results of deep mental analysis. It is instructive to re-read Immanuel Kant's *Kritik der reinen Vernunft* from the standpoint of modern historical science. Events do indeed follow one another 'according to a rule' (*nach einer Regel*), but deeper connexions of meaning have to be unravelled before the true 'rule' becomes apparent."

As one listens to a patient during a course of prolonged and deep mental analysis, one is impressed by the importance of "choice" and "decision" at critical moments of his life, and one sees his life unfolding as an evolutionary process and not as a mere mechanical sequence of events. My experience in the consulting-room, in association with my training as a philosopher, has convinced me that individual mental life is a historical process, and that the mental sciences (*Geisteswissenschaften*) reach their fullest development along the lines of historical explanation. But this, of course, leaves scope for many other legitimate (though more abstract) points of view from which to develop the science of psychology.—I am, etc.,

London, W.1. WILLIAM BROWN.

SIR,—Dr. F. M. R. Walshe's Linacre Lecture (August 12, p. 379) contains much wisdom, and many, including myself, will agree with most of what he says. It is a pity, however, that in such a thoughtful lecture he should have embarked upon the subject of methodology in psychiatry with so little circumspection. In the course of his argument he upbraids medical psychologists for their blindness in claiming to use the scientific method of natural science. He exonerates those "sage medical psychologists" who, using physical methods, know them to be empirical. He does not, by the way, specify which physical methods. Apparently he is thinking mainly of leucotomy. All other psychiatrists, in their anxiety to be "scientific," are thought to be actuated by unconscious yearnings to acquire some sort of academic prestige within the world of ordered knowledge. He anticipates that his remarks will set off rhetorical land-mines, but, undismayed, he proceeds upon his hazardous way. The expectation of rhetorical land-mines will hardly be realized. Dr. Walshe is not opening up new ground. It is true that the Goulstonian Lecturer of 1926 supported the claim that psychiatry was within the ambit of natural science and used its method. But other psychiatrists disputed this claim, as they had done earlier. Dr. Walshe is apparently unaware of their contributions upon this somewhat ancient theme.

Some psychiatrists—by no means all—have clear ideas upon the subject of methodology, and their number is not limited to those who employ physical methods—in his use of this term. Dr. Walshe may be glad to know that within psychiatry itself there are those (for example, certain psychotherapists) who have repudiated the claim that the only acceptable method in psychiatric practice is that of the natural sciences.—I am, etc.,

London, W.1. E. A. BENNET.

Inflammability of Ethyl Chloride

SIR,—Having read the instructive article on "Poisoning due to Inhalation of Methyl Bromide," by Drs. A. C. MacDonald, I. C. Monro, and G. I. Scott, in the *Journal* of August 19 (p. 441), I feel that their remark, "Like chloroform, ethyl chloride, and carbon tetrachloride it is not inflammable," should not pass without comment. Ethyl chloride is, surely, highly inflammable, burning, in fact, with a greenish flame. When mixed with 5–15% of air, it is actually explosive (*B.P.C.*, 1949). Few anaesthetists would feel justified in using "open E.C." in the presence of the diathermy, and disaster might result if one attempted to put out a fire with a bottle of ethyl chloride.—I am, etc.,

London, S.E.1. T. H. S. BURNS.

SIR,—Drs. MacDonald, Monro, and Scott state in their article on methyl bromide poisoning in your issue of August 19 (p. 441) that ethyl chloride is not inflammable. A surgeon who was about to remove a wart from my abdomen by means of cautery and local anaesthesia, with ethyl chloride spray as the anaesthetic, was also of this opinion. I can assure Drs. MacDonald, Monro, and Scott, with considerable warmth, that ethyl chloride is very much inflammable. The wart was undoubtedly removed, but the surgeon and I spent a very exhilarating few seconds extinguishing the resulting conflagration on my abdomen.

Fluid ethyl chloride can easily be ignited by the pea flame of a bunsen, but not, I believe, by a dull red fire. It was the latter fact that had led to my surgeon's belief.—I am, etc.,

Liverpool. H. E. VICKERS.

An Interesting Advertisement

SIR,—The grave shortage of psychiatric social workers is now well known, and makes discussions of improved mental health services, both preventive and therapeutic, largely academic. All with knowledge of the problem are agreed that the present salary scale is inadequate for workers who bear considerable responsibilities, and whose training lasts at least three years. That it is wholly out of relation to current rates is illustrated by a recent county council advertisement for mental health workers which reads as follows:

". . . Preference will be given to duly qualified Psychiatric Social Workers or candidates with a Diploma or Certificate in Social Science, and if so qualified the salary will be £370 by £20 to £530 per annum, commencing according to experience. For unqualified persons the salary would be £480 by £15 to £525 per annum."

This means that the unqualified start at £110 per annum higher than the qualified. Is it surprising that for several years past insufficient suitable candidates have come forward to fill training vacancies?—We are, etc.,

London, W.1. JOHN D. SUTHERLAND.
JOHN BOWLBY.

Chlorinated Swimming-pools and Poliomyelitis

SIR,—In recent announcements concerning poliomyelitis it has been stated that in certain places the swimming-pools were to be closed. This seems prudent. I have only three or four times swum in such places, but on each occasion I was immediately aware of an intense nasal irritation set up by the chlorinated water. Since then I have always believed that this is probably one important factor which encourages the spread of poliomyelitis, owing, I think, to the chlorine being ineffective as an agent for the destruction of the virus, but being present in quite sufficient concentration to disturb the normal resistance of the nasal mucosa and thus lay open an easy portal of entry, through the cribriform plate of the ethmoid and elsewhere, through the mucosa. Non-chlorinated water may be unpleasant to bathe in, but it is not necessarily dangerous.

I well remember the Merton Street Bath at Oxford. This was reserved for members of the University for bathing and for water-polo matches, but we boys of Magdalen College schools were allowed to use it, and we went there every evening in the summer when we were not swimming in the Cherwell. In Eights Week the bath was crammed with those who, having run and sweated on the tow-path, wished to cool down before going into Hall. There were no showers for a preliminary rinse; everybody just pulled off his zephyr and shorts and went in. The content of bacteria and other low forms of life must have been prodigious, for the water was only changed two or three times in the term of eight weeks, the signal for this being the impossibility of seeing the bottom—an event which occurred quite suddenly and was due, I suppose, to the rapid growth of some mould. Admittedly, poliomyelitis was uncommon in those days. None the less, it is of interest that, despite the filth of the water—of which, of course, we took no heed—I do not remember any case of otitis media among us, and the school was then a small one. During my five years as a schoolboy I am certain there was never a case of mastoid suppuration, nor, so far as I am aware, was there any unusual incidence of serious nasal or eye disease.

The nose is designed to probe into strange places and to be assailed in a variety of ways, but it will look after itself. I think it is fair to say that to wash it out with the attractive-looking water of a chlorinated swimming-pool is to invite disaster.—I am, etc.,

London, W.1. R. OGIER WARD.

The Internal Spermatic Fascia

SIR,—I would like to make some comments on Mr. C. Brun's article (August 19, p. 443). First, I think he will agree that (1) a stretched internal ring means a prolapsed cord and a defective muscular (valvular) mechanism; (2) there is no new surgical procedure which will completely restore a defective muscle action; (3) sutures in fascia, such as the transversalis fascia, cannot be regarded as a preventive against further stretching. Secondly, I cannot help feeling that if he agrees that the essential weakness of any well-developed inguinal hernia lies in the posterior wall of the canal, then buttressing of this wall by obliteration of the gap between the inner part of the

conjoined tendon and the inguinal ligament should be continued laterally, using either continuous or interrupted sutures. In this way the size of the internal ring is constricted until the new posterior wall fits snugly up to the forefinger, pressing the cord and ring outwards and backwards. Thirdly, I see no point in visually defining the internal ring in indirect herniae, as it can be palpated so much more easily, and there is no real hindrance to the action of displacing the cord outwards by finger pressure. The sutures used in the outer part of the new posterior wall should of course pick up the stretched fibres of the internal ring, in passing from the internal oblique muscle to the inguinal ligament.—I am, etc.,

Peterborough. D. W. BRACEY.

Domiciliary Treatment of Tuberculosis

SIR,—I feel I must express my sympathy for the patients who, under Dr. Crosbie Walsh's care (*Journal*, August 26, p. 525), are presumably denied the benefits of attending the local chest clinic. For his information and that of any other practitioners who may feel that they should "by-pass the tuberculosis officer," it may perhaps be well to enumerate a short selection of the services provided at chest clinics.

These include:

(1) Assessment of the significance of radiological appearances by the comparison of comparable films by physicians continuously confronted with the hazards and difficulties of this aspect of diagnosis.
(2) Advice given by physicians and health visitors versed in the special problems associated with these long-term cases.
(3) Arrangements for prompt financial assistance as afforded by the present scale of Government allowances.
(4) Arrangement of home-helps, boarding-out of children, special schools, recommendations for suitable jobs, and a hundred other vital forms of social assistance.
(5) Examination of contacts—primarily a radiological technique.
(6) Recommendation for sanatorium, surgical treatment, etc., which must in the vast majority of cases be done through these clinics.
(7) The controlled maintenance of adequate collapse therapy.

It is difficult to see how Dr. Crosbie Walsh can claim to provide a comparable form of assistance to his patients in these matters, quite apart from being able to assess the indications for streptomycin, etc., the hazards of which are being continuously stressed.[1,2]

In our area, in which we enjoy a full degree of co-operation with general practitioners,[3] we still get at least one new case a month in which valuable weeks or months have been wasted by trying to arrive at a diagnosis without reference to the chest clinic.

Finally, as the question of co-operation between general practitioner and chest clinic has been raised, may I put in a plea for careful history-taking, with special reference to time factors, in all cases who attend the doctor's surgery with a condition which might prove to be pulmonary tuberculosis? The history is the important factor in the early diagnosis of pulmonary tuberculosis, and the practitioner gets this first.—I am, etc.,

Hounslow. B. MEYER.

3 Heller, R., *Tubercle, Lond.*, 1949, **30**, 204.

SIR,—The last thing I desire is for this correspondence to degenerate into a war between tuberculosis officers on the one hand and general practitioners on the other, because I have always believed that we must work together. However, I feel that the letter from Dr. R. Crosbie Walsh (August 26, p. 525) calls for comment.

I desire that every tuberculous patient should have the skilled treatment necessary in his particular case. I do believe that a tuberculosis officer who keeps himself up-to-date by working in close co-operation with the tuberculosis hospital and thoracic surgery centre is better qualified to assess cases for chemotherapy than a general practitioner. The analogy made between tuberculous cases suitable for streptomycin and puerperal sepsis cases requiring penicillin does not stand scrutiny. We all know that puerperal sepsis cases require penicillin, but on the other hand all cases of tuberculosis are not suitable for streptomycin. Furthermore, Dr. Walsh must have little idea of the respective functions of a medical officer of health and a tuberculosis officer if he does not know that the former is an administrator, not concerned with treatment, whereas the latter is a clinician.

I agree that it is the responsibility of the general practitioner to treat his tuberculous patients as well as others, but I think that treatment should be discussed with the tuberculosis officer, who should know what the future plan of treatment is likely to be and whether the suggested treatment will be beneficial or otherwise. Dr. Walsh appears to have been most unfortunate in his dealings with his local tuberculosis clinic, for I am sure that most tuberculosis officers, overworked though many of them are, are only too pleased to discuss their cases personally with the general practitioner if this be desired, and I think they all try to keep him informed by letter of any changes in *x*-ray or other findings.

The limited facilities placed at our disposal in the past by some local authorities may have caused some tuberculosis officers to be less helpful to the general practitioner than they might have been. It is to be hoped that all chest clinics will soon be adequately equipped and staffed to deal properly with the tuberculous population of their areas.—I am, etc.,

Liverpool, 18. WILLIAM D. GRAY.

SIR,—With great surprise I read Dr. Walsh's reply and criticism (*Journal*, August 26, p. 525). Dr. Walsh most likely has been very lucky to get a "teaching hospital chest physician" to deal with his difficult cases arising out of the antibiotic treatment of tuberculosis. It would be a really sad day when we see the general practitioners, who are the main pillars of an efficient medical service, by-passing any branches of specialized medicine. But I want to ask him a few questions.

What procedure does a provincial doctor take when requiring institutional treatment for tuberculous patients? What percentage of his open tuberculous patients have been admitted to teaching hospitals? (We ought to remember there is only one Brompton Hospital in the whole country.) I am only very new in the tuberculosis service of the country, but my short experience shows that in dealing with tuberculosis, which not only requires curative treatment but entails massive social and economic adjustments, proper co-operation between general practitioners, chest physicians, and tuberculosis officers must be maintained on the highest level.—I am, etc.,

Manchester, 13. S. S. CHATTERJEE.

The Case for Abortion

SIR,—It will surely be the general view among your readers that Mr. Albert Davis and yourself have done a considerable service in publishing his "Report on 2,665 Cases of Abortion" (*Journal*, July 15). The report is defined as intended "to determine the relative merits of active and passive treatment in cases of incomplete abortion," and within these terms adds considerably to our knowledge. One cannot help feeling, however, that the material provided among the incidental findings raises farther-reaching questions. I trust a comment may be permitted along these lines.

Of the cases generally (the great majority of which were those of attempted illegal abortion among married women) it was noted that in almost 1 in 10 there was a history of previous abortion. Also, that the abortions had been induced either medicinally or by douching. These facts lead to two conclusions: (1) that women in the relatively favourable state of legal marriage had been brought by unwanted pregnancy to such mental distress that in 253 cases they were willing to attempt abortion again, *after having had the experience*, which argues a certain desperation; (2) that these women must already have been in a very poor state of physical health if "female pills," purgatives, or douches could produce effect. Upon the healthy system they are quite ineffective; but for which fact very many people living to-day would not have entered this world.

If it is a fact that psychological health affects physical health, if to endure humiliation, pain, and danger of death rather than

fulfil a natural function implies some degree of psychological sickness, then there must be a case for close consideration of psychological and environmental factors as they affect health when the decision for or against the termination of a pregnancy is made. This decision should be neither in the hands of the mother, who cannot see beyond her immediate situation or understand all the factors involved, nor in the hands of the gynaecological specialist, who cannot be expected to be fully informed regarding psychological and environmental factors and their probable results, nor in the hands of the psychological practitioner alone, since he needs friendly conference with both the gynaecological specialist and most particularly with the general practitioner, the key-man immediately in touch with the personality and background of the patient.

Mr. Davis gives, as a permissible indication for termination of pregnancy, "*gross* physical disease." This requires elaboration. What, in fact, is "gross" physical disease? Has the mother to have both feet in the grave before relief is afforded her? Mr. Davis states: "The indications were those usually accepted as necessary for therapeutic induction, with the possible exception of pulmonary tuberculosis, *but the difficulty of obtaining suitable sanatorium accommodation for these patients is usually an overriding factor*" (my italics).

This in fact means that in such circumstances environmental factors—indeed, economic factors—were taken into account, in so far as they would in all likelihood eventually render the mother unfit to give birth. Upon this basis, is it unreasonable to conclude that, where environmental factors will cause such tremendous stress as to affect mental health to the extent of rendering a mother unfit to give birth, relief should also be indicated? Yet Mr. Davis notes, "Several patients with temporary mental instability were referred by psychiatrists, but this was invariably transient, the result of unwanted pregnancy, and interruption was refused."

This must inevitably prompt the question whether the after-histories of such patients are available over a long period of years. In the experience of every psychological practitioner (not merely in theory) it is found that temporary mental instability never results only from an immediate stress. The unwanted pregnancy is not the cause of the temporary mental instability, it is only the precipitating factor. The original cause usually lies many years back. Since the true cause of the mental instability remains untouched, let a new stress arise years later (and in the case of the unmarried mother in poor circumstances, how many chances there are that this will happen), and the mental instability will be back again *in more acute form*. Unless a secure and not greatly troubled future can be guaranteed for the woman suffering temporary mental instability as the result of an unwanted pregnancy, or unless a cure is effected by prolonged analytical treatment, then she is almost bound to relapse at the next practical crisis of her life, and her child, too, will suffer. Therefore psychological treatment should always be given as the natural accompaniment of refusal of termination.

When a woman is found to be suffering from temporary mental instability, precipitated by unwanted pregnancy, the psychiatric practitioner must (with the aid of the family doctor) endeavour to assess the environmental factors, together, of course, with those "inner" factors upon which the pregnancy has, from the practical viewpoint, acted only as the precipitating agent. These may include the unmarried status of the mother, the overburdened lot of the mother of several children, extreme poverty, lack of housing accommodation, unhappy marriage, and so on. No one of these things could by itself ever be accepted as an indication for termination. They may, however, singly or in combination, constitute that final stress which (added to other "inner" factors) might push a woman over the edge of sanity.

For a married woman who has already been through the ghastly experience to attempt second (and even more) abortions argues *ipso facto* a degree of mental instability for the time being (and of latent instability which may be permanent) sufficient to justify examination of her case.

Mr. Davis notes (and the experience of most of us, as well as the statistical evidence, will confirm) that "the complication rate is much higher in illegitimate abortions. In the present series of 315 unmarried women severe complications—gross haemorrhage, virulent infection, pelvic abscess, etc.—were present in 43 (14%) of the cases, while the corresponding figure for the 2,350 married patients was only 6%. . . . The most likely explanation lies in a combination of several factors—the inexperience of these girls, their isolation, and the desperate nature of their predicament." Here, if more is needed, is sure confirmation of the fact that mental factors exert deep influence upon physical health.

It is not, again, suggested that the fact that a girl is unmarried is *in itself* an indication for termination, or should ever be so; or that the decision should lie in her own hands. The proposal is rather that, when the decision is taken by gynaecological specialist, psychiatrist, and family doctor in consultation, the greater actual physical and mental risks run by the unmarried mother should be borne in mind—in precisely the same way that the risks run by the unhospitalized phthisic expectant mother are borne in mind by Mr. Davis.

The note that only 1% of the cases mentioned in the report were instances of therapeutic abortion leads one to wonder whether there is not some connexion between this figure and the far greater (and frightening) figure of 90% of cases considered to have been improperly induced. This appalling figure should make us begin to realize the nature of our individual responsibility when we refused consideration to such a request. Surely of those 2,400 cases there must have been a number of individual instances where there were in fact legal grounds for termination?

If not only the frequency of abortion and the state of physical health of individual patients in these cases, but also some details of their background, could be obtained, a great new light would be thrown upon this whole subject. The following heads would cover some of the most pertinent points: the precise reason driving the mother to the desperate expedient of illegal abortion; existing number of children; relationship between husband and wife (or between unmarried girl and her parents, and the man responsible); and family income and accommodation. No doubt more could be added.

I myself hope one day to publish the results of cases (of a different section of society from that of Mr. Davis's series) considered on psychological grounds; a certain number where the pregnancies were terminated and a larger number where the patient was made to understand the rightness of continuing to full term.—I am, etc.,

London, W.1. EUSTACE CHESSER.

Abortion

SIR,—There is a good deal to criticize in Albert Davis's article on abortion in the *Journal* (July 15, p. 123). May I consider a few points?

Under "Civil State" he writes, "Of the 2,665 women, 2,350 were married, 303 were single, and 12 widows. This is in accord with McIlroy's (1929) report that abortion is most frequent in the married." Must he not also consider the relative frequency of married, single, and widowed women in the general population?

I am quite incapable of believing that of 2,665 patients only 13 had a retroverted uterus. I suggest with some confidence that many of the case-papers lacked a specific note on the position of the uterus and that there must have been far more in retroversion. Mr. Davis writes: "In nine cases the patient had aborted incompletely before admission. The uterus was replaced in the remainder, but in only one case was this *successful in producing continuation of the pregnancy*" (italics mine). I believe that if you wish a patient with a retroverted uterus to miscarry, the simplest plan is to manipulate her uterus into anteversion.

As there were four cases of impaction and only two of retention of urine, I should be interested to know what Mr. Davis means by impaction of a retroverted uterus without retention: it is not a condition with which I am familiar.

I am completely floored by the logic of the last two lines of this paragraph on retroversion. The fact that of 13 patients admitted for abortion 9 were incomplete on admission, and 3 more aborted after the uterus was manipulated, does not prove

to anybody "the difficulty of preserving such pregnancies": it proves nothing. Every gynaecologist of experience has seen many patients with a retroverted uterus who have threatened to abort and then gone on to term.

Under "peritonitis" on page 128 one successful hysterectomy leads him to conclude that "there is a definite though necessarily limited indication for its use in post-abortal peritonitis." The conclusion may possibly be right, but it is not justified by the evidence given.—I am, etc.,

Leeds, 2. ANDREW M. CLAYE.

Haemorrhage from Peptic Ulcer

SIR,—Sir Robert Hutchison's suggestion that "every peptic ulcer once established as chronic be operated on in the cold" (August 19, p. 459) is utopian rather than practical and fails to take into account several obvious difficulties:

(*a*) A local practitioner discussing the incidence of peptic ulcer stated that he had in his practice approximately 100 patients "of duodenal type," of whom not an inconsiderable number would merit surgical consideration. The North-eastern Region (Scotland) area serves a population of roughly 400,000, which by simple computation would yield some 16,000 duodenal dyspeptics. Assuming that only 1 in 20 be "definitely established as chronic"—and such assumption cannot be an overestimation—the waiting-list for gastrectomy would be 800.

(*b*) The practising surgeon and physician must have encountered perforations and haematemeses which occur unheralded in a clinically silent duodenum. Thus, even although the established chronics have been dealt with, a fruitful source of perforation and haematemesis remains.

(*c*) Since 1945 the number of beds available for general surgery has decreased by virtue of the demands of thoracic, neurosurgical, and vascular clinics. The National Health Service too, far from increasing the accommodation, has meant a reduction in the number of available beds in this area.

Hence, in this area at least, in which Drs. Needham and McConachie (July 15, p. 133) have compiled their recent statistics, any attempt to forestall perforation and haematemesis by mass surgery on the established chronic ulcer would inevitably fail.—I am, etc.,

Aberdeen. W. MICHIE.

SIR,—Having been brought up since childhood to respect the name and opinions of Sir Robert Hutchison I was delighted to read his letter under the above heading in the *Journal* of August 19 (p. 459) expressing so succinctly the beliefs of many surgeons. Twenty-five years ago gastro-jejunostomy held sway in the treatment of even the most unsuitable types of peptic ulcer, and the mortality of gastrectomy was forbiddingly high except in the hands of one or two pioneer experts. In recent years surgeons working on the unpromising material provided by the failures of medical treatment, the half-starved, the exsanguinated, and the chronically enfeebled have succeeded in restoring a large proportion of patients to a decent level of digestive and general good health with a small operative mortality. Nevertheless, we are still not having ulcer dyspeptics referred for surgical treatment until disaster is at hand or has actually occurred. There then ensues a period fraught with anxiety and alarm for the patient, the relatives, and all concerned; during these hours the question of an emergency operation must be considered, continuous transfusion and constant nursing vigil add to the strain on all until, only too often, the dismal revelations of the post-mortem room humiliate us with the information that the patient must have been living with the threat of a lethal haemorrhage from a chronic peptic ulcer for many years. Few would question the advisability of operating on an inguinal hernia before strangulation occurs; why then should the profession accept the risks of haemorrhage, perforation, or malignant change in a chronic peptic ulcer with equanimity?

In conclusion I would strongly endorse Sir Robert Hutchison's appeal not only as a measure that will save the patient chronic invalidism and a constant threat of sudden death, but as a measure that will save the hospital service hundreds of beds, the nursing profession untold hard work, and the transfusion service gallons of blood.—I am, etc.,

Weymouth D. J. ROSS STEEN.

Extreme Hyperpyrexia with Recovery

SIR,—I would bring the following case to your notice as illustrating the tenacity of life among the Chinese.

The patient, a rather emaciated Chinese aged 67, came under my care complaining of right-sided abdominal pain and constipation of four days' duration. He had not vomited, and there was no history of preceding dyspepsia or jaundice, or of previous attacks. On examination his condition was good (pulse 100, temperature 98° F. (36.7° C.)). The whole of the right side of the abdomen was rigid, and he placed the site of maximum pain and tenderness just to the right of his umbilicus. The conjunctivae were pale, and the patient was anaemic. A diagnosis of acute cholecystitis, ? acute appendicitis, was made.

The abdomen was opened through a right paramedian incision and the gall-bladder found to be acutely inflamed and full of small stones. The sounder courses of closure or cholecystostomy were discarded, and cholecystectomy was embarked upon; this was accomplished with some difficulty and the loss of a modicum of blood by the patient. On leaving the theatre his condition was still fairly good, the pulse being 130 but of good volume. One and a half pints (840 ml.) of saline was given intravenously during the next three hours.

After this time it was decided to give him blood, and one pint (560 ml.) Group B was obtained from a donor and cross-matched. After half a pint had been given at about 20 drops per minute the patient began to have rigors. The transfusion was stopped, but the rigors continued and became worse. After half an hour his temperature had risen to 107° F. (41.7° C.) and his pulse to 150, being barely perceptible. Nikethamide 1 ml. was given and cold sponging commenced. During the next half-hour the patient became worse. The pulse could not be felt anywhere, the breathing was shallow and laboured, and the limbs cold and wet. The axillary temperature rose to approximately 112.5° F. (44.7° C.). (The thermometer scale stopped at 110 degrees, but by producing the marking it appeared that the reading lay midway between 112 and 113. This was checked by three readings in the next five minutes.) Quinine 15 gr. (1 mg.) was given intravenously together with a further 1 ml. of nikethamide, which was continued hourly. The cold sponging was continued. The patient now appeared moribund. However, an hour later he improved slightly, the pulse being just perceptible (150), and the temperature 101° F. (38.3° C.). The improvement continued, and by the next morning he was conscious and taking fluids by mouth, with a pulse of 120 of fair volume and temperature of 100.5° F. (38° C.). His subsequent convalescence was uneventful. For three days his temperature remained about 100° F., after which it became normal. He began to sit up on the fifth day and to walk about on the tenth. It would seem that he has suffered no permanent harm from his pyrexia.

I am at a loss to account for his somewhat alarming rise in temperature. The strife and bloodshed occurring in this particular part of the Empire necessitate frequent massive blood transfusions, but we are not accustomed to meet with such reactions. The grouping and cross-matching were properly carried out and the apparatus was clean and sterile. The patient showed no evidence of chronic malaria.

I am grateful for permission to publish this case.—I am, etc.,

Malaya. J. T. ROWLING, Lieut., R.A.M.C.

Sulphonamide Therapy

SIR,—Professor D. M. Dunlop (August 12, p. 408) made no mention of sulphanilamide, of which I happen to have a stock in tablet, powder, and cream form. Nor did he mention the application of sulphonamides in the treatment of burns. Could he, moreover, express opinion as to the value, if any, of a couple of doses (2 g. each) of, say, sulphanilamide as a prophylaxis of gonorrhoea on "the morning after"? Such information would be much appreciated.—I am, etc.,

H.M.T.S. "Monarch" J. L. BARFORD, Ship Surgeon.

Poliomyelitis and Inoculations

SIR,—The incidence of muscular paralysis, confined to the inoculated limbs, which is described in Dr. J. Newcombe's letter (*Journal*, August 12, p. 416) is a classic example of the type of case which still startles medical opinion. Such cases, however, offer a good opportunity for an analysis, because here we are at least dealing with some known factors, similar to those we encounter with the inoculation of vaccines, or antibiotics, or sera. But so far the factor of an adjuvant, apart from the needle, has not been taken into consideration, whether it is the micro-organisms present in the vaccine or the micro-organisms causing infection. This factor of infection, for which Dr. Newcombe injected penicillin, was completely ignored as an additional causative agent, although the febrile reaction and boil formation were due to some of the staphylococcal series.

Trauma can always be regarded as a precipitating factor for an entry of the virus, since it exposes the muscle motor-end plates to an open attack at the myo-neural junctions. In the case of the neurotropic virus, such an entry is a prerequisite for it to be able to exert its pathogenic activities.

But there are also chemical changes taking place as a result of trauma: muscle tissue is hydrolysed, in consequence of which there will be released a series of enzymes, like myosin ATP-ase, carboxylase, phosphatases, and also adenosine compounds like ATP, ADP, or creatine phosphate. Also we find liberated a series of ions, such as Ca, Mg, K, P, and organic acids, resulting in a gross shift of the *p*H and ionic balance. Micro-organisms contain large amounts of nucleic acids in combination with proteins. When infection as well as trauma is present some of the micro-organisms will die or be disintegrated under the influence of antibiotics and their nucleoproteins released into inflammatory tissue, still physiologically active. The best comparison one can offer is with Griffith's discovery of the transformation of one type of pneumococcus into another type by bringing into contact, *in vivo* or *in vitro*, the living form "R" variant of the type to be transformed with the heat-killed form "S." Avery and McCarty and MacLeod isolated this transforming agent, which is a sodium-desoxyribonucleic acid.

I quite agree that these are complex factors, but without an understanding of the biochemical principles involved the problem of poliomyelitis can hardly be solved.—I am, etc.,

Hayes, Kent. L. RETI.

But Was it Poliomyelitis?

SIR,—Last year when I was in Brigg (Lincs) I had some cases of children febrile and perhaps dragging a leg or not using an arm which seemed painful if moved. I used to give 1 mega unit of penicillin. This—or perhaps three subsequent doses of ½ mega unit daily—cleared the condition.

It may have been mild poliomyelitis: I did not diagnose it at the time, being satisfied if the child was well again, and all the cases were well with this treatment. Therefore I think penicillin in huge doses given *early* in any febrile condition in any district where poliomyelitis is known to be is justified. No time should be lost awaiting results of swabs.—I am, etc.,

Keighley. FLORENCE M. E. DAVIES.

Treatment of Acute Yellow Atrophy

SIR,—On p. 214 of the *Journal* (July 22) an account is given of the meeting of the North of England Obstetrical and Gynaecological Society held at Newcastle-upon-Tyne on Friday, June 2, 1950. I gather that you have been given an incorrect description of the infusion I used for treatment of yellow atrophy of the liver. The quantity of nicotinamide should be 150 mg. and the infusion should also contain potassium chloride. It is correct to state that three pints of the infusion are given daily, but this is followed, not by a pint of saline, but by a pint of plasma to which vitamins have been added. The treatment is actually more complicated than would be inferred from reading the report and is given in detail in the paper which is awaiting publication in your *Journal*.

At the meeting, Mr. Stabler made it very clear that he was showing these cases solely because of their obstetric interest, and that they were included in a series of five cases to be reported upon by myself.—I am, etc.,

Newcastle-upon-Tyne. A. L. LATNER.

Osteoarthritis

SIR,—Some of the detail in Dr. C. W. Buckley's Refresher Course paper (June 17, p. 1415) is a strong stimulus to criticism.

Trauma can hardly be an important cause of osteoarthritis, as the condition is common in persons whose occupation is of a sedentary nature. It also occurs in persons who have abstained from exertion as far as possible throughout their lives on account of cardiac lesions or other reasons. The effect of injuries on joints is well known and often loosely termed "osteoarthritis," but the condition is not the same. Massage is recommended to relieve muscle spasm. Surely the existence of such an unusual feature as muscle spasm calls for a review of the diagnosis? If surgery is left till pain is severe and deformity serious the results are certainly likely to be disappointing, and if as stated the patient remains in hospital in splints for a long period failure is almost certain.

Osteoarthritis of the hip is more commonly bilateral than unilateral, though commonly symptoms commence first on one side. The alternatives to cup arthroplasty of the hip-joint—namely, arthrodesis and osteotomy—are not mentioned, and manipulation under anaesthesia, which is a popular method of treatment of osteoarthritic joints and spondylitis, is not discussed.

Patients are justified in objecting to wearing callipers or Marsh knee cages. If they need them they could probably be served better by surgery.

—I am, etc.,

Melbourne, Australia. FRANKLYN STONHAM.

Penicillin and the Skin

SIR,—Professor L. P. Garrod in his article on "Administration of Penicillin" (*Journal*, August 19, p. 453) states that it has "all the properties of an ideal antiseptic . . . without doing the slightest harm to tissue." During the war, however, as well as later, I have had the opportunity to observe that skin-grafts to which penicillin had been applied disappeared rapidly and with distressing regularity. I have seen ulcers of many months' standing. Soon after the appearance of a small lesion the patient had been applying penicillin ointment for several weeks and months. Remembering the resorption of skin-grafts, I ordered the discontinuation of the ointment. The ulcers disappeared under a dry dressing within a few days.—I am, etc.,

London, S.W.3. E. F. BLUMBERG.

Strangulated Hernia in Infants

SIR,—On December 23, 1949, a 21-day-old African male was admitted to hospital at 7.30 p.m. suffering from a strangulated right inguinal hernia. This had occurred the previous night, about 20 hours earlier. The bowels had not been open for 24 hours, and the abdomen was slightly distended. The child had vomited six times and there was a tense irreducible swelling in the right inguinal region. The temperature was 98° F. (36.7° C.) and the pulse rate 142.

No anaesthetic was used for the operation: the child was crucified on splints, and the anaesthetist who was standing by kept the child quiet by letting it suck his little finger. At operation there was a loop of small intestine in the sac, in good condition. The inguinal ring was then enlarged, and attempts were made to replace the gut. Owing to straining, this was very difficult, as the intestines were constantly being forced out. It was finally accomplished at the end of 45 minutes. While the incised ring was being repaired there was a flood of urine all over the field of operation. The source of the puncture in the bladder could not be traced, so the area of leakage was oversewn. The inner surfaces of the sac were sewn together, and the wound closed. As the operation had now taken 60 minutes, the skin was closed with a continuous suture to save time.

There was no post-operative leakage of urine from the wound, but it broke down on the fifth day, partly as the result of the mother enthusiastically bathing the child and pulling off the "elastoplast" dressing. The skin suture came away with the dressing. The gaping skin wound was treated with eusol, and healed at the end of 26 days.

Immediately following operation the temperature rose to 101° F. (38.3° C.) and the pulse increased to 160, but the temperature had returned to normal next day and thereafter never rose above 98.6° F. (37° C.). Post-operative treatment consisted of penicillin 25,000 units three-hourly for six doses, and pot. brom. 1 gr. (65 mg.) p.r.n. The child continued to suckle normally, and put on weight. He was discharged well on the twenty-sixth day, and returned home eight miles by canoe, the way he had come.

Three months previously an African baby of 9 months was admitted with a tense right scrotal swelling of three days' duration, a distended abdomen, and vomiting. The temperature was 102° F. (38.9° C.) and the pulse rate 154. An operation was performed under general anaesthetic. There was an excess of fluid in the sac, and the loop of the small intestine was very

congested, but viable. The ring was incised and the intestine replaced. The ring was repaired and the neck of the sac closed. A drainage tube was placed in the scrotum. Post-operative treatment was penicillin 100,000 units, followed by the treatment as above. The temperature and pulse were normal by the third day. The child suffered no inconvenience, and was discharged cured on the thirteenth day.

I am grateful to the Director of Medical Services, Gold Coast, for permission to publish this report.—I am, etc.,

Gold Coast. M. P. BROWNE.

Damage to the Antrum During Dental Extraction

SIR,—The maxillary antrum is vulnerable during extraction of a lone premolar or molar tooth with alveolar atrophy around it. The danger is not at all obvious to the inexperienced. First, the tooth may shoot up into the antrum. In such case a snare is a suitable instrument with which to effect delivery. Secondly, part of the antral floor may come away with the tooth, leaving a permanent oro-antral fistula. Thirdly, an ill-advised plastic operation has the effect that, when the patient eats, saliva drips from the nose. (Such fistulae have been established deliberately in the treatment of atrophic rhinitis.) There is a better method of closing an oro-antral fistula of this kind. A palatal flap based upon the posterior palatine foramen is reflected under a longitudinal bridge of palatal tissue and sutured to the buccal margin of the fistula. This is in accordance with the soundest principles and practice of reparative surgery, and may therefore be relied upon to put matters right again.—I am, etc.,

Huddersfield. W. O. LODGE.

Minority Crusade

SIR,—Tuberculosis is very much in the news, and this is all to the good, provided it leads on to effective measures to combat the disease. We, the undersigned, fear, however, that the calls being made for a crusade against tuberculosis may result in a big expenditure of public money without any worth-while improvement in the position. Our fear is based on two considerations: (1) no known antibiotic or therapeutic agent of low toxicity is highly effective against tuberculosis, and (2) the profession as a whole closes its eyes to what is probably the main cause of our failure to get rid of tuberculosis—namely, our failure to get rid of tobacco.

In a high proportion of cases—about 60%, we estimate—pulmonary tuberculosis is complicated by tobacco smoking (tobacco smoking is a drug addiction, a specific disease). Tobacco smoking violates almost every principle in the treatment of pulmonary tuberculosis—fresh air, immobilization of diseased lung (smoking gives rise to coughing, the activity which above all others disturbs healing and starts off haemorrhages; it also spreads infection), comfortable economic circumstances (smoking is expensive and leaves less money for food, housing, leisure, etc.), and good nutrition (almost everyone who gives up smoking puts on weight, often measurable in stones rather than pounds in a few months, and this is done without resting or "stuffing" in a sanatorium; the increase in weight is accompanied as a rule by increase in well-being). Can it therefore be doubted that smoking aggravates the course of pulmonary tuberculosis in a degree dependent in the main on the consumption of tobacco and the type of smoking? The importance of this lies in the fact that tobacco smoking, unlike pulmonary tuberculosis, is readily preventable and curable. It is no more difficult to prevent than opium smoking.

The principal obstacle in the way of preventing and curing tobacco smoking is, in our view, its prevalence among medical men and women. Nicotinism in common with other drug addictions is characterized by subtle psychopathological changes. Addicts of tobacco (and of other drugs) are deluded as a rule about matters concerning their drug; about, for example, its virtual harmlessness and the reality and importance of the contribution it makes to their happiness. So fixed oftentimes are these delusions that many addicts (including medical addicts) are quite inaccessible to logic on the subject and merely project on to those who seek to undeceive them their own unconscious disturbance of judgment, dubbing them cranks or fanatics. Even those who say they are convinced about the harmfulness of tobacco smoking are often unable or unwilling to express this conviction in their actions.

Although getting rid of tobacco would not completely solve the tuberculosis problem it would be a rational and, in our view, an important step in the right direction. The harm caused by tobacco smoking is by no means confined to its effects on pulmonary tuberculosis, and we are of the opinion that the upheaval that would be caused to our economy and mode of life by abolishing tobacco smoking would be a small price to pay for the substantial gain in the health and economy of the country that would quickly result.—We are, etc.,

Wallasey. LENNOX JOHNSTON.
F. C. MORGAN.

Johann Mikulicz-Radecki

SIR,—Sir Gordon Gordon-Taylor's tribute to the memory of Mikulicz-Radecki, "the great German [*sic*] surgeon," at the 67th Congress of the Deutsche Gesellschaft für Chirurgie (*Journal*, July 8, p. 103) prompts me to sketch briefly the life of this eminent Pole. His father Andrzej, born in Sniatyn (Poland) in 1806, came from an ancient noble family of Polish patriots which goes back to the fourteenth century. Their ancestral castle Radek (from which the name is derived) is at Osmiany. One of his ancestors was a member of the Polish royal household. Another distinguished himself so much in the battle against the Turks that the King of Poland added the cross and half-moon to the family coat of arms. In 1792 the Austrians seized the family properties of all Polish patriots, and Mikulicz's grandfather lost everything.

Mikulicz had a hard life as a student. He had to make his own way by giving piano lessons and teaching languages. After graduating in 1875 he was admitted to Billroth's clinic as *Operationzöglinge* (voluntary worker), and after the publication of his paper on rhinoscleroma he was quickly promoted. He became *Privatdozent* in 1880. Having achieved this title Mikulicz had automatically to leave the faculty. This was followed by the most tragic period of his life. The brilliant young surgeon was without a workshop, and there was no hope that as a Pole he would ever get one in Austria. Things were no better when he was ordered by the Habsburg authorities to remove the Polish eagle from his coat of arms. For two years he was at the Polyclinic, and during this time he had not done a single major operation. One can imagine his state of mind when he had to turn to general practice to support his wife and child. His Polish colleagues could not see such a talent wasted, and they invited him to take charge of what was left of the Jagiellonian surgical clinic in Cracow.

One can imagine with what joy Mikulicz received this invitation. The university clinic consisted of a few rooms on the second floor, sixteen beds in all, primitive conditions, and no funds for improvement. Obviously the Habsburgs could see no advantage in spending money on a Polish university. Mikulicz put all his zeal and energy into his work. This was the only place where he could work and show the Teutonic world what he was capable of. He lectured—in Polish, of course—and, surrounded by the love and esteem of both colleagues and students, he achieved miracles in this poor little "clinic" (a useful reminder to modern surgeons who would consider work inconceivable without teams, units, and vast "labs.").

Mikulicz was at Cracow from 1882 to 1887. As Sir Gordon relates, he was the first to operate successfully for gastric haemorrhage. This took place at Cracow in 1885, and the same year saw the publication of this case. His greatest surgical pioneer work was done during his stay at Cracow. This included lateral pharyngotomy for resection of malignant pharyngeal tumours (*Gazeta Lekarska*, 1883), osteoplastic resection of foot (*Przeglad Lekarski*, 1882), plastic nose surgery (1884), thyroidectomy (1886), surgical treatment of suppurative sinusitis (*Pamietnik Lekarski*, 1882), treatment of gangrene, intestinal resection, myomectomy, etc. While at Cracow Mikulicz published over forty original papers. By 1887 he had made famous both Cracow University and himself.

When the chair at Graz became vacant everybody thought he would get it. But he was a Pole and the place went to Wolfler. However, in 1887 he was offered the chair at Königsberg. He accepted with mixed feelings, for he was sorry to leave his Polish colleagues who had helped him so much in his hour of need. It is safe to say that without their help a great surgical genius would have been lost to the world. When Mikulicz became the recognized leader of world surgery and international honours were showered on him the Austrians felt it incumbent on them to do something also. When Mikulicz was approached on behalf of the Emperor he asked for only one honour—permission to reinstate the Polish eagle in his coat of arms. This was granted by decree in 1899.

I am relating these few historical details to show how inaccurate Sir Gordon Gordon-Taylor is when he calls Mikulicz "the great German surgeon." He may have his own views on Mikulicz's nationality, but when speaking on behalf of the Royal Society of Medicine and the Royal College of Surgeons these facts should not be overlooked. It is again becoming fashionable to flatter the Germans, but must it be done by removing Mikulicz from the ranks of great Poles and turning him into a German?—I am, etc.,

London, W.1. S. GALEWSKI.

POINTS FROM LETTERS

Clinical Impression versus Cold Science

Colonel W. H. CRICHTON writes: I do not presume to dispute the findings of the Medical Research Council or of Lorriman and Martin on their carefully conducted trials of antihistaminics in the common cold (*Journal*, August 19, p. 425). I do, however, feel that my own personal experience with this type of treatment which led me to arrive at a very different conclusion should be placed on record. I should explain that I am prone to get "colds in the head" about two or three times in a year, usually in spring and autumn with the change of the weather, but at other times as well if indiscreet with coverings, especially after exercise. On April 24 this year I was due to proceed to Eastbourne to attend the Congress of the R.S.I. On the 23rd at midday I was conscious of a roughness of the throat and a slight fullness in the head. By the afternoon I had begun to sneeze. By evening the symptoms of a cold in the head were clearly established. I went to bed early (9 p.m.) with a hot drink and 10 gr. aspirin—my usual remedies. The next morning (April 24) the symptoms were worse: shattering and more frequent sneezes, profuse watery discharge from the nose, eyes suffused, headache, general malaise. I took 10 gr. aspirin and stayed in bed, cancelling my departure for Eastbourne and cursing my luck at missing the congress, as my colds usually last at least a week to 10 days once they are established. For this reason I was tempted to try treatment by "anthisan," and in the late afternoon I took a tablet of 0.1 g. The effect produced was that of drowsiness and slight dizziness. I slept soundly. The following morning (25th) to my delight I was obviously much better: nose practically dry, no sneezes, general malaise gone. I stayed in bed and had a second tablet of anthisan. The effect was the same as before and I slept soundly again till lunch-time. By afternoon all symptoms had disappeared and I made arrangements to proceed to the congress the following morning, but I stayed indoors (not in bed), as the weather was exceptionally bad, with snow storms. The following morning I left for Eastbourne in the most inclement weather but feeling perfectly fit and *without* the usual aftermath of a persistent purulent nasal discharge. I had no recurrence and no unpleasant sequelae. The duration of my cold before the exhibition of anthisan was 24 hours approximately, and the symptoms were by then fully established in spite of my staying in bed and taking aspirin. A complete cure was effected with two tablets of anthisan within a further 24 hours. So impressed have I been with my own cure that I have recommended it strongly to others similarly affected since then, but I have found it necessary to insist that it is useless to expect any good results *unless the patient is prepared to go to bed* for at least 24-36 hours (maximum 48 hours). If this condition is fulfilled I am confident that a complete cure can be effected in every case.

Dr. A. J. AMBROSE (Beckenham) writes: I am not satisfied that the Research Council are 100% correct. Whereas before taking "benadryl" I was troubled with frequent colds which persisted for weeks, now, since taking at most five capsules of benadryl, my colds are of minor degree. In my own family, I found that one child responds dramatically to benadryl and two children do not. Perhaps the true summing-up would be that some people do respond and others do not. And I notice the trials the Research Council made were not with benadryl, as originally advocated by Captain Brewster.

An Adjustable Bed for Patients at Home

Mr. T. M. PROUDFOOT writes: The bed which your correspondent Dr. T. H. Gillison saw in Skye (August 26, p. 530) is a model which was manufactured about 20 years ago, and my firm, John Bell and Croyden, had exhibited such a bed in the surgical section of their business in Wigmore Street. About this time the London Clinic was being equipped, and two or three of this particular bedstead were supplied for use in the Clinic. If I recall correctly, the bedstead was manufactured in Liverpool and distributed by Messrs. Alexander and Fowler, Pembroke Place, in that city, and Mr. J. D. Gray of that firm could probably give further information.

Obituary

SIR REGINALD ST. JOHNSTON, K.C.M.G., M.R.C.S.

Sir Reginald St. Johnston, formerly Governor of the Leeward Islands, died at Eastbourne on August 29 at the age of 78.

St. Johnston was the son of a doctor, and after leaving Cheltenham College he studied medicine at Edinburgh and Birmingham. He qualified in 1905, and became house-surgeon at the Dudley Hospital. After holding clinical assistantships at St. Peter's Hospital and the Hospital for Women, he was appointed assistant medical superintendent of Lewisham Infirmary in 1907. Shortly afterwards, however, he went to Fiji and worked as a general practitioner. Almost immediately he accepted an appointment under the Government of the Colony, and, finding a useful career open to him, he obtained leave to study law and was duly called to the Bar.

During the first world war St. Johnston was at first in Fiji, but he was seconded for war service in France, where he did much medical work, both practical and administrative. He was eventually attached to the War Office for special duty and was given the rank of lieutenant-colonel. At the end of the war he served for a short period as Acting Governor of the Falkland Islands, and was then appointed in 1920 as Colonial Secretary of the Leeward Islands. On a number of occasions in the next few years he acted as Administrator of Antigua, of Dominica, and of St. Kitts and Nevis. He was made Governor of the Leeward Islands in 1929. From then until 1936, when he retired, he did much to improve social conditions in the Islands. He was created C.M.G. in 1923 and promoted to K.C.M.G. in 1931. He was the author of a number of books, including *Dream Faces, The Leeward Islands, South Sea Reminiscences, From a Colonial Governor's Notebook*, and *Strange Places and Strange Peoples*.

A. D. MACPHERSON, M.B.

Dr. Angus Duncan Macpherson, assistant medical secretary of the British Medical Association from 1904 to 1935, died in London on September 3 at the age of 79. He studied medicine at Edinburgh, Dublin, and King's College, London, and he graduated M.B., C.M. (Edinburgh) in 1897. He entered the service of the British Medical Association in 1904, when the medical secretariat in the old building in the Strand was beginning to take shape under the new constitution. During the thirty-one years Macpherson worked for the Association he gained a detailed knowledge of constitutional procedure, and this knowledge he put to good effect as secretary to the Organization Committee. He was responsible each year for the production of the B.M.A.'s annual handbook, at first called *Handbook for Recently Qualified Medical Practitioners* and later renamed *Medical Practitioners' Handbook*, and it was due to his efforts that this booklet became such an invaluable aid to the general practitioner. Many correspondents and visitors at B.M.A. headquarters will remember Macpherson's invariable courtesy and helpfulness. The sturdiness of his character was exemplified by the fact that at the age of 70, during the worst period of the last war, he took a post as a ship surgeon in the Merchant Navy.

We are indebted to Dr. Alfred Cox for the following appreciation: By the death of Angus Macpherson the Association loses a former veteran of its staff who devoted to its service the best years of his life. He was little known to most members of the Association, for the work in which

he was chiefly engaged did not take him to the Representative Meeting nor indeed much into committees.

When I joined the staff in 1908 as deputy medical secretary I found Macpherson there as the only medical assistant to Dr. (later Sir) James Smith Whitaker. But for his comparative youth and lack of experience in the then burning question of contract practice it is probable that he might have been promoted to the position I then took. He continued till he retired in 1935, having found his *métier* in work which, though little attractive to most of us, he thoroughly enjoyed. He loved the detail connected with the drafting and revision of articles and by-laws and regulations. He was the soul of accuracy and could always be relied on.

I saw him but rarely after his retirement. For a time he engaged in general practice in Chelsea, and then went on several voyages as ship surgeon. A few weeks ago I heard he was very ill and went to see him. He was suffering from malignant disease of the prostate, and I found him a mere shadow of his former self. He was obviously near his end, but I never met anybody who faced death with greater equanimity. He made no complaints and was still full of interest in the work of the Association. On this he was a mine of information, and I regret that he never committed it to writing, for his term of service covered a period of great importance.

All of us who knew anything of his domestic circumstances admired him for his striking devotion to his wife and two sisters, who lived with him. Our sympathy goes out to those he has left behind, and his memory will live with us as a good man and loyal colleague.

Dr. MATTHEW BURROW RAY, for many years senior physician to the British Red Cross Clinic for Rheumatism, died in London on July 5 at the age of 80. He studied medicine at Edinburgh University, and graduated M.B., C.M. in 1893, proceeding M.D. in the same year. He was admitted M.R.C.P.(London) in 1934. Before the first world war he held a number of appointments, and at one time he was pathologist and assistant medical officer at the West Riding Mental Hospital, assistant surgeon to the Eston Hospital, and honorary surgeon to the Harrogate Infirmary. He was a past president of the Harrogate Medical Society. He served as a colonel with the R.A.M.C. in the 1914–18 war, being A.D.M.S. of his division, the 47th (2nd London), T.A. He was awarded the D.S.O. in 1917. After the war he and the late Dr. Fortescue Fox were instrumental in establishing with the British Red Cross Society the well-known clinic which is now the Arthur Stanley Institute for Rheumatic Diseases at the Middlesex Hospital. He was the first chairman of the honorary medical committee of the Clinic, and in recognition of his services the British Red Cross Society decided that he should remain a member of the active staff as long as he wished. In fact he worked at the Clinic until it was taken over by the National Health Service and absorbed into the near-by Middlesex Hospital in 1948. He continued to act as physician and director of the department of physiotherapy at the St. Marylebone and Westminster General Dispensary. Dr. Ray was a great expert on hydrotherapy, and his knowledge of the spas of Europe was in a class by itself. He was an active and useful member of the British Medical Association, being chairman of the Marylebone Division in 1934–5. He was a representative of the Division at several Annual Meetings, and for two years he was also an officer of the Section of Physical Medicine. He served on a number of committees connected with his specialty, and he was at one time honorary treasurer of the British Association of Physical Medicine. In 1930 he gave a Chadwick lecture on "The Treatment of Rheumatism," and among his publications were books entitled *Rheumatism in General Practice* and *Hydrotherapy and Climatotherapy*. Dr. Ray was a sound clinician, a physician of the old school in the best sense. His character was exemplified by his devotion to his work and his patients. He obtained great satisfaction from his two creative hobbies—painting and carpentry. He is survived by his widow, to whom the sympathy of his friends, colleagues, and patients will be extended.

Dr. ALEXANDER CHRISTIE REID died suddenly while on holiday in Edinburgh on August 20 at the age of 76. He was educated at Aberdeen University, taking the degrees of M.A. and B.Sc. before entering on his medical studies. He graduated M.B. in 1902 and proceeded M.D. with honours in 1905. In 1913 he took the Oxford Diploma in Ophthalmology. For nearly 40 years he was honorary surgeon to the Nottingham and Midland Eye Infirmary, and for many years was consultant ophthalmic surgeon to the Kesteven county council and the Mansfield and Worksop Hospitals. He retired from active consulting practice four years ago, and for his distinguished service was appointed consulting surgeon to the Nottingham and Midland Eye Infirmary. During the 1914–18 war he served as a captain in the R.A.M.C. Dr. Reid made a study of miners' nystagmus, and to gain first-hand knowledge of working conditions went down the pit on many occasions. He always brought a clear, analytical mind to bear on any difficult problem. Apart from his professional work his interests were wide and varied. Dr. Reid will be remembered with affection and admiration by all who knew him.—G. G.-N.

Dr. FRANCIS JAMES STRONG HEANEY died at his home outside Chester on August 26 at the age of 76. He was educated at Dundask School, and later was a Stewart medical scholar at Trinity College, Dublin, where he qualified in 1901. In 1902 he proceeded M.D., and in the same year became a Fellow of the Royal College of Surgeons of Ireland. From 1907 he was a member of the Liverpool Medical Institution, where he held many offices. He was president of the Lancashire and Cheshire Branch of the B.M.A. in 1923–4, and chairman of the Liverpool Division in 1926–7. He served on the Council in 1921–4 and as a representative in the R.B. in 1920–2 and again in 1924. He also served on the Journal Committee for a year in 1921–2. Among other committees on which he served was the English and Welsh Consultants and Specialists Group Committee, 1934–40. For a number of years he was president of the Liverpool Hospital Staffs Association, and in this capacity gave his services ungrudgingly for the establishment of good professional relationships. During the war of 1914–18 Strong Heaney, who retired with the rank of Surgeon Captain, R.N.V.R., served in the R.N. hospital ships *Plassy* and *Asmirias*, and he always retained his interest in the Service. In 1919 Heaney was appointed to the Stanley Hospital at Liverpool and remained on the teaching staff of the medical school until 1946, having worked untiringly through the heavy raids which made such demands upon the hospitals in the war years. He also held appointments in Ormskirk, at the Providence Hospital, St. Helens, and in the Radium Institute. His many friends will remember Frank Strong Heaney for his great courage in tackling the difficult operative problems of cancer in the early days, for his enormous energy, and for his unfailing, cheerful, and purposeful kindliness. He was a splendid spokesman and advocate who was always loyal to his ideals, who faithfully represented the views of his colleagues, and who was logical, lucid, and determined, but pleasant and tactful withal.—C. A. W.

Dr. W. A. MILLIGAN died at his home in London on August 25 at the age of 78. He was one of the best-known medical practitioners of Mayfair and had practised there for close on fifty years. Wyndham Anstruther Milligan was the fourth son of a family of 11 children, his father being Dr. William Milligan, professor of Biblical criticism in the University of Aberdeen. His brother William became a distinguished ear, nose, and throat surgeon in Manchester. Milligan was educated in that famous seminary "The Gym," founded by the Rev. Dr. Anderson, and at Aberdeen University. He graduated M.B., C.M. in 1895, and proceeded M.D. in 1906. He became a Fellow of the Royal College of Surgeons of Edinburgh in 1899. His sincerity, mental alertness, and directness of manner could not conceal the warm-hearted soul within. His large clientele of patients of all types had complete trust in his judgment and his diagnosis. Though busily engaged in practice, he extended his medical interests by becoming physician to the Margaret Street Hospital for Diseases of the Chest. Many patients still remember with gratitude his skill in diagnosis and his deep personal interest in their welfare. His wide view of general practice and his desire to keep himself efficient led him to become honorary gynaecologist to the Farringdon Dispensary and district surgeon to the City of London Lying-in Hospital. His special gynaecological experience merited his appointment in 1931 to a post of high responsibility as medical inspector in nullity cases coming before the High Court of Justice. He succeeded the late Dr. Gilbert Orme as chairman of the Westminster and Holborn Division of the B.M.A. in 1945. There was no more loyal or steadfast member, and none more patient or impartial ever presided over the meetings of the Division, which passed a special resolution to enable his colleagues to re-elect him unanimously as chairman for the fourth year. All his professional life he cherished a lasting affection for the Aberdeen University Club in London. He had been joint honorary secretary for many years and later vice-president, and on the death of Lord Meston in 1948 the club elected him president, a well-deserved honour. Although he was approaching his seventieth year, the second world war found him, as always, ready for whatever task might fall to him. He spent long and strenuous hours in the Home Guard, and was always on call to attend air-raid casualties at the first-aid post in Berkeley Square. The loss of his son, a naval surgeon, torpedoed in the Atlantic, caused him deep grief. During the half-century he worked in Mayfair he saw a great many changes in that area of London, but all these he viewed with equanimity, for his strong sense of service and duty never wavered. He remained at work until a few weeks ago, detaching himself with stoic calm from his own anxieties while sharing the cares of others. Dr. Milligan had been a widower for 30 years. He is survived by three sons and one daughter.

Medico-Legal

DEATH AFTER NEW DRUG

An inquest was held in June on a woman aged 67 who died after being treated with G.T.41, a drug that was being tried in the treatment of cancer. The coroner recorded a verdict of death from misadventure.[1] The woman was first admitted to hospital in July, 1945, and a radical mastectomy was performed for carcinoma of the right breast. Secondary deposits were present in the axillary nodes and surrounding tissues, and a full course of radiotherapy was given.

G.T.41 is a dimesyloxyalkane, its formula being $CH_3OSO_2(CH_2)_4SO_2OCH_3$. Though the drug is not a nitrogen mustard, its action is similar. The substance is one of a long series of nitrogen mustards and related compounds the biological properties of which have been the subject of experiment for several years. G.T.41 and other associated substances have from time to time been selected for clinical trial by oral administration in cases of advanced malignant disease, since they have an inhibitory action on the growth of certain tumours. The inhibition is not exerted against the malignant cells specifically, and various normal tissues are also affected. One of the most sensitive of these is the bone marrow. While the effect on the bone marrow can normally be controlled, in the present case agranulocytosis developed, though no other toxic side-effects had been observed during administration. The case suggests that G.T.41 is peculiar in its effects as compared with related substances which have been used clinically. It may be abnormally accumulated in the tissues, or its effects may be much less reversible than is usually the case. Its further clinical trial has been suspended.

[1] *Birmingham Post*, June 30.

Universities and Colleges

UNIVERSITY OF OXFORD

In a Congregation held on July 29 the following degrees were conferred:

D.M.—R. T. C. Pratt.

M.CH.—P. A. L. Roberts.

B.M.—W. G. Dewhurst, W. F. P. Gammie, H. Yellowlees, J. L. Godden, J. M. D. Hooper, R. S. Walsh, L. Robertson, J. G. Danaher, B. N. McQuade, R. A. Riseley-Prichard, J. H. Wilson, C. S. Pitcher, P. H. Watkins, F. B. E. Kampfner, G. E. Rousseaux, Ursula F. Rowlatt, Myrtle J. Raynor.

UNIVERSITY OF CAMBRIDGE

The following medical degrees were conferred on August 5:

M.D.—*J. R. Handforth, A. J. Rook, J. G. Benstead, G. F. Roberts.

M.B., B.CHIR.—*H. de Glanville, *J. M. Hodson, M. J. D. Newman, *K. W. Gray, *R. P. Holmes, *M. Binnie, *P. R. Gittins, *J. R. Gough, *M. J. Peel, *J. B. Spargo, *R. Thomas, *P. O. Williams, *D. R. Sweetnam, *H. B. Eckstein, *J. S. McCormick, *T. B. Scott, J. W. B. Dalgleish, *H. F. Juckes, P. G. A. Irvine, *D. R. Bowsher, *J. M. Brown, *D. Butcher, *G. E. Heald, *T. M. Howell, *K. Last, *R. D. Montgomery, *R. H. Oram, *S. T. Pickles, *R. B. Prowse, *C. R. Robinson, J. L. Milligan, B. J. Muir, A. C. Townsend, *J. E. Dalby, *M. L. E. Espir, *J. N. Redfern, *P. R. V. Tomson, D. R. Pugh, J. H. Ross, *H. H. Broadhead, *G. N. St. J. Penney, J. S. W. Chambers, *C. R. Leeson, *T. S. Leeson, *A. G. Wallace, *P. Ll. Williams, K. E. Halnan, H. M. Michaelson, *P. G. I. Stovin, *S. E. Trickey, *M. S. Aldridge, *M. G. Rinsler, *A. C. Chovil, *T. D. W. Davies, *W. J. Wigfield, *J. P. Williams, A. D. Muirhead, *P. B. Brown, *Verity G. Wills, Frances E. Kirk, Dora W. Lemmon, Joan K. Perkins, Alison M. Richardson, *Mrs. Elizabeth R. Taylor, Mrs. Mary E. Kendrew, Mrs. Jane Lodwick, *E. Marley.

M.B.—*G. A. Mandow.

*By proxy.

UNIVERSITY OF LONDON

The following have been appointed, or nominated for appointment or reappointment, as representatives of the University on the governing bodies indicated in parentheses: Sir Archibald Gray (Bedford College); Sir Archibald Gray and Mr. J. B. Hunter (British Postgraduate Medical Federation); Mr. P. H. Mitchiner and Sir James Paterson Ross (Guy's Hospital Medical School); Professor L. P. Garrod (St. Mary's Hospital Medical School, Inoculation Committee, Wright-Fleming Institute); Dr. Ruth E. Proctor (Battersea Training College of Domestic Science).

The Municipal Borough of Luton has been added to the list of areas approved by the University for the purpose of instruction in public health administration for the Academic Postgraduate Diploma in Public Health.

The examination for the Postgraduate Diploma in Psychological Medicine (University Extension and Tutorial Classes Council) will be held for the last time in March–April, 1952. An Academic Postgraduate Diploma in Psychological Medicine has been instituted, the regulations for which may be obtained on application to the Academic Registrar, University of London, Senate House, London, W.C.1.

UNIVERSITY OF BIRMINGHAM

The opening ceremony of the new session of the Faculty of Medicine will take place in the Nurses' Recreation Hall, Nuffield House, Queen Elizabeth Hospital, Birmingham, on Tuesday, October 3, at 3 p.m., when Viscount Addison will distribute the prizes awarded for the session 1949–50 and will deliver an address to students.

UNIVERSITY OF BRISTOL

G. F. M. Hall has been approved at the examination for the degree of M.D.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a meeting of the Council of the Royal College of Surgeons of England held on August 3, with the President, Sir Cecil Wakeley, in the chair, the Honorary Medal of the College was awarded to Lord Webb-Johnson in recognition of his many generous acts and

continued labours in the interests of the College throughout the eight years of his presidency.

The Gilbert Blane Medal was presented to Surgeon Commander E. B. Martin, R.N., for his research on naval aviation medicine.

A resolution of condolence was passed on the death of Mr. E. Cranmer Hughes, past member of the Court of Examiners.

Professor B. W. Windeyer was appointed a Hunterian Professor for 1951, for a lecture on "The Place of Radiotherapy in the Treatment of Malignant Disease."

Mr. R. J. Last, F.R.C.S., was appointed Professor of Applied Anatomy in the College.

Mr. L. E. C. Norbury was again nominated as the representative of the College on the Advisory Board on Nursing Education.

The Hallett Prize was awarded jointly to Tara Chandra (Lucknow University) and Malik Shaukat Hasan (Punjab University).

Diplomas of Fellowship were granted to R. H. Cram and O. V. Jooma.

Diplomas of Membership were granted to K. M. McFadyean and to the other 107 successful candidates whose names were printed in the report of the meeting of the Royal College of Physicians of London in the *Journal* of August 5 (p. 373) as recipients of the diploma of L.R.C.P.

Diplomas in Public Health and in Ophthalmic Medicine and Surgery were granted, jointly with the Royal College of Physicians of London, to the successful candidates whose names were printed in the report of the meeting of the Royal College of Physicians of London in the *Journal* of August 5 (p. 373).

Diplomas in Ophthalmology were granted, jointly with the Royal College of Physicians of London, to R. St. H. Warren and to the 21 other successful candidates whose names were printed in the report of the meeting of the Royal College of Physicians of London in the *Journal* of August 5 (p. 373).

The following hospitals were recognized under paragraph 23 of the F.R.C.S. regulations: Bury General Hospital (*junior registrar* for general surgery; junior registrar for orthopaedics; resident casualty officer; two house-surgeons (all for six months)). Coventry and Warwickshire Hospital (additional recognition of registrar and house-surgeon for otolaryngology). Hexham General Hospital (surgical registrar (*for twelve months*); first and second house-surgeons (general); orthopaedic registrar; and orthopaedic house-surgeon (all for six months)). *Lister Hospital, Hitchin (surgical* registrar (for twelve months); senior and junior house-surgeons (for six months)). Whipps Cross Hospital (three house-surgeons (for six months); house-surgeon to orthopaedic department (for six months)). Northampton General Hospital (registrar and house-surgeon for otolaryngology). Manfield Orthopaedic Hospital, Northampton (senior and junior orthopaedic registrars (for six months)). Rush Green Hospital, Romford (*senior and surgical* registrars (each for twelve months); and house-surgeon (for six months)). North Staffordshire Royal Infirmary (two house-surgeons; orthopaedic house-surgeon; ophthalmological and ear, nose, and throat house-surgeons; senior surgical registrar; assistant resident surgical officer; registrars in ophthalmology, orthopaedics, and ear, nose, and throat; junior orthopaedic registrar (all for six months only)). Sunderland Royal Infirmary (*senior surgical registrar; second* surgical registrar; registrar to ear, nose, and throat department; registrar to casualty department; registrar to orthopaedic department). Maelor General Hospital, Wrexham (two registrars and two house-surgeons (for six months only)). City General Hospital, York (two house-surgeons; orthopaedic registrar and orthopaedic house-surgeon (all for six months)).

CONJOINT BOARD IN SCOTLAND

The following candidates, having passed the final examinations, have been granted the diploma of L.R.C.P.Ed., L.R.C.S.Ed., L.R.F.P.S.Glas.: G. E. Aitken, Eleanor K. Althorp, R. F. Armstrong, J. G. Bhatt, A. F. Bushby, A. J. Cameron, J. Clougherty, A. P. Davidson, Elspeth G. Davie, Joy L. Di Marco, Audrey E. Evans, Margaret R. Farrell, T. A. Frewin, Eileen M. Gorman, Monica C. Grant, P. J. Halket, Mary T. Hill, G. E. Horseman, C. R. Hosein, J. D. Hughes, D. M. Johnstone, I. Kantor, H. L. Kinman, A. W. Laughland, Winifred A. Lloyd, I. N. H. Luck, C. N. McFarlane, G. C. UNIVERSITY OF MICHIGAN

In June the degree of Master of Public Health was conferred on Kenneth I. E. Macleod, M.B., Ch.B.

No. 33

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended August 19.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each Infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1950 (a)	(b)	(c)	(d)	(e)	1949 (Corresponding Week) (a)	(b)	(c)	(d)	(e)

Deaths (0–1 year)	196	23	17	20	6	220	29	27	14	19
Deaths (excluding still-births)	3,886	577	481	166	101	3,910	635	513	167	108
Annual death rate (per 1,000 persons living)			9·7					10·3	10·3	
Live births	7,061	1150	821	323	209	7,087	1099	831	400	247
Annual rate per 1,000 persons living			16·5					16·7	24·8	
Stillbirths	179	15	20			188	29	21		
Rate per 1,000 total births (including stillborn)			24					25		

* Measles is not notifiable in Scotland, and the returns are therefore an approximation only.

† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

‖ Includes puerperal fever for England and Wales and Eire.

¶ Primary pneumonia no longer notifiable in Eire.

EPIDEMIOLOGICAL NOTES

Poliomyelitis

Notifications of poliomyelitis in the week ended August 26 were: paralytic, 369 (375); non-paralytic, 220 (175); total, 589 (550). The figures for the previous week are in parentheses. A decrease in paralytic cases of 6 was offset by an increase in the non-paralytic of 45, with a total increase for the week of 39 cases. A satisfactory feature is the increased percentage of non-paralytic cases from 32% in the preceding week to 37% in the week under review.

The main increases in total notifications occurred in the following county areas:

	Week Ended August 19	Week Ended August 26	Increase
Durham	9	31	22
Lancashire	29	44	15
Gloucester	26	38	12
Leicester	8	18	10
Yorks (E.R.)	1	11	10
Surrey	9	18	9
Dorset	6	13	7

Significant decreases occurred as follows:

	Week Ended August 19	Week Ended August 26	Decrease
Isle of Wight	19	6	13
Worcester	26	15	11
Warwickshire	47	39	8
Kent	17	9	8
Yorks (N.R.)	45	38	7

The following county areas have notified no cases in the period of three weeks up to August 26: Cambridge, Suffolk West, Cardigan, Radnor. In the same period the following notified one case only: Isle of Ely, Huntingdon, Soke of Peterborough, Anglesey, Brecknock.

The uncorrected notifications for the week in 1947, 1948, and 1949 corresponding to that under review were 676, 77, and 280 respectively.

Discussion of Table

In *England and Wales* decreases in the numbers of notifications were recorded for measles 891, scarlet fever 81, dysentery 70, acute pneumonia 23, diphtheria 18, while increases were reported for whooping-cough 517 and acute poliomyelitis 158.

The largest falls in the incidence of measles were Yorkshire West Riding 161, London 112, Hertfordshire 95. A small fall in the number of notifications of scarlet fever was reported from most areas. The notifications of diphtheria were the smallest ever recorded and were 8 below the previous lowest level of eight weeks ago. The chief feature of the returns of diphtheria during the week was a fall of 5 in London. The largest rises in the incidence of whooping-cough were London 83 and Middlesex 71.

The number of notifications of dysentery was the smallest for 36 weeks. A new outbreak involving 20 persons was reported during the week from Kent, Broadstairs and St. Peters U.D. The other large returns of dysentery were Lancashire 36 (Preston C.B. 9); Yorkshire West Riding 12; Durham 13.

The notifications of acute poliomyelitis were 158 more than in the previous week. The paralytic cases rose by 100 and the non-paralytic by 58. The largest returns during the week were Warwickshire 47 (Birmingham C.B. 24, Sutton Coldfield M.B. 6, Coventry C.B. 4, Meriden R.D. 4); Yorkshire West Riding 45 (Leeds C.B. 12, Wakefield C.B. 7, Bradford C.B. 4, Hemsworth R.D. 4); London 38 (Woolwich 7, Lewisham 6; the remaining cases were notified from 15 boroughs); Lancashire 29 (Liverpool C.B. 10, Manchester C.B. 5, Salford C.B. 5); Lincolnshire 28 (East Kesteven R.D. 10); Gloucestershire 26 (Bristol C.B. 18); Staffordshire 26 (Sedgley U.D. 4); Worcestershire 26 (Dudley C.B. 9, Worcester C.B. 8); Middlesex 23 (Hayes and Harlington U.D. 4); Essex 23 (Barking M.B. 4); Isle of Wight 19 (11 in Rural District); Kent 17; Northumberland 17 (Newcastle-upon-Tyne C.B. 9); Yorkshire North Riding 15 (Middlesbrough C.B. 4, Flaxton R.D. 4); Devonshire 14.

In *Scotland* decreases were recorded in the number of notifications of whooping-cough 36, measles 11, and rises were reported for dysentery 19, cerebrospinal fever 14. The chief centres of dysentery were Glasgow 60, Stirling county 10, and Edinburgh 8. The largest returns of acute poliomyelitis were Glasgow 22, Fife county 11, Dundee 4, Kirkcaldy 4.

In *Eire* a fall in the number of notifications was recorded for measles 64, scarlet fever 13, diarrhoea and enteritis 6. In Dublin C.B. the notifications of measles fell by 42, but a rise of 11 occurred in the notifications of whooping-cough.

In *Northern Ireland* a decline in incidence was recorded for measles 32 and scarlet fever 9, while a rise of 12 was reported for whooping-cough. The trends of these diseases were similar throughout the country. The chief returns for acute poliomyelitis were Down county 6, Belfast C.B. 5, and Antrim county 3.

Week Ending August 26

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 635, whooping-cough 3,725, diphtheria 41, measles 4,277, acute pneumonia 177, acute poliomyelitis 589, dysentery 137, paratyphoid fever 10, typhoid fever 11.

Medical News

The Boston Medical Library

On October 18 the Boston Medical Library will celebrate the seventy-fifth anniversary of its foundation. Two ground-floor rooms were opened as a library on Hamilton Place, for the use of Boston physicians, on Monday, October 18, 1875, with James Read Chadwick as librarian, E. H. Brigham as assistant librarian in charge, and Oliver Wendell Holmes as president of the new association. The present building was occupied in 1900. Long associated with the library is *The New England Journal of Medicine*, formerly the *Boston Medical and Surgical Journal*, and, more recently, the *Journal of Bone and Joint Surgery*. The Massachusetts Medical Society is housed in the present building and this year has acquired the adjacent property as a permanent home. To mark its birthday, the library will hold "open house" on October 18 with a scientific session and a dinner.

Alfred Adler Medical Society

The Alfred Adler Medical Society has been formed, and the following officers appointed: Professor Alexander Kennedy (president), Professor W. C. W. Nixon (vice-president), Dr. James Moore (chairman of council), Dr. E. N. Snowden and Dr. R. Strom-Olsen (vice-chairmen), Dr. A. R. Redfern (honorary secretary), and Dr. Donald Blair (honorary treasurer). The first meeting will be held at 8 p.m. on September 14 at 11, Chandos Street, London, W.C.2, when Dr. James Moore will deliver the inaugural address on "The Meaning of this Society."

Dominion Travelling Fellowships

The Nuffield Foundation is extending its scheme for Dominion travelling fellowships to Ceylon, India, and Pakistan. It already operates for Australia, Canada, South Africa, and New Zealand. The object of the fellowships is to advance the interests of the new Dominions and to strengthen their academic ties with the United Kingdom. Men and women graduates of outstanding ability and some postgraduate experience from the Dominions will gain further experience in Britain. The Nuffield Foundation will appoint Fellows on the recommendation of an advisory committee in each Dominion, the fellowship lasting one year and being valued at between £770 and £890. Travelling expenses will also be paid, as well as those of the Fellow's wife if he is married at the time of application. One fellowship in medicine will be awarded in Ceylon, and two in India. Three fellowships, the subjects for which are not yet chosen, will be awarded in Pakistan.

Touring U.S.A.

Professor W. C. W. Nixon, of University College Hospital, is leaving for a three-months tour of obstetric centres in the U.S.A., and on October 27 will give the DeLee Lecture at the Chicago Lying-in Hospital on "Uterine Action—Normal and Abnormal." The tour is sponsored by the Rockefeller Foundation.

COMING EVENTS

Society of Chemical Industry

A joint meeting of the Edinburgh Section and the Fine Chemicals Group of the Society of Chemical Industry will be held at Edinburgh on October 6–7. On October 6 Mr. F. Bergel, Ph.D., will speak at 10 a.m. on "The Biological and Therapeutic Significance of Organic Phosphates Occurring in Nature"; and on October 7 Professor G. F. Marrian, F.R.S., will deliver the third Lister Lecture on "The Adrenocortical Hormones." Particulars may be obtained from Mr. G. W. Walker, F.R.I.C., c/o T. and H. Smith, Ltd., Wheatfield Road, Edinburgh, 11.

Institute of Dermatology

The Institute of Dermatology will begin its winter course of lectures on October 3 at St. John's Hospital for Diseases of the Skin, Lisle Street, Leicester Square, London, W.C. The course will include special lecture demonstrations on medical mycology and a number of lectures on various branches of pathology relating to diseases of the skin.

Institute of Ophthalmology

The academic year 1950–1 of the Institute of Ophthalmology (University of London), (Judd Street, London, W.C.) will be inaugurated on Wednesday, October 4, at 4.30 p.m., with an address by Dr. W. Russell Brain, President of the Royal College of Physicians of London. The annual dinner of the institute will be held at Claridges Hotel, Brook Street, London, W., at 7.30 p.m. the same day. Past students of the institute and of Moorfields Westminster and Central Eye Hospital are invited to both these functions. Tickets for the annual dinner are 25s. each and may be obtained on application to the secretary of the institute at the above address.

Health of the Tuberculous

The Welfare Group of the Lambeth Civic Society will hold a conference on tuberculosis on September 30 at 3–9 p.m. Local organizations have been invited to discuss what can be done to help sufferers from tuberculosis. Anyone interested in the subject is invited, and should communicate with the secretary, Mr. J. S. Marrin, Welfare Group, Lambeth Civic Society, Lambeth Town Hall, Brixton Hill, London, S.W.2.

William Meredith Fletcher Shaw Memorial Lecture

Professor A. Leyland Robinson, emeritus professor of obstetrics and gynaecology in the University of Liverpool, will deliver the William Meredith Fletcher Shaw Memorial Lecture before the Royal College of Obstetricians and Gynaecologists, 58, Queen Anne Street, London, W., on Friday, September 29, at 2.30 p.m. His subject is "The Evolution of the Gynaecologist," and all medical practitioners who are interested are invited to attend. Admission is by ticket only, allotted in order of application, obtainable from the secretary of the college at the above address.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Tuesday

EDINBURGH POSTGRADUATE BOARD FOR MEDICINE.—At University New Buildings (Anatomy Lecture Theatre), Edinburgh, September 12, 4.30 p.m., *"Sensitivity in Disease,"* by Professor J. H. Biggart.

Thursday

ALFRED ADLER MEDICAL SOCIETY.—At 11, Chandos Street, Cavendish Square, London, W., September 14, 8 p.m., *"The Meaning of This Society,"* Inaugural Address by the Chairman, Dr. James Moore.

LONDON COUNTY MEDICAL SOCIETY.—At St. Stephen's Hospital, Fulham Road, Chelsea, S.W., September 14, 3 p.m., clinical meeting.

APPOINTMENTS

Drs. F. A. Ibiam, O.B.E., and K. A. Abayomi have been reappointed Members of the Executive Council of Nigeria.

DAVIES, DONALD MAITLAND, M.D., M.R.C.P., Consultant Physician, Bury and Rossendale Group of Hospitals.

FLEMING, CHARLES, M.B., Ch.B., D.P.H., Medical Officer of Health for Rugeley Urban and Tutbury Rural Districts.

HUDSON, JOHN HARRAL, M.B., Ch.B., D.T.M.&H., D.P.H., additional post of Acting Part-time Medical Officer of Health, Borough of Dartford.

JARMAN, THOMAS FRANCIS, M.D., Consultant Chest Physician and Director of Mass Radiography, Wales, under Welsh Regional Hospital Board.

LIVERPOOL REGIONAL HOSPITAL BOARD.—The following senior medical staff appointments are announced: *Consultant Physician to Clatterbridge General Hospital*, F. J. Zacharias, M.D., M.R.C.P. *Consultant Orthopaedic Surgeon to Walton Hospital*, J. H. Redding, F.R.C.S.Ed. *Consultant Paediatrician to certain hospitals in Liverpool*, Anne E. McCandless, M.D., M.R.C.P. *Assistant Venereologist (whole-time) with duties at V.D. clinics in Liverpool*, P. Morgan, M.D. *Assistant Venereologist (whole-time) with duties at V.D. clinics in Birkenhead, Wallasey, and Liverpool*, T. Lyall, M.B., Ch.B. *Tuberculosis Medical Officer (whole-time) for North Liverpool area*, A. D. M. Hamilton, M.B., B.Ch., D.P.H. *Tuberculosis Medical Officer (whole-time) for Ormskirk area*, R. S. Nicholson, M.R.C.S., L.R.C.P.

LORANT, STEPHEN, M.D., Consultant Pathologist, Rochdale Group of Hospitals.

MITCHELL-HEGGS, FRANCIS S., M.B., F.R.C.S., F.R.C.S.Ed., Consultant Surgeon to Bury and Rossendale Group of Hospitals, Manchester Regional Hospital Board.

POWELL, K. J., M.B., B.S., D.A., Consultant Anaesthetist in the Exeter Clinical Area, South-western Regional Hospital Board.

REEVES, ANTHONY JOSEPH, M.D., D.P.H., County Medical Officer, Offaly, Eire.

ROBERTSON, GEORGE STUART, M.D., Chief Assistant School Medical Officer, Liverpool.

UNGLEY, GORDON, V.R.D., M.D., F.R.C.S., Consultant Surgeon to Lambeth Hospital, Brook Drive, London, S.E.

WILLIAMS, J. R. D., M.B., B.S., D.P.H., Assistant Venereologist at Ipswich, Bury St. Edmunds, and Lowestoft, East Anglian Regional Hospital Board.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Bremner.—On August 22, 1950, at Newcastle-upon-Tyne, to Mary Bremner (formerly Cammock), M.B., Ch.B., and Alan E. Bremner, F.R.C.S.Ed., a son.

Murray.—On August 27, 1950, to Ailsa (formerly Tully), wife of Dr. Laurence H. Murray, Park Way, Rickmansworth, Herts, a son.

Perkins.—On August 4, 1950, at Stamford Hospital, Lincs, to Royce (formerly Thompson), wife of Squadron Leader I. M. Perkins, M.R.C.S., L.R.C.P., R.A.F., a daughter—Alison Villiers.

Tatlow.—On August 21, 1950, at Bristol, to Anne, wife of Dr. W. F. T. Tatlow, M.D., M.R.C.P., a son—John William Tissington.

Thomas.—On August 10, 1950, at 27, Welbeck Street, London, W., to Judith, wife of Trevor Meyrick Thomas, M.Chir., F.R.C.S., The Tudors, Farnborough, Kent, a son.

Watson.—On August 18, 1950, at Harrogate General Hospital, to Peggy (formerly Lowis), wife of Dr. J. E. Watson, 6, St. Roberts Road, Knaresborough, Yorks, a son.

Weiner.—On August 27, 1950, at the Radcliffe Infirmary, Oxford, to Marjorie (formerly Daw), wife of Dr. J. S. Weiner, a son.

Wilkie.—On August 12, 1950, at the Jessop Hospital, Sheffield, to Noreen (formerly Keer) and Dr. D. J. K. Wilkie, a daughter—Rosemary Elizabeth.

DEATHS

Agnew.—On August 30, 1950, at 44, Eastern Avenue, Reading, Berks, Henry Murray Agnew, L.R.C.P., L.R.C.S., D.P.H.

Badger.—On August 29, 1950, at his home, Guildford, Walter Spencer Badger, M.B., Ch.B., D.P.H., aged 78.

Boyd.—On August 17, 1950, at Gloucester, the result of an accident, Ringland Gilmore Boyd, M.C., M.B., B.Ch., aged 33.

Bushe.—On August 19, 1950, at Winchester, Charles Kendal Bushe, O.B.E., M.D., Surgeon Rear-Admiral, R.N., retired.

Cobbledick.—On August 20, 1950, at Coulsdon, Surrey, Arthur Stanbury Cobbledick, M.D., of London and Trevone, Cornwall, aged 79.

Crooks.—On August 31, 1950, at the General Hospital, Nottingham, Frederick Crooks, M.Ch., F.R.C.S.Ed., of 6, The Ropewalk, Nottingham, aged 63.

Dilling.—On August 18, 1950, at Thwaite, Coniston, Lancs, Walter James Dilling, M.B., Ch.B., aged 64.

Eccles.—On August 29, 1950, at Bon Accord, New Herrington, Co. Durham, Herbert Anderson Eccles, T.D., M.B., Ch.B.

Graham-Smith.—On August 30, 1950, at Forvie, Cambridge, George Stuart Graham-Smith M.D., F.R.S., aged 75.

Heaney.—On August 26 1950, at Chester, Francis James Strong Heaney, M.D., F.R.C.S.I., of 68, Rodney Street, Liverpool.

Hillier.—On August 18, 1950, at Birmingham, William Thomas Hillier, M.R.C.S., L.R.C.P., D.P.H., aged 74.

Low.—On August 24, 1950, at Calverley Lodge, Tunbridge Wells, Percy Charles Low, M.B., B.Ch., aged 88.

Milligan.—On August 25, 1950, at 9, North Audley Street, London, W., Wyndham Anstruther Milligan, M.D., F.R.C.S.Ed., aged 78.

Purser.—On August 22, 1950, at 55, Wimborne Road, Bournemouth, Robert Williamson Kinross Purser, M.R.C.S., L.R.C.P., M.R.C.O.G., aged 57.

Reid.—On August 19, 1950, at Edinburgh, Alexander Christie Reid, M.D., D.O., of 16, Pelham Road, Nottingham, aged 73.

Richardson.—On August 24, 1950, at Worthing Hospital, Horace Richardson, M.R.C.S., L.R.C.P.

Slade.—On August 16, 1950, at the Middlesex Hospital, Florence Slade, M.D., M.R.C.P., of 26, Church Row, Hampstead, London, N.W.

Strathearn.—On August 14, 1950, at his home, The Manor House, Verwood, Wimborne Minster Dorset, Sir John Calderwood Strathearn, C.B.E., M.D., F.R.C.S.Ed., Lieutenant-Colonel, R.A.M.C. (T.F.), retired, aged 71.

Twort.—On August 21, 1950, at Hammersmith Hospital, Charles Claud Twort, M.D., of "Romans," Roman Road, Southwick, Sussex.

Watt.—On July 24, 1950, Robert Watt, M.B., B.Ch., of 62, Crumlin Road, Belfast, aged 88.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Judging a Baby Show

Q.—*What points should I consider in judging a baby show? Granted that most of the babies are healthy, well nourished, and of normal weight, what other factors should I take into consideration?*

A.—This empirical art, productive of fierce maternal jealousies, requires an estimate of intelligence, social behaviour, physical state, beauty of appearance, and maternal care. On the whole the qualities which give aesthetic appeal go together with good health, and a largely subjective judgment is likely to be of most value. The features which make a fine baby and which can be assessed rapidly include brain, muscle, bone, and skin. Intelligence shows in an alert appearance and appropriate motor behaviour for age (any standard textbook on children will give a scale sufficiently simple and comprehensive for the purpose) and can be estimated quite well with a little practice; quiet and friendly behaviour will give evidence of social adaptation. Muscular development and tone can be tested simply and quickly. Bone structure can be seen best in legs and skull; generous allowance must be made for apparent bowing of the legs of plump babies. The skin provides essential evidence. The texture of a really healthy child's skin is unmistakable, and the presence of sun tan is at any rate evidence of sensible care. Scurf on the scalp and pustules on the face are misfortunes at least partly preventable by adequate use of soap and water. The hair is a further index of care: good condition is not to be achieved by five minutes' work before the show. Clothing deserves attention; it should be suitable and not excessive. The judge will probably find himself excluding a few babies by his olfactory sense, for the well-treated baby is a far more pleasant-smelling object than his less lucky neighbour, who tends to smell stale in spite of any amount of last-minute washing. Finally, it is probably fair to give a considerable number of marks for a pleasant, though not necessarily beautiful, face.

Family History

Q.—*Teachers and textbooks often assert the usefulness in diagnosis, treatment, and prognosis of the patient's family history. In so far as "usefulness" means practical benefit to the patient, is this assertion well founded? If so, in what kinds of case, and how does the benefit arise? Where can I find a critical analysis of the evidence purporting to establish such benefit in any fairly common condition?*

A.—There can be few physicians who would be prepared to jettison inquiry into the family history and to accept the patient as an isolated individual without antecedents, collaterals, or descendants. Nevertheless the questioner must not be disappointed if the "practical benefit" which results from such information is of a less obvious character than that which follows the drainage of an abscess. Perhaps its most easily appreciable value lies in those diseases of which the familial incidence is so high that the diagnosis is in serious doubt if relatives are not affected. Huntingdon's chorea, haemophilia, certain of the myopathies, acholuric jaundice, and the cerebellar ataxias provide examples. In many other disorders, of which essential hypertension, diabetes mellitus, peptic ulcer, pernicious anaemia, migraine, diseases of the gall-bladder, and the allergic states are instances, a family history is common; here diagnosis does not depend on this knowledge, but an indication of the prognosis may often be obtained. This is well shown by those families in which several members die of cerebral haemorrhage about the same age. Again, the prognosis of mental disorder, and in particular of depression, can be accurately assessed only in the light of the family history.

More important, if less easy to expound, is the part played by the family history in revealing to the physician the character and personality of his patient. No individual exists and develops in isolation; his parents and siblings in his early years, his wife and children in later years, people his environment, form his character, implant his habits, and shape his personality. It is a commonplace that the only son of a divorced couple will react to the stresses and strains of life differently from a member of a large and happy family. Without knowledge of the family history the doctor may be able to attach a suitable nosological label, but he will certainly have less insight into the man consulting him. His failure to seek this knowledge will deprive the patient of the "practical benefit" of advice founded on complete diagnosis, a term which Galen defined as "the thorough comprehension of things present."

Radium for Uterine Cancer

Q.—*Can you give me the latest figures for the five- and ten-year cure rates for carcinoma of the body of the uterus treated by radium? Is the modern tendency to treat this condition by radium in all cases, irrespective of the patient's fitness for operation?*

A.—The figures published in the 1948 report from Stockholm of the Radiumhemmet show that, of 264 cases treated during the years 1934–8, 171 (65%) were symptom-free after five years and 124 (47%) were symptom-free after ten years (Table XII, p. 114). The results are calculated by the method used in the League of Nations reports estimating the relative cure rate for cases of carcinoma of the cervix; they also take into account the patients operated upon after failure of radiological treatment. The series comprises all except the frankly untreatable cases, and therefore includes many cases inoperable at the time of institution of treatment by radium. The method used is the packing of the uterine cavity with many small sources of radium, the time being decided from the number of such sources and depending therefore on the size of the cavity, according to the method described by Heyman and published in the *British Journal of Radiology* (1947, **20**, 85). There are probably no better figures for a truly comparable series, and a study of the table referred to, which covers 980 cases from 1914 to 1943, indicates that since this method of treatment has been started the results have improved significantly. The general procedure in most countries is to operate on all operable cases, although a rational consideration of the evidence would suggest that treatment on the lines adopted in Stockholm will produce better results.

Chronic Synovitis of the Knee

Q.—*What is the modern treatment for chronic synovitis of the knee? Treatment has to be undertaken in an African village hospital where there are no facilities for laboratory investigations. I have tried repeated aspirations with replacement by penicillin, normal saline, and so forth, without success. The fluid continues to be yellowish and mucilaginous, and a course of N.A.B. injections has not been helpful.*

A.—The treatment of chronic swellings of the knee depends upon their cause. In general, the causes can be grouped into three classes: mechanical, inflammatory, and neoplastic. A fair idea of the group into which a particular case falls may be gained from a careful consideration of the history (noting particularly the circumstances of the onset, details of any injury, progress, etc.) and a full clinical examination. Swelling due to thickening of the synovial membrane, especially when associated with a local increase of temperature and limitation of all movements, suggests an inflammatory lesion (low-grade non-specific infection, tuberculosis, and rheumatoid arthritis are the commonest causes). Initial treatment should be by rest. On the other hand a recurrent effusion, varying in degree and unaccompanied by synovial thickening, suggests a mechanical cause (in a young adult a torn cartilage or loose body is usually responsible; in older patients the cause is almost always osteoarthritis). Treatment here is directed towards remedying the mechanical defect when possible, and this is followed by intensive muscle exercises. There are many cases, however, in which the diagnosis cannot be established without facilities for *x*-ray and laboratory

investigations, and if these are not available the problem becomes difficult. In such circumstances, if it is impracticable to transfer the patient to a centre where appropriate facilities are available, treatment should err on the side of caution. Thus in the case mentioned—though a definite opinion cannot be given because of the lack of information about the age of the patient, presence or absence of synovial thickening, local increase of temperature, movements, etc.—caution would suggest that the lesion be regarded as inflammatory and that treatment should be by resting the knee in a plaster case, from groin to ankle, for an initial period of at least six to eight weeks. Subsequently, if improvement in the local condition is apparent, a clinical trial out of plaster, with intensive quadriceps redevelopment exercises, should be advised; but should further signs of inflammatory reaction occur further rest may be required. In each individual case the programme to be adopted depends so much upon the clinical state and progress of the condition that it is not possible, in a short answer, to lay down any more definite plan of treatment.

Peribuccal Pigmentation

Q.—*A girl of 16, otherwise healthy, complains of brown pigmentation on either side of the upper lip. There is also some pigmentation of the brow. I should be grateful for suggestions about treating or bleaching the affected areas.*

A.—This peribuccal pigmentation, described by Brocq, is very common and certainly indicates some little derangement of endocrine function at puberty. This usually corrects itself, and active treatment may be unwise unless there is some other indication such as dysmenorrhoea. Small doses of oestrogens given for two or three weeks, starting with the first day of the period, may then be helpful. There is often waxing and waning of the pigmentation with each period. No attempts at removing or bleaching the pigmentation should be made. They are likely to damage the skin and are unnecessary, since the condition will clear.

Breast-feeding and Immunity

Q.—*Is there any evidence that breast-feeding produces any protection in the child from infectious diseases, particularly exanthemata, and, if so, in what way is this effected?*

A.—Passive transfer of antibody from mother to offspring occurs almost entirely via the placenta in the human species, whereas in the ruminants ingestion of the colostrum is the most important means of protection. Hence confusion often arises about the protection against infectious disease afforded by breast-feeding. There is no evidence that breast-fed babies are better protected against the exanthemata than are artificially fed infants; instead the degree and duration of immunity are closely correlated with the amount of antibody—e.g., diphtheria antitoxin—transferred from mother to foetus by way of the placenta. The relative immunity of the breast-fed baby to infantile enteritis is most probably due to factors other than the transfer of antibody.

Stilboestrol and Cancer of the Breast

Q.—*A woman aged 28 has obtained great relief from a prostrating dysmenorrhoea by the use of stilboestrol. The dose used two years ago was 1 mg. t.d.s. for the first fourteen days of the cycle. She now takes less than half that dose, with adequate relief. The patient's grandmother, mother, and maternal aunt have all had cancer of the breast. Is there any good reason to believe that stilboestrol might further predispose her to this condition? Apart from the stilboestrol, what are the risks of her contracting carcinoma of the breast, and at what age should one be particularly on the alert? Are there any recent advances in early diagnosis or prevention?*

A.—There is a strong family predisposition to cancer of the breast in this case, but it is impossible to assess the risk of this patient developing the disease; it would appear to be greater than for a woman without her antecedents. Although the disease can occur at a younger age, special attention should be given from 35 years onwards. As to early diagnosis, the outstanding sign is a lump in the breast, and it would be a wise precaution if the patient were examined at intervals of, say, six months. She should also feel her breasts from time to time and report immediately any lump which may be present. As to the prevention of cancer of the breast, women should avoid wearing brassieres which are unduly tight; uniform, even pressure should be applied to the breasts. It is wise to keep under observation a breast which is the site of an old abscess. After lactation the breasts should be emptied of all residual milk so that this is not allowed to stagnate. A blood-stained discharge from the nipple requires treatment, and special supervision should be given to patients who develop periductal fibrosis, cysts, and other forms of chronic mastitis. In view of the strong familial tendency to cancer of the breast it would seem that the taking of stilboestrol is inadvisable in this case, especially for so long. Could not the cause of the dysmenorrhoea be found and the appropriate treatment given? In any case, it would be wise to discontinue the use of stilboestrol.

NOTES AND COMMENTS

Corrections

Through an oversight, for which we must apologize, we included no summary of Professor V. F. Lambert's paper in our report (August 5, p. 356) of the meeting of the combined Sections of Oto-Rhino-Laryngology and Radiology at the Annual Meeting of the B.M.A. in Liverpool on July 20. Professor Lambert reviewed a series of 62 cases treated at the Manchester Christie Cancer Hospital and Holt Radium Institute since 1932 by means of the Finzi-Harmer radium technique, after fenestration of the thyroid cartilage. In the properly selected cases this treatment yielded a cure rate of 83%, a figure which included deaths from intercurrent disease as well. In the patients who died within the first three years the larynx was never well after the treatment. The cases in which the best results were obtained were those in which the growth was in the middle third of the cord. Anterior spread should not rule out treatment, but posterior spread was a definite contraindication to this type of therapy. The voice in all successfully treated cases was very good. Professor Lambert also reviewed his experience in the use of contact x-ray therapy for malignant growths limited to one side of the larynx according to the technique which he and T. A. Watson described in April, 1942. In a series of 53 cases, only 22 could be regarded as cured. In addition to the high percentage of failures morbidity was high, and consequently this method of treatment had now been abandoned. In the subsequent discussion Professor Lambert, who admitted that his views might not be shared by many of his surgical and radiological colleagues, also expressed the view that hyperkeratosis of the vocal cord should be regarded as a pre-malignant condition which should be treated by some form of irradiation therapy, even in the absence of clinical or microscopical evidence of malignant change. Once the condition crossed the narrow dividing line between the precancerous and the cancerous stage it tended to spread with great rapidity.

Professor E. W. Anderson, of the Department of Psychiatry, the Royal Infirmary, Manchester, has written to point out that we were wrong in stating in the *Journal* of August 26 (p. 516) that the training course in psychiatry at Manchester University is for one year. The course for the D.P.M. at this university now covers eight university terms.

Under the title "Professional Training of Army Medical Officers" (August 26, p. 517) we erroneously said that two revision courses in surgery a year are held at Westminster Hospital Medical School for senior officers of the Millbank College. In fact, officers attending the Senior Officers Postgraduate Course attend at the Westminster Hospital for clinical tuition in medicine and surgery during the second part of the course.

CONGENITAL HEART DISEASE*

A REVIEW OF ITS CLINICAL ASPECTS IN THE LIGHT OF EXPERIENCE GAINED BY MEANS OF MODERN TECHNIQUES

BY

PAUL WOOD, O.B.E., M.D., F.R.C.P.

Director of the Institute of Cardiology (National Heart Hospital); Physician in Charge of the Cardiac Department, Brompton Hospital

[WITH SPECIAL PLATE]

PART I

In the past the chief contributions to the better understanding of congenital heart disease have been based on necropsy studies, particularly those by Peacock (1866), Keith (1909), and Maud Abbott (1928). More recently, Brown (1939) and Helen Taussig (1947) have presented us with important monographs from a more practical angle, but even these have depended on the correlation of clinical and post-mortem findings. In some respects all these works have necessarily been influenced by the selected nature of the material, and have tended to create a number of false impressions. For example, of Abbott's 1,000 cases there were 37 with three-chambered hearts, 81 with partial or complete transposition of the great vessels, 40 with pulmonary atresia, 21 with persistent truncus, and 16 with tricuspid atresia (total 195); against 33 with atrial septal defect (A.S.D.), 55 with uncomplicated ventricular septal defects (V.S.D.), 105 with uncomplicated patent ductus, 9 with simple pulmonary stenosis, and about 71 with Fallot's tetralogy (total 273), giving a ratio of the rare to the common types of 2:3. Again, in 1947 Helen Taussig stated that she had never had an opportunity of studying a single case of pure pulmonary stenosis. The suggestion that V.S.D. accounts for 35–40% of all congenital hearts seen in school-children (Perry, 1931; Muir and Brown, 1934) is also unacceptable.

In recent years, modern techniques have made it possible to prove the precise nature and physiological effects of 90% of all congenital cardiac anomalies during life. In the light of this rapidly acquired knowledge of dynamic processes, many physical signs have acquired a new significance and their proper interpretation has so greatly improved bedside diagnosis that the special investigations responsible for their discovery have already become superfluous in many cases. The time is ripe, therefore, for a review of the whole subject of congenital heart disease from a more functional standpoint, to present a fresh account of these physical signs, to offer a more practical and physiological classification of the common or well-recognized anomalies, and incidentally to give a truer picture of their clinical incidence. By implication, stillborn infants and those dying shortly after birth have been excluded from the study.

Material.—Observations are based on 233 cases of supposed congenital heart disease examined personally by me during the last two and a half years at the National Heart Hospital, Hammersmith and Brompton Hospitals, in private practice, and at the Rheumatic Fever Centre, Taplow. Of these, 152 were catheterized, and in 42 angiocardiograms were taken. Further confirmation of the diagnosis was obtained at operation in 44 cases and at necropsy in 20.

Techniques

1. Cardiac Catheterization

American nylon catheters and saline manometers were used throughout, as described by McMichael and Sharpey-Schafer (1944). Mean pressures are expressed in millimetres of mercury above the sternal angle with the patient horizontal. Blood gas analysis was carried out by trained technicians using Haldane's or van Slyke's apparatus. The catheter was inserted into a median antecubital vein in all cases but one, in which the external jugular had to be used. Failure to enter the superior vena cava was always due to inexperience and could usually be overcome by asking the patient to breathe deeply or by causing an anaesthetized patient to cough or gasp; changing the position of the head, arm, or body was usually a waste of time. Occasionally it was necessary to change the catheter or to use the other arm. The services of an anaesthetist are required for children under 7 or 8 years old. Dr. B. G. Lucas, at the Heart Hospital, has usually given rectal thiopentone with intravenous supplements.

Venospasm is a reflection on the skill of the operator, and never occurs if the skin is properly anaesthetized, if all traces of disinfectant are washed off the catheter before use, and if the catheter is not too large for the vein. It has caused no embarrassment in the last 100 cases.

Air embolism is avoided by keeping the hilt of the catheter below right auricular level when sampling. It has not occurred in this series.

Thrombo-embolism, paradoxical or pulmonary, is avoided by giving 50 mg. of heparin to the patient, by adding a smaller quantity to the saline reservoir, and by taking care to keep blood out of the catheter, especially when entering a high-pressure chamber and after sampling. It has not been encountered in this series.

*St. Cyres Lecture delivered on June 13 at the Royal Society of Medicine under the auspices of the National Heart Hospital.

Rigors are due to pyrogens in a previously used catheter. They do not occur if catheters are thoroughly washed out and subsequently cleaned by running hydrogen peroxide through the lumen until bubbles cease.

Ventricular fibrillation developed in two patients, and proved fatal in one of them (a severe case of atrial septal defect with gross cardiac enlargement and congestive heart failure). Since then all cases have received quinidine (5–10 gr.—0.32–0.65 g.) half an hour beforehand.

Subsequent infection, such as thrombophlebitis, pulmonary or cerebral abscess, septicaemia, and bacterial endocarditis, should not occur with aseptic technique, but all our cases have been given penicillin for 48 hours after the procedure, as a precaution. No such infection has yet arisen.

X-ray overdosage has been avoided by limiting the screening time to 30 minutes at 1 mA, 20 minutes at 2 mA, and 15 minutes at 3 mA. The operator wears a lead apron and does not regularly perform more than two catheterizations a week.

Failures.—Of 152 cases of suspected congenital heart disease an attempt was made to catheterize the pulmonary artery in 129, and was successful in 110 (85%). This figure includes failures due to inability to enter the right ventricle. The latter was entered in 135 out of 146 attempts (92%). There was only one failure to catheterize the right auricle in the 152 cases. Many of the failures occurred in difficult cyanosed cases, including six with tricuspid atresia and at least one with pulmonary atresia. In acyanotic cases, including simple pulmonary stenosis, the right ventricle was catheterized in 98%, and the pulmonary artery in 91%. In Fallot's tetralogy the pulmonary artery was entered in 15 out of 21 cases. The high incidence of successful catheterization is attributed to the development of what we have called "the coil technique." Instead of attempting to pass the catheter direct into the right ventricle, its tip is first rotated outwards against the lateral wall of the right auricle; a half-loop is easily formed in this situation, and when this is rotated medially the upwardly directed tip passes straight towards the pulmonary artery after slipping through the tricuspid valve.

2. Angiocardiography

I am indebted to Dr. Maurice McGregor, of Johannesburg, for personally constructing the angiocardiograph now used at the Brompton Hospital, and for helping to develop the technique. Copies or slightly modified copies of his model are used at the Hammersmith and the Heart Hospitals. Angiocardiograms have been carried out mostly by the cardiological registrars at these hospitals, particularly by Dr. J. B. Lowe at Brompton and at the Heart Hospital, and by Dr. E. Petrie at Hammersmith. Technical details have been described elsewhere. There were no fatalities.

Incidence

The series was closed at the 233rd case, for by then the nature of the congenital anomaly was virtually certain in 200. Of the residue, 13 proved to have normal hearts, 4 had rheumatic aortic and/or mitral valve disease, 6 had idiopathic pulmonary hypertension, and 10 eluded analysis.

The incidence of the various forms of congenital heart disease encountered is given in Table I. It is believed that weighting in favour of those lesions amenable to surgical repair is slight, because the clinics at which most of the cases were seen did not have a surgical flavour or unduly close surgical link. It is concluded that the commonest forms of congenital heart disease are Fallot's tetralogy (18%) and atrial septal defect (17%); followed closely by patent ductus (14.5%), ventricular septal defect (12%), and simple pulmonary stenosis (11.5%); whilst coarctation of the aorta comes next (8%). Together these six conditions accounted for 81% of the total.

TABLE I.—*Incidence of Chief Anomalies*

Total No. of cases investigated		233
Rheumatic A.S.; M.I.; or A.I.+M.S.		4
Proved normal		13
Primary pulmonary hypertension		6
Nature still obscure		10
True congenital heart disease		200
	No.	%
Acyanotic		
Coarctation of the aorta	16	8
Aortic or subaortic stenosis	6	3
Simple pulmonary stenosis (4 with V.S.D.)	23	11·5
Atrial septal defect	35	17·5
Ventricular septal defect (excluding 4 with pulmonary stenosis)	24	12
Patent ductus arteriosus	29	14·5
Cyanotic		
Fallot's tetralogy (including 3 with pulmonary atresia)	36	18
Pulmonary stenosis with reversed interatrial shunt	5	2·5
Tricuspid atresia	6	3
Eisenmenger's complex	2	1
Transposition of the great vessels	2	1
Others	16	8
Total	200	100

Clinical Features

In attempting to make a bedside diagnosis of the precise nature of any case of suspected congenital heart disease, due consideration should be given to 10 major items, all of which have multiple facets.

1. Other Congenital Stigmata

Mongolism and arachnodactyly are well-recognized associations, but in their complete form are uncommon. Partial arachnodactyly, especially high arched palate and pigeon chest, however, is common. Brown also stresses accessory nipples. When the diagnosis rests between normality, congenital heart disease, or acquired heart disease, any such stigmata favour a congenital anomaly.

2. Effort Intolerance

Breathlessness may be divided into four grades: (1) slight—the patient attempts to compete with his fellows, but is always at a disadvantage; (ii) moderate—he is obviously breathless on effort, but can walk several miles; (iii) severe—he can walk only several hundred yards, certainly not more than a mile; and (iv) gross—incapacitated and cannot walk 100 yards.

Squatting (Taussig, 1947) should always be noted. It is especially common in Fallot's tetralogy, but not limited to it. It occurred in practically every cyanotic form of congenital heart disease in this series, but whereas it was recorded in two-thirds of those with Fallot's tetralogy, it was mentioned in only one-quarter of the others. It was noted only once in an acyanotic case (severe pulmonary stenosis).

Angina pectoris and syncope were rare, but occurred occasionally in severe pulmonary stenosis with or without reversed interatrial shunt. Angina occurred in three of the six cases with idiopathic pulmonary hypertension, and syncope in one of them.

Palpitations had a nuisance value in several severe cases of patent ductus, and in a few advanced cases of atrial or ventricular septal defect.

3. Cyanosis

It is usual to grade the intensity of cyanosis and clubbing so that some idea of their degree may be recorded. Central cyanosis is best seen on warm surfaces such as the conjunctivae, the inner side of the lips, the palate, and the tongue. Peripheral cyanosis may occur on exposed surfaces which may be cold, such as the nose, ears, face, outer side of the lips, and hands. The distinction is very important. Clubbing always means central cyanosis when other causes can be excluded.

Polycythaemia is also recorded under this heading, and usually implies central cyanosis; but it sometimes helps to compensate for an extremely low cardiac output.

Central cyanosis in congenital heart disease means a veno-arterial shunt. It may occur, however, in the late stages of primary pulmonary hypertension, and of course in anoxic cor pulmonale.

4. Pulse

A small pulse is characteristic of all the severe cyanotic and severe acyanotic forms of congenital heart disease except patent ductus, aorto-pulmonary septal defect, and perforated aortic sinus, when it is water-hammer in quality. It is normal in mild cases in both groups. In the absence of aortic incompetence Corrigan's sign provides valuable evidence in favour of patent ductus or its near relatives. Both water-hammer pulse and Corrigan's sign were present in 18 out of 22 such cases in which they were looked for.

Hypertension is limited to coarctation of the aorta, and then, of course, it can be detected only in the upper extremities. The blood pressure was normal in all other conditions except the ductus group, although the pulse pressure was small in the most severe cases. In the ductus group the diastolic pressure was significantly reduced in the majority.

5. Jugular Venous Pressure

The general level of the jugular venous pressure was usually normal, excluding cases of heart failure; but it tended to be within the upper limits of normal or even slightly raised in the group with arteriovenous shunt and in cases of simple pulmonary stenosis or idiopathic pulmonary hypertension. It was slightly raised in 4 out of 28 cases of Fallot's tetralogy.

Giant *a* waves were conspicuous in the neck in the most severe cases of simple pulmonary stenosis with or without reversed interatrial shunt. These were easily recognized and distinguished from the well-known venous pulse of tricuspid incompetence by their presystolic timing, by their abrupt and collapsing quality (venous Corrigan), and by the fact that they represented a pressure far above that of the *c* and *v* waves. In two cases they were transmitted to the liver. Giant *a* waves may also be seen in acquired tricuspid stenosis and severe primary or secondary pulmonary hypertension, but rarely in other conditions. They resemble in quality, but not in timing, the cannon waves of heart-block. They are not seen in uncomplicated A.S.D., V.S.D., patent ductus, aortic stenosis, or mitral incompetence.

6. Pulsation

The quality of the cardiac impulse is very important. It may be described as normal (gentle left ventricular thrust), heaving (from a hypertrophied left ventricle), hyperdynamic (a quick tumultuous thrust), or tapping. It is believed that the tapping cardiac impulse represents absence of pulsation at the apex beat associated with an easily palpable first heart sound. This may result from clockwise rotation or from enlargement of the right ventricle, usually both. It is characteristic of A.S.D., Fallot's tetralogy, and severe pulmonary stenosis. A hyperdynamic left ventricular thrust is characteristic of patent ductus and V.S.D. Occasionally a tumultuous cardiac impulse is due to a grossly hyperkinetic right ventricle in A.S.D. (Roesler, 1934).

When the left ventricle is enlarged the normal precordial systolic retraction tends to be exaggerated. When the right ventricle is enlarged there is a diffuse lift in the third and fourth spaces between the sternum and the nipple line. This lifting outflow tract or conus is very rarely recorded in hospital notes, yet it is highly important, and is probably the best clinical evidence available of an enlarged right ventricle.

Systolic pulsation in the second left space offers good evidence of a dilated pulmonary artery, and is a most helpful and reliable physical sign. It was recorded positively in 7 out of 25 cases of A.S.D. in this series, but negatively only twice, and was never seen in any form of pulmonary stenosis. Occasionally, however, it may be due to a large aorta, as in pulmonary atresia, or to a persistent truncus.

7. Murmurs and Thrills

The significance of the site, intensity, and conduction of most murmurs and thrills is well recognized and needs little comment. But more attention should be paid to functional murmurs; particularly to the Graham Steell murmur of pulmonary incompetence, which was heard in 13 out of 25 cases of A.S.D. in this series, and which always indicates a dilated pulmonary artery; and to the mitral diastolic murmur that denotes a torrential mitral blood flow—this was heard in 16 out of 18 cases with either a large patent ductus or a large V.S.D. There can be no doubt that it is functional, for it disappears immediately the ductus is ligated. Phonocardiograms show that it follows the third heart sound at the mitral area and is indistinguishable in timing, quality, intensity, and duration from the mitral diastolic murmur associated with mitral valvulitis.

8. Second Heart Sound

It is nearly always possible to distinguish two components of the second heart sound in normal children and in most healthy adults who are neither emphysematous nor overweight, particularly during inspiration. In other words, the second heart sound is normally split. The first component represents aortic valve closure, the second pulmonary valve closure. The second heart sound is usually single in the neck, at the aortic area, and at the cardiac apex—at these sites only the aortic element is normally heard. At the pulmonary area both elements are heard, and the loudest is usually the aortic. Phonocardiograms taken by Dr. Aubrey Leatham confirm the clinical view that the pulmonary valve normally closes after the aortic. The significance of this fact will not be overlooked, for it offers a bedside method of detecting pulmonary hypertension, pulmonary hypotension, and right bundle-branch block (or its functional equivalent).

Thus in primary or secondary pulmonary hypertension the second element of a normally split second heart sound is usually obviously accentuated; in Fallot's tetralogy the second sound at the pulmonary area is always single and usually loud—it is the aortic sound that is heard and the vessel is not covered by the pulmonary artery; in severe simple pulmonary stenosis the pulmonary element is also absent, but may be present in mild cases; in A.S.D. with functional right branch block or its electrocardiographic equivalent, and a grossly overfilled right ventricle, the second heart sound is widely split and the second or pulmonary element is but little accentuated. No sign will repay closer study than the second heart sound at the pulmonary area. It is believed that Helen Taussig (1947) was the first to point out the value of hearing a split second sound, stating that it offered clear evidence of the existence of both great vessels.

9. The Electrocardiogram

The important findings in congenital heart disease include the P pulmonale, evidence of left or right ventricular preponderance, and appearances resembling partial or complete right bundle-branch block. The P pulmonale is common, and therefore not very helpful, in all cyanosed cases, but in acyanotic cases it usually means pulmonary stenosis or severe pulmonary hypertension. It is never conspicuous in uncomplicated A.S.D., V.S.D., or patent ductus.

The electrocardiogram is the most reliable clinical means of deciding which ventricle is predominant, and the point is of the utmost importance in differential diagnosis. Details cannot be discussed here.

Partial or complete right bundle-branch block occurs in 95% of all cases of A.S.D., the clinical diagnosis of which is almost untenable in its absence.

10. X-ray Appearances

The most valuable recent addition to well-known radiological signs is perhaps the recognition of overfilled or underfilled peripheral pulmonary arteries. Pulmonary plethora (Plate, Fig. 1) occurs in A.S.D., V.S.D., patent ductus, and transposition of the great vessels; pulmonary ischaemia (Fig. 2) in all cyanotic cases with veno-arterial shunt, including Eisenmenger's syndrome. The difference is very obvious and does not necessarily bear any relation to the size of the pulmonary artery itself or to its main left and right branches; thus dilatation of the pulmonary artery itself without pulmonary plethora occurs in pulmonary valve stenosis, pulmonary hypertension, and

Eisenmenger's complex; on the other hand, diminutive main pulmonary arteries occur only when the pulmonary blood flow is reduced.

Another point of great importance is the quality of pulmonary artery pulsation: whether it is abrupt and collapsing as in A.S.D. and pulmonary incompetence, or whether it is relatively slow-rising and sustained as in pulmonary stenosis (Wells, 1950).

Coarctation of the Aorta

Of the 16 cases in the series 8 were male and 8 female. Their ages ranged from 5 to 47. The findings were characteristic, and there is very little to add to the well-known clinical picture.

Patent ductus was associated in one, V.S.D. in two, and aortic stenosis in one (possibly two). The coarctation was of the usual adult type in all of these.

A mitral diastolic murmur was heard in no fewer than 9 of the 16 cases. There was a ready explanation for it in five (ductus, 1; V.S.D., 2; calcific mitral stenosis, 1; and active rheumatic carditis, 1). But there was no explanation for it in the other four; there was no rheumatic history, and the murmur disappeared after surgical repair in one of them. The contrary evidence that an unexplained mitral diastolic murmur may persist after successful surgical repair is still lacking. According to Brown, cases of coarctation of the aorta, like cases of A.S.D., are peculiarly apt to develop rheumatic mitral valvulitis in childhood, and at present there is no better explanation to offer.

A radiological sign that too often escapes notice is the double aortic knuckle (Fig. 3) described by Bramwell (1947) and others. This at once distinguishes coarctation from obstruction lower down.

Retrograde aortography was carried out on three cases, but the results were little better than those obtained by the intravenous route, and the procedure is probably more dangerous. Good aortograms are essential, however, so that cases which are anatomically unsuitable for repair need not be subjected to thoracotomy.

The mortality rate for Crafoord's operation is now 10–16% (Gross, 1949; Shapiro, 1949).

Patent Ductus Arteriosus

There were 29 cases of patent ductus in the series—21 female and 8 male. Only one was seriously incapacitated, but five others had moderate breathlessness and complained of palpitations.

Of the physical signs, Corrigan pulsation in the neck, a water-hammer pulse, a normal venous pressure and pulse, a thrusting hyperdynamic left ventricular cardiac impulse, a high continuous murmur in the first and second left intercostal spaces, a normally split (when not obscured) second heart sound at the base, often with some accentuation of the pulmonary element, and a functional mitral diastolic murmur were the most important. The electrocardiogram showed normal P waves, a varying degree of left ventricular preponderance, and no bundle-branch block. S waves were always dominant in Lead V_1, and a small secondary R wave was seen only once; but the main R wave in this lead was sometimes notched, and S was occasionally slurred. The most severe cases showed T-wave inversion in left ventricular surface leads or their equivalents, and one patient had auricular fibrillation, which reverted to normal rhythm after ligation of the ductus. Skiagrams usually revealed left ventricular enlargement, pulmonary plethora, and a varying degree of dilatation of the pulmonary artery.

The mildest cases showed no abnormality apart from the Gibson murmur. Nine out of ten severe cases had a functional mitral diastolic murmur which disappeared immediately the ductus was ligated. Two patients did not have a continuous murmur at any time, and in two others the murmur was atypical and was thought by some observers to be absent in one of them and discontinuous in the other. The two without the classical murmur were the most severe in the series. Both were proved by cardiac catheterization and subsequent ligation of the ductus. Four acyanotic patients with continuous murmurs did not have a patent ductus. Two had aorto-pulmonary septal defects, and two had a perforation of the aortic sinus—one into the pulmonary artery and one into the right ventricle. Several other continuous murmurs were heard in acyanotic patients during the two-and-a-half-year period under review, but have been excluded from the series. Some represented a venous hum and were louder in the neck. One was due to a needle causing an aorto-pulmonary fistula; another was caused by an arteriovenous aneurysm in the lung. No case of coronary arteriovenous aneurysm was encountered.

The venous hum is accentuated when the patient sits up and may be abolished by compressing the jugular vein at the root of the neck. Continuous murmurs due to aorto-pulmonary septal defects or to a perforated aortic sinus tend to be loudest a little lower than the classic ductus murmur; they are also extremely coarse and accompanied by a gross thrill. Both cases of perforated aortic sinus in this series developed during or after an attack of bacterial endocarditis.

Arteriovenous aneurysm of the lung usually causes cyanosis; if not, it may yet be recognized by means of pulmonary angiocardiography and by finding a lowered arterial oxygen saturation. Coronary arteriovenous aneurysm should show an unusually high oxygen content in samples obtained from the coronary sinus.

Cardiac catheterization was undertaken in 13 cases. Mean pressures in the pulmonary artery were normal in four and raised, often considerably, in nine (Table II).

* Increased resistance. d = Diminished resistance.

There was some relationship between the height of the pressure and the size of the shunt, but it was not close. The peripheral resistance in the lungs was variable: it was reduced in four, normal in six, and raised in three. When it was low a relatively large shunt was associated with a relatively low mean pressure in the pulmonary artery; when it was high a relatively small shunt was associated with a high pressure in the pulmonary artery. Only when the peripheral resistance was normal was the pressure proportional to the shunt (Fig. A). This, of course, is obvious and may be calculated by the formula B.P. = T.P.R. × C.O., which applied here becomes: pulmonary artery pressure = pulmonary peripheral resistance × pulmonary blood flow.

FIG. A.—Graph illustrating the relationship of the pulmonary blood flow to the pulmonary artery pressure in patent ductus.

To the three patients with true pulmonary hypertension mentioned (aged 8, 8, and 23) must be added a fourth (a girl of 12) who was catheterized only a year after successful ligation. Her mean pulmonary artery pressure was then 33 mm. Hg. above the sternal angle. The prognosis of these cases should be guarded, for the hypertension may be irreversible; on the other hand, before ligation a moderate increase of peripheral pulmonary resistance may be beneficial, for it reduces the size of the shunt and the work of the left ventricle. By far the worst case (a woman of 35) in this series had a low normal resistance. Another point that emerges is that three of those with true pulmonary hypertension were younger than the average of those without, which was 14.

It is clear that the duration of the shunt does not determine whether the peripheral resistance rises or not, but some other factor. Should the resistance rise precipitously, reversal of the shunt is theoretically possible, and this might occur in childhood. The point will be discussed again in relation to Eisenmenger's complex.

The pulmonary blood flow was usually two to four times the systemic flow—that is, about 10–20 litres a minute. The whole of the extra work entailed in pumping the shunted blood falls on the left ventricle. The systemic flow (and therefore the right ventricular output) was usually a high normal (5–6 litres a minute).

Differential Diagnosis

1. *Aorto-pulmonary Septal Defect or Perforation of an Aortic Sinus into the Pulmonary Artery.*—Apart from the fact that the thrill and murmur are especially coarse and loud, respectively, and tend to be maximal in the third rather than the second intercostal space, there is nothing to distinguish this condition from patent ductus. Cardiac catheterization revealed the same kind and degree of shunt in three cases studied, and angiocardiography has not helped. If the onset of the thrill and murmur can be dated to an attack of bacterial endocarditis, however, a perforated aortic sinus may be diagnosed with confidence.

2. *Perforated Aortic Sinus into the Right Ventricle.*—Only one case was encountered. The clinical findings were similar to those of patent ductus, but the continuous thrill and murmur were distinctly lower, being maximal in the fourth space. Cardiac catheterization proved that the shunt was from the aorta to the right ventricle, pressures and samples being similar to those found in cases of V.S.D.

3. *Other Causes of a Continuous Murmur.*—These include a jugular venous hum, and arteriovenous aneurysm of the lung or of coronary, intercostal, or internal mammary vessels. These have already been discussed.

4. *Rheumatic Aortic Incompetence and Mitral Stenosis.*—The combination of a water-hammer pulse, systolic and diastolic murmurs at the base, left ventricular enlargement, and a mitral diastolic murmur with or without slight enlargement of the left auricle may occur in rheumatic heart disease or patent ductus, and the distinction between the two occasionally presents difficulty: this is when opinion differs about whether the basal murmur is to-and-fro or continuous, or when a continuous murmur is missing in a case of patent ductus with pulmonary incompetence. The presence or absence of a rheumatic history or of other rheumatic manifestations and of radiological evidence of pulmonary plethora should prevent error. If there is still doubt, cardiac catheterization should be performed.

5. Ventricular septal defect with aortic incompetence gives rise to a water-hammer pulse, a systolic and diastolic basal murmur, left ventricular enlargement, a functional mitral diastolic murmur, and pulmonary plethora. The differential diagnosis rests entirely on the site and timing of the thrill and murmur, and if these should be atypical serious error resulting in ill-advised thoracotomy may result. Moreover, cardiac catheterization in V.S.D. occasionally yields data compatible with patent ductus plus pulmonary incompetence.

Treatment

Surgical ligation is advised in all severe cases of patent ductus, and in all infected cases after preliminary penicillin treatment. As the operative mortality is still 2–3%, mild uncomplicated cases should be left alone. Whether moderate cases are ligated or not often depends on the attitude of the parents or patient; on the whole they are probably best ligated.

Ventricular Septal Defect

There were 24 cases with uncomplicated V.S.D.—11 male and 13 female. Their ages ranged between 3 and 55, 15 of them being children under 12 years old, 5 adolescent, and 4 adult. The majority were symptom-free, but five could not compete physically with their fellows, and one (aged 5) had congestive failure.

The important physical signs included a small or normal peripheral pulse, a normal jugular venous pressure without a conspicuous *a* wave, a thrusting hyperdynamic left ventricular type of cardiac impulse, a lifting right ventricular outflow tract and pulsating pulmonary artery, a Roger murmur and thrill, a normally split second heart sound at the pulmonary area (if not obscured by the murmur) with accentuation of the pulmonary element, and a functional mitral diastolic murmur.

Mild cases showed little but the Roger murmur and thrill. The least common sign in the more severe cases was detectable pulsation of the pulmonary artery.

A thrill accompanied the Roger murmur in every case. It was maximal in the fourth or third and fourth intercostal spaces in all but three, when it was maximal in the second (two) or second and third (one) spaces. In two patients it was unusually far to the left towards the apex beat and could have been mitral in origin. A mitral diastolic murmur was distinct in 10 out of 12 relatively severe cases, and was heard by some observers (but not by

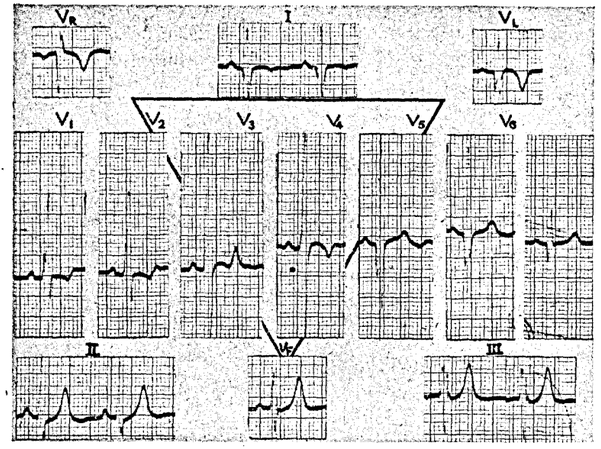

FIG. B.—Electrocardiogram in a case of V.S.D. showing large Q waves, tall R waves, and inverted U waves in left ventricular surface leads; and tall secondary R waves and inverted T waves in right ventricular surface leads.

me) in one of the other two. It was also heard in two relatively mild cases. A Graham Steell murmur from functional pulmonary incompetence was heard in four patients, and what was believed to be an aortic diastolic murmur in a fifth.

The electrocardiogram showed normal P waves, and QRS complexes that sometimes resembled the appearances in A.S.D. and sometimes those of patent ductus, but which as a rule lay somewhere between the two. Thus there might be prominent Q waves, tall R waves, and inverted U waves in left ventricular surface leads (Fig. B), and yet V_1 might show a well-formed secondary R wave. Partial right bundle-branch block, indistinguishable from that in A.S.D., was seen in three cases. In mild "maladie de Roger" the electrocardiogram was normal.

X-ray appearances were indistinguishable from those of patent ductus. Pulmonary plethora and left ventricular enlargement were very conspicuous in the more severe cases (Fig. 4).

By all standards at least 13 of the 24 cases were severe. Only four showed nothing but the characteristic Roger thrill and murmur.

Cardiac catheterization was undertaken in 16 cases. The mean pulmonary artery pressure was raised considerably in six, slightly in four, and was normal in six (Table III). As with patent ductus, the height of the pressure did not parallel the size of the shunt at all closely but depended on the pulmonary peripheral resistance: this was increased in four cases, decreased in four, and normal in eight. The patient with the largest shunt had a low resistance, and three of the four patients with high pressures had only average shunts (Fig. C). The pulmonary blood flow was usually at least double the systemic flow, being of the order of 10–15 litres a minute, but in four mild cases it was only about one and a half times the systemic flow. The contention that very mild cases of "maladie de Roger" may not be detectable by the method of cardiac catheterization is difficult to dispute in the absence of necropsies, but seems improbable.

Angiocardiography was carried out in the patient with the highest pulmonary artery pressure to see if transient reversal of the shunt could be demonstrated. The mean pulmonary artery pressure was 95 mm. Hg, and the systemic blood pressure 160/100 mm. Hg, there being associated coarctation of the aorta. No reversal of shunt could be seen in the angiocardiogram. Nevertheless reversal of the shunt is likely to occur in rare cases that develop an extremely high pulmonary resistance (see under Eisenmenger's syndrome).

* Increased pulmonary resistance. d = Diminished pulmonary resistance.

Differential Diagnosis

The clinical diagnosis of V.S.D. by specialist physicians was often incorrect, and many cases of V.S.D. had been diagnosed otherwise. Thus, of 33 cases proved by means of cardiac catheterization, 17 had been diagnosed as uncomplicated V.S.D.

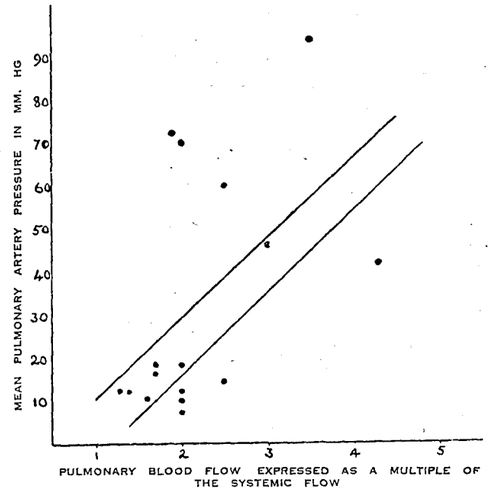

FIG. C.—Graph showing the relationship of the pulmonary blood flow to the pulmonary artery pressure in V.S.D.

in error, 7 with V.S.D. had been diagnosed otherwise, and 9 were correctly diagnosed as having V.S.D. The chief sources of confusion in suggested mild cases were innocent left parasternal murmur, simple pulmonary stenosis, subaortic stenosis, and organic mitral incompetence; and in cases with pulmonary plethora, patent ductus, and A.S.D.

If there is no thrill, a left parasternal murmur unaccompanied by any of the clinical features of V.S.D. mentioned above should be regarded as innocent.

Simple pulmonary valvular stenosis can usually be distinguished by the higher position of the thrill and murmur, by the softness of the pulmonary element of the second heart sound (if it can be heard at all), by the tapping cardiac impulse, and by dilatation of the pulmonary artery in the absence of pulmonary plethora. Subvalvular stenosis is more difficult, because turbulence may then be lower and the pulmonary artery may not be dilated; but the second heart sound and the quality of the cardiac impulse should prevent mistakes. Severe pulmonary stenosis is easily distinguished by the electrocardiogram. Mild subaortic stenosis may be clinically indistinguishable from the "maladie de Roger" if the murmur and thrill are low; if the left ventricle is enlarged, however, absence of other evidence of V.S.D. strongly favours subaortic stenosis.

Organic mitral incompetence with left ventricular enlargement, a mitral diastolic murmur, and a systolic thrill and murmur rather centrally placed may deceive the most experienced; but skiagrams should reveal the tell-tale systolic expansion of the left auricle if there is mitral incompetence, and pulmonary plethora if there is V.S.D.

Patent ductus without a Gibson murmur should be recognized by the peripheral pulse. Confusion is scarcely possible unless V.S.D. is complicated by aortic incompetence; and if systolic turbulence then happens to be high, real difficulty may be encountered. Clinical or electrocardiographic evidence of right ventricular dilatation (as well as left) favours V.S.D.

Afrial septal defect with a relatively low systolic thrill and murmur, and with a hyperdynamic right ventricle forming the apex beat, may closely simulate V.S.D. But the second heart sound is much more widely split in A.S.D., and the pulmonary element is not accentuated. Moreover, the Roesler type of thrusting cardiac impulse is much less common in A.S.D. than was at one time thought: in clinical diagnosis few mistakes will be made if a left ventricular type of cardiac impulse is accepted at its face value.

Terminology

It is suggested that the term "maladie de Roger," if retained at all, should be applied only to mild cases showing nothing more than the Roger murmur and thrill. The majority of cases of V.S.D. present a very different picture from that described by Roger himself and from all textbook descriptions of the "maladie de Roger." Nor is Taussig's classification of high and low defects acceptable. She regards cases with pulmonary plethora and dilated pulmonary arteries as examples of high V.S.D., the left ventricle pumping much blood almost direct into the pulmonary artery. She thinks that trivial shunts mean low V.S.D. This is incorrect. Selzer (1949) has already reviewed the literature from the pathological point of view and shown that only 10% of all cases of uncomplicated V.S.D. have low defects in the muscular septum and that these present no distinctive clinical features. In the present series cardiac catheterization has shown that high and low right ventricular samples are similar to one another and to samples from the pulmonary artery in nearly all instances (Table III); only in the mildest case was there any significant difference, and then the lowest sample was the least saturated.

(The conclusion of the paper will appear next week, with a full list of references.)

A circular from the Ministry of Health to local health authorities points out that many soldiers discharged from the Army on psychiatric grounds need social rather than medical aftercare. A special procedure has therefore been devised for these people as an experiment for one year. Army Form D.487, with which medical officers of health are familiar, will be marked "psychiatric aftercare" and sent to the M.O.H. of the area where the soldier will live. The local health authority should arrange for an initial visit to be paid to the ex-soldier by a social worker soon after the form is received. The authority may then arrange for aftercare services to be provided.

DIFFUSE EOSINOPHILIC ARTERITIS

BY

GEORGE LUMB, M.D.

Honorary Consultant Pathologist, Westminster Hospital; Senior Lecturer in Pathology, Westminster Medical School

[WITH SPECIAL PLATE]

During the past years considerable interest has centred on the problems of tissue changes in conditions of allergic origin, and an increasing quantity of evidence has been collected demonstrating that certain abnormalities, such as vascular proliferative lesions, focal necrosis, and tissue oedema, are to be found in a variety of apparently different diseases linked only by the probability of their having an allergic background.

Essentially similar changes have been found in cases of rheumatic polyarthritis and polyarteritis nodosa (Bergstrand, 1946), whilst evidence of associated allergic skin phenomena have been demonstrated in these conditions; and the association of polyarthritis with clear-cut cases of polyarteritis nodosa is not unknown (Herlitz, 1930–1; Friedberg and Gross, 1934). Further, Rich and Gregory (1943) have shown that the lung lesions in rheumatic pneumonia are essentially similar to those found in cases in which hypersensitivity to sulphonamide drugs exists. There is also certain evidence (Salvesen, 1938; Ehrström, 1941) that glomerulo-nephritis—also considered to be of allergic origin—may, more often than was first supposed, be an associated factor in cases of rheumatism.

More recently, examples of vascular and tissue changes of a similar type, occurring particularly in the lungs, have been described in cases of asthma, and Wilson and Alexander (1945) have shown that 18% of their cases of polyarteritis nodosa had an associated bronchial asthma.

A group of cases has therefore emerged which, although presenting widely differing clinical pictures, has in common the possibility of a similar type of aetiology—namely, an allergic manifestation. Experimental proof of such a theory is so far lacking, and the threads of evidence which do exist are disappointingly inconclusive. Evidence of similar or related morbid anatomical and histological changes in the tissues of patients suffering from this group of diseases provides another method of approach to this problem which has been followed principally by Bergstrand. Opportunities for post-mortem examination have been scanty, for diseases of the asthma group are of relatively benign type, and it is considered justifiable to place on record a further case in which necropsy was performed and full clinical details are available, in order to add to the few examples of this type already in the literature.

Case Report

A married woman aged 33, with one healthy child aged 3, first consulted her doctor in the autumn of 1948 complaining of a cough which had been present for nine months. Previously she had been healthy, with no personal or family history of any complaint of an allergic nature. She gave a history of frequent streaking of blood in the sputum, and for two months she had suffered from dysphagia and hoarseness associated with a swelling of the thyroid gland, together with some increase of nervousness and irritability. She was admitted to hospital on October 10, 1948.

A blood count showed: Hb, 82%; red cells, 4,570,300; white cells, 7,400 (23% eosinophils). Sputum examined for tubercle bacilli was negative on three occasions, but 9% of the total number of nucleated cells were eosinophils. A radiograph of

the chest revealed no abnormalities. It was considered that a non-toxic goitre was causing some non-specific laryngitis which by this time had disappeared. Whilst in hospital the patient had a low-level pyrexia, which settled, and she was discharged improved on November 11.

Within a week of her leaving hospital laryngitis returned, and she was readmitted on December 29. The thyroid enlargement had increased and was giving rise to definite respiratory obstruction and dysphagia. Additional symptoms of swelling of the eyelids and oedema of the dorsum of the hands, together with chemosis of the conjunctivae, had manifested themselves. She was again running a low-grade pyrexia. The white cells numbered 13,200 (19% eosinophils). Subtotal thyroidectomy was performed on February 1, 1949, and histological examination showed no signs of toxicity. The patient was discharged improved after operation, but in April and again in June required hospital treatment on account of dyspnoea, dysphagia, and swelling of the eyelids. Each time a blood count was performed eosinophilia was revealed. On April 5 a radiograph of the chest showed for the first time abnormal irregular shadows in both lower zones, which had increased in size and distribution by June 20 (Plate, Fig. 1).

In view of her increasing dyspnoea at this time she was recommended for early admission to Westminster Hospital, where she arrived in the early evening of July 1 dyspnoeic but

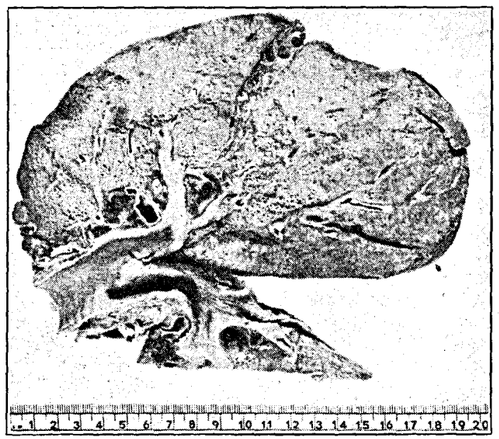

FIG. A.—Cut surface of lung, showing diffuse patchy consolidation.

not unduly distressed. She ate a reasonable dinner soon after admission, but three hours later became extremely distressed with inspiratory and expiratory stridor. Direct laryngoscopy revealed no obstruction and she finally lapsed into a coma and died 12 hours after admission.

Post-mortem Examination

This was performed three and a half hours after death. The body was that of a young woman in a good state of general nutrition. A well-healed scar at the site of thyroidectomy was seen in the neck. There was some oedema of the face, more marked on the right side than on the left, and considerable swelling of the right lacrimal gland caused prominence of the right eyelid.

Respiratory System.—The pharynx and larynx were filled with thick sticky mucopus, and the walls of the pharynx, larynx, trachea, and main bronchi were thickened and intensely oedematous. The mucous surface was flattened and very pale. The vocal cords were normal, and there was no abnormality in relation to either recurrent laryngeal nerve. Both pleurae showed easily broken-down adhesions, more marked on the right side, and at the right base a small collection of serous fluid was found. Both lungs were heavy and had an irregular shotty feel on palpation. Examination of the cut surface proved this to be due to very widespread irregular patches of consolidation of greyish yellow colour, involving the vast majority of the lung substance, with small intervening areas of compensatory emphysema (Fig. A).

Heart.—No abnormalities of valves or coronary vessels were found, and the musculature appeared normal on naked-eye examination, with the exception of one small area at the base of the left ventricle anteriorly, where it was very soft and yellowish in colour.

Spleen.—This was normal in size. The cut surface was rather pale and fatty, showing numerous scattered areas of greyish yellow infiltration varying in size from a pinhead to 0.5 cm. in diameter.

Kidneys.—These were normal in size, but scattered through the cortex were numerous yellowish areas of infiltration similar to those seen in the spleen and liver.

Thyroid.—A small remnant remained on the right side which was normal in appearance.

Lymphatic System.—Numerous enlarged lymph nodes were found in the neck, mediastinum, and para-aortic regions. The nodes were rubbery and discrete, and on the cut surface some of them had a yellowish appearance similar to the nodules in the liver, spleen, and kidneys.

The cause of death was considered to be acute respiratory obstruction associated with extensive bilateral pulmonary consolidation. The possibility of some bacterial infection of the lungs leading to a septicaemia was considered, but cultures taken from the blood, lungs, and the nodules in the spleen and kidneys were all sterile, and material injected into guinea-pigs and hamsters caused no abnormalities in these animals.

Microscopical Features

Lungs.—The normal architecture was replaced by a diffuse fibrous process showing irregular collagen bands and inflammatory cells, including numerous eosinophils, a few plasma cells, and some multinucleate giant cells (Fig. 2). Frequently the collagen strands were seen to be split up by oedema, and areas of hyaline degeneration were seen which failed to take up the aniline blue by Mallory's method or even to retain the first dye—in this case azocarmine. This collagen change has been described particularly in the so-called "Frühinfiltrat" of rheumatic pneumonia. Foci of necrosis were frequent and were invariably surrounded by a dense infiltration of eosinophils. Where an alveolar network remained signs of compensatory emphysema were seen. The bronchi were everywhere grossly thickened by oedema and infiltrated by eosinophils. The arterioles showed considerable intimal proliferation with thrombosis; necrosis of the wall with eosinophilic infiltration of the type found in polyarteritis nodosa was often seen (Fig. 3). Hyaline degenerative masses in the walls of the arterioles were a frequent finding.

Heart.—The myocardium showed a generalized degeneration of muscle fibres and these were widely separated by oedema and an infiltration of eosinophils. In the yellow area noted macroscopically focal necrosis with intense eosinophilic infiltration had occurred (Fig. 4).

Spleen.—There was a diffuse infiltration of eosinophils throughout the organ, and in the macroscopic yellowish areas focal necroses packed with eosinophils were seen. The majority of arterioles showed intimal proliferation.

Liver.—Accumulations of eosinophils were found around many portal tracts, and isolated cells of this type were found lying free in the sinusoids. No areas of necrosis were seen.

Kidneys.—Both had focal necrotic areas scattered in the cortex, where a few convoluted tubules had been destroyed and accumulations of eosinophils existed. Glomeruli were for the most part normal, but occasional capillary thrombi were seen (Fig. 5). The arterioles showed intimal proliferation and occasional thromboses, but no vascular necrosis was found.

Lymph Nodes.—The three lymph nodes examined revealed sinus catarrh with numerous eosinophils.

Lacrimal Gland.—This showed oedema and considerable infiltration by eosinophils.

Discussion

To summarize, one may say that here was a woman with no relevant family or past history, who had complained of cough for 18 months, and who gave a nine-months history of associated dyspnoea and dysphagia. Partial thyroidectomy had been performed five months before death, with apparent temporary relief. The first sign which might have led to the suspicion of an allergic background was the eosinophilia discovered nine months before death. The first time any specific lesion was found in the lungs was two and a half months before death, whilst the oedema of the face and hands began six months before death. The only attack which might have been called asthmatic was the terminal one during which the patient died.

The morbid anatomical and histological changes, however, seem to be identical with cases described by a number of authors under various titles, notably, Meyer-Dörken (1934), Harkavy (1943), Bayley *et al.* (1945), Bergstrand (1946), Smith (1948), and others. The generalized lesions found in the above case may be said to fall under three headings—namely, intimal proliferation, necrosis, and thrombosis of small vessels; focal necroses; and tissue oedema and eosinophilia.

The most striking lesions were the vascular changes in small arteries and the eosinophilia, which was constant in the peripheral blood throughout the course of the disease and was such a pronounced feature of the histological picture. For this reason in discussing this case I have decided to use the non-specific term diffuse eosinophilic arteritis rather than attempt to make any particular diagnosis.

In studying this case it is at once apparent that there are certain similarities to a number of other conditions. Thus the vascular changes are almost identical with those seen in polyarteritis nodosa. The focal necroses which have not been described in this latter condition are common, however, in other conditions in which hypersensitivity plays a part, as, for instance, after the use of sulphonamide drugs (Lederer and Rosenblatt, 1942). In this connexion it is interesting to note that, despite the patient's pyrexia, no drug of this group was at any time administered. The lung fibrosis is reminiscent of rheumatic pneumonia, and the eosinophilia and oedema are common findings of allergic phenomena.

It is difficult to escape the conclusion that the changes described both in this case and in the literature represent not a particular disease syndrome but a non-specific tissue reaction of allergic type which may vary from the benign lesions of the so-called Loeffler's syndrome (von Meyenberg, 1942) to lethal conditions such as the one described here. Examples of intermediate pathology may be quoted from the numerous varieties and gradations of polyarteritis nodosa.

In the cases of rheumatism, hypersensitivity to sulphonamide drugs, and nephritis many data exist concerning the exact precipitating factors, whereas in conditions such as polyarteritis nodosa no such evidence is yet forthcoming.

The above record is therefore presented as one of violent allergic reaction to some unknown precipitating stimulus, with widespread lesions of a type seen in a number of other conditions, and which it is perhaps justifiable to regard as representing part of the general pathology of the allergic state.

My grateful thanks are due to Professor R. J. V. Pulvertaft for help with this paper, to Dr. W. E. Lloyd for making the case notes available, and to Dr. Peter Hansell, of Westminster Hospital Photographic Department, for the illustrations.

OBSERVATIONS ON SYMPTOMATOLOGY AND TREATMENT OF CERVICAL EROSION

BY

JEAN R. W. ROSS, M.B., Ch.B., B.Sc.

(From the Gynaecological Department, Royal Salop Infirmary, Shrewsbury)

The large number of cases of cervical erosion seen in this out-patient department has focused attention on that condition, which was present in 36% of all the cases seen there from April, 1947, to June, 1949—some 870 cases of erosion in all. This prevalence may be due in part to the lack of post-natal care in the surrounding districts, though Fulkerson (1926), in his study of all cases attending the gynaecological department of the Cornell University Medical School, found that the incidence of cervicitis with erosion was 33%.

All patients were subjected to speculum examination of the cervix, and diagnosis was by direct observation either of an erosion or, in a few cases, of Nabothian follicles associated with a mucopurulent discharge from the external os.

The diversity of symptoms presented when cervical erosion was the only lesion found became evident. These symptoms have been analysed in 128 cases out of the 870 treated. The remaining cases of erosion have been set aside because they were associated with other conditions which clouded the issue, or because follow-up was impossible. In all other respects these 128 cases are unselected.

The symptoms of which the patients complained, and the numbers cured by healing of the erosion, are presented. The patients were examined six weeks after treatment, and were followed up for a period of from six months to two years, in order to observe the permanency of cure and to eliminate any purely psychological effect of treatment.

The treatment employed was thermo-cauterization of the cervix, using the electric cautery. The results of treatment in the 128 cases are analysed, and, in addition, the complications which occurred after cauterization in the 870 cases treated are reviewed.

Symptomatology

The symptoms observed in the 128 patients (summarized in Table I) were, in order of frequency, as follows.

Leucorrhoea.—As is generally recognized (Young, 1930; and others), the cardinal symptom was leucorrhoea. The discharge was typically not more than moderately profuse, mucoid, and white or yellowish in colour. No fewer than 102 (80%) complained of leucorrhoea, and 92 (90%) of these were cured as a result of treatment. Of the remainder four were found to have persistent or recurrent erosion,

TABLE I.—*Symptoms Present in 128 Cases of Cervical Erosion*

Symptom	No. of Cases	Percentage Incidence	Percentage Cured
Leucorrhoea	102	80	90
Backache	75	59	60
Abdominal pain	75	59	56
Frequency of micturition	32	25	75
Menorrhagia	24	19	67
Pruritus vulvae	15	12	100
Dysmenorrhoea	14	11	71
Dyspareunia	11	9	73
Cervical haemorrhage	11	9	100
Sterility	9	7	33
Sense of pelvic weakness	3	2	67

two had trichomonas vaginitis which had not been present at the time of treatment, and in four cases no abnormal discharge could be found on examination.

Backache.—Of the 75 (59%) patients who complained of backache 45 (60%) were cured by cauterization of the cervix, and were still cured when seen six months to two years later. The backache associated with cervical erosion was typically of a constant aching character and was felt in the lumbo-sacral region. It is not claimed that the majority of cases of backache in women are due to cervical erosion. Barns (1948) has stressed the importance of causes other than lesions of the pelvic viscera. Yet the fact that 60% of the women in this series who had cervical erosion and complained of backache were permanently cured by treatment of the cervix demands careful consideration. This is at variance with the views of many writers such as Fulkerson (1926) and Wilfred Shaw (1948), but Young (1930) states that a low backache is not infrequently associated with cervicitis. It is submitted that cervical erosion can by no means be ignored as a cause of this common symptom.

Abdominal Pain.—Of the 75 (59%) patients who complained of abdominal pain 42 (56%) were permanently cured by cauterization of the cervix. The pain in these 42 cases is thought to have been due to the erosion; it was localized in the right iliac fossa in 11 cases and in the left iliac fossa in 4, and was more generalized in the lower abdomen in 24. The pain was of two types—either dull, aching, and constant, or acute and lancinating. The importance of cervical erosion as a cause of troublesome and sometimes severe abdominal pain must be stressed. In this series 56% of patients with erosion and complaining of abdominal pain were permanently cured by treatment of the cervical lesion. Six patients had already undergone abdominal operations without relief, and were subsequently cured by simple cauterization of the cervix. The following two cases illustrate this point.

Case 1.—A married woman aged 34, with one child aged 7, complained of attacks of pain in the right iliac fossa for one year, and of leucorrhoea. An emergency appendicectomy had been performed four months previously. The removed appendix was normal. The pain continued. On examination she was found to have a cervical erosion, which was cauterized. After six weeks the cervix was healed and the patient was symptom-free. Two years later the cervix was healthy and there was no abdominal pain and no discharge.

Case 2.—A married woman aged 44 complained of dragging lower abdominal pain, with intermittent acute exacerbations, since the birth of her only child 18 years before. Three years after delivery a pelvic floor repair had been carried out, followed two years later by subtotal hysterectomy, appendicectomy, and right oophorectomy. There was no relief from the abdominal pain. On examination a marked chronic cervicitis with an erosion and numerous Nabothian follicles was found. The cervix was cauterized. Six weeks later the cervix had healed and the patient was symptom-free. After one year the pain had not recurred, and the patient felt better than for nearly twenty years.

These facts will be sufficient to emphasize the association of abdominal pain with cervical erosion. It is suggested, therefore, that before any operation is performed on a patient complaining of abdominal pain of no clear origin, and particularly if such pain is associated with a vaginal discharge, the cervix should be examined and cervical erosion excluded.

Frequency of Micturition.—Of the 32 (25%) patients who complained of day-and-night frequency 24 (75%) were cured by cauterization of the cervix, with no other treatment. Unfortunately, microscopical and bacteriological examination of a catheter specimen of urine was carried out in only 16 of the 32 cases: only one showed evidence of infection, the organism being *Bact. coli.* Of the remaining 15 cases of frequency known to be unassociated with infection 14 were cured by cauterization of the cervix. This supports the hypothesis that cervical erosion often causes a trigonitis, in which no organism can be recovered from the urine, and is in agreement with the observations of Vassallo (1936). The one case of infection is of interest, as it illustrates how cervicitis can be an aetiological factor in the production of recurrent cystitis (Winsbury-White, 1933). In the case under review, in which there had been numerous attacks of recurrent cystitis, the condition has remained entirely cured for two years, following a single course of sulphonamide therapy and healing of the cervical erosion.

Menorrhagia.—There were 24 (19%) patients who complained of an excessive menstrual loss—that is, the loss was more than their normal or their periods had become more frequent. No treatment other than cauterization of the cervix was employed, and as a result no fewer than 16 (67%) were cured. Details of these cases in which the periods returned to normal after cauterization are given in Table II. It would appear, therefore, that menorrhagia

TABLE II.—*Details of 16 Cases of Menorrhagia Cured by Cauterization of Cervix*

Age of Patient	Menstrual Cycle in Days		Remarks
	Before Cauterization of Erosion	After Cauterization of Erosion	
33	5–6/21. Profuse loss	3/24–26. Average loss	
35	9–10/28. Profuse loss	6–7/28. Average loss	
27	5/14–20	5/26	
44	7/14	7/28–49	Probably climacteric
22	7/26. Profuse loss	6/26. Average loss	
43	5/14–21. Moderate loss	5/28. Average loss	Child 3½ years

17	7/14. Profuse loss	7/28–34. Average loss	
28	10/21	4/28. Average loss	
30	8/28. Profuse loss	7/28. Average loss	

is in some cases associated with cervical erosion. This fact has been noted also by Young (1930), Ground (1936), and Joubert (1946).

Pruritus Vulvae.—Fifteen patients (12%) complained of pruritus vulvae; no demonstrable cause, other than a cervical erosion, was found. All were cured by cauterization of the cervix. This eliminated the cervical discharge, which was probably the cause of the pruritus. These findings differ from those of Jeffcoate (1949).

Dysmenorrhoea.—Fourteen patients (11%) complained of dysmenorrhoea. Ten (71%) were relieved of the symptom by cauterization of the cervix. The dysmenorrhoea

was of the spasmodic type in nine, six being cured by treatment of the cervix. It was of the congestive type in five, four being cured by cervical cauterization. It seems possible that cauterization may cure spasmodic dysmenorrhoea in some cases by interfering with the sympathetic innervation of the cervix in a manner similar to that following cervical dilatation.

Dyspareunia.—Of the 11 (9%) patients who complained of deep dyspareunia 8 (73%) were cured by cauterization of the cervix. In none of these was the dyspareunia associated with any other obvious clinical cause. It has been noted that, in some cases in which there is cervical erosion, movement of the cervix during vaginal examination causes pain, and it is therefore not surprising that these patients complain of dyspareunia.

Cervical Haemorrhage.—There were 11 (9%) cases of bleeding from the cervix. Seven complained of intermenstrual bleeding and two had a post-coital loss. In addition, two patients complained of post-menopausal bleeding for which curettage of the uterus showed no cause. The bleeding, which was from the "eroded" area of the cervix, was cured in every case by treatment of the cervix.

Sterility.—Nine patients (7%) complained of sterility. Three of these, of whom one was a 1-para and two were nulliparous, conceived six, five, and one month after cauterization respectively. Cervical erosion is a recognized cause of subfertility, and these figures, though small, bear this out.

Sense of Pelvic Weakness.—Three patients, in whom no prolapse was demonstrable, complained of a sense of pelvic weakness simulating prolapse. This was entirely eliminated in two of the cases by cauterization of the cervix.

Comment on Symptomatology

Of the 128 cases of erosion, 19 (15%) were "congenital" in origin—that is, occurred in patients who had never been pregnant. A separate analysis of the symptoms in these 19 cases revealed no noticeable difference in the symptomatology.

In addition, many of the patients complained of general fatigue and listlessness, and experienced an improvement in their general health after the cervix had been treated. Many and varied symptoms not localized to the pelvis have been attributed to cervicitis by some writers (Derow, 1940; and others), and Young (1930) and others stress the role of cervicitis as a focus of infection in the aetiology of systemic disease. No instance was observed in this series.

An attempt to analyse these general symptoms has not been made, but it may be fairly stated that the local symptoms already discussed may in themselves be sufficiently worrying to the patient to make her feel a great deal better when they have been cleared up.

Treatment

Treatment consisted of cauterization of the cervix with the electric thermo-cautery. This was done in the out-patient department, except when the hymen was intact, the erosion was very large, or an anaesthetic was required for some other reason. Cauterization was not carried out during pregnancy, and six weeks were allowed to elapse after delivery before an erosion was cauterized. The technique was to expose the cervix with a speculum and to cauterize the cervical canal as the first step, without preliminary dilatation. The area of the erosion was then cauterized in lines radiating from the external os.

This procedure caused little distress in the majority of cases. It is noteworthy that during the cauterization most patients experienced aching lower-abdominal pain, in many instances similar to that of which they had previously complained.

The patients were instructed to douche twice daily with a dilute "milton" solution and to avoid coitus for six weeks. Each was given a printed slip warning her to expect a temporary worsening of such symptoms as backache, lower abdominal pain, and vaginal discharge, and to be prepared for some bleeding at the time of the separation of the slough, eight to ten days later.

All patients reported after six weeks, and if the cervix had not healed the treatment was repeated.

Results

In 109 cases the cervix was healed six weeks after the first treatment. A further 17 were healed after two treatments, and in one case three treatments were carried out before healing occurred. In the remaining case the cervix failed to heal after being cauterized three times. This cervix was subsequently amputated, but microscopical examination revealed no pathological change other than chronic cervicitis with erosion. Simple cauterization of the cervix therefore resulted in healing in 99.2% of cases.

Recurrence Rate.—When the patients were followed up six months to two years after treatment 6 of the 128 cases (4.7%) were found to have a cervical erosion, with a recurrence of symptoms. These cervices were known to have been healed six weeks after cauterization. None of the patients had been pregnant in the interim. They were therefore cases of recurrent erosion, representing a failure of treatment in 4.7% of cases and necessitating recauterization. This was carried out, and in four of the six cases the cervix was healed six weeks later. The remaining two cases were not followed up.

Complications

The complications which have been described after cauterization of the cervix are haemorrhage, pelvic infection, and atresia or stenosis of the cervical canal (Dell, 1938; Henkin, 1937; and others).

Of the 870 cases of erosion cauterized, six (0.7%) developed complications. There were two cases of haemorrhage, two cases of pelvic infection, and two cases of atresia of the cervical canal. No complications occurred in the 128 cases already analysed above.

Haemorrhage

Only two patients experienced bleeding severe enough for admission to hospital. That it was not serious even in these cases is shown by the fact that in each instance it was readily controlled by rest, sedatives, and hot douches.

Of the 128 cases analysed 47 (37%) experienced bleeding after treatment—in 42 the bleeding was slight, and in 5 it was "like a very profuse period" and the patients had to rest in bed at home for 24 to 48 hours. The occurrence and severity of haemorrhage in these cases bore no relation to the phase of the menstrual cycle in which cauterization had been carried out. This is at variance with the opinion of Maryan (1943).

Pelvic Infection

There was one case of pelvic cellulitis and one case of an acute exacerbation of a chronic salpingitis following cauterization. The two case histories are given below.

Case 3.—A nullipara aged 32 complained of constant lower-abdominal pain and of leucorrhoea for one year. There was

no history suggestive of abortion or salpingitis; the appendix had been removed. On examination the only gynaecological abnormality found was a cervical erosion. This was cauterized. Five weeks later the patient came to hospital complaining of increasing lower-abdominal pain since the cauterization, and of feeling "ill and feverish." She was flushed, her temperature was 99.8° F. (37.7° C.), and her pulse rate 96 a minute. There was tenderness but little guarding in the right lower abdomen. On vaginal examination the cervix was found to be healed. A tender, firm, ill-defined mass was palpable in the right fornix. On rectal examination the right utero-sacral ligament was found to be indurated, thickened, and very tender. A diagnosis of pelvic cellulitis was made. A five-day course of penicillin and sulphatriad, followed by short-wave pelvic diathermy, was given. The temperature and the pain subsided rapidly, though the induration in the right utero-sacral ligament persisted for some weeks. Three months later the patient was symptom-free and no sign of the cellulitis remained.

Case 4.—A 5-para aged 36 complained of a dragging pain in the left iliac fossa and of a profuse yellow vaginal discharge for eight years, since the birth of her last child. She also had menorrhagia. She was said to have had an attack of acute salpingitis two weeks before. On examination her general condition was satisfactory. Pelvic examination revealed an enlarged and tender left tube and a cervical erosion. The erosion was cauterized. A week later she complained of severe pain in the left iliac fossa and a profuse blood-stained discharge. Her temperature was 101° F. (38.3° C.). The lower abdomen was tender, particularly in the left iliac fossa. Vaginal examination revealed an acutely tender swelling, with pulsation, in the left fornix. Acute salpingitis was diagnosed and a course of penicillin and sulphatriad was begun. Next day her condition had deteriorated, and laparotomy was performed. The peritoneal cavity contained thin offensive pus, from which anaerobic streptococci were later isolated. A small necrotic left pyosalpinx was found, surrounded by adhesions. The abdomen was closed, with drainage. Convalescence was stormy for two weeks, but the patient made a satisfactory recovery.

This danger of an acute exacerbation of a chronic salpingitis after cauterization of the cervix has been pointed out by Cannell and Douglass (1935), Dell (1938), and others and is again emphasized.

Stenosis

Two cases of haematometrium occurred; these were caused by occlusion of the external os by scar tissue.

Case 5.—A 2-para aged 36 complained of abdominal pain and discomfort, and of amenorrhoea, since cauterization of the cervix in the out-patient department ten weeks before. On examination under anaesthesia the external os was found to be occluded by a thin layer of fibrous tissue, and after the passage of a sound a small quantity of dark-red blood escaped. The patient subsequently remained well.

Case 6.—A 2-para aged 56 complained of post-menopausal bleeding and of soreness of the vulva. On examination a mild degree of prolapse, kraurosis vulvae, and a cervical erosion was found. In December, 1948, dilatation and curettage, biopsy of the cervix, and cauterization of the cervical erosion were carried out under general anaesthesia. The subsequent histological examination of the curettings showed no malignant change in the endometrium, and biopsy of the cervix confirmed the diagnosis of cervicitis with erosion. Ethinyl oestradiol was prescribed on account of the kraurosis vulvae. In February, 1949, there was no further bleeding and the patient was symptom-free.

In June, 1949, six months after cauterization, she complained of lower-abdominal discomfort and of a sense of pelvic weakness. On bimanual examination the uterus was found to be bulky. When the cervix was drawn down to test the degree of uterine prolapse an adhesion over the external os gave way and a large quantity of dark-red blood escaped from the cavity of the uterus. Subsequently a vaginal hysterectomy with pelvic repair was performed on account of the concealed post-menopausal bleeding associated with prolapse. No evidence of malignancy was found in sections prepared from the uterus. The patient made an uneventful recovery.

First-stage dystocia is said to result occasionally from rigidity of the cervix due to scarring after extensive cauterization. Seven patients in the series of 128 cases were confined from 10 to 17 months after cauterization, and each had a normal first stage of labour. There is therefore no evidence in this series of dystocia following cauterization of the cervix.

Conclusions

Cervical erosion is a common and incapacitating lesion, and its clinical manifestations are not sufficiently recognized. This lack of appreciation of the symptoms of cervical erosion leads to the failure to look for, find, and treat the cause of many gynaecological complaints, thus in many instances condemning the patients to chronic ill-health as a result of such symptoms as leucorrhoea, backache, abdominal pain, and dysuria.

Worse still is the case of the patient who is subjected to some unnecessary operation on a mistaken diagnosis, when abdominal pain is the presenting symptom and the presence of a cervical erosion is overlooked.

The teaching so commonly heard that pain felt in the lower abdomen in one or other iliac fossa is ovarian in origin is, in my submission, unsound. Much more often such pain is due to cervical erosion, and the cervix should be inspected in such cases. Indeed, it should be inspected in all cases presenting the symptoms which have been discussed.

The treatment of cervical erosion by cauterization of the cervix in the out-patient department, without anaesthesia and without preliminary dilatation of the cervix, was in most cases found to be very satisfactory. Of 128 cases treated by cauterization, 99.2% were cured, with a recurrence rate of only 4.7%.

Serious complications after this treatment were few, and occurred in only 0.7% of a series of 870 cases. Although mild secondary haemorrhage from the cauterized area was relatively common, it was exceptional for the bleeding to be severe enough to necessitate the admission of the patient to hospital. Haematometrium and pelvic cellulitis may occasionally occur. In my opinion, if the cervix is cauterized in the presence of chronic pelvic infection, such as a chronic salpingitis, there is a very considerable risk of a severe acute exacerbation.

My thanks are due to Mr. Vivian Barnett for permission to use his cases, and for his kind help and encouragement in the preparation of this paper; to the nursing staff; and to Mrs. Ecclestone and other members of the secretarial staff of the Royal Salop Infirmary who helped with the follow-up of the patients.

GASTRIC ULCER OCCURRING AFTER VAGOTOMY

BY

D. M. MORRISSEY, M.Ch., F.R.C.S.

(From the Department of Surgery, Queen Elizabeth Hospital, Birmingham)

Increasing experience of the late results of vagotomy for duodenal ulcer has shown that the percentage of patients thus treated who are not relieved of their ulcer distress may be as high as 25% (Orr and Johnson, 1949) even though there is a satisfactory reduction in the free gastric acid level. Other authors, reviewing their results after shorter periods, report more favourable figures (Moore, 1947, 1948; Cameron *et al.*, 1949; Healy and Sauer, 1949) Search of the literature for the causes of unfavourable results has revealed only two records of the occurrence of gastric ulceration after successful vagotomy for duodenal ulcer. Orr and Johnson (1949) report one such case in their series of 71 cases, and Dragstedt *et al.* (1949) record two examples of this complication in their series of 197 cases of duodenal ulcer treated by vagotomy alone.

The complication is therefore rare, but is important because of the malignant potentiality of gastric ulcers and because such ulcers are sometimes remarkably painless after vagotomy (Kugel and Janzen, 1949). For this reason it is felt that the following two case reports will be of interest, as they provide further evidence of the inefficacy of vagal section in interrupting the normal course of simple gastric ulceration. These cases come from a series of 79 cases of duodenal ulcer treated by vagotomy alone at the Queen Elizabeth Hospital, Birmingham. Over fourteen months have elapsed since the most recent of these cases was operated upon, and every case has been followed up at six- and twelve-monthly intervals with barium-meal examinations and an insulin test.

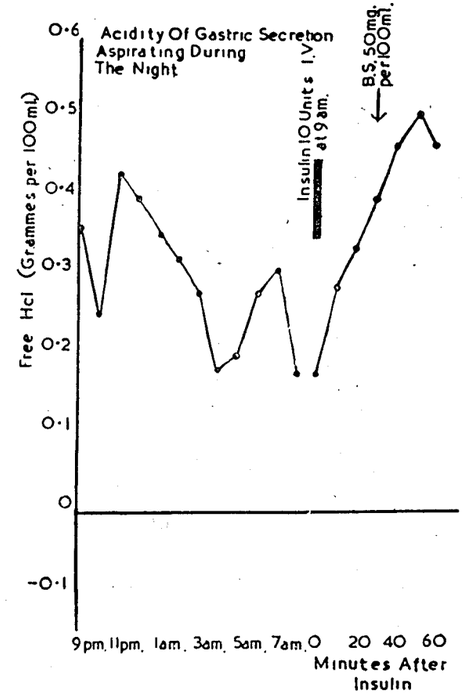

FIG. 1.—Case 1 (April 10, 1948). Night gastric secretion and insulin test before vagotomy.

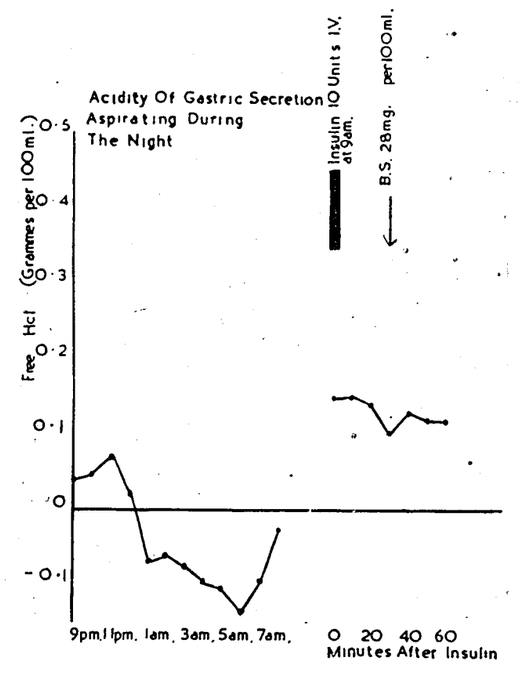

FIG. 2.—Case 1 (October 11, 1948). Night gastric secretion and insulin test six months after vagotomy.

Case 1

A wood machinist aged 40 was seen in the out-patient department in March, 1948, complaining of symptoms of duodenal ulcer of 13 years' duration. From 1935 to 1938 his periods of pain lasted approximately one week, with intervals of freedom up to three months. From 1939 onwards his symptoms were more persistent and were associated with vomiting. Barium-meal examination in 1944 revealed a duodenal ulcer, and from that time he followed a careful dietary regime which controlled his symptoms so that he was able to continue at work. During May, 1946, the ulcer perforated. After operation he was symptom-free for seven months. From January, 1947, his symptoms were more or less continuous. There was no haematemesis or melaena.

Examination revealed a well-built man, weighing 142 lb. (64.4 kg.) and 5 ft. 9 in. (175 cm.) in height, with an abdominal scar from his previous operation. Except for tenderness on palpation of the epigastrium, physical examination revealed no further abnormality. The relevant points from his laboratory investigations and *x*-ray examination were as follows:

Barium meal and screening: duodenal deformity present; stomach emptying in four hours. Radiograph of chest was normal. Blood count: red cells, 5–6 millions per c.mm.; Hb, 15.7 g.%; C.I., 1.01; white cells, 5,700 per c.mm. A fractional test meal revealed the following: fasting juice 29 ml.; no mucus in any specimen; bile in the 2¼-hour specimen; maximum acidity in 1¼-hour specimen (0.22 g. of free HCl per 100 ml.); residual juice 2 ml. The histamine test showed maximum acidity in a 30-minute specimen (0.42 g. of free HCl per 100 ml.). The night fasting gastric secretion (maximum acidity 0.43 g. of free HCl per 100 ml.) and the insulin test are graphically presented in Fig. 1.

On consideration of these findings the case was thought suitable for treatment by vagotomy, but it was felt that, even though there was no evidence of pyloric narrowing, the site of the previous perforation should be inspected.

On April 15, 1948, under general anaesthesia, the left side of the chest was opened after excision of a segment of the eighth rib. Through a 4-in. (10-cm.) incision in the diaphragm, forward from the region of the oesophageal hiatus, the stomach was carefully inspected and the patency of the pyloric canal and duodenum confirmed by palpation. A duodenal ulcer was present, but there was no evidence of gastric ulcer. The diaphragmatic incision was closed and vagal section carried out in the usual manner with resection of 2-in. (5-cm.) segments of the nerves.

Convalescence was uneventful, the patient being discharged on the 11th day. His weight on leaving hospital was 138 lb. (62.6 kg.). By the third month following his operation he was perfectly well, had resumed work, and had gained 14 lb. (6.4 kg.) in weight to 152 lb. (68.9 kg.). On October 1 he complained of epigastric pain after food, relieved by vomiting, and volunteered the information that these fresh symptoms were quite unlike his previous ones. He began to lose weight, and when readmitted to hospital on October 15 he weighed 136 lb. (61.7 kg.). The insulin test was repeated (Fig. 2), and barium-meal examination now showed a gastric ulcer about the middle of the lesser curve, with no delay in stomach-emptying. The duodenal cap was deformed but not tender. His symptoms were not controlled by diet and alkalis, and four weeks later a partial gastrectomy was performed.

At operation the gastric ulcer was readily identified about midway along the lesser curve, as was the scar of the old duodenal ulcer, which appeared to be healed. Examination of the stomach afterwards showed a peptic ulcer about ½ in. (1.2 cm.) in diameter, with yellow necrotic base, penetrating deeply into the stomach wall. Histological section revealed a complete breach of muscular coat and replacement by fibrous tissue without evidence of malignancy. The patient's convalescence was again satisfactory, and he remained symptom-free 21 months later.

Case 2

A man aged 45 had had epigastric pain after meals for 12 years, with periods of freedom from symptoms up to two months. He had been treated by six weeks' rest in bed and dietary measures on two occasions, but pain recurred on resuming full work. There had been no haematemesis or melaena. Examination showed a well-nourished man of 5 ft. 7 in. (170 cm.) in height, weighing 129 lb. (58.5 kg.). Physical examination was entirely negative.

FIG. 3.—Case 2. Photograph of stomach showing two gastric ulcers.

Fractional test meal: "high normal" acid curve with a large volume of resting juice (194 ml.) containing charcoal. Blood count: red cells, 5,090,000 per c.mm.; Hb, 14.1 g.%. A barium meal showed deformity of the duodenal cap, thought to be due to chronic ulceration.

On February 11, 1949, laparotomy was carried out by Mr. B. N. Brooke. A chronic duodenal ulcer was seen on the anterior wall of the first part of the duodenum with some scarring, but no appreciable stenosis and no evidence of gastric ulcer. In view of this he considered that vagal section was justifiable, and this was effected below the diaphragm.

The patient's immediate convalescence was uneventful, and he was discharged from hospital 12 days later. Three months after the operation he was still symptom-free, had gained 17 lb. (7.7 kg.) in weight, and had resumed his normal occupation of grocer. He was enthusiastic about his progress and was now able to eat a variety of foods which he had not been able to do for many years. He was seen again on July 13, 1949, when he complained of foul eructations and occasional attacks of diarrhoea, but no postprandial pain or discomfort. On August 25 he had a sudden severe haematemesis (he alleged that he vomited about three pints (1.7 litres) of blood-stained fluid), followed by repeated tarry stools.

On admission to hospital next day his red blood cells numbered 2,300,000 per c.mm. and haemoglobin was 44%. He was given a slow transfusion of two pints (1.14 litres) of blood, and after a temporary rise his blood count and haemoglobin began to drop steadily. The stools still contained altered blood on the tenth day after admission. In view of the continued bleeding a further transfusion was given and a partial gastrectomy was performed on September 6 by Mr. Brooke. On this occasion the old duodenal ulcer appeared to have healed, but there were now two small but deep gastric erosions about 3 in. (7.5 cm.) from the pylorus on the lesser curvature. Histological examination of the ulcers revealed a complete breach of the muscle coat and fibrous tissue formation at their bases (Fig. 3). The patient's convalescence was again uneventful. He was discharged from hospital 12 days after operation with a blood count of 4,900,000 red cells per c.mm. and 98% haemoglobin. He has remained symptom-free up to the present time (July, 1950).

Comment on the Cases

Post-operative insulin test results are not available in Case 2, as the patient was admitted to hospital with haematemesis within the six-months period, but the direct evidence of healing of his duodenal ulcer with the entire relief of symptoms while on a full mixed diet probably indicates that complete vagal section was achieved. The result of the insulin test six-months post-operatively in Case 1 is considered to be compatible with complete vagal section, as there was no rise of the acid level following an induced hypoglycaemia of 28 mg. per 100 ml. The view that the gastric ulcer developed after the vagotomy is based on the *x*-ray evidence and examination at the time of operation, which of necessity, by reason of the approach used, involved manual retraction of the lesser curve.

Discussion

The addition of these two cases to those already reported gives an incidence of 5 in 347 cases of complete vagotomy for duodenal ulcer. Many of the other causes of unfavourable results, such as recurrence and non-healing of the duodenal ulcer, may be explained on the grounds of incomplete nerve section, but such tests as we possess—the insulin test, lowering of gastric acidity, clinical and radiological healing of the original ulcer—indicate that in these cases the vagal section was complete. Dragstedt thought that gastric stasis may have been a causal factor, as he has not had this complication in any of 262 cases of duodenal ulcer treated by vagotomy and gastroenterostomy; and Orr and Johnson found gastric retention in their case, which also presented with painless haematemesis. There was evidence of gastric retention in my Case 2, but barium-meal examination of Case 1 at the time of onset of ulcer symptoms did not reveal any delay in gastric emptying.

It is difficult to reconcile the occurrence of gastric ulcer after successful vagotomy with current views on the pathogenesis of the condition. There is after vagotomy a lowering of the gastric acid level and particularly of the volume and degree of acidity of the night acid secretion. This problem might be solved if an unequivocal test of complete vagal section were available; and the observations of Brooke (1949) with regard to the insulin test are supported by the findings of Walters and Brownson (1948) and Walters *et al.* (1949) that in their series the clinical results in those cases showing a negative post-operative insulin test were similar to those showing a positive response. Without therefore being able to say that vagotomy has any causal relationship to the gastric ulcers in the cases described above, it does seem that the lowering of acidity brought about by vagal section affords no protection against ulceration developing. Further confirmation is forthcoming from the report of Nuboer (1949), who has described the occurrence of gastric ulceration in some of his cases following resection of the oesophagus for malignant disease, when the vagi were necessarily completely divided.

These two cases are obvious failures following vagotomy in the treatment of duodenal ulcer. The Birmingham series referred to above contains cases which have had other undesirable sequelae of the operation: these will be recorded when the series is fully analysed.

Summary

In a series of 79 cases of duodenal ulcer, two cases developed gastric ulcer following successful vagal section. These two cases are described.

The view is expressed that vagotomy is unsuitable as a treatment of gastric ulceration and confers no protection against the development of a gastric ulcer.

In both cases the gastric ulcers developed within six months of the vagal section.

I am indebted to Mr. B. N. Brooke for permission to publish Case 2, and to Professor F. A. R. Stammers for his guidance and help in the preparation of this paper.

According to a press report the New York Academy of Medicine has arranged a series of "refresher" lectures for doctors in New York which will be given over the radio. Believed to be the first of its kind, the series is designed to bring the latest scientific developments in medicine to doctors who are unable to attend medical conventions, who have no hospital connexions, or who are too busy to read through the medical journals. The one-hour programmes, to be broadcast every Thursday evening, will actually be transcriptions of papers delivered at the Academy's regular Friday afternoon lectures. A test broadcast last April on A.C.T.H. and cortisone received such wide response that planning went ahead for the series. The New York radio authorities are now planning to start a similar series of "refresher" lectures for lawyers and are hoping to expand the idea to other professions.

EPIDEMIC OF BENIGN DRY PLEURISY

BY

D. G. H. SYLVESTER, M.B.

Medical Superintendent, St. Mary's Hospital, Paddington, W.2

(From the Student Health Service)

Since Sylvest's original monograph on Bornholm disease, or epidemic myalgia, was published in 1933, a similar condition has been described in countries as widely separated as Scandinavia, India, and the United States. A diagnosis of benign dry pleurisy has been made in cases with associated pleural friction.

In this country epidemics have been sporadic in appearance and often confined to localized communities such as schools (Attlee *et al.*, 1924; Carter, 1933), children's hospitals and convalescent homes (Lloyd, 1924; Williamson, 1924), or to single households (Howard, 1938), while Pickles (1933, 1939, 1948) has described several outbreaks in village communities in Yorkshire.

Scadding (1946) reviewed the literature on Bornholm disease and described a series of similar cases observed among soldiers in the Middle East. These were characterized by a high incidence of pleural friction (55% of 20 cases), and he consequently named them benign dry pleurisy.

This paper records an epidemic of benign dry pleurisy occurring in two households in the Bayswater district of London during September and October, 1949. Eleven cases in all were encountered, two of which were observed during the course of their illnesses.

Case 4

A healthy medical student aged 22 became ill on October 4: he complained of severe pain in both upper quadrants of the abdomen, which was lancinating and worse on coughing or deep breathing. It radiated first to the right, then to the left shoulder, and was accompanied by headache and sweating.

When first seen on October 5 his breathing was shallow and painful and his temperature 100.8° F. (38.2° C.), but, apart from upper abdominal tenderness, there were no abnormal physical signs. In view of the position and radiation of the pain, the absence of cough or abdominal rigidity, and his clean tongue, a tentative diagnosis of diaphragmatic pleurisy was made.

On October 6 his temperature had risen to 101° F. (38.3° C.) and his respirations were 40 a minute. The pain and tenderness were now localized in the region of the left costal margin. A chest radiograph showed no abnormality at the left base; there was, however, a slight but definite decrease in translucency at the right base, together with slight elevation of the right half of the diaphragm. The total leucocytes were 8,000—polymorphs 6,000 (75%), lymphocytes 1,600 (20%), monocytes 400 (5%).

On October 7 there was a pleural rub in the right axilla which persisted for three days. His E.S.R. (Westergren) was 18 mm. in one hour and the Mantoux reaction was positive to 1 in 1,000 tuberculin. The diaphragm moved normally on screening. Recovery was rapid; by October 11 he was free of symptoms and there was no relapse. A radiograph of the chest taken on November 16 showed no residual shadowing.

Case 10

On October 22, eighteen days after the above patient had fallen ill, a second medical student, aged 26, was seized with pleuritic pain in the right shoulder which wakened him in the night and which spread to the right upper abdomen when he got out of bed. The pain was worse on lying down and prevented him from lying on the affected side. His temperature was 99° F. (37.2° C.) and there were no abnormal physical signs. On October 23 the pain had spread to the left shoulder and

right lower chest, there was right upper abdominal tenderness, and a pleural rub which persisted for twenty-four hours was heard below the right nipple. By the 24th he was free of symptoms. The total leucocyte count was 7,000—polymorphs 4,340 (62%), eosinophils 770 (11%), basophils 70 (1%), lymphocytes 1,540 (22%), monocytes 280 (4%). The E.S.R. (Westergren) was 4 mm./hour. A chest radiograph, however, was normal.

The second patient stated that other residents at his lodgings had also suffered from similar symptoms. When they were interviewed it was evident from the typical history given in nine cases that there had been an epidemic of benign dry pleurisy similar to that described by Scadding (1946).

All the cases occurred in two lodging-houses under common ownership in adjacent streets in Bayswater. The patients were healthy adults between the ages of 19 and 28, in the proportion of nine males to two females. The onset of the epidemic was dated to September 28, when, in House A, the manageress, aged 24, wakened with pain under both costal margins. Four days later (October 2) her sister, living in House B, fell ill with similar symptoms. Seven further cases were identified in House A and two in House B. They are listed in Table I.

TABLE I

House A (16 Residents)				House B (20 Residents)

11	20	,, 24	,, ,,				

Summary of the Eleven Cases

Prodromal Symptoms.—One case only had catarrh preceding the attack of pain; there were no cases with sore throat (as have been reported by Attlee *et al.*, 1924). The onset was sudden in all cases, with pain as the presenting symptom. The pain was always suggestive of pleurisy and was worse on lying down. Unlike the pain of pleurisy associated with pneumonia or tuberculosis, it was worse when lying on the affected side, possibly because immobility of the intercostals in this position caused increased movement of the diaphragm. The situation of the pain at onset was right-sided in 9 of the 11 cases, and is set down in Table II. The position of the pain and its reference to

TABLE II.—*Situation of Pain at Onset*

	No. of Cases
Right shoulder	3
Upper abdomen	3
Under right costal margin	2
In right arm and under right costal margin	1
In right chest and right shoulder	3

the shoulders suggests its origin in the diaphragm, and it is interesting that in Case 7, whose pain was in the right subcostal region, referred pain in the right shoulder was produced by pressure below the right ribs.

The average length of illness was three to four days, the minimum being two and the maximum seven days, and no relapses occurred. Pleural friction was heard in the two cases seen during the illness. It was of short duration and unilateral in both cases.

Radiographic and Blood Examinations.—Leucocyte counts were normal in both cases treated in hospital; the E.S.R. was normal in Case 10 (4 mm./hour) and raised in Case 4 (18 mm./hour). In previous series, chest radiographs have been normal and the diaphragm has moved normally on screening. In one of the two cases radiographed in the present epidemic abnormal findings were present. On the second day of illness Case 4 had a slight but definite decrease in translucency at the right base, which was more marked on the fourth day and was associated with slight elevation of the right half of the diaphragm. These *x*-ray changes were minimal but definite, and were possibly caused by pleural oedema.

Differential Diagnosis.—Finn (1947), in Boston, writing of a large series of cases, reports confusion with pneumonia, glandular fever, influenza, "non-paralytic poliomyelitis," lymphocytic chorio-meningitis, hepatitis, and acute abdominal emergencies. Pickles (1933) has emphasized that faulty diagnosis from the acute abdomen may lead to needless laparotomy. The pleural friction heard in the two cases here described clearly indicated the source of the pain.

Complications.—Pericarditis and orchitis have been quoted by Finn *et al.* (1949) in Boston and by Jamieson and Prinsley (1947) in Aden, while McConnell (1945), in Pennsylvania, recorded a high incidence of neurological symptoms (68% of 16 cases). There were no complications in this series.

Epidemiological Aspects

Seasonal Incidence.—The disease seems to be most prevalent in the summer and early autumn, when these cases occurred, resembling poliomyelitis in this respect. It is of interest that three cases of paralytic poliomyelitis and one of polio-encephalitis occurred among the hospital staff during the same period as the cases of epidemic pleurisy.

The incubation period is quoted by Finn (1947) as 8–10 days. In this epidemic it would appear to lie between 2 and 19 days. The cases occurred in two groups at intervals of ten days, the first group including occupants of both houses.

Case 2 may have been infected from her sister (Case 1), or both may have derived their infection from a common unidentified source. If Case 4 was infected from one of the preceding cases this could only have been from Case 2, making the minimum incubation period two days. The longest possible incubation period in these cases is provided by Case 11, who returned from holiday on October 5 and developed symptoms on the 24th (19 days).

The second group, Cases 8 to 11, consists of students who returned to London from holiday on October 5. Two of them, Cases 10 and 11, returned to share adjacent rooms with Cases 3 and 7 respectively, Case 3 being in bed with the disease at the time. Their accommodation on and after October 5 is shown in Table III.

TABLE III.—*Occupants of Adjacent Rooms in House A on October 5*

	Case	Onset of Symptoms
Room 1	3	October 3
	10	,, 22
Room 2	7	,, 9
	11	,, 24

Cases 10 and 11 returned from holiday on October 5. Prior to October 5, Room 1 was occupied by Cases 3 and 7, Room 2 being let to temporary visitors.

Causative Agent

Attempts to isolate any infective agent have met with little success. Small (1924) suggested a plasmodium; other workers have failed to isolate any bacteriological agent; nor has any virus been isolated from stools or nasal washings. Henle (quoted by Finn *et al.*, 1949), in complement-fixation tests for the viruses of influenza and chorio-meningitis, had negative results.

The absence of any other infective agent and the nature of the outbreaks suggest a virus as the probable cause. In the present series complement-fixation tests for the Coxsackie 2 strain of virus were kindly performed by Dr. G. M. Findlay in March, 1950 (five months after the last recorded case). Sera from five cases were tested, and the results are listed in Table IV. Three cases were strongly positive and two faintly positive; two normal students taken as controls were negative.

TABLE IV.—*Result of Complement-fixation Tests*

Serum	Antigen		
	Coxsackie 1	Coxsackie 2	Normal Mouse
Case 4	—	+ 1 in 5	—
Case 7	—	+ 1 in 20	—
Case 9	—	+ 1 in 20	—
Case 10	—	+ 1 in 20	—
Case 11	—	+ 1 in 5	—
Control I	—	—	—
Control II	—	—	—

This virus, which is transmissible only through newborn mice, was originally isolated by Dalldorf and Sickles (1948) and later by Melnick *et al.* (1949) from the faeces of cases of "non-paralytic poliomyelitis" in the United States. In mice the infection involves skeletal muscles, producing severe myositis and paralysis, while the central nervous system is unaffected. Death commonly occurs within twenty-four hours of the onset of paralysis.

Transmission

The exact mode of transmission is unknown. Melnick *et al.* (1949) isolated the Coxsackie strains from sewage and from flies in areas where epidemics of "non-paralytic poliomyelitis" occurred.

It is interesting that the first case in the present series was the cook for the whole of House A, in which seven further cases occurred, and that Case 2, the first in House B, assisted her parents in preparing food for this household. While this strongly suggests an alimentary spread at the onset of the epidemic, later cases may have arisen from droplet infection owing to the close proximity of their living quarters. On inquiry, however, no cases could be traced outside the two households among their day-to-day contacts at work.

Coincident with the epidemic, one sporadic case was also seen during the illness. A transitory bilateral pleural rub was present and the complement-fixation reaction to the Coxsackie 2 strain was strongly positive (1 in 20). This case also had a minimal unilateral pleuritic reaction on *x*-ray examination which did not persist.

Summary

An explosive outbreak of benign dry pleurisy is reported in two near-by households under common ownership. Two cases are described in detail.

The epidemiological aspects of the outbreak are discussed.

Five months after the illness the sera from five cases were shown by Dr. G. M. Findlay to give positive complement-fixation reactions to the Coxsackie 2 strain of virus as compared with negative results in two normal controls.

It is suggested that, in view of the seasonal incidence and the possible relationship to "non-paralytic poliomyelitis," the mode of spread may be similar to that of poliomyelitis itself and is possibly alimentary.

I wish to thank Dr. G. M. Findlay for his advice and for performing the serological tests, and Professor R. Cruickshank and Dr. T. A. Kemp, physician in charge of the Student Health Service, St. Mary's Hospital, for their guidance and helpful criticism.

ADRENAL INSUFFICIENCY AFTER SURAMIN TREATMENT OF PEMPHIGUS

BY

L. J. MAHONEY, B.A., M.D.

AND

H. J. BARRIE, B.M., B.Ch.

(From the Department of Pathology, University of Toronto, Toronto, Canada)

[WITH SPECIAL PLATE]

Suramin ("germanin") has been used for the treatment of pemphigus since 1931. It is a carbamide of a complex salt of trisulphonic acid, is also known as "naphuride" and "Bayer 205," and was originally introduced for the treatment of trypanosomiasis. It is known to have toxic effects on the renal tubules and haemopoietic system. Wells *et al.* (1937) have shown that when given to guinea-pigs in amounts comparable with human doses it causes damage to the renal tubules and adrenal cortex, but the full picture of so-called adrenal atrophy was not achieved in their experiments. Two cases of acute adrenal insufficiency following suramin treatment have been reported (Wells *et al.*, 1937; Tomlinson and Cameron, 1938), but any conclusion that these adrenal changes were solely due to the drug is confused by the fact that many of the features of pemphigus, especially in acute cases, strongly resemble those of adrenal insufficiency and are sometimes improved by the administration of cortical extracts.

Furthermore, Goldzieher (1945) has shown that signs of severe organic damage may be found in the adrenal cortex in deaths from pemphigus. None of the six cases he studied had received suramin,* and he regarded their lesions as terminal secondary processes such as occur in other severe debilitating diseases.

The paradox is a familiar pharmaceutical one—that a drug which mimics the effects of a disease should be beneficial for it—and perhaps the problem is one of correct dosage for the individual.

Wells *et al.* state that none of the persons who have been followed up for some time after suramin therapy for trypanosomiasis have shown any delayed symptoms attributable to adrenal insufficiency. We are therefore in somewhat

*Personal communication.

the same position as we once were with agranulocytosis and sulphonamide therapy. From consideration of only a few cases it is hard to be certain whether the disease or the drug plays the dominant part in producing the lesion. It seems to us likely that in the case of suramin it is a summation effect. We think that this further experience with suramin should therefore be reported. No further comment is necessary.

Case Report

A 37-year-old woman of Scottish-Canadian ancestry was perfectly well until seven months before death, when, in the second month of pregnancy, she developed typical lesions of pemphigus. During the next four months two courses of suramin were started but were stopped after one injection (0.25 g.) because of the development of fever. Three months before death she was delivered of a normal seven-months male infant by elective caesarean section and two weeks later developed rapid mood swings, hallucinations, and delusions, and was admitted to hospital.

Examination revealed a dehydrated, confused, belligerent, agitated, and hallucinated woman whose skin was covered with lesions in all stages of healing, varying from patches of erythema to bullae measuring 2 in. (5 cm.) in diameter. Her temperature varied from 99 to 100° F. (37.2 to 37.8° C.). Her blood pressure was 108/60. The haemoglobin was 70% and the leucocytes numbered 16,000 per c.mm. The urine contained many white cells but no albumin, and cultured *Bact. coli*. Her N.P.N. was 27 mg. per 100 ml.

She was treated with electric shock, and a third course of suramin was completed five weeks before death (1 g. every two days for ten doses), with definite improvement in her mental condition and her skin lesions. No albumin appeared in the urine immediately after the course of suramin. Because of a falling haemoglobin 500 ml. of whole blood was given. At this time she developed an upper respiratory infection which persisted. Two weeks before death abnormal pigmentation of her skin and buccal mucous membrane was noticed, and over a period of a few days she developed anorexia, nausea, and vomiting, and her temperature rose suddenly to 104° F. (40° C.), her pulse to 130, her respirations to 30, and her blood pressure fell to 60/46. Her urine now contained 1+ albumin and her blood chlorides were 489 mg. per 100 ml.

Because of the signs of adrenal insufficiency 10 ml. of "cortin" was given every four hours, at first intravenously and then intramuscularly, together with a continuous intravenous infusion of 5% glucose in normal saline and 100,000 units of penicillin intramuscularly twice a day. The nausea and vomiting decreased, her blood pressure remained around 90/50, and her temperature varied from 99 to 100° F. with occasional elevations up to 102° F. (38.9° C.). Her serum chloride level remained around 540 mg. per 100 ml.

Five days before death her temperature rose to 105° F. (40.6° C.) and then fell to normal, and, though her blood pressure was 100/50 and she appeared to be getting no worse, she died suddenly in the middle of the night.

Necropsy Findings

At necropsy typical Addisonian pigmentation of the buccal mucous membrane and skin was found, and large branny brown macules were scattered over the trunk and extremities.

The heart was soft and flabby; the spleen (470 g.) and liver (2,200 g.) were enlarged and both were congested. Several of the abdominal lymph nodes were enlarged and firm. The adrenals were thin, weighed 10 g. combined, and on cut section all laminae were narrow. The lipoid zone was even and contained lipoid which varied slightly in brightness. It was separated from the grey medulla by a vivid, sharply demarcated reddish black stripe which was much darker than the usual pigment zone.

There was moderate oedema of the brain (1,420 g.), with some herniation of the hippocampal unci and cerebellar tonsils, and moderate compression of the ventricles. All other organs appeared normal.

Microscopical Examination

Fragmentation of the myocardium, congestion of the liver and spleen, and oedema of the abdominal lymph nodes were found, but nothing else of importance except in the adrenals and thyroid.

Adrenals.—Sections of each adrenal were alike. The capsule and its blood vessels appeared normal. The most obvious change was a band of extreme congestion and haemorrhage occupying the inner half of the cortex (Plate, Fig. 1). In it could be seen isolated ghosts of pigmented cells. Peripherally there were radial bars of dilated sinusoids traversing the rest of the cortex, but the capillaries of the medulla were only slightly dilated and then only at the line of junction with the cortex. Because of the variable arrangement of the laminae in the centre of the adrenal it was difficult to be certain that none of the medullary cells were necrotic; most of them showed no evidence of it but were rather widely separated by oedema. In the outer half of the cortex the sinusoids could be recognized, and the spaces between were occupied by vacuoles separated by thin wisps of cytoplasm. Sometimes one could be certain that these vacuoles were in cells and sometimes it was difficult to be sure. At rare intervals there were cells without lipoid occurring singly and in clumps, and many of these showed an acute autolytic form of necrosis and the adjoining sinusoids were enormously dilated (Fig. 2). In frozen sections the vacuoles were found to contain abundant lipoid, most of which was doubly refractile. In summary, there was complete necrosis of the zona reticularis, and vacuolar degeneration and patchy necrosis of the remainder of the cortex.

Thyroid.—The thyroid acini were small, lined by flattened epithelium, and contained little but rather darkly staining colloid. There were many bands in which the acini had atrophied and had been replaced by lymphoid tissue.

Summary

A case is reported of a woman of 37 who developed pemphigus in pregnancy and died of acute adrenal necrosis five weeks after finishing a course of suramin therapy.

We would like to thank Dr. W. Garbe for permission to publish this case.

A professional conference organized by the Royal College of Nursing and attended by some hundreds of nurses was held in London on June 28 to discuss the educational scope and potentialities of the Nurses Act, 1949. Miss Ethel Strudwick presided, and the principal address was given by Miss Enid Russell Smith, Under Secretary, Ministry of Health. Miss Russell Smith said that the Act provided for the first time for the financing of nurse training separately from the finances of the hospital. It ensured that the money for such training would not be diverted to any other object. The General Nursing Council had been reconstituted and strengthened, educationally and financially, to enable it to carry out its new function. There had previously been a two-tier system, consisting of the General Nursing Council and some 600 training schools; this was bound to be inflexible. Under the Act there would be an intermediate tier of 14 area management committees, each with responsibility for about 40 training schools. Miss Joan B. Price, sister-tutor at the Sheffield Hospitals School of Nursing, said that this school was an educational establishment for four hospitals with 1,200 beds, meeting the educational needs of 500 to 600 nurses. It was financially and administratively independent of the group of hospitals with which it was associated. The teaching staff were appointed by the school itself. There was a most valuable connexion with the medical faculty of the university. Student nurses attended the university and used the lecture theatre, and university lecturers visited the school.

THE INDICATIONS FOR GLOBIN INSULIN

BY

DAVID W. PUGH, D.S.C., M.D., M.R.C.P.

Physician, Bath Clinical Area; Late Senior Registrar, the London Hospital

When globin insulin was introduced over six years ago it was hoped that a single daily injection of this type of insulin would control most diabetics. Mosenthal (1944) reported on a series of 50 ambulant diabetics treated with globin insulin (G.I.) and showed that as a rule G.I. produces a fall in blood sugar within two hours of injection. This effect is intermediate between that of soluble insulin (S.I.) and zinc protamine insulin (Z.P.I.). The action lasts for 12 to 16 hours and sometimes 24 hours, depending on the size of dose and other factors.

Eaton (1944) reported on a series of 41 diabetics treated with G.I. who had failed to do well on other types of insulin. He showed that a combination of Z.P.I. and S.I. produces a lower fasting blood sugar than G.I., but that in suitable cases G.I. gave results more nearly physiological than did any other single type of insulin, and that its action closely resembled that of mixed doses of Z.P.I. and S.I. containing over 50% of the latter.

These favourable reports encouraged other clinicians to use G.I. Wauchope (1948) reported enthusiastically on a series of 366 diabetics treated with G.I. as out-patients thus: "All types of patient do as well on a single dose of globin insulin each day as on other kinds of insulin, singly or in combination." This has not been quite the experience at the diabetic clinics of the London Hospital, and I was prompted, therefore, to review the records of diabetic patients who had been treated with G.I. since its introduction in 1943. In that year a large number of patients attending the London Hospital were changed from a twice-daily dose of S.I., or a single combined dose of S.I. and Z.P.I., to a single daily dose of G.I. This dose was usually two-thirds of the previous total dose of other insulins. In addition, a small number of new diabetics were treated with G.I. from the start. Out of a total of approximately 1,800 diabetics treated between 1943 and 1948, 360 were given G.I. In 55 of these, control of the diabetes proved unsatisfactory, so that a change to some other kind of insulin had to be made.

It is of interest to note at this point that during the same period over 750 patients were being maintained satisfactorily on a twice-daily dose of S.I. or a combined daily dose of Z.P.I. and S.I.

The methods of control were those in general use at diabetic clinics. Some patients attended weekly or fortnightly, others at monthly or three-monthly intervals. The urine examined was the early morning specimen, unless otherwise stated, using Benedict's reagent. Control was mainly by the result of urine examination, blood sugars being estimated in difficult cases. The diet employed during the period was the calorie-control type of Crooke and Scott (1943); usually of 2,000 calorie value, but higher in adolescent subjects and lower in the overweight and more elderly.

Of the 305 cases successfully treated by G.I. the majority were elderly patients with diabetes of no more than moderate severity. Only 36 (12%) were under 40 years of age, and 79% received a single daily dose of G.I. of less than 40 units. Thus the cases successfully treated by G.I. were usually not severe and they belonged to the older age groups. Such cases are usually easy to control on any regime.

Of the 55 cases who failed on G.I., 22 were males and 33 females. The majority were young (18 were below the age of 40—i.e., 35%). The 55 cases were made up of (*a*) 17 new diabetics who began treatment on G.I.; and (*b*) 38 old diabetics who had previously been treated with either twice-daily S.I. or a once-daily injection of Z.P.I. and S.I. Of this latter group all except one were receiving more than 30 units of insulin per day.

The patient who is poorly controlled on G.I. often shows a characteristic picture. He is usually under middle age, and his diabetes is of moderate or greater severity. He complains of nocturnal thirst and polyuria, and an early morning specimen of urine will show heavy glycosuria (more than 2% sugar, Benedict's test brick red precipitate). There is usually steady loss of weight (7 patients lost over a stone (6.3 kg.) in weight, and 13 patients over 10 lb. (4.5 kg.) in weight, in periods varying from three to nine months). Female patients complain of troublesome pruritus vulvae. If the dose of G.I. is increased to overcome these symptoms midday reactions usually occur, as happened in 18 of these cases.

The reactions tended to occur about four to six hours after taking the insulin. Ten patients suffered reactions at midday, eight in the late morning, and two in the late afternoon. Those patients who had experienced reactions from S.I. or Z.P.I. usually complained that G.I. produced more severe reactions. The feature that particularly worries the patient is the suddenness of the reaction. Patients on a single daily morning dose of G.I. should therefore have their main meal of the day at midday.

I believe that this combination of nocturnal thirst and polyuria, with midday or afternoon reactions if the dose of insulin is increased, along with heavy morning glycosuria, loss of weight, and pruritus vulvae in women, constitutes a clinical picture which might be called the "failed-globin syndrome," and it is not uncommon when globin insulin is used in unsuitable cases. When it appears, a different insulin arrangement is obviously necessary. This may be either a twice-daily dose of S.I., or often more conveniently a combined daily morning dose of Z.P.I. and S.I.

As would be expected, if a patient continues with a heavy glycosuria, the risk of ketosis is increased. Ten of these patients had episodes of ketosis while taking G.I. Since changing back to S.I. twice daily or S.I. and Z.P.I. there has been only one incident of ketosis, in a patient with cellulitis of the leg, among the 55 cases.

All of the 55 patients have subsequently been adequately controlled on a twice-daily dose of S.I. or on a combination of Z.P.I. and S.I. Over 80% of them have now been under observation for a further two years. The glycosuria has been stemmed, with gain in weight and relief from nocturnal thirst and polyuria. The troublesome nocturnal pruritus vulvae has disappeared in nine out of ten women affected.

Conclusions

(1) Globin insulin is often successful in the treatment of diabetes of older persons when the total daily dose of insulin does not exceed 40 units.

(2) Young and severe diabetics, when treated with a single daily injection of globin insulin, may show heavy morning glycosuria and suffer from nocturnal polyuria, thirst, and loss of weight.

(3) An increase in the dose of globin insulin in such patients usually produces midday reactions without relief of these symptoms.

(4) Such patients can be better controlled by a twice-daily dose of soluble insulin, or a combination of soluble insulin and zinc protamine insulin.

It is a pleasure to acknowledge the help and criticism of Dr. R. R. Bomford and Professor Clifford Wilson in preparing these notes, and the permission to use the case histories of their patients.

SOME ASPECTS OF SCHISTOSOMA MANSONI INFECTION

BY

DAWOOD MUSTAFA, D.K.S.M.

Medical Registrar, Khartum Civil Hospital

Extensive subperitoneal miliary infiltration of the small intestine by *Schistosoma mansoni* and enlargement and heavy invasion of the mesenteric and retroperitoneal lymph nodes by ova of the same schistosome are rare enough to warrant being recorded. The post-mortem findings of three cases are therefore given.

Case Reports

Case 1. "Miliary Schistosomiasis" of Subserous Surface of Small Intestine.—A man aged 35 was admitted to hospital on September 14, 1949, with acute dysenteric symptoms. *Sch. mansoni* ova were found in his stools. He died five days later. On post-mortem examination the outer surface of the whole length of the small intestine was found to be studded with tiny nodules which were macroscopically indistinguishable from miliary tubercles. Only a few such tubercle-like lesions were seen on the surface of the lowermost portion of the large bowel. The mesenteric and retroperitoneal lymph nodes were moderately but universally enlarged. Some were haemorrhagic. The outer surface of most of the large bowel as well as the parietal peritoneum were devoid of nodules. The inner lining of the small intestine was congested and showed some minute submucous haemorrhages, but no ulceration or overgrowth. Ulcers and polypoid growths were, however, seen on the mucous surface of the whole length of the large bowel. The liver was cirrhotic. Scrapings from the miliary nodules on the surface of the small intestine revealed large numbers of ova of *Sch. mansoni*, while digested sections (with sodium hydroxide) of the mesenteric and retroperitoneal lymph nodes were simply clumps of such ova. They were negative for tuberculosis.

Case 2. Heavy Adult Infection; Enlargement and Heavy Invasion of Mesenteric and Retroperitoneal Lymph Nodes by Ova.—A man aged 30 was admitted on September 11, 1949, with acute watery diarrhoea. On admission he was extremely toxic, dehydrated, and anaemic. Stools were positive for *Sch. mansoni* ova. He died ten days later. At necropsy a very heavy adult infection of the portal vein and of its intrahepatic tributaries was found. Most were present in the portal vein. The cut surface of the liver, which was soft and dark red, showed many adult worms as well as ova. The mesenteric and retroperitoneal lymph glands were all enlarged and were teeming with ova. The transverse and descending colon showed extensive submucous polypoid growths and ulcers.

Case 3. Minimal Intestinal Lesions; Enlargement of Mesenteric Lymph Nodes.—A man aged about 40 was admitted on August 8, 1949, for fever. He had no intestinal symptoms or signs on admission. Blood culture was positive for *Salmonella paratyphi A*. He went downhill and became more and more toxic and anaemic. A terminal diarrhoea developed and he died on September 26. Stool examination was negative for schistosoma ova. On post-mortem examination the mesenteric lymph nodes were slightly enlarged. Sections showed the presence of many ova. The mucous membrane of the small intestine was slightly congested, while that of the large bowel was a trifle thickened. There were no overgrowths or ulcers. The liver was slightly enlarged but otherwise normal.

Comments

The points of interest in these cases are:—Case 1: the miliary lesions, their simulation of miliary tuberculosis, and the heavy infection of the mesenteric and retroperitoneal lymph nodes. Case 2: the heavy adult infection of the portal system and enlargement of the lymph nodes. Case 3: the paucity of intestinal lesions while the lymph-node infection was the predominant feature.

Subserous miliary schistosomal infiltration of the small intestine is an abnormal feature in *Sch. mansoni* infection, which could easily have been mistaken for miliary tuberculosis, while enlargement of the mesenteric and retroperitoneal lymph nodes is rare. Small-intestinal and lymph-node lesions are, however, the usual findings in Asiatic schistosomiasis.

The most interesting feature of these cases is therefore that their pathology resembles in some respects that of *Sch. japonicum* infection.

In *Sch. mansoni* infection the organs and tissues most seriously involved are the colon and rectum, though eggs carried in the mesenteric current into the portal vessels may filter out in the liver and lead to cirrhosis.

The essential difference in *Sch. japonicum* infection is the location of the adult worms and the discharge of ova primarily in the mesenteric vessels draining the small intestine. Thus the organs and tissues most seriously involved are jejunum, ileum, appendix, and mesentery. But the relatively short distance for transportation of eggs in the mesenteric current into the intrahepatic portion of the portal vessels and the large numbers of eggs discharged by *Sch. japonicum* females combine to set up periportal fibrosis and other visceral lesions—for example, lymph nodes—as more important in this disease than intestinal lesions.

It is stated that the same schistosome may present different pathological features in different parts of the world. It may therefore be that lymph-node involvement is not an uncommon feature in Sudan schistosomiasis (*mansoni*). Many post-mortem examinations are required to prove this.

I am indebted to the Director of Health Services for permission to publish these cases, and to Dr. R. Kirk, assistant director of research, for his kind criticism and comments.

A report on the British Legion Village covering the years 1947–9 has recently been issued. It pays tribute to the work of Professor F. R. G. Heaf, consulting physician to the Village, whose methods are used in the training schemes. Over 10,000 tuberculous ex-Service men and women of the 1914–18 war have benefited from the services provided by the Village, and many of the second world war are now doing so. The hospital section of the Village has been transferred to the Ministry of Health, but the settlement will still be considered as a unit. Throughout the organization national scales of salaries and wages are paid, and men undertaking full hours of occupational therapy receive increases in wages in accordance with their technical skill. This arrangement benefits morale, since the disabled men know that they are working under conditions like those of their fellows in the outside world.

Medical Memoranda

Uterine Sepsis from Unabsorbable Sutures

The following case report may be of interest to those obstetricians who still advocate the use of unabsorbable ligatures for sewing up the uterine wound after caesarean section.

CASE REPORT

A woman aged 44 was admitted to the Royal Masonic Hospital on August 8, 1949, complaining of irregular uterine bleeding and a purulent vaginal discharge. The average duration of her menstrual period was 7 to 14 days, and the cycle was irregular. The loss was variable, but enough to cause a moderate anaemia. In 1938 an artificial menopause had been induced with radium, but her periods had returned after three months' amenorrhoea and had continued since. She had had two children, aged 19 and 13 years, both delivered by caesarean section. The Fallopian tubes had been tied at the second operation.

Uterus with abscess, showing old caesarean suture.

As this was a case of persistent irregular haemorrhage after radium it was considered advisable to perform a total hysterectomy, and this was undertaken on September 5. The uterus was found to be densely adherent to the anterior abdominal wall by a broad adhesion about 1 in. (2.5 cm.) in diameter. This was dissected away from the anterior abdominal wall and a small abscess, containing frank pus and several long strands of silk ligature, was opened in the middle of the adhesion. The abscess connected with the cavity of the uterus and there was a nest of silk sutures in the abscess.

On section, the myometrium showed considerable fibrosis, possibly the result of the radium menopause. The wound was closed, with drainage to the extraperitoneal space, and the patient had a smooth convalescence. The accompanying illustration shows the uterus with adhesions cut away and a probe passing down the abscess cavity into the uterine cavity. The thick plaited strands of silk are clearly visible, and one or two strands have been removed to show that they are no more absorbed than on the day when they were inserted. The cause of the bleeding and discharge was a stitch abscess in the endometrium.

Most gynaecologists condemn the use of unabsorbable ligatures in the uterus, but a few still advocate the practice. This case is perhaps instructive in showing that such sutures are never absorbed and may give rise to serious mischief—in this case over 13 years after their insertion. I would further submit that nylon used for suturing the uterine incision after caesarean section may well give similar trouble in the future. Though not ideal, catgut is the best suture material to use in the uterus.

JOHN HOWKINS, M.D., M.S., F.R.C.S., F.R.C.O.G.,
Assistant Obstetrical and Gynaecological Surgeon,
St. Bartholomew's Hospital.

Volvulus of Transverse Colon Complicating Labour

The following case is reported because of its rarity and also because it brought to mind that host of differential diagnoses of collapse occurring during labour and in the immediate period post-partum.

CASE REPORT

A woman aged 22, in her third pregnancy, was admitted at term with abdominal pain and nausea on the evening of May 12, 1949. Her past general and obstetric history was normal. She was believed to be in labour. Her blood pressure was 160/110, pulse rate 130, and temperature 97.8° F. (36.55° C.); the urine contained a heavy cloud of albumin. The foetus was presenting by the vertex, and the head was engaged. The foetal heart rate was 84, and the rhythm was irregular.

As she was thought to be in the pre-eclamptic state, treatment was carried out in the routine manner. Six hours after admission an asphyxiated female infant, weighing 7 lb. 9 oz. (3.4 kg.), was delivered spontaneously and survived after resuscitative treatment. The mother collapsed and was treated for obstetric shock. Moderate abdominal distension and generalized tenderness was then discovered. She vomited during the night, and eight hours after the birth her blood pressure was 70/50 and her pulse rate 156.

Gastric suction was begun and intravenous fluids were administered. She had received an enema shortly before admission, but since then had passed neither faeces nor flatus. Her condition did not deteriorate further. Two days after the child was born a lump could be felt in the abdomen above and to the right of the umbilicus. The abdomen was tender, and the fundus of the uterus was felt 3 in. (7.5 cm.) above the symphysis pubis, 1½ in. (3.75 cm.) from the lower border of the tumour.

Four and a half days after the onset of abdominal symptoms laparotomy was performed by Mr. Keith Vartan under general anaesthesia. The lump was found to be distended transverse colon: the mesocolon was longer than normal, and the ascending colon was freely movable. A volvulus had occurred, involving the upper half of the ascending colon and the proximal two-thirds of the transverse colon. It was thought that the mesentery had become untwisted to some extent spontaneously, and nothing was done by the surgeon, apart from completing the untwisting. The other abdominal viscera were examined and found to be normal. The patient was discharged with her baby on June 8, 28 days after admission.

COMMENT

Involvement of the ascending and transverse colon is rare in volvulus occurring during pregnancy. All authors consider the condition from the point of view of intestinal obstruction and discuss the maturity of pregnancy at which such obstruction is most common. Lambert (1931) found the greatest number of cases of volvulus at term or during labour. Kohn *et al.* (1944) also found the last trimester to be the most common time, but remark the strangeness of its occurrence at a time when the abdomen is so distended by the pregnant uterus that torsion of abdominal contents would seem most difficult. On the other hand, it is easy to see the strength of the theoretical argument of Spence (1937) that immediately after delivery there is such a great alteration in the position of the alimentary tract that it is a wonder volvulus is not more common at that time.

The case reported was characterized by three features: (1) the extreme degree of peripheral vascular failure complicating labour and the immediate period post-partum; (2) the dominance of this feature over all other signs and symptoms, and (3) the spontaneous partial resolution of the pathological condition. For, indeed, vomiting as a symptom

was not such as seriously to lead to the suspicion of alimentary obstruction, and constipation was minimal. The enema return was satisfactory and the post-partum abdominal distension was not significantly greater than that occasionally seen after uncomplicated childbirth. Finally, the patient was undoubtedly suffering from pre-eclampsia.

I wish to thank Mr. Keith Vartan, medical director of the British Hospital for Mothers and Babies, London, S.E.18, for permission to publish this report and for his encouragement and suggestions.

Massive Lipoid Deposit in Atrophied Muscle

The following case is of interest not only on account of its rarity but because of the increasing importance which is being attached to the role of the fat-storage depots in diabetes mellitus.

CASE REPORT

A married woman, aged 46, with eight children, gave a history that in 1932 she had developed a severe cold and sore throat, and that four days later weakness of the left ankle had ensued which spread upwards until, in three days, the entire limb was paralysed. The leg then became painful, and despite rest in bed the pain involved the whole leg from the buttock down to the foot. The pain gradually decreased over the succeeding nine months, during which time she remained in bed. As the pain decreased the wasting of the leg and buttock became progressively worse. On gradually resuming activity she regained considerable use in the leg, though movements at the ankle were impossible. This improvement continued, without any treatment, for the next 16 years. In March, 1948, the left calf began to swell, at first mainly at night, but later it remained permanently swollen and slightly tender. The patient did not consider the condition a great disability and she had had three children since its onset in 1932.

On examination she was seen to be a short, very stout woman, rather pallid, with sparse hair and eyebrows. She walked with a stick, dragging the left leg, but was not greatly handicapped. All muscles of the left thigh and buttock were grossly wasted, being 3 in. (7.5 cm.) less than the right in circumference; the calf appeared hypertrophied, the tissues being firm, tender, and measuring 1½ in. (3.7 cm.) more than the right. Power was grossly diminished on the left, being fair at the hip and poor at the knee; the movements of dorsiflexion and plantar flexion of the foot were very small. The tendon reflexes were totally abolished in both limbs, except for the right knee-jerk, which was just detectable. No other abnormality was discovered.

On admission to hospital she was found also to be suffering from diabetes mellitus. Electrical reactions for the muscles of the left leg gave no response either to faradic or to galvanic stimulation. A biopsy of the left calf (by Mr. J. M. Sanderson) showed that the superficial tissues were normal, but the "muscle" was seen to be totally replaced by soft, yellowish white fatty tissue with occasional more resistant areas suggestive of fibrous remnants of muscle bundles. Dr. W. St. C. Symmers, reporting on the microscopical appearances, stated that the muscle was replaced by mature adipose tissue in which small blood vessels and nerve bundles were scattered. Occasional distorted skeletal muscle fibres remained, and small groups of what appeared to be sarcolemmal cells.

COMMENT

The neurological disorder which precipitated the extreme wasting of this patient's leg in 1932 can now be diagnosed only by presumption, but it seems to have been an infective condition of the nervous system, such as an acute poliomyelitis or polyradiculitis, a theory which finds some support in the absence of reflexes in the other limb and their gross diminution elsewhere. Nor can the duration of the diabetes be estimated, as the patient had no symptoms whatsoever: however, glycosuria had not been noted at the out-patient department four months before admission.

It has been known for many years that fatty infiltration precedes and accompanies the atrophy of muscle fibres following lesions of the anterior horn cells such as occur in poliomyelitis (Vulpian, 1870), but excessive deposition of fat to the extent of limb hypertrophy has not been recorded as a sequel to this disease. The outstanding condition in which fatty replacement of muscle fibres occurs is, of course, the pseudohypertrophic muscular dystrophy, but the clinical and histological features of this case were entirely different.

Complete fatty replacement of the soleus of one limb, discovered at post-mortem, was described by Barnes (1932) in a member of a family showing a hereditary myopathy. Weaver and Maun (1942) described a case in which, during post-mortem dissection, the gastrocnemius and soleus on one side were found to have been completely replaced by fat. This was unsuspected during life. Both these patients died of cardiac disease with oedema of the extremities, and it is interesting to note that my patient stated that the swelling of the calf at first came on only towards the end of the day, suggesting that a peripheral oedema, not uncommon after poliomyelitis, may have preceded the permanent deposition of fat.

The other feature of this patient's condition—the diabetes—is also interesting, for in the knowledge that fat deposits in internal organs are commonly associated with diabetes (Goldzieher, 1927), and that high lipaemia is a phenomenon of the severe disease, it is tempting to associate the two conditions in this case.

I wish to thank Professor P. C. P. Cloake for permission to publish this case and for invaluable criticism.

EDWIN R. BICKERSTAFF, M.D., M.R.C.P.,
Senior Registrar, Neurological Unit,
United Birmingham Hospitals.

Nearly 15% of the Fijian population is affected by filariasis, according to a report just issued by the Filariasis Control Division in Suva, Fiji, after a five-year investigation. Blood samples were taken from 61,967 Fijians, or nearly 81% of the inhabitants of 1,150 villages. Results showed that 14.84% of those tested had microfilaria in the blood stream. In males the percentage was 18.23; in females 11.37. The difference may be due to the fact that the clothing worn by men leaves more of the body exposed to mosquito bites. Filariasis is carried in Fiji by a species of mosquito which bites during the day-time. It shelters in long grass or bush, and its flight range is limited to a maximum of 150 yards. The control methods, therefore, are to destroy all possible breeding-places, clear villages of all possible shelter, and then clear all bush in a belt 100 yards wide round each village. These methods are simple, but they require continuous community team-work among the villagers, which is not always easy to obtain. Next year the Filariasis Control Division will make blood tests in selected areas where the control methods have been in force for five years, with the object of finding out how effective this control has been. It is also intended to experiment with other methods of control, including the mass use of the drug "hetrazan," the spraying of villages with D.D.T., and a combination of these with the existing method.

Reviews

X-RAY DIAGNOSIS

A Textbook of X-ray Diagnosis. By British authors. Volumes 3 and 4. Second edition. Edited by S. Cochrane Shanks, M.D., and Peter Kerley, M.D., F.R.C.P., F.F.R., D.M.R.E. (Volume 3, pp. 830; 694 illustrations. £3 10s. Volume 4, pp. 592; 553 illustrations. £3.) London: H. K. Lewis and Co. 1950.

The immense advances made by medical science in the last 30 years are such that only by team work can their fruits be fully gathered. In no branches is this more certain than in radiology and surgery, and it is only by the close co-ordination of the surgeon and the radiologist that either can succeed. The modern radiologist must have a full appreciation of the problems confronting the surgeon and of the attempts which he makes at their solution, while the surgeon must understand fully the assistance which the radiologist can afford him and the great advances which his art has made. It is one of the most remarkable features of these volumes that these axioms have been fully grasped; as a result they may be read with equal pleasure and profit by either the radiologist or the surgeon.

Throughout the work another principle of the greatest value has been followed. In each section a short though precise anatomical description has been given, illustrated by radiographs of normal anatomy, of the region concerned. It is only after this substantial foundation that abnormalities are described, with illustrations so clear that no doubt can arise about their nature. Moreover, in every case a brief account is given of the surgical procedures required, and the picture is completed by *x*-ray photographs which show the results achieved.

Volume 3 covers a wide field; it includes discussion of the whole alimentary tract, the abdomen, the urinary tract, and obstetrics and gynaecology. Most of the account of the alimentary tract is by Cochrane Shanks, and it is a masterly achievement. The normal stomach and the abnormal conditions which may occur are illustrated by admirable radiographs, and the same course is followed with great skill in the case of the duodenum. This is followed by one of the most important chapters in the volume, describing and illustrating the results of the various surgical procedures which have been adopted. We cannot imagine any account which could be read with more interest by an abdominal surgeon, or one from which he would derive information of greater value. The chapter on the diaphragm is indeed a great achievement, for it gives a complete epitome of what is known on this difficult subject. The developmental anatomy is briefly but accurately described and is so admirably illustrated by diagrams and radiographs that it can be clearly understood. The whole article attains a high scientific level, and the research involved is indicated by the complete bibliography which is attached.

The biliary tract is discussed by Peter Kerley and illustrated by superb examples of radiography. The precise information given on how these are obtained will be welcomed by every worker in this field. Kemp Harper contributes an article on the liver, spleen, and pancreas, with excellent illustrations of the difficult problems involved.

The urinary tract is discussed by Cochrane Shanks and Johnstone and reaches the same high level as the rest of the volume. The account of the precise details of the various procedures required for the successful performance of urography, which is followed by a discussion of the difficulties, will be of value to surgeons as well as radiologists, and both will envy the superb results which are here so admirably illustrated.

The great advances of radiology in obstetrics during the last 20 years are admirably described by Rohan Williams. He gives a clear and fascinating account of a field of research which must have an important influence on the future of the art of obstetrics and assist in its further advance as an exact science. The difficult subject of *x*-ray pelvimetry is made clear by excellent diagrams, while perfect radiographs, some demonstrating the placental site and some showing the actual process of labour, suggest the possibilities of the future.

Volume 4 is on the bones and joints and follows the lines we have already indicated. The many and perfect radiographs show clearly every abnormality, whether from injury or disease, with which the surgeon is likely to meet. Two articles, however, call for special mention. The first is by Baker on the general pathology of bone. He not only gives a clear description of the normal growth and structure of bone but describes with equal clarity the complex processes by which bone is absorbed and replaced. The second is an article by Hunter and Jupe on the constitutional diseases of bones and joints. They describe fully the disturbances of growth, nutrition, metabolism, and of the endocrine glands, giving a clear account of a most complex and important subject. Both articles are on a high scientific level and elucidate many problems in connexion with the skeletal system. Their inclusion in this volume adds greatly to its value.

The editors and the many contributors to these volumes are to be congratulated on a really superb achievement.

POCKET-BOOK OF OSTEOLOGY

Osteology for Dissectors. A Tutorial Pocketbook. By Robert King Howat, M.B., C.M.(Glas.), F.R.C.S.(Eng.), F.R.F.P.&S.(Glas.). (Pp. 292; 46 illustrations. 15s.) London: Henry Kimpton. 1950.

This booklet is described as "an attempt to meet a desire for notes on osteology that can be used conveniently in the dissecting room as well as at home." It is doubtful whether such a desire really exists or, if it does, to what extent the present work will meet it. Mr. Howat's book, both in style and in content, is essentially a rough compilation of tutorial notes. In notes of this short compass there must inevitably be a number of omissions, many of which have been judiciously made. One would have thought, however, in view of the emphasis placed on the clinical applications of anatomy, that the nucleus pulposus might at least have been mentioned in describing the articulations between the vertebral bodies.

There is room for considerable improvement in the diagrams. Most teachers of anatomy endeavour to simplify their diagrams so that they may be the more readily understood and learnt by students, and within limits it is a matter of personal taste how far such simplification should proceed. It is astonishing how informative the simplest of line diagrams can be, but the diagram must bear a reasonable resemblance to the original. Some of the diagrams in the present work have been over-schematized to the point of being misleading or unrecognizable—for example, Figs. 1, 3, and 26. It is perhaps only fair to add that Mr. Howat does not stand alone in this respect, and that the practice of making anatomical diagrams too diagrammatic has grown increasingly in recent years.

J. M. YOFFEY.

THE SENSITIVE NOSE

The Nose: An Experimental Study of Reactions Within the Nose in Human Subjects During Varying Life Experiences. By T. H. Holmes, M.D., and others. (Pp. 154; 37 figures. 32s. 6d.) Oxford: Blackwell Scientific Publications. 1950.

In this carefully documented book the authors correlate the effects of environment and social factors with the reaction of the nasal mucous membrane. Rhinologists have long realized that sneezing, nasal engorgement, and excessive secretion, three factors in the entity known as vasomotor rhinitis or spasmodic rhinorrhoea, while often a response to a specific irritant, are nearly always associated with an unstable emotional background.

In this work the facts are established beyond dispute by a meticulous clinical examination of the nasal mucosa carried out concomitantly with an analysis of mental conflicts in a wide variety of people. While in many people placed in situations of conflict there is but little change in the nasal mucosa, it is convincingly established that in the susceptible the same emotional situations tend to give rise to the same physical reactions over and over again; and in unresolved and chronic cases these reactions may become an irreversible pathological state. The same team of research workers performed a similar survey on the effects of emotional disturbances on gastric mucosa, and in one case with a large gastric fistula it was possible to correlate the nasal reactions also. The findings were significantly parallel.

It is suggested that the occlusion of the nasal passages which occurs is a manifestation of a desire to shut out noxious or harmful influences and its relationship to such varying conditions as "specific threats to respiratory apparatus; general threats to bodily integrity; home environment; relations to siblings; fear, anger, hostility, and resentment; sexual function, menstruation, and pregnancy." While it is not implied that all nasal disease stems from difficulties in interpersonal and social adjustment, nevertheless they occupy a position of importance and may modify the course of morbid processes.

No suggestions are made about treatment, but the conclusion is inescapable that the salvation of many must depend, if not on psychiatry, at least on the good offices of social welfare workers. This is a good piece of work which greatly needed to be done.

F. C. W. CAPPS.

MEDICINE IN GERMANY

Lehrbuch der Inneren Medizin. By H. Assmann and others. Edited by H. Schwiegk and A. Jores. Volumes I and II. (Pp. 1,984; illustrated. No price.) Berlin: Springer. 1949.

The new edition of this textbook has an interest transcending that of its intrinsic merits, for it is one of the first works of its kind to be published in post-war Germany. Thus it gives the reader a conspectus of authoritative German teaching which has been denied to him since 1939. In this respect the opening section, in which Professor Siebeck discusses such general notions as the aim of medicine, the nature of ill-health, and diagnosis, is of particular value. These topics are not mentioned in textbooks in the English language, and the problems they raise are unsuspected by many students.

Thereafter the book follows conventional systematic lines. It is remarkable both for the detail and for the wide range covered by its various contributors. The general discussions of such matters as infection, fever, immunity, and epidemiology by Professor Doerr are particularly noteworthy. The differences from comparable English textbooks are chiefly those of emphasis. Some of these may be traced to difficulty of supply; for instance, in the section on the general treatment of infective diseases, the antibiotics, of which only penicillin and streptomycin are mentioned, are accorded less space than the sulphonamides. In considering heart disease the approach remains that of the morbid anatomist, and the importance of aetiology is disregarded. Electrocardiography is treated superficially, and only limb leads are mentioned. No attempt is made to assess the value of streptomycin in pulmonary tuberculosis, although all other aspects of this disease are most adequately considered. Of the other sections, that by Professor Heilmeyer on blood diseases requires mention for its special excellence.

Such criticisms are only of minutiae. In the present edition this well-known textbook fully maintains its reputation and bears witness to the international character of latter-day medical practice. It can be warmly recommended to the English reader.

R. BODLEY SCOTT.

BOOKS RECEIVED

Review is not precluded by notice here of books recently received

Techniques in British Surgery. Edited by R. Maingot, F.R.C.S. (Pp. 733. 75s.) London: Saunders. 1950.

Plastic and Reconstructive Surgery. By F. Smith, M.D., F.A.C.S. (Pp. 895. 75s.) London: Saunders. 1950.

Faith Healing and Healing Methods Founded Thereon. By M. Shipsey, M.B., B.Ch. (Pp. 123. 10s. 6d.) Birmingham: Michael Shipsey. 1950.

Tuberculosis Control in a British Colony. By V. Hetreed, M.B., B.S. (Pp. 50. 7s. 6d.) London: National Association for the Prevention of Tuberculosis. 1950.

The Four Pillars of Wisdom. By Sir Sheldon F. Dudley, K.C.B., F.R.S. (Pp. 246. 8s. 6d.) London: Watts and Company. 1950.

Emergencies of Childhood. By R. Gamlin, M.A., M.B., B.Ch., M.R.C.S., L.R.C.P., M.H., D.P.H. (Pp. 64. 6s.) London: James Nisbet. 1950.

The Psychology of Inteligence. By J. Piaget, D.Sc. (Pp. 182. 15s.) London: Routledge and Kegan Paul. 1950.

A Textbook of Gynecology. By A. H. Curtis, M.D., and J. W. Huffman, M.D. 6th ed. (Pp. 799. 50s.) London and Philadelphia: W. B. Saunders Company. 1950.

Medical Diagnosis: Applied Physical Diagnosis. Edited by R. L. Pullen, M.D., F.A.C.P. 2nd ed. (Pp 1,119. 63s.) London and Philadelphia: W. B. Saunders Company. 1950.

Les Frottis Vaginaux et Cervicaux. By J. P. Pundel. (Pp. 350. 2,000 francs.) Paris: Masson. 1950.

Thérapeutiques Cardiologiques Internationales. By C. Lian. (Pp. 167. No price.) Paris: L'Expansion Scientifique Française. 1950.

Werdnig-Hoffmann's Infantile Progressive Muscular Atrophy By S. Brandt. (Pp. 328. 20 Danish kronen.) Copenhagen: Ejnar Munksgaard. 1950.

Grundriss der chemischen Physiologie. By F. N. Schulz. (Pp. 234. M. 7.50.) Jena: Gustav Fischer. 1950.

Wesen und Herkunft endogener Pigmente. By B. Oebike. (Pp. 92. M. 10.80.) Jena: Gustav Fischer. 1950.

Grundsätzliches zur Diabetestherapie. By F. Bertram. (Pp. 40. M. 1.) Stuttgart: Georg Thieme. 1950.

Lehrbuch der Röntgendiagnostik. By H. R. Schinz and others 5th ed. (Pp. 878. M. 70.) Stuttgart: Georg Thieme. 1950.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY SEPTEMBER 16 1950

A SECRET REMEDY FOR CANCER

A weekly with a large popular circulation, *Picture Post*, has recently thought fit to champion a cancer treatment practised by a Mr. D. Rees Evans and to demand a full official trial, which they say has hitherto been refused. In furtherance of this aim they have circulated to certain scientific bodies a record containing case histories and experiments on which their claim is based, together with some account of the treatment. The evidence in favour of the treatment has been compiled by Mr. D. W. Morley, a biologist with no medical training, who has previously done research on the habits of ants and has been for some months a scientific journalist. Rees Evans, "having no scientific training himself . . . was unable to undertake any research on his own behalf. Such research has now at last been undertaken in the U.S.A." Sixteen cases of cancer were made available to him for treatment in the Presbyterian Hospital, Newark, N.J. According to Mr. Morley, Mr. Evans went to the U.S.A. "to obtain the test of his methods of treatment which he had failed to get in Britain. . . ." And Mr. Morley, in the record referred to, stresses the American work "because it is the most detailed, both in records of treatment and methods of diagnosis." Mr. Morley, acting as a sort of scientific compère for Mr. Evans, evidently sets great store by the American experiment: "discussion of the English cases is of necessity less detailed . . . [partly] because in many of the cases the diagnosis is less certain." The Presbyterian Hospital is officially recognized by the American College of Surgeons and by the Council on Medical Education and Hospitals. It is evidently, as our friends in the U.S.A. say, in "good standing." To learn if any further light could be thrown on Mr. Evans and his treatment we asked for information and received this cable in reply from the "Tumor Therapy Committee" which sponsored the investigation (periods inserted):

> "Work entirely experimental. No definitive results obtained. Evans statement unwarranted and unauthorized. No results to be published. Would disavow all unproven claims by Evans."

The Tumor Therapy Committee evidently refused to go any further with the trial of Mr. Evans's treatment unless he agreed to divulge the composition of his drug or drugs to the Food and Drug Investigation and to one or more members of the committee "so that clinical evaluation of Mr. Rees Evans's preparations and method of treatment can be carried out ethically in accordance with the usual procedures of the leading scientific and medical societies of this country. . . ." Mr. Evans, it appears, thereupon returned to England—and to *Picture Post*, which took upon itself to present to the British public evidence on his behalf, resorting to the startling device of beginning its article on the cover of the magazine.

No doubt the exponents of Mr. Evans's treatment are acting in all sincerity. No doubt the Editor of *Picture Post* sees himself as the champion of the unorthodox and as a bold innovator in the history of scientific journalism. No doubt it would be only human on his part to appreciate the publicity value for his magazine of this strange incursion into the complicated and baffling nature of the treatment of a disease which claims an ever-increasing number of victims in an ageing population. No doubt, too, unfortunately, the hopes of many sufferers will be tragically raised that here at last is something which will cure cancer. It is true the caution is uttered that "this is not . . . a general 'cancer cure.' This is a treatment which—we claim—has achieved success over a period of years in certain cancer cases, when carried out by a particular person." But the untutored reader will be heavily influenced by the peculiar evidence of the photographs. In treating in this manner such a difficult question *Picture Post* has done a grave disservice to science and to the British public.

What is the evidence thus presented in all the glare of modern journalistic presentation? Mr. Evans, in investigating whose work *Picture Post* "has spent thousands of pounds," went to the U.S.A. in November, 1949, and returned in May, 1950. During this time he treated sixteen cases of cancer. Of these sixteen patients four died, and three others were regarded as unsatisfactory for other reasons. It is claimed that the remaining nine "were completely cured," but one of these was "believed" to have developed metastases since the completion of the treatment and is dead—according to Mr. Morley from pneumonia. A second cable from the Tumor Committee in America informs us that another patient for whom partial success in treatment is claimed is now dying; also that no biopsies were obtained in three patients said to be cured, though it is claimed in the *Picture Post* records that biopsy was obtained in two of these. Much is made in this magazine of the so-called cure obtained in the case of Rousch (spelt Rauch on the same page). The cable from America informs us that "Rausch skin cancer now requires surgery kidney mass": is this the same mass described in *Picture Post* as "white kidney stones"?

It is difficult to understand how Mr. Morley can state on one page of *Picture Post* that "nine cases were completely cured," and on the opposite page write this: "As these cases in America were treated within the past twelve months it cannot be established that they will not suffer from a return of the disease." In the light of this second, and accurate, statement the first is dangerous nonsense.

Mr. Evans inherited his therapeutic armamentarium from his uncle and father, David and John Evans. In 1907 another journalist, Mr. W. T. Stead, took up the cudgels on behalf of what was known as the Cardigan Cancer Cure and against the medical profession. The pretentiousness of these claims was exposed in these columns at that time.[1] A year later, in 1908, Mr. Lynn Thomas described a case of cancer of the breast "cured" by Mr. John Evans, who had then come under his, Mr. Lynn Thomas's, care.[2] Mr. Thomas published photographs which showed extensive scar tissue at the site of the right breast, with cancerous ulceration. Another photograph showed the breast at the time of treatment by Mr. Evans—the surface converted into a mass of dark, necrotic tissue. This bears a very close resemblance to one of the photographs in *Picture Post* of a treated cancerous breast. Analysis of the necrotic tissue and of the fluid used by the Evans brothers in 1908 showed the presence of a high percentage of zinc chloride. The caustic effect of this has been exploited in many "cancer cures," often in the form of pastes. Mr. Rees Evans claims to have improved on his father's remedies, but the *Picture Post* photographs strongly suggest that whatever is applied destroys the skin and the breast tissue immediately under it. As Mr. Evans has so far refused to disclose the constituents of his remedies, it would be legitimate to suppose that its principal ingredient is zinc chloride—the favourite prescription of many self-dubbed cancer-curers of the past and present in Mr. Evans's father's remedy. But information in the second cable from the Tumor Therapy Committee suggests there may be something else as well. We give the information as received (periods inserted).

> "Patients exhibited effects colchicine. Although nature drug not known pharmacologist chemists agree possibly some form colchicine orally. Mixture colchicine plant material plus acid possibly tannic to skin. Several patients exhibited gastrointestinal symptoms cerebral disorientation convulsions local muscular spasms and severe pain."

Mr. Evans had the opportunity of submitting his treatment to authoritative investigation in 1923, when he appeared before a Ministry of Health Cancer Committee. He refused to disclose the nature of his remedy. He refuses in 1950 to reveal his secrets to the U.S.A. Food and Drug Administration.

Advertising of cancer cures is now illegal, but are the articles in the last two issues of *Picture Post* very different in effect from an elaborate form of advertisement for a secret remedy and Mr. Rees Evans?

We can but repeat what was written in these columns in 1908: "'Cancer curing' is to our mind the most execrable of all forms of quackery, for, in addition to the bitterness of disappointed hope, it inflicts an incalculable amount of unnecessary suffering."

POLIOMYELITIS AND THE COMMUNITY

The risk of contracting poliomyelitis in its paralytic form is, even in a sharp epidemic, far less than it is popularly imagined to be. The publicity given to an outbreak is useful in at least one way, for it leads the doctor to consider poliomyelitis as a possible diagnosis even if the symptoms are not typical. The greatest contribution which the doctor in practice can make to the prevention of paralysis in the individual is to diagnose the disease early and secure rest for the patient. A reminder of the diagnostic signs and symptoms was given by Dr. W. H. Kelleher in a recent Refresher Course article.[1] After the diagnosis of poliomyelitis has been made in a member of a family or community the doctor is often asked for advice on problems which arise. He will probably find it difficult to answer some of these questions because of the lack of precise information about how the disease spreads, and it is worth recalling the facts which are known about its epidemiology.

Poliomyelitis is caused by one of a group of viruses, and infection is mainly spread from person to person. Occasionally the patient is known to have been in contact with another patient who developed paralysis, and the time from the known contact to the onset of symptoms is usually between 7 and 14 days, though it may be shorter or longer. Sometimes the contact has been with a person who had only a mild illness with no signs of involvement of the central nervous system, but more frequently the source of infection is a healthy person who has been in contact with a case or who has visited an area in which cases were occurring. In such instances the line of spread of infection can be seen, but in many others no such direct or indirect contact can be established. It sometimes appears that there has been indirect contact with two or more carriers intervening between cases, as when the fathers of two patients meet at work or brothers or sisters from two affected families attend the same class in school. Evidence of person-to-person spread is also provided by the frequent observation that cases occur successively in different parts of a town or village and show a centrifugal or radial spread from the first focus. Even these indications of the line of spread of infection are sometimes lacking, and it may be necessary to postulate a number of initial foci and a whole series of carriers between cases in order to justify the concept of person-to-person transmission. Virus studies have shown that the infection tends to be widely distributed, for many of those in close contact with patients excrete the virus in their stools, as do a smaller number who have been in more casual contact and a few who have had no known contact with a case. Epidemiological studies have often shown a patchy distribution of foci of high incidence with areas of diminishing incidence surrounding them, and scattered, apparently sporadic, cases in the rest of the area.

[1] *British Medical Journal*, 1950, **2**, 570.

Outbreaks of poliomyelitis are usually fairly abrupt in onset: the majority of cases in a village or in part of a town where the incidence is high occur within four to six weeks. The spread of infection through the community is therefore quite rapid, and this also suggests a widespread carrier epidemic, since careful investigations as a rule yield no evidence of spread by mass contamination of food or drink. Spread by flies has been shown experimentally to be possible and may sometimes be the mode of infection, but person-to-person spread appears to be more important. The way in which infection is transferred has been the subject of debate between those who emphasize the importance of the presence of virus in the throat of carriers and of patients for a few days before and after the onset of symptoms and those who are impressed by the frequency with which the virus can be recovered from the stools of patients at the time of onset of illness and for four or more weeks afterwards. The conclusion to be drawn is that both pharyngeal secretions and faeces may be the source of infection, and that hands contaminated from either source may transmit infection either directly or indirectly. In a household where a case of poliomyelitis occurs it is therefore wise to assume that the other members, particularly children, are excreting the virus in their stools and to point out the need for careful personal hygiene. Some school medical officers recommend exclusion of brothers and sisters of a patient from a day school for three weeks, and "home and garden quarantine," or some approximation to it, of these children and of any pre-school children in the family may be advised. These precautions diminish the danger of spread from some sources of infection and are probably welcomed by other parents, but it is only in the early stages of an outbreak, before the virus is widespread, that they can appreciably diminish the total risk of infection in the community. No restrictions are usually placed on the adult members of a family in which a case of poliomyelitis occurs, except when a medical officer of health has to guard against special dangers in the case of food-handlers and those whose occupation brings them into close contact with children. Quarantine may be advised for children outside the family who have been in close contact with the patient at the time of onset of illness, but the activities of other casual contacts of a case are not restricted. During an epidemic it is sound practice to discourage gatherings of people (particularly of children) who do not normally meet, but there should be a bias in favour of allowing the normal activities of the community to continue.

Closure of day schools or day nurseries is called for only if it is clear that spread of infection is still occurring by contact of children who come from widely separated homes and so would not meet if they did not come to school. It is sometimes wiser, even in such circumstances, to keep the children in school rather than to free them to play with other younger children in or near their homes. The opening of day schools has been postponed where cases have been occurring at the end of the holidays and where the mixing in school of children from affected and unaffected areas seems likely to lead to further dissemination of infection. In a boarding school parents are usually notified if a single case of paralytic poliomyelitis occurs, and school life continues with precautions to prevent the spread of infection and to bring under medical observation any case of suspicious illness. When several cases occur the alarm of the school authorities and the anxiety of the parents may lead to school closure, especially if many parents decide to withdraw their children. Dispersal is of course attended by the risk of disseminating the infection in the homes to which the pupils go, and it disrupts the term's work. It is seldom possible to be confident that dispersal is justified on the grounds that it diminishes the risk of paralysis to individuals.

WIDENING HORIZONS OF MEDICINE

The unification of ideas has been long pursued, yet with an elusive quality shown in side-steps to diversity whenever the framework provided has seemed too rigid. One such unification was in the Middle Ages, when empire and papacy stood as twin symbols which between them covered all human activity. The barriers were broken at the Renaissance, if not before; and men such as Linacre for medicine, Newton (on his own pinnacle) for physics, and Boyle for chemistry set out in their own times and ways to follow their separate roads, freed in

varying degree from preconception but with a lack of specialization which now would seem surprising. Specialization has grown since and abundantly. Yet in an age in which the holder of a chair of anatomy can express embarrassment at being called upon to speak in a physiology lecture theatre there is also evident a contrary tendency towards unification which, being based on knowledge rather than preconception, may prove more enduring than its predecessors. Professor J. Z. Young[1] can see similarities between the operation of memory in brains and calculating machines, and draw surprise from neither physicist nor physiologist at a meeting of the Royal Society—unless that his own researches should have so far made progress. Equally it was possible for Sir Harold Hartley, a physical chemist by training, in his Presidential Address to the British Association[2] on the broad theme of energy and man's use of it, to glance in passing at the human machine and note that "life is dynamic, and the slender thread on which it hangs is that ceaseless flow of energy." With the same broad approach the difference between the rusting of iron and the resistance of the living organism to decay is that the one is not dynamic and the other is. The one sinks to the lowest energy level, sooner or later, with the remorselessness of the Greek Fates; the other is held above it like "a ball of celluloid poised on a jet of water," keeping its place and spin so long as energy is supplied to maintain it.

That this dependence on energy expenditure for maintenance is no fanciful generalization was illustrated in the section of physiology, also at the British Association, when Dr. R. B. Fisher discussed the lining layer of the intestinal mucosa as "the one barrier across which all ingested foodstuffs must pass before they enter the body fluids." The relevance of this contribution is that the mucosa is seemingly no inert membrane across which this or that material may pass, as in the classical demonstration of osmotic pressure—with water finding its way from a weaker solution to a stronger as of its own volition. The operation of the mucosal layer seems rather to be that of a chemical pump, with the energy for its working supplied by its own quick metabolism. Glucose can pass from lumen to tissue fluid against the gradient of concentration: so to an engineer might a wheel coast uphill impossibly, unless energy were provided to counter the gradient. So, too, do water and probably fat pass the mucosal boundary. With protein, the supreme necessity, it seems "eminently reasonable" that the first step in protein absorption should be the synthesis of mucosal protein, and the second the breakdown of this, with the breakdown products passing into the tissue fluids. Here, surely, is the pump that lifts the water over the hill, to run under gravity in the succeeding stage—as planned on transatlantic scale through the operation of the Grand Coulée Dam in the U.S.A.

So the horizons of medicine are widening, as from this or that vantage-point—hillock, perhaps, rather than hill—the surrounding territory can be surveyed. Another such has been quoted lately by Professor W. T. Astbury[3] from the knowledge, given largely by his own researches, of the structures characteristic of long-chain molecules. To see a resemblance between material of human weaving and the cell wall of an alga, viewed at 10,000 magnification, might at one time have seemed fanciful only—a resemblance no more illuminating than the microscopist's trick which transforms a sheet of reasonably smooth metal into a corrugated and jagged landscape. But if the underlying architecture is found to be common, if the strands of the algal weave are of the same kind as the component fibres of rayon thread, if the comparison can fairly be extended to range from natural proteins to synthetic plastics—then the laugh is with the *x*-ray physicist and electron microscopist, for Professor Astbury is both, and not with those who would see no more in such a resemblance than a conjuring trick of magnification. "In its material aspect," Astbury states, "life is more than anything else a manifestation of the physics and chemistry of chain molecules." It is a necessary reservation that by "material" is meant "structural" and all that structure implies, including the ability to change from one variant to another and back again, as was first shown by Astbury for wool fibres.

For the energetics of living organisms it is necessary to turn to those sciences which deal with energy considerations, as Sir Harold Hartley has graphically illustrated. To illuminate mechanisms it may be helpful in some connexions to look, with Professor Young, at the devices of the electronic engineer, although with the biologist's reservation that no calculating machine has yet been designed which is self-modifying in the light of experience. The principle remains good—that with the growth of knowledge in one field it becomes possible to see valid resemblances with events in others. In the two last of these examples the resemblance is experimental and liable to modification or qualification from further knowledge. In Sir Harold's it is fundamental, provided that the same answer as his is given to a question asked by Gilbert Lewis—whether in living organisms Nature obeyed her laws of energy. "This we may never know for certain, but the presumption is—she does." So when the mucosal layer of the intestine is found to act as a chemical pump, when the same deduction is reported, as lately by Dent and others,[4] of the role of the placenta in foetal nutrition, the response of the biochemist is to look with renewed interest for the mechanisms by which energy is made available—and the celluloid ball balanced, spinning, on the water-jet.

SWEAT AND ADRENAL FUNCTION

During recent years advances in clinical endocrinology have been due largely to the development of more accurate methods for determining the activity of the patient's endocrine glands. Often only indirect methods are available—for example, the metabolism of radioactive iodine as an index of thyroid function—but in some instances the amount of hormone secreted by a particular gland can be measured by chemical or biological methods. The adrenal cortex secretes three main types of hormone, which are classified according to their chief physiological effect. Steroids with sex hormone activity can be measured by estimating the urinary excretion of 17-ketosteroids in the case of androgenic substances, and of oestrogens in the case of oestrogenic substances. Steroids which affect protein and carbohydrate metabolism can be measured by estimating the urinary excretion of 11-oxysteroids. An indirect method of assessing 11-oxysteroid production is to measure the fall in circulating eosinophils which normally occurs when the adrenal is stimulated by a test dose of A.C.T.H. or adrenaline. Other more indirect evidence of oxysteroid production may be obtained from the glucose- and the insulin-tolerance tests. The third main type of steroid secreted by the adrenal cortex is concerned with sodium, potassium, and chloride metabolism. An example of this type is the synthetically prepared desoxycorticosterone (D.C.A.). There is little evidence that this particular steroid is actually formed by the adrenal, but hormones which exert their main effect on electrolyte metabolism are often called the D.C.A.-like, desoxy-like, salt-active, or salt-retaining corticosteroids. At the present time no satisfactory chemical or biological method has been devised for measuring the urinary excretion of desoxy-like steroids. It is well known that many of the manifestations of Addison's disease are due to a deficiency of this type of hormone. The tests of Power and his colleagues[1-3] are used to reveal adrenal hypofunction, but they are influenced by a deficiency of other substances besides the D.C.A.-like hormone.

During the last few years Conn and his colleagues have reported a number of observations which suggest that the concentration of salt in the sweat bears a close relationship to the desoxy-like steroid production of the adrenals.[4 5] While studying the electrolyte metabolism of men subjected to humid heat, Conn confirmed previous findings that the concentration of salt in the sweat was reduced. Thus a man excreting 8 litres of sweat a day would lose 32 g. of salt before acclimatization, whereas he lost only 10–13 g. when fully acclimatized. This 60–70% reduction in salt loss from the skin was associated at first with a parallel conservation of salt by the kidneys; but the renal retention of salt was not sustained, whereas the excretion from the skin continued at a low level for as long as the subject remained in the heat. It seemed probable that this salt-conserving phenomenon was due to increased formation of D.C.A.-like hormone. The process of acclimatization was also associated with a negative nitrogen balance which persisted for 2–4 weeks and was independent of the nitrogen intake. This could be attributed to increased secretion of 11-oxysteroids. Thus Conn proposed that increased adrenal activity, as shown by a greater secretion of desoxy-like and 11-oxysteroids, was part of the process of acclimatization, and that the adrenals were stimulated by increased secretion of A.C.T.H. from the pituitary. He was able to show that injections of A.C.T.H. caused similar metabolic changes to those observed during acclimatization—namely, a reduction in the salt content of the sweat and a negative nitrogen balance. Injections of D.C.A. also reduced the salt content of the sweat, but as would be expected there was no disturbance of nitrogen metabolism.[6 7]

Conn then turned to pathological conditions in which there was a disturbance of adrenal function.[8] In Addison's disease the salt content of the sweat was greatly increased above the values found in normal subjects. Two patients with chronic adrenal insufficiency had 105 milliequivalents of chloride per litre of sweat, whereas the range in controls was 15–60 mEq. per litre. Treatment with D.C.A. reduced the salt loss nearly to normal. In three patients with panhypopituitarism the values were 70–75 mEq. per litre, indicating a deficiency of D.C.A.-like steroids not as great as in Addison's disease. In patients with Cushing's syndrome, whether associated with adrenal carcinoma or hyperplasia, increased steroid production was shown by a marked reduction in the salt content of the sweat. These studies indicate that the salt content of sweat collected under standard conditions may prove a reliable index of endogenous salt-active corticosteroid production. Unfortunately the collection of samples of sweat under conditions in which the body is exposed for two hours to a temperature of 95° F. (35° C.) and a relative humidity of 90% is not a practical proposition. Perhaps the originators of this sweat test will be able to evolve a method more suitable for use in the clinical laboratory.

ELECTROENCEPHALOGRAPHIC CONTROL OF ANAESTHESIA

The effect of anaesthetic drugs on the output of electrical energy by the brain cortex has been studied by Bickford[1] in the laboratory of electroencephalography at the Mayo Foundation. He found a constant relationship between the depth of anaesthesia and the output of electrical energy, and was able to devise an apparatus for the automatic electroencephalographic control of dosage in general anaesthesia. The fluctuating brain potentials are amplified and made to charge a condenser, the rate of charge being proportional to the number and amplitude of the waves in a given time. At a predetermined voltage the condenser discharges, actuating a relay which pushes forward by a small amount the plunger of a syringe delivering thiopentone or any other anaesthetic agent into the patient's vein or into a vaporizer. The rate of injection is therefore dependent on the amount of cerebral electrical activity, and anaesthesia can be steadily maintained at a depth which may be varied by controlling the gain of the amplifier.

The device has been used for barbiturate and ether anaesthesia in the rabbit, cat, and monkey and also in man.

[1] *Electroenceph. clin. Neurophysiol.*, 1950, **2**, 93.

Anaesthesia has been maintained automatically in animals "on many occasions . . . for periods as long as two or three days without any readjustment of the circuit controls." Bickford stated that a modified version of the apparatus adapted for the prolonged administration of ether to human patients has been used successfully in the operating theatre, and he proposes to publish later a full description of the technique.

SYPHILIS AND YAWS IN HAITI

Haiti, or Hispaniola as it was formerly known, looms large in the history of syphilis, for it was to or from this island, or perhaps both, that Christopher Columbus and his men conveyed syphilis on their return to Spain at the end of the fifteenth century. Both syphilis and gonorrhoea are common among the Haitians, affecting perhaps 25% of the population, but it is yaws—a para-venereal disease closely akin to syphilis, which is said to have an incidence of 85% among all the inhabitants and 75% among children under 15 years of age—which causes the greatest amount of disability; this it does by attacking mainly the skin and bones. An ambitious scheme to eradicate all three diseases from the island is under way, sponsored by the World Health Organization and the United Nations International Children's Emergency Fund.[1] Fortunately penicillin is effective against all these diseases, so that theoretically it should be possible to eliminate them within the two years allotted. There are, however, several practical difficulties: the cost will be high, but Unicef is putting up 320,000 dollars for the purchase of supplies and the Haitian government will provide 290,000 dollars a year for running expenses. The area to be covered is large—10,714 square miles—and many of the 3½ million inhabitants live in out-of-the-way places, some of which doctors will be able to reach only by travelling on foot or horseback. It may be difficult to impress the more backward and illiterate inhabitants with the objects of the campaign, but the help of local newspapers, police, and priests is being sought, and it is believed that the population will co-operate, particularly when they see the almost magical results of treatment. For administrative purposes the island will be divided into geographical areas, and 10 mobile treatment units, consisting of teams of four travelling in "jeeps," will each be allotted an area. The physicians will mostly come from other countries, since there are only about 300 medical practitioners on the island, and only 26 to look after the rural population of 2½ millions,[2] but the auxiliary staff will mainly be Haitians. The campaign will be carried out in three stages: mass diagnosis and treatment; establishment of permanent treatment dispensaries at strategic points from which mobile squads will work so as to reach all areas; and the organization of a system of case-finding and home-treatment. The proposal is to give two doses of penicillin separated by an interval of 10 or 12 hours. Whether this will bring about biological cure in anything approaching 100% of cases remains to be seen, but it should at least render patients non-contagious.

The undertaking is an immense one, probably the largest anti-venereal-disease campaign ever launched. The results may be expected to be good, but history has few if any records of a widespread disease being completely eradicated by treatment alone. Nevertheless, this project offers a valuable opportunity to study a disease such as yaws, about which so little is known. Specimens of the causative organism are to be sent to Professor T. B. Turner at the Johns Hopkins Hospital at Baltimore, so that the relationship between *Treponema pertenue* and *Treponema pallidum*—the causative organisms of yaws and syphilis respectively—can be examined. Hitherto these two organisms have been morphologically indistinguishable, but it may be that their immunological reactions differ. Perhaps an answer will at last be found to the question, "Are yaws and syphilis two diseases or one?"

THE DOCTOR AS A PUBLIC SPEAKER

One accomplishment which the prospective doctor should seek after, and which need not add to the burden of the curriculum, is the ability to speak in public—to give clear and succinct expression to his ideas in a company of his fellows. He will probably find it easiest to acquire this ability in a debating society or similar body, for it is more a matter of cultivation than of natural endowment. The level of public speaking in the medical profession is lower than in the professions of law and teaching and in the Church and the Civil Service. It is below the level which used to obtain in medical societies, whose old members, accustomed as they were to deliberate speech, with a slight polish on it, would be aghast at the slovenliness prevailing to-day. There are outstanding exceptions, but in general the standard of speaking in medical assemblies—scientific, business, or social—has deteriorated. Discussions are casual and conversational, speech is slipshod, articulation is disregarded. It is a refreshment to find a speaker who has not only something to say but a way of saying it, a sense of phrase and structure, with sentences that do not lose their way in parenthesis.

In Plutarch's *Lives* it is told of Demosthenes that he claimed he was a good member of the democratic State because he always came prepared to the rostrum; he held that such preparation was a mark of respect to the people he addressed. The medical profession does not need a Demosthenes; but some preparation before speaking, some attention to form, is, after all, a courtesy to the audience, as well as a way of impressing the speaker's ideas not only upon others but upon his own mind. This is not the unimportant frill that some may suppose. The doctor, especially in a small community, will probably be called upon to take a lead in public affairs, which will bring him occasionally to the platform. He may also be expected to take a part in the meetings of his profession, and the ability to put his points so that they can be comprehended by the slower-witted and the partially deaf will be a recommendation. From time to time he will go into the witness-box, and in court a habit of clear statement will serve him well. It is the young doctors and research workers, full of knowledge of their subject, who should be particularly on guard against incoherence. Some of the older men, brought up in a different tradition, are less prone to be glib and diffuse—both more audible and more comprehensible. Their example is one which the eager young speaker should follow.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

CHEMOTHERAPY—III. STREPTOMYCIN

BY

LAWRENCE P. GARROD, M.D., F.R.C.P

Bacteriologist, St. Bartholomew's Hospital; Professor of Bacteriology, University of London

Streptomycin was the first successful product of the world-wide search for further antibiotics with chemotherapeutic powers following the demonstration of these properties in penicillin. It is formed by a soil fungus, *Streptomyces griseus*, and is of more complex chemical structure than penicillin. It is basic in nature, and the compounds which have been used in therapeutics are the hydrochloride, sulphate, and calcium chloride complex. More recently a slightly modified form, dihydrostreptomycin, has been introduced, for which it is claimed that toxic effects are less often produced when administration has to be prolonged.

Administration

When streptomycin is given by mouth its behaviour is entirely different from that of penicillin: it is not destroyed, but neither is it absorbed. Hence this route is indicated only in order to produce an effect in the intestinal tract itself. To obtain a systemic effect, streptomycin must be given, like penicillin, by intramuscular injection. Absorption after injection is somewhat slower, as also is excretion: following a single full dose—for example, of 1 g.—the drug can be detected in the blood for eight hours or more. It reaches all important areas in the body except the cerebrospinal fluid; like penicillin, it has to be injected intrathecally for the treatment of meningitis. It is excreted by the kidney, and thus attains a high concentration in the urine.

Dosage varies within much narrower limits than that of penicillin, because streptomycin is by no means free from toxicity. A daily dose of 4 g. has rarely been exceeded, and for long-continued treatment it is now more commonly 1 g. How many doses are given daily depends on the condition being treated. Tuberculosis is a special case, since a single daily dose (or injections at even longer intervals than one day) is used in treating this disease. On the other hand, the short-term treatment of an acute infection is usually accomplished by giving two, three, or four daily doses. It cannot be said that the best system for this kind of purpose has yet been defined by any deliberate comparison.

Mode of Action

Streptomycin is actively bactericidal. There is no optimum concentration for this effect, as with penicillin: the higher the concentration, the more rapidly are bacteria killed. The equivalent of that attainable in the urine will in a nutritive medium *in vitro* markedly reduce a susceptible bacterial population in a few minutes and extinguish it within an hour. The lower concentrations reached in the blood and tissues cannot act so rapidly, but there is no reason to assume any qualitative difference in the effects produced there.

If this were all that need be said about the action of streptomycin on bacteria, it would be a most remarkable drug and much more regularly successful than in fact it actually is. Its disadvantage is that bacteria can acquire a high degree of resistance to it with extraordinary rapidity. This is of such a degree that further treatment is futile, and it has often been observed within 24 hours of the beginning of treatment, though its appearance may be delayed rather longer than this. The change is also permanent. It follows that in many cases only a single course of treatment can be given: either this succeeds, the infection being totally eradicated, or further treatment is precluded by acquired bacterial resistance. This is sometimes accompanied by "dependence"—the existence in the bacterial population of some cells which actually utilize streptomycin as a nutrient and cannot grow without it.

A sensible conclusion from these facts would seem to be that treatment should be brief and vigorous, allowing the least possible opportunity for bacterial recovery. This policy would require that the drug concentration in the blood and tissues be well maintained, and thus would call for frequent administration.

The time needed for tubercle bacilli to acquire resistance corresponds with their much slower growth, and is at least five weeks. Systems of dosage different from those applicable in other conditions have been found advisable for treating tuberculosis.

Toxic Effects

In patients with impaired renal function, streptomycin may accumulate in the body and has occasionally thus caused death. The only serious common toxic effect is on the eighth nerve, vestibular disturbances (vertigo and incoordination) being produced first, and deafness in more severe cases. Either effect may be permanent, but some degree of recovery occurs in more mildly affected patients.

These changes are never produced by any ordinary doses given only for a short period, such as a week. They are the product of long-term treatment, and their frequency and severity are then directly proportional to the dose: if this does not exceed 20 mg. per kg. daily no permanent damage will result. Intrathecal injections are particularly apt to have these effects. It is claimed for dihydrostreptomycin that it is much less apt to produce them, but this claim has not been fully borne out in recent experience.

Indications

Penicillin being the perfect chemotherapeutic agent, there is no need for any other except in infections insensitive to it. There are unfortunately many such, but each new discovery is effective against some of them. Streptomycin began this process by subtracting from the list infections due to the tubercle bacillus and to a number of Gram-negative bacilli. A satisfactory table of species classified according to their sensitivity to streptomycin cannot be prepared because strain variation in sensitivity is so marked. It must suffice to say that *Mycobacterium tuberculosis*, unless it has had previous contact with streptomycin, is uniformly and highly sensitive, being inhibited by not more than 0.2 μg. per ml.; that almost all species of Gram-negative bacilli are also sensitive, but to concentrations varying from as little as 0.1 to as much as 25 μg. per ml. or more; and that most penicillin-sensitive organisms, such as streptococci and staphylococci, are usually also sensitive to streptomycin, though to a less degree.

The main clinical indications for streptomycin are therefore tuberculosis, various infections due to Gram-negative

bacilli, and occasionally coccal infections if they are abnormally penicillin-resistant. The latter are usually much better controlled by "aureomycin," if this is obtainable.

Tuberculosis

This is no place to discuss in detail the indications for streptomycin in various forms of this disease or the systems of dosage advisable. At the risk of seeming to belittle the functions of general practice, it has to be said that the decision to undertake this treatment is one in which the expert should usually have a say, while the conduct of the treatment itself may be difficult outside a hospital or sanatorium.

Streptomycin is of course imperatively indicated in otherwise fatal forms of the disease—in miliary tuberculosis and meningitis. It has been strikingly successful in rapidly extending lung infections and in ulcerative tracheobronchitis. Its place in the treatment of more chronic disease, whether of the lung or elsewhere, is much more dependent on the features of the individual case and on the possibilities of combined surgical treatment.

Tubercle bacilli cannot be successfully attacked either in a cavity in the lung or in a large caseous focus in, for example, the kidney. There is thus no prospect of eliminating the infection in patients with such lesions. The only effect will be to limit extension while treatment continues, and to deal with bacilli in smaller and more accessible foci. This may be valuable if surgery is undertaken at the same time, and particularly if it is necessary in order to render surgery feasible. On the other hand, to rely solely on streptomycin in a case of chronic pulmonary tuberculosis with cavitation is expecting altogether too much of the drug, and will rarely produce any ultimate benefit.

Indiscriminate treatment may be positively harmful, not only to the patient but to others, because its effect is usually to make the bacillus resistant to the drug. This means that streptomycin will be useless in any subsequent acute exacerbation, and in treating the disease in anyone else who may acquire it from this patient. The danger of breeding and spreading streptomycin-resistant strains of tubercle bacilli is a very real one, and disastrous instances of its results have already been seen in the U.S.A. American studies have made it clear that cavitation is a major factor in promoting acquired bacillary resistance in treated patients. Fortunately combined treatment with *p*-aminosalicylic acid (given orally at the rate of 12 g. daily) diminishes the frequency of acquired resistance as well as reinforcing the action of streptomycin on the tubercle bacillus.

Plague and Tularaemia

It may be that in years to come these will be the only diseases for which streptomycin is used. Both are derived from wild-animal reservoirs in which the micro-organism has no chance of acquiring resistance to the drug, and in both it is strikingly successful. In pneumonic as well as bubonic plague streptomycin has been found curative, and in tularaemia, even in its more severe forms, all reports are agreed that the effect is immediate and invariable. These are in fact the two specific diseases in which the drug has had its greatest success, and we should not forget that there are some parts of the world in which to possess an effective treatment for plague constitutes a therapeutic advance of the first order.

Septicaemia

The forms of septicaemia in which streptomycin is principally indicated are those due to Gram-negative bacilli of coliform type—usually *Bacterium coli* itself, *Proteus vulgaris*, or *Pseudomonas pyocyanea*—and seen as complications of severe urinary-tract infection, middle-ear disease, wound sepsis, and lesions of the intestinal tract. It is important to determine the sensitivity of the organism to the drug, since if this is subnormal another antibiotic such as "chloromycetin" may be indicated. Full and frequent doses (1 g. three or four times a day) are required until the generalized infection has been overcome.

Meningitis

There are several kinds of meningitis in which Gram-negative bacilli are concerned for which streptomycin is strongly indicated. One is the spontaneous form occurring in young infants and due to *Bact. coli* or sometimes to a species of *Salmonella*. In *Haemophilus influenzae* meningitis, usually seen at a later stage of infancy, streptomycin should also be used, but sulphadiazine and immune serum may be advisable in addition. Thirdly, *Ps. pyocyanea, Proteus vulgaris*, or other coliform bacilli may cause meningitis complicating trauma or otitis media, or resulting from contamination of materials used in operative procedures on the central nervous system; the meningitis which has unfortunately followed spinal anaesthesia or even simple lumbar puncture is an example.

Streptomycin should be given intrathecally as well as intramuscularly: the full daily dose by this route is 100 mg. for an adult. Here again not only the initial but subsequent tests of sensitivity (if cultures continue to yield growth) should be carried out, and one of the newer antibiotics substituted if resistance develops.

Urinary-tract Infections

Streptomycin is the most potent of all urinary antiseptics, with a wide range of activity. Properly used, it will often succeed, even in long-standing infections, when everything else has failed. There are three main conditions which must be satisfied in order to ensure a good prospect of success. First, any underlying predisposing cause must if possible be removed; in the presence of obstruction or calculi only temporary benefit, if any, can be expected.

Secondly, it must be determined by cultivation of a properly collected fresh specimen of urine and by sensitivity tests of the organisms found that streptomycin is the right drug to use. If a staphylococcus, a streptococcus, or even *Proteus vulgaris* is found, penicillin is likely to be preferable. On the other hand, *Bact. coli, Bact. aerogenes, Ps. pyocyanea*, and various paracolon bacilli, which should normally be more or less sensitive to streptomycin, are nowadays sometimes found to be completely resistant. This is often the consequence of previous treatment, but is now beginning to be seen in patients who have never had the drug, and must therefore be attributed to the dissemination of resistant strains from other treated persons, a development which has long been foreseen and which must tend steadily to restrict the field of usefulness of streptomycin.

When treatment has been decided on, the third condition to secure is alkalinity of the urine, since the drug possesses little activity in an acid medium. Unless the infection is due to a urea-fermenting organism, when of course the urine will be persistently alkaline owing to the formation of ammonia, it may be necessary to give 2 g. of sodium bicarbonate four times a day for one or two days before this condition is secured. The specimen tested should be that passed on waking in the morning, and not until this is at least neutral to litmus, if not frankly alkaline, should

streptomycin be given. The object is then to maintain a high concentration in the urine for the short period required to sterilize it, and theoretically three or more doses daily are advisable: two have been used with success, but one only is inadequate. A dose of 0.5 g. three times a day or of 1 g. twice a day will usually suffice, though more vigorous treatment is safer and can do no harm in the short period necessary.

Sterility in successful cases is achieved in less than 24 hours, and it is useless to continue for more than three days: to what extent the period of treatment can be shortened further without risk of failure is not yet known, but in my own experience patients have been cured of long-standing infections by only three and four 0.5-g. doses. If the organism persists it will usually be found to have acquired a high degree of resistance, precluding any further treatment with this drug.

Intestinal Infections

Streptomycin given by mouth—for example, in 1-g. doses four times a day—is of value in bacillary dysentery and in acute salmonella enteritis, although, unfortunately, it does not seem to diminish the liability to subsequent persistence of a carrier state. Its usefulness in infantile gastro-enteritis is a subject of dispute, possibly because there are varieties of this condition, some of its imperfectly known causes being streptomycin-sensitive and others not. Despite its *in vitro* activity against *Salmonella typhi*, the drug is practically useless in enteric fever, for reasons which are still obscure. It may be used either alone or together with sulphasuxidine to disinfect the bowel preparatory to operations on the colon: administration should not be begun more than two days before operation, since otherwise resistance may have been acquired before this takes place.

It may be added here that streptomycin and other antibiotics have been successfully used in peritonitis. It is exceedingly difficult on the available evidence to decide what their effect is, and which is likely to be most useful in any given case, but owing to its wider range of activity, including many intestinal species (with the notable exception of the clostridia), streptomycin is at least theoretically preferable to penicillin.

Lung Infections

A strong indication for streptomycin has been pneumonia due to *Bact. friedländeri* or *H. influenzae*. How far it should be replaced by the newer antibiotics for this purpose is not yet clear. More chronic lung and bronchial infections due to these and similar organisms may also be treated, but the benefit is likely to be only temporary if there are underlying structural changes, as in bronchiectasis. The value of the drug in whooping-cough is doubtful.

Local Application

Like penicillin, streptomycin can also be applied locally in a number of ways. It has been administered by inhalation for infections of the bronchial tree. It can be employed in the same way as penicillin for infections of the conjunctiva, cornea, and the interior of the eye itself. The instillation of a solution is useful in the treatment of otitis externa and otitis media when Gram-negative bacilli such as *Proteus vulgaris* and *Ps. pyocyanea* are concerned. The same organisms can rapidly be eliminated from superficial wounds, burns, and such lesions as varicose ulcers by spraying a solution or the application of dressings wet with it, if these operations and the general aseptic management of the case are conducted with care and skill.

Only a short period of application should be necessary for such purposes. It has to be remembered that repeated contact with streptomycin over a period of some weeks leads to sensitization. This has been seen frequently in nurses handling the drug, who develop erythematous and oedematous lesions of the face and hands. It should be possible by careful technique to avoid such contact in making up and administering doses, but once the condition is established there is no remedy but avoidance of any further dealings with the drug.

INTERNATIONAL SOCIETY OF HAEMATOLOGY

MEETING IN CAMBRIDGE

The third congress of the International Society of Haematology was held in Cambridge under the presidency of Sir Lionel Whitby from August 21 to 26. Some 500 delegates attended from many parts of the world, and nearly 200 papers were read during the conference, grouped under the four headings, anaemia, leukaemia, problems of coagulation, and immunohaematology.

The social events included a reception by the president on Monday, August 21, and the society's dinner on Wednesday, August 23, at which it was announced that Dr. A. Pavlovsky, of Argentina, would be president for the next congress. A reception was also held by the vice-chancellor in Pembroke College on Tuesday, August 22, and garden parties were given by Captain R. G. Briscoe, Lord Lieutenant of the county, at Longstowe Hall, and by Sir Lionel Whitby in the grounds of Downing College.

A number of delegates showed scientific exhibits, and several commercial firms displayed products of interest to haematologists. Films were shown and a demonstration of colour television microscopy was given by Messrs. W. G. Pye and Co., Ltd.

Anaemia

The first meeting on this subject was devoted to therapy, and Dr. E. LESTER SMITH (England) opened with a paper describing the isolation and properties of vitamin B_{12}. The effect of its oral administration in pernicious anaemia in the absence of known sources of intrinsic factor was then discussed by Dr. E. H. MORGAN *et al.* (U.S.A.), and Dr. GRACE GOLDSMITH (U.S.A.) described the effects of vitamin B_{12} given orally and parenterally and of a concentrate of intrinsic factor in macrocytic anaemia. Other contributions concerned the therapeutic effect of vitamin B_{12} obtained from a variety of new sources, the use of the vitamin in the treatment of tropical macrocytic anaemia, and the effect of cobalt therapy in various anaemias. A further session on pernicious anaemia and vitamin B_{12} was opened by Dr. O. P. JONES (U.S.A.), who described the action of anti-anaemic substances on embryonic prehepatic erythropoiesis. Dr. G. LARSEN (Norway), describing the pathogenesis of the macrocyte, pointed out that even in adequately treated pernicious anaemia macrocytes occur in the peripheral blood. These cells have a normal mean corpuscular volume, but their thickness is about half normal. Their life-span is about 40 to 60 days, and they are more resistant than normal cells to hypotonic saline. Experiments were described which suggested that there may be alterations in the haemoglobin of these macrocytes, with a failure of normal haemoglobin maturation. Drs. J. MOSBECH and A. VIDEBAEK (Denmark) presented the results of an investigation, with adequate controls, into the prognosis in 301 cases of pernicious anaemia (see *Journal*, August 12, p. 390). Further papers and discussions centred on the question of whether vitamin B_{12} alone was a fully adequate haemotherapeutic agent in pernicious anaemia. Experimental work on the megaloblast problem and the maturation of erythroblasts was discussed by Drs. G. ASTALDI (Italy), D. DANTCHEV (Bulgaria), and P. COLOMBO (Italy).

On August 25 a session was devoted to nutritional factors in anaemia when Dr. C. R. DAS GUPTA (India) discussed the aetiology of nutritional macrocytic anaemia. Drs. V. RAMALINGASWAMI and H. M. SINCLAIR (England) spoke on the aetiology and pathogenesis of polycythaemia in pyridoxin deficiency in the rat, and Dr. J. F. RINEHART *et al.* (U.S.A.) gave an account of experimental pyridoxin deficiency in the rhesus monkey. The action of folic acid, liver extracts, vitamin B_{12}, and other substances with anti-anaemic properties were described by Drs. A. ASCHKENASY (France), L. TENTORI and G. VIVALDI (Italy), O. CARERE-COMES (Italy), and G. SOTGIU and C. CACCIARI (Italy). Drs. A. R. AXELROD and L. BERMAN (U.S.A.) presented their findings in the bone marrow in hypo- and hyperthyroidism. The incidence of lymphocytes in bone marrow in hyperthyroidism may reach levels comparable to chronic lymphatic leukaemia with no peripheral lymphocytosis.

A session on haemoglobin metabolism was opened by Drs. C. V. MOORE and R. DUBACH (U.S.A.), who discussed radioactive iron studies in the understanding of iron metabolism. Further papers were devoted to the action of vitamin B_{12}, folic acid, and liver extracts on the synthesis of protoporphyrins (Dr. A. GAJDOS, France), the role of nuclear functions in the synthesis of ribose-nucleic acid and the formation of haemoglobin in erythroblasts (Dr. I. G. GUZMAN, Mexico), the metabolism of haemoglobin, porphyrin, and bile pigment (Dr. I. M. LONDON, U.S.A.), the interrelationship of red cell stroma and haemoglobin production in the normal and anaemic-hypoproteinaemic dog (Dr. G. H. TISHKOFF *et al.*, U.S.A.), and the fate of transfused red cells tagged with radioactive iron (Dr. L. E. HUMMEL *et al.*, U.S.A.).

An interesting session on hypersplenism was opened by Drs. T. S. EVANS and C. A. DOAN (U.S.A.), who described haemolytic crises of acquired hypersplenism in the course of giant follicle lymphoma. The secondarily enlarged spleen which may develop during the course of this normally long and rather benign disease can and should be removed by splenectomy. The results of splenectomy in cases of leukaemia with haemolytic anaemia were described by Drs. P. S. HAGEN and C. J. WATSON (U.S.A.), who demonstrated the very considerable fall in transfusion requirements in such patients after splenectomy.

Further excellent papers from Sweden, Denmark, Holland, Greece, and Austria demonstrated the very widespread interest in the problem of hypersplenism.

Dr. W. DAMESHEK (U.S.A.) gave the first paper in a session devoted to haemolytic anaemia. He analysed the possible mechanism of auto-immunization in acquired haemolytic anaemia and discussed the rationale of therapy with A.C.T.H. and splenectomy. Further contributions dealt with the role of the spleen in familial spherocytosis (Dr. C. A. A. SCHRUMPF, Norway), photo-electric study of permeability and lysis of red blood corpuscles in anaemia (Dr. P. MOSER, Germany), and Rh antibodies in haemolytic anaemia (Dr. E. WITEBSKY, U.S.A.). The pathogenesis of the haemolytic crisis and the effect of dicoumarol on the course of the disease were discussed by Dr. W. H. CROSBY *et al.* (U.S.A.).

Leukaemia

Leukaemia due to benzine, one of the rare human leukaemias of which the cause is known, was the subject of papers by Dr. J. BERNARD (France) and by Dr. L. BRAIER (Argentina). The cytology of acute leukaemias, unusual types of leukaemia in children, the possibility of a virus in the aetiology with some supporting experimental work, and the significance of leukaemic plasma in cytogenesis were also discussed. During the next session, devoted to leukaemia and related diseases, Drs. SHIMKIN and S. R. METTIER (U.S.A.) analysed the mortality and longevity statistics for myelocytic leukaemia. Dr. M. MORRISON *et al.* (U.S.A.) described a rare type of leukaemia showing dwarf cells, and Drs. G. DI GUGLIELMO and E. STORTI (Italy) presented some interesting observations on erythromyelosis in the fowl and man. Dr. S. MOESCHLIN (Switzerland), who was convinced of the neoplastic nature of Hodgkin cells, advised that this condition should be regarded as a malignant tumour and recommended radical excision of affected lymph glands.

The first of two sessions on treatment dealt mainly with the use of A.C.T.H. and cortisone therapy. Papers were read by Drs. J. M. STICKNEY *et al.* (U.S.A.), R. H. SAUNDERS *et al.* (U.S.A.), and A. VIDEBAEK (Denmark). These authors, and those who took part in the discussion, agreed that, while striking haematological remissions could be produced in many cases of lymphatic leukaemia, the improvement was transitory and often accompanied by a distressing type of obesity. The principles which should govern titrated, regularly spaced radioactive phosphorus, or spray x-ray therapy, were dealt with by Dr. E. E. OSGOOD (U.S.A.), and Dr. P. BJERRE-HANSEN (Denmark) described his clinical experience with urethane.

The second session was opened by Dr. F. H. BETHELL *et al.* (U.S.A.), who discussed the metabolism of folic acid in leukaemic patients. Aminopterin in the treatment of leukaemia (Dr. J. INNES, Scotland), urethane in the treatment of multiple myeloma (Drs. W. C. MOLONEY and W. J. HARRINGTON (U.S.A.), and clinical and experimental observations on the action of urethane (Dr. C. MALAGUZZI-VALERI, Italy) were also discussed. Dr. A. PAVLOVSKY and Dr. G. C. VILASECA (Argentina) recorded their results in acute leukaemia with radioactive phosphorus, and Dr. H. R. BIERMAN *et al.* (U.S.A.) described the disappearance of leukaemic cells transfused into non-leukaemic recipients. The treatment of acute leukaemia with blood transfusion and antibiotics was the subject of a paper by Dr. L. M. MEYER (U.S.A.).

A session on aetiology was opened by Dr. J. HOOGSTRATEN (Canada), who compared the characteristics of leukaemia and neoplasia and concluded that the neoplastic nature of leukaemia must be regarded with some scepticism. Dr. J. C. WHITE *et al.* (England) presented the results of quantitative studies on the content of nucleic acid in normal leukaemic cells from blood and bone marrow. There was a tendency towards high ribose, nucleic acid, phosphorus values in leukaemia where primitive cells predominate. The cytochemistry of leukaemia (Dr. W. LAVES, Germany), the cytochemistry of leukaemic chromosomes (Dr. E. E. POLLI, Italy), and the significance of pathological polyploidy in leukaemia (Dr. E. UNDRITZ, Switzerland) were also discussed.

A session on experimental observations was opened by Dr. J. BICHEL (Denmark), who described tissue culture of leukaemic cells. The effects of folic acid antagonists on leukaemic and blood-forming cells were dealt with by Dr. U. HAENEL (Switzerland) and Dr. W. JACOBSON (England). Dr. P. BASTRUP-MADSEN (Denmark) discussed the action of adenine antagonists on living cells *in vitro*. Dr. A. FIESCHI (Italy) described his tissue culture experiments with leukaemic cells, and Dr. R. H. GIRDWOOD (Scotland) presented evidence that 4-amino-pteroylglutamic acid had an action other than that of a folic acid antagonist.

In a session on special types of leukaemia a case of acute erythraemic myelosis was discussed by Dr. E. NEUMARK (England), and several other papers were read on erythroleukaemia, plasma cell leukaemia, histoleukaemia, and the relationship between lymphatic leukaemia and lymphosarcoma.

Problems of Coagulation

The first session here was opened by Dr. F. J. LEIBETSEDER (Austria), who discussed the effect of adrenaline and dihydroergotamine on the first stage of coagulation. Drs. R. BREDA and R. BERNARDI (Italy) described a condition present in two brothers belonging to a family affected with hereditary haemorrhagic telangiectasia who showed a prolongation of prothrombin time. Experiments conducted with plasma from these cases suggested the possibility of an anti-prothrombin-conversion factor. Drs. K. N. KAULLA (Switzerland) and V. D. BORI (Italy) described the coumarin treatment of experimental thrombosis. The correlation between deficiencies or increases of blood-clotting factors and dysproteinaemias was described by Dr. P. DE NICOLA (Italy). The clinical and haematological problem of thrombophilia (Drs. A. MARMONT and A. PALMIERI, Italy), the present status of the thrombopathies (Dr. N. QUATTRIN, Italy), and a case of haemophilia-like disease due to the presence of circulating anticoagulants (Drs. M. CRISALLI and G. COTELLESSA, Italy) were the subjects of further papers presented.

A session was devoted to the role of the liver, and papers were read by Dr. CROSBY for Dr. M. STEFANINI (U.S.A.) on the haemorrhagic diathesis of liver dysfunction; by Drs. P. NOLF and M. ADANT (Belgium) on the function of the liver in blood coagulation; by Dr. W. RIEBEN (Switzerland) on the coagulo-hepatogram, which presented a measurement of acglobulin, prothrombin, and natural plasma-antithrombin, all predominantly formed in the liver, and Dr. P. MENEGHINI (Italy), who discussed the occurrence and significance of mast cells in haemorrhagic conditions.

A stimulating session on physiology was opened by Dr. P. A. OWREN (Norway). He discussed the prothrombin-activating complex and its clinical significance, and introduced new terminology for various coagulation factors. Other papers in this session were read by Dr. W. H. SEEGERS (U.S.A.) on "Studies on Purified Prothrombin," Dr. K. JACOBSON (Sweden) on "Plasminogen," Drs. P. CAZEL and IZARN (France) on "Rapid Neutralization of Thrombin after Coagulation," and Dr. L. LORAND (England) on "Contributions to the Fibrinogen-Fibrin Problem."

A session devoted to haemophilia was opened by Drs. R. G. MACFARLANE and R. BIGGS (England), who described studies on the coagulation of haemophilic blood. Their experience suggested that the abnormally slow speed of thrombin formation in haemophilic blood may be due to its insensitivity to added thromboplastin. Several further papers were read on experimental and clinical observations in haemophilia in man and dog.

During a session on purpura several papers were read on the cytology, physiology, and pathology of platelets and factors involved in capillary function. An interesting communication by Dr. E. L. LOZNER *et al.* (U.S.A.) concerned the endocrine aspect of thrombocytopenic purpura, and the evidence presented strongly suggested that oestrogenic substances were concerned with the development of this disease in adults.

A later discussion on anticoagulants concerned principally the mode of action of dicoumarol, water-soluble polyamino acids, and heparin.

Immuno-haematology

In the first meeting devoted to immunology papers were read by Dr. L. BERMAN *et al.* (U.S.A.) on the so-called "Lupus Erythematosus Inclusion Phenomenon," and by Drs. A. D. CAJANO and C. MAUREA (Italy) on anti-cellular and anti-organ sera. The latter authors immunized rabbits against guinea-pig leucocytes, bone marrow, and spleen, and were able to show that the antisera obtained had not only species-specificity but also organ-specificity.

The present position of blood groups was reviewed briefly by Dr. J. VAN LOGHEM (Holland). Drs. M. CUTBUSH and P. L. MOLLISON (England) gave an account of the Duffy blood-group system. Dr. A. E. MOURANT (England) described the distribution of blood groups in relation to transfusion organization, and Dr. G. FULTON ROBERTS (England) discussed the prozone inhibition which some anti-globulin sera show when tested against weakly sensitized cells.

The next session was opened by Dr. A. S. WIENER (U.S.A.), who described with illustrative cases the medico-legal application of the rhesus blood types. Dr. P. LEVINE (U.S.A.) summarized the position of the Kell–Cellano system of blood factors, and Drs. R. R. RACE and R. SANGER (England) described a blood lacking any detectable representative of the C and E series of allelomorphic antigens. This case represents a probable deletion in a human Rh chromosome and supports the separability of the C, E, and D genes. A notable paper was presented by Dr. S. FILITTI-WURMSER *et al.* (France) on the differentiation of "A" blood groups by their agglutinins.

Dr. L. E. YOUNG *et al.* (U.S.A.) gave a paper on erythrocyte-iso-antibody reaction in dogs, and further papers were presented on an experimental haemolytic syndrome by Drs. T. FORMAGGIO and PIOVELLA (Italy) and Dr. D. H. HEARD (England). Dr. R. CEPPELLINI (Italy) discussed the Rh antigen E^u, Dr. F. STRATTON (England) the D^u group of Rh, and Drs. S. D. LAWLER and R. R. RACE (England) the quantitative aspects of Rh antigens.

The final session began with a communication from Dr. P. VOGEL (U.S.A.) on technical considerations and results in replacement transfusion in infants, and Dr. T. J. GREENWALT (U.S.A.), Dr. W. C. MOLONEY (U.S.A.), and Dr. L. J. UNGER (U.S.A.) presented papers on various aspects of treatment and prevention of Rh sensitization. An interesting paper by Dr. J. V. DACIE (England) described the presence of non-specific incomplete "cold" antibodies in most normal sera. These incomplete antibodies differ in some ways from other types of antibodies such as anti-Rh, and might be a source of confusion in carrying out tests for "warm" antibodies, particularly in cases of acquired haemolytic anaemia.

MEDICAL PHOTOGRAPHY AT THE ROYAL PHOTOGRAPHIC SOCIETY

The photographs of medical interest at the 95th Annual Exhibition of the Royal Photographic Society at Prince's Gate are provided by comparatively few exhibitors. A possible explanation is the counter-attraction of the International Exhibition of Medical Photography which the Society sponsored earlier in the year and which was shown at the house of the Medical Society of London. This exhibition has also been seen at the Congress of Radiology and is due in Manchester in October. In the present exhibition all branches of photography are covered, and the medical prints must be comprehensible to the non-medical visitor assisted by no more extensive notes than can appear on the mounts.

The University of Zürich eye clinic has provided three mounts which are of fine quality, their pattern alone having a great appeal. The photomacrograph of the ciliary body will delight the ophthalmologist and the anatomist. The eye is always a popular subject, and Manchester Royal Infirmary shows an interesting traumatic arteriovenous aneurysm of the choroid. Other exhibits from this department are noticeable for clarity of detail; a composite mount of osteochondritis dissecans using radiographs and operation photographs may be cited also as a workmanlike piece of applied photography—it could not fail to be valuable to the teacher.

Pathological preparations are usually well represented. The sole example this year is from St. James's Hospital, Leeds, and shows a concurrent ulcer and remote carcinoma in a single specimen of stomach. The standard of pathological specimen photography, not only in Britain but generally, is surprisingly low when the large output is considered. This print is not of the quality we have come to associate with this department; it has probably been hung more on account of its rarity than its quality, for there is no doubt that it is flat, even making allowances for fixed material. The texture in the ulna exposed by a third-degree burn, from the same hospital, is nearer to their customary standard.

Medical photomicrography is provided by the radiotherapists. The Cambridge entry, optical sectioning of the unstained nucleus by ultra-violet light, is of excellent quality and exemplifies a valuable technique. Mr. Mitchell is to be congratulated on this mount. The Chester Beattie Institute shows several fine examples of mitotic figures in stained material.

There is a small group of transparencies, the majority in colour and all good. (Colour prints are still not within practical bounds for a busy hospital department.) St. James's shows stages in fasciectomy for Dupuytren's contracture. From Newcastle come two dental subjects; that of attrition of the upper incisors makes good use of a mirror to record the lingual aspect of the teeth. Manchester makes an interesting point with a pair of slides demonstrating the "mitral flush." One is an accurate "ektachrome" colour transparency, the other a black-and-white slide made on orthochromatic film. The latter shows not only the distribution of the flush but some freckles also, which are

barely noticeable in colour. This pair may provide some comfort to those who are prevented by budgets and lack of dollars from having all the colour they would like. The monochrome version, if the clinician or teacher will take the trouble to learn its interpretation, may well be equally useful at a fraction of the cost.

BRITISH ASSOCIATION MEETING

MATTERS OF MEDICAL INTEREST

The 112th annual meeting of the British Association for the Advancement of Science was held at Birmingham from August 30 to September 6. It was the most largely attended meeting outside London since the Association's jubilee year meeting, held at Manchester in 1887.

The presidential address, on "Man's Use of Energy," was given by Sir HAROLD HARTLEY, F.R.S., chairman of the Fourth World Power Conference, held lately in London. He ended his address with a strong plea for a survey, in respect of each country, of its natural resources, human geography, economic structure, and capacity to produce and consume: for only if the resources and potentialities of each country were known could the "natural wealth of the world, distributed in such an accidental way," be used to the best advantage.

Muscle Movements

The Section of Physiology, under the presidency of Professor R. J. BROCKLEHURST (Bristol), began its meetings with a discussion on muscle movements. This was introduced by Mr. W. GISSANE (Birmingham). His approach was that there was much to be learnt from the detailed study of the anatomical problems confronting the orthopaedic surgeon. This was illustrated by an account of recent research in the University of California on the movement of the limb bones during walking, in relation to artificial limbs.

Twelve medical students allowed pins, several inches long, to be inserted into the pelvis, femur, and tibia in order to serve as indicators of rotatory movements. The movements of the pins in normal walking were then recorded by film cameras in front view and from the side. The results showed that transverse rotations or angular displacements are more important in walking than has been previously accepted in Great Britain, and that function is intimately co-ordinated between muscles and joint ligaments.

Mr. Gissane also discussed the use of skin grafts in the treatment of extended burns; for full restoration of function it was necessary that the healing of the grafts should be complete within about 30 days—possibly due to the thickening of exposed fascial planes over longer periods.

Dr. H. D. DARCUS (M.R.C. Unit for Research on Climate and Working Efficiency, Oxford) described a dynamometer for the study of isometric muscular contraction in man. A twisting movement imparted to the dynamometer by the hand causes deformation of a tempered steel bar, the extent of which is measured with electrical strain gauges. The position of the subject can be varied with respect to the machine, and by a suitable choice of positions the performance of a single muscle can be studied. For example, it is possible to show that the biceps muscle is incapable of effective contraction between full pronation and about the mid-range of the movement, the supinator muscle being then effective. Other factors which may affect the result are training, muscular fatigue, and the variation in will shown by all subjects to exert the greatest force possible.

Mr. W. F. FLOYD (Middlesex Hospital), in a joint contribution with Dr. P. H. S. SILVER, showed oscillograms in which the degree of electrical activity in six muscles was simultaneously displayed for a variety of postures and movements. The act of standing requires little activity, and in most subjects a position of practically zero activity can be found. This is in contrast with commonly expressed views based on earlier observations on "four-footed and decerebrate cats," the relevance of which to an intact human subject might well be doubted. In standing with the eyes closed, corrective activity is increased, suggesting that the eye is an important agent in maintaining the upright position. In bending there is a critical point beyond which activity of the spinal muscles is inhibited, and this may have a bearing on the occurrence of slipped disks when a heavy weight is lifted with the spine bent. In sitting, the forward-slumped position makes a smaller demand on activity than postures conventionally regarded as more correct.

Dr. L. GUTTMAN (Spinal Injuries Centre, Stoke Mandeville) illustrated with films the teaching of "trick movements" to paraplegics with the object of obtaining maximum function from available muscles. "If a paralysed man can tilt his pelvis," he stated, "then he can walk." In reply to a question, Dr. Guttman said that much could be done even 8–11 years after injury. It was suggested that to the conventional anatomy of muscular movement there would have to be added a second anatomy based on the abnormal development and use of muscles which can be acquired.

Two papers bearing on the chemical basis of muscular contraction were presented at a later session held jointly with the Section of Chemistry. In the first, Dr. S. V. PERRY (School of Biochemistry, Cambridge) reported the shortening of myofibrils, isolated from rabbit skeletal muscle, in the presence of low concentrations of adenosine triphosphate. In the second, Dr. J. R. BENDALL (Low Temperature Research Station, Cambridge) described experiments on the shortening of muscle during rigor mortis—when work can be done by muscles in lifting a load. There is good correlation in time between shortening and the breakdown of adenosine triphosphate. This correlation holds good with a variety of prior treatments—for example, in muscles which have been fatigued or depleted of glycogen by starvation, in muscles well provided with glycogen at death, and in muscles from animals paralysed with myanesin or narcotized with "dial."

Functions of the Skin in Vertebrates

A joint meeting on the functions of the skin in vertebrates was held between the Sections of Physiology and Zoology. This was opened by Professor P. B. MEDAWAR (Birmingham), and consisted rather of a series of isolated contributions than of a discussion in the normal sense.

Professor Medawar reviewed research, largely in his own department, on the anatomical basis of skin pigmentation. Whereas the epidermis of the mammal is usually figured in textbooks as if all its cells belonged to a single division lineage, that of the Malpighian cell, there are in reality cells of a second and quite distinct lineage—dendritic cells. Their branches intertwine with the Malpighian cells and at their ends are button-like terminations or cups. Whatever other function these cells may have, they "are the sole origin and seat of the pigmentary function in mammalian skin," the melanin which they form being caused to enter the cytoplasm of neighbouring cells. The difference between negro skin and white is not in the number, shape, size, or distribution of dendritic cells, but in their physiological activity.

Dr. J. D. FINDLAY (Hannah Dairy Research Institute, Ayr) described experiments with Mr. W. R. BEAKLEY on the differences between Ayrshire and zebu (tropical adapted) cattle in relation to skin function and heat dissipation. Their conclusion is that neither of these breeds sweats, but that cooling in zebu cattle is facilitated by the large dewlap, in which there is a capillary network about ten times as great as in Ayrshire cattle.

Dr. W. S. BULLOUGH (Sheffield) spoke on skin replacement. Close observation shows that the cells of the epidermis divide according to set patterns and rhythms which vary from place to place across the surface of the body, the normal pattern being destroyed only in regions of inflammation or wounding. Epidermal replacement occurs mainly during sleep, and glycogen is normally the critical substance limiting replacement, but oestrogen has a positive activity of its own. The physiology of epidermal cell division, Dr. Bullough stated, is important not only for its own sake but in relation to the mechanics of growth and development, wound healing, and possibly cancer—the incidence of which may be related to the rates of cell division, normal and abnormal, in the various tissues of the body.

Dr. J. S. WEINER (Oxford) described the experimental methods of sweat collection developed in the Climatic Research Unit at Oxford, and discussed the influence of skin temperature and other factors on variations in sweat composition. Professor J. D. BOYD (London Hospital Medical College) demonstrated with slides the effects of fungal infection associated with excessive sweating and the patterns of denervation resulting from neuromuscular surgery.

Hormones of the Digestive Tract

The presidential address of the Section of Physiology was given by Professor R. J. BROCKLEHURST (Bristol) on "Hormones of the Digestive Tract." His review covered work in this field from the time of Pavlov onwards and cannot be adequately summarized. It will be published in full in the October issue of *The Advancement of Science*. The distinctions were emphasized that, whereas the salivary glands are stimulated solely by their nerve supply, the stomach is stimulated by both nerves and hormones, and the intestine and its glands probably by hormonal mechanisms alone. Perhaps the most striking feature of these humoral mechanisms is that "there is nothing which corresponds with a co-ordinating centre for them; each mechanism is brought into play, when it is needed, by a particular event in the sequence of digestive process. So far as we know at present, they are found only in connexion with the stomach, the small intestine, and its associated glands." The investigation of the cells in which the hormones originate has barely commenced.

Professor A. A. HARPER (King's College, Newcastle-upon-Tyne) then described a modification of the secretin test. The modification consists in giving an intravenous injection of pancreozymin 30 minutes after the injection of secretin. This is followed by an increase in the output of amylase, lipase, and trypsin in the duodenal samples, as well as by further changes. The modified secretin-pancreozymin test thus gives additional information about the ability of the pancreas to secrete enzymes.

The activities of the intestinal mucosa were discussed by Dr. R. B. FISHER (Oxford). Its lining layer is of particular interest as the one barrier across which all ingested foodstuffs must pass before they enter the body fluids, and it is becoming increasingly clear that the majority of exchanges between the body and the intestinal lumen depend on the performance of work by the mucosal layer. Transfer, in other words, is not passive, but involves physiological activity in this layer. Glucose, for example, passes from lumen to tissue fluid even when the initial concentration is the same on each side. There is evidence also for the active transport of water across the intestinal mucosa, and strong indications that fat and the products of protein digestion are also actively transported. From previous work on the oxygen consumption of isolated intestines, it appears that the metabolic rate of the small intestine is very high; and the rate of cell division is so rapid (Leblond and Stevens) as to suggest complete replacement every 36 hours. Corresponding with this rapid growth process, a high rate of turn-over would be expected of mucosal protein. There have been no studies as yet of the incorporation of labelled amino-acids into the mucosa alone, but it has been shown by this method that the turn-over of proteins in the intestinal wall as a whole is higher than in any other tissue in the body. Together with evidence suggesting that the whole cytoplasmic protein of the body acts as a protein store, "it seems eminently reasonable" that the first step in protein absorption is the synthesis of mucosal protein, and the second its breakdown, with the products of breakdown passing into the tissue fluids.

Nerve Fibres

A group of papers on "The Nerve Fibre" was introduced by Professor J. D. BOYD (London Hospital Medical College), who reviewed the anatomy and histochemistry of vertebrate peripheral nerve fibres and their sheaths. He drew attention to the problems of remote control by the cell nucleus, of tracing the fibrils of the axon back to the cytoplasm of the cell body, where they divide on either side of the nucleus, of the origin of the myelin sheath as between nerve cell and Schwann cells, and of the doubtful validity of any hard-and-fast distinction between myelinated and non-myelinated fibres.

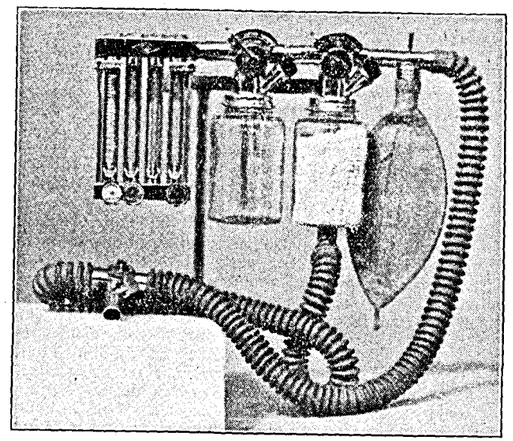
Dr. A. L. HODGKIN (Physiological Laboratory, Cambridge) summarized recent work at Cambridge relating nerve conduction on the one hand with changes in electrical potential as between the inside and outside of a fibre, and on the other with the permeability of the fibre to sodium and potassium ions. The two effects are complementary. In the resting nerve, the outside of the fibre is 50–100 millivolts positive with respect to the inside, and the membrane is selectively permeable to potassium. On activation, conditions are reversed: the outside of the fibre is now 30–50 millivolts negative, and the membrane is selectively permeable to sodium. The potential difference is reversed by the entry of sodium into the fibre, and restored by the exit of potassium. On the other hand, the permeability change is itself initiated by electrical stimulation. The progression of activity along the nerve is interpreted as being due to the cancellation of the external negative charge at the point of activity by the positive charge of adjoining sections of fibre; and the effect of the myelin sheath, interrupted at the nodes of Ranvier, is to increase the distance over which cancellation takes place, so speeding conduction along the fibre. Repeated stimulation increases the sodium content of the axon and reduces its potassium content, and time is necessary for these changes to be reversed.

Dr. B. KATZ (University College, London), who was unable to be present, was to have put forward the view that an electrical change must be produced in a sense organ before messages can travel along the appropriate sensory fibres; and that this is so whether the initial stimulus is light, sound, mechanical pressure, or a chemical substance.

Dr. F. K. SANDERS (Oxford) described experiments on the migration of virus particles along nerve fibres, and the multiplication of the virus. He has worked with the spontaneous encephalomyelitis virus of mice (mostly with the "severe" strain, G.D.VII). This is not closely related to the virus of poliomyelitis, but its behaviour is similar to that of the poliomyelitis virus in monkeys and possibly in man. The virus particles travel at 0.5 mm. per hour (compared with the 2.5 mm. per hour reported for poliomyelitis in monkeys). If inoculated into tongue muscle, the virus particles are first detectable in the first group of nerve cells serving the tongue at about 20 hours from inoculation. Between 30 and 60 hours, virtually no virus can be demonstrated in these cells, which may mean that the virus has been "dis-assembled" in some way so that it is no longer infective. Yet from 60 hours onwards there is very rapid increase, and at 100 hours more than one million times as much virus can be recovered from these cells alone as was originally inoculated. The attainment of maximum virus concentration closely coincides with, or perhaps precedes, the onset of tongue paralysis.

Psychology

The presidential address to the Section of Psychology was given by Professor J. C. FLUGEL (University College, London). In a discussion of "Human Affairs and the Psychological Point of View," he suggested that there was room for a closer psychological approach to economics (e.g., on the motivation of spending and saving). He referred to the conflict between the legal and the moral points of view resulting from the increasing penetration of the psychologist into the field of delinquency, and to the further conflict raised by the application of psychological approach to the investigation of the religious attitude. The most urgent need was perhaps for the greater adoption of the psychological point of view in the field of politics, with which existing "social psychology" had little contact.



Professor C. W. VALENTINE (Birmingham) suggested that the tendency to explain every problem child in terms merely of environmental factors had gone too far, and that "even in America" a back-swing had now begun. Mr. P. SMITH (late principal assistant organizer, City of Birmingham Education

Committee) reviewed experience of 25 years of research on vocational guidance in schools; the most important single conclusion being perhaps that "vocational guidance cannot easily, and indeed should not, be separated from educational guidance."

Preparations and Appliances

NOVEL MODIFICATION OF BOYLE'S ANAESTHETIC APPARATUS

Dr. W. B. PRIMROSE, senior anaesthetist, Glasgow Royal Infirmary, writes: The conventional gas–oxygen anaesthetic apparatus installed in most hospitals now consists of a sight-feed unit for the gases, followed in series by a chloroform bottle, ether bottle, and breathing-bag with tubular connexion to the patient, all parts being under the control of valves. This arrangement does not permit the use of carbon dioxide absorption: for this a special absorbing unit of elaborate design and make is required which is fed with gases from the machine through a tubular connexion. The accompanying photograph

shows the manner in which a simple absorbing unit can be incorporated with the anaesthetic apparatus, rendering any elaborate means for CO_2 absorption unnecessary.

The alterations required are very simple, and the arrangement depends upon the fact that neither chloroform nor "trilene" should be used with an absorber. This means that the chloroform bottle is removed. Its place is given to the ether bottle, which remains an essential component of the system. The header to which the ether bottle was previously attached has its immersion tubular parts removed by unscrewing them in the case of the bakelite mount: the plunger rod is, however, left in place. The exit orifice of the header through which the vapour normally passes to the patient is carefully enlarged to 7/16 in. (1.1 cm.). In the case of the all-metal mount, nothing is removed. The exit aperture is again enlarged to a corresponding degree, both on the bottle side and also on the breathing-bag side of the barrel valve. This is done with the turning lever at the full "on" position, and in such a way that the valve closes completely at the "off" position.

The absorber consists of an ether bottle which has a hole drilled in the bottom to take the British metal-tube fitting. This is fixed by screw collars with rubbers to protect the glass and to give gas-tightness. To this fitting is attached the expiratory tube from the face-piece mount. The absorber, filled with 1 lb. (454 g.) of soda-lime granules, screws into place in the usual way. The circuit is completed by the inspiratory tube which passes from the breathing-bag to the face-piece.

The face-piece mount, to which the hoses are attached, consists of a Barth three-way valve with an adjustable expiratory valve suitably fixed to it. This very light and convenient valve provides all requirements for breathing. Air can be breathed. The "no valves" position with the expiratory valve provides the ordinary gas–oxygen–ether (or other) anaesthesia. In this position the absorber is shut off at the face-piece in addition to its being cut out at the header valve when in the "off" position. The "valves" position provides circuit breathing through the absorber, which must also be "on" at the header valve.

In circuit breathing the rubber flap valves are kept moist unless they are allowed to get dry from periods of inaction. It is generally known that rubber will not distort for a long time if kept damp and cool. The valves should, of course, be changed at intervals of from three to six months, and, provided this precaution is observed, there should be no leakage.

If it is desired to use trilene or chloroform the absorber is removed and the fittings for the chloroform bottle are replaced in the case of the bakelite mount. The expiratory tube can be detached from the Barth valve, when the apparatus becomes as originally arranged. Confusion or accident from decomposition of these drugs cannot take place.

The advantages of this simple modification are considerable. The changes themselves are easily carried out and there is no essential interference with existing parts. The absorber can be changed in a few seconds, during the operation if necessary, as the only screw to be manipulated is that of the bottle—about one and a quarter turns. The original Boyle machine with absorber is now self-contained and eminently portable.

The method of single-phase absorption has been found quite satisfactory in anaesthetic work over the past 12 years. In the past 20 years I have tried circuit and to-and-fro breathing in both liquid and solid absorbents, and find that expiratory absorption is as good as any.

I am indebted to Messrs. Vicarey, Davidson and Co., 162, Bath Street, Glasgow, C.2, for carrying out my instructions in producing this modification.

According to a report from the Director of Medical Services, Uganda, the incidence of yaws has been exceptionally high for many years among the 266,000 inhabitants of Lango District, where the number of sufferers seeking treatment was never sufficiently great to reduce the reservoir of infection. Consultations were held in 1948 between the African local authorities and medical department representatives, as a result of which it was decided to embark upon an intensive campaign. The whole population has now been examined, and some 22,000 infectious cases were treated with arsenicals and bismuth during the last sixteen months. The district was divided into sectors, which were covered methodically by teams of trained African staff under a European medical officer responsible for organization and supervision. The results of the campaign appear to be excellent. A follow-up scheme in progress aims at the elimination of infections which were not detected during the campaign. One of the most difficult problems facing the public health workers of colonial territories is to find means of arousing popular interest in simple sanitary matters, any attempt to impose new habits by edict being of no avail. With this in mind a mass health education scheme was started early this year in one of the most densely populated areas between Kampala and Jinja. The scheme was designed to draw attention to the transmission of intestinal bacteria and worms. Lectures, demonstrations, and discussions were held, and films, photographs, and slogans were displayed. Chiefs and other African officials from all over the country attended the course, which lasted a week. The whole "school" was then moved to each county subcentre for a week, where many local people came to see what was happening, stayed to ask questions, and often lent a willing hand in the construction of latrines and the protection of water supplies. There were signs that those who attended the "schools" were beginning to show interest in the reduction of intestinal infections.

Correspondence

Psychology as Science

SIR,—It is good, even at the cost of an expressed difference of opinion by an old pupil in whose psychiatric education he can never have taken great pride of achievement, to have stimulated the return of Dr. Bernard Hart (September 9, p. 623) to a scene in which he has been so distinguished a figure, and his letter must increase our regret that his wisdom and experience do not more often find public expression in a field of medicine where they were never more needed than to-day. Nevertheless, I believe that there is a greater measure of agreement between us than of difference, though I still must feel that the inferences I drew from his lecture are valid and necessary. He allows that psychopathology comes only in part, and then imperfectly, within the discipline of science. But since Dr. Hart accepts Karl Pearson's postulates, this element of science can only be natural science, for the postulates are not applicable to a science of history. Indeed, we may doubt whether Pearson would accede to the notion that there could be a historical "science." It is for this reason that I felt I had to equate Dr. Hart's use of the term "science" with "natural science." Further, if the intrusion of "purpose" in psychopathology requires this to be placed within the fold of biology, then this "purpose" can only be teleology. Yet surely it is not teleology that he had in mind. Thus I conclude that there is involved in his thesis the error of using one term in two senses in one argument.

Dr. Hart now believes that false systems of thought should be allowed to die of natural decay while we passively await their replacement by sounder systems. If a purely philosophic system were in question, this view would have the sanction of history, though even the ghosts of dead philosophic systems still haunt us. But psychological medicine is more than a system, if less than a philosophy. It is also a methodology, indeed a number of methodologies, and these have the widest effects upon the community. They influence thought and practice in every field of medicine. Views about them, of varying degrees of naivety, are put abroad by politicians, journalists, and novelists, and now by the terms of the Criminal Justice Act of 1948 the State has made the psychiatrist an official participant in the administration of the law, and in a manner which gives him a dangerous latitude in his treatment of certain offenders before the courts who are certifiable neither as mental defectives nor as persons of unsound mind. In these circumstances we cannot stand silently by while unsound systems and methods of medicine die tediously of natural decay, doing perhaps an infinity of harm in the process.

In the past literature has owed an immeasurable debt to literary criticism. Is it to be assumed that the science and arts of medicine do not need, and should not receive, the same kind of salutary corrective? If Dr. Hart had really thought this he would never have given us his critical and stimulating Goulstonian lectures, which still contain valuable lessons and great delight for all who read them.—I am, etc.,

London, W.1. F. M. R. WALSHE.

Training for General Practice

SIR,—The consensus of opinion in your recent educational number was that medical education was barking up the wrong tree in that it produces ill-developed polyvalent quasi-specialists instead of general practitioners. As your contributors pointed out, the course for a medical student as at present designed pays but the scantiest attention to the needs of the general practitioner. Therapeutics are rather frowned upon by physicians when teaching students. I well remember one of my chiefs answering a question on the treatment of a case by saying, "Learn the signs and symptoms now: therapeutics will come later." That eventual time did not come until I had left my hospital and, away from the guiding hands of sister and dispenser, I was faced with the difficult problems of medicine in a Families Welfare Centre in the Army. No time now to sneak away and look up a textbook of therapeutics. Only time to write a prescription and hope it was the correct line of therapy and that its ingredients would be palatable and compatible.

Paediatrics, now forming a large part of my practice, was taught by six weeks' children's clerking combined, if I remember correctly, with venereal diseases, but it was August and the chief was away on his summer holiday.

As a student I just achieved my 25 midwifery cases, and if I had not had the privilege of being resident accoucheur after qualifying I should soon have become one of those who were recently described in your columns as wildly wielding the forceps. Skins, fevers, minor orthopaedics, and oto-rhino-laryngology are all now painful exercises in temporizing while I have time to ask somebody's opinion or read it up.

Not only are the wrong things taught to students but the methods employed are inefficient. Despite all the evidence of special methods of teaching presented in your pages, I am not convinced that they will ever replace some of the traditional methods. I was surprised that no one called for an extension of ward teaching, and in fact the general impression was that this method was disparaged by your reformers. Ward teaching has always been one of the prides of the English medical schools. It is still paid great lip service by our teachers, and many complain that they do not see the students in the wards as much as in the old days. The reason for this is not far to seek. When I held my clinical appointments in 1945 I had from eight to ten cases to look after at any one time. When I came on the house in 1948 I found that the clerks and dressers were lucky if they had three or four cases, and I know of some students who from no fault of their own had never seen a case of acute appendicitis when they qualified. In the same period the introductory course had been extended from three weeks to three months, the teaching in psychology and psychiatry had increased, and now it is rumoured that the students are soon to be taught French and German. Surely the time is out of joint. Yet one of the solutions has been so often hinted at. I remember a friend who in desperation before finals was able to spend an afternoon in a cardiac ward of a municipal hospital. There he discovered that there was a difference between early and mid-diastolic and pre-systolic murmurs and that the third and fourth heart sounds really existed. Here is one efficient way to train the primary instruments of the doctor—his eyes, ears, and fingers.

But even when the student has gained a knowledge of the well-known and well-defined textbook illnesses and has qualified, it will be many years before he becomes proficient in that most difficult of all specialties, general practice.—I am, etc.,

Farnborough. J. D. BURY.

SIR,—May a practitioner 40 years qualified venture some comments on the article by a general practitioner (August 26, p. 493) on his medical education 25 years ago? Inevitably these comments must be reminiscent and egotistical, but I am glad to say that they are of a purport relating to my own day quite contrary to the somewhat disgruntled carping with which your younger contributor refers to his. Perhaps because I lacked his more enviable background of University culture and came straight from a rather spartan northern public school, and also, no doubt, because a medical career was my own avid choice and not a parental *Diktat*, I entered the busy world of the London Hospital and its college in 1905, and remained there as a student and resident until 1912 with unalloyed enthusiasm and satisfaction. With a bare minimum of cash, an old football injury limiting games, and a "cribriform" type of memory, it was possibly for my good that hard work was imposed upon me; but I still remember with respect and gratitude all my teachers, and their inculcation of principles and practice which have remained throughout the years as an inspiration and guidance for the work of each day. The emphasis was always upon the practical, and was focused on

the patient, his history and physical examination. The ancillary methods of clinical pathology were—and properly so to my archaic mind, *pace* the strictures of a research scholar of much erudition and less horse-sense on the imperfections of British general practice—relegated to the pathological laboratory as the only environment in which they could attain a true accuracy.

Many of my teachers are gathered to their fathers. Some happily remain, but all my generation and later ones who came under the influence of Arthur Keith, Leonard Hill, William Bulloch, Hubert Turnbull, Robert Hutchison, Henry Head, James Sherren, Russell Howard, and James Walton and their contemporaries must remember them with respect, gratitude, and affection. The hospital itself was a world teeming with the activity of all sorts and conditions of humanity, of all races, creeds, trades, and temperaments. Apart from formal teaching there were unceasing opportunities for increasing knowledge of men and things by continuous intercourse and contact with keen and often brilliant minds among teachers, residents, students, and laymen alike, whilst an ever changing pageant of clinical material unfolded itself before the inquiring eye.

Medical education was in those days much simpler, to-day it is no doubt much better, but I would aver that in my day at "The London" it was a vital and invigorating discipline.—I am, etc.,

Minehead. H. B. WALKER.

The Importance of Preventive Medicine

SIR,—Last year I commented on the section on public health services in your educational number. Your contributor then said that prospects in public health had never been better. Many of us considered this to be wishful thinking, and the pitiful contribution in this year's educational number shows how right we were. The disquieting drop in the numbers taking the D.P.H. course is confirmation if any were needed.

Financial prospects apart, what is wrong with public health, or, as I prefer to call it, preventive medicine? The preventive specialist used to have his roots in hospital and domiciliary medicine, and one of his main contacts with the public through them. The National Health Service Acts have cut these roots. Owing to financial stringency no new ones have grown, and the result is that the preventive specialist has had his potentiality for good very severely restricted. Prior to July 5, 1948, approximately two hospital beds out of three in Scotland were provided by the local authorities. The extent of the restriction will thus be seen by reference to the following table taken from the national estimates:

National Health Service Estimates Scotland 1950-1 and 1949-50

	1950–1	1949–50
	£	£
Hospital and specialist services ..	31,986,000	28,761,000
General medical services	16,402,000	17,449,000
Local authority services	1,350,000	1,100,000
All other services	1,516,000	1,668,300
Totals	£51,254,000	£48,978,300

In other words, one-fortieth of the expenditure under the Scottish National Health Service Act is directed towards the prevention of illness and preservation of health. That is what is wrong with public health.

Dr. Frank Gray's presidential address (*Supplement*, August 12, p. 85) indicates part of the way. He says that the hospital is antagonistic to preventive medicine, and that the way of salvation for the general practitioner lies in interesting himself in the trivialities with a view to the prevention of serious illness. I heartily agree. The general practitioner is in a position to do more for the nation's health than anyone else. There has sometimes in the past been antagonism between him and the local health department. Provided that he realizes that the local health department has much help to offer him, and he to offer to the department, there is no need for any antagonism.

The local authority clinic did great service in the days when every visit to the private doctor cost money. Now that the general practitioner's surgery is a "free for all" in more ways than one, the general practitioner should welcome the opportunity to see pre-school children on his list, at the clinic, for a fee. Similarly he should be prepared to act as medical officer to a school, to get to know the pupils and the relationship between their health and their educational progress. Before undertaking such duties, however, he should have training and experience which as a rule are not his. There is much in the D.P.H. course that could and should be included in that for the undergraduate, and there is much specialist training in the latter which should be jettisoned. The discipline of applied physiology and applied bacteriology, the latter leading on to epidemiology, is in my view vital. And, above all, the introduction to preventive medicine should be made no later than that to curative medicine.

So much for the general practitioner's approach to and place in public health. What now of that of the trained preventive specialist? Hitherto he has, as a rule, been drawn to public health at an early stage in his postgraduate career. Perhaps this has had something to do with the antagonisms previously mentioned. I do not think that recruitment from the ranks of general practitioners could be improved on. And incidentally I consider that this applies to clinical specialism as well as preventive. Satisfactory work in the child welfare, school health, and epidemiological branches should count towards a specialist diploma in preventive medicine. This should preferably be granted by a national college or faculty of preventive medicine and replace the existing statutory D.P.H.

Finally, a new local health authority must be set up, under which the general practitioner, preventive expert, and clinical specialist all play their part in the health team. General practitioners will form the forward line, leading the attack, preventive specialists will be the half-backs, and clinic specialists the backs and goal-keeper to cover up when play goes against the attackers. This local health authority must have all the functions, health and welfare, of the existing local health authority. It must take over the functions of the local executive council, and of the local hospital management committee. It must have the closest possible liaison with the National Assistance Board and the Ministry of National Insurance. By this means alone, full inter-service co-operation, can the full potential for health of all parties be developed and the National Health Service be made to pay dividends instead of swallowing money in its present prodigal way.—I am, etc.,

Elgin. I. C. MONRO.

Mechanical Aids to Instruction

SIR,—The excellent article on this by Drs. R. Ollerenshaw and P. Hansell (*Journal*, August 26, p. 488) serves to stress the importance of these aids, which was very obvious at a recent large international congress where the failure of many speakers to make proper use of the diascope and epidiascope was a cause of great discomfort to the audiences. After attempting to see and read wholly illegible matter projected by epidiascope, one came to the conclusion that societies should prohibit the use of this form of projection until speakers learned to use it properly. Even lantern slides were often of very poor quality, or overcrowded with figures.

On one point one cannot agree with Ollerenshaw and Hansell. They say, in speaking of lantern slides, "Script is always more legible when projected as a white image on a black field than in the more usual black and white." I have always found that staring at a black screen with white script has a curiously irritating effect, and that one soon tires. Other members of the audience usually agree that this is an unsatisfactory form of projection. When this form has been used, one has usually blamed the speaker for showing negatives and being too lazy or too parsimonious to have proper positives prepared. The subject appears to be worth investigating from the physiological and psychological aspects.—I am, etc.,

Edmonton, N.18. A. B. ANDERSON.

Traumatic Neurosis and Electro-shock

SIR,—It must be so rarely that electro-shock treatment administered in this country meets with misadventure that it may be of interest to mention a case in which it led to a severe traumatic neurosis—the most severe case of conversion hysteria I have met with, even in the psychotherapy of two world wars.

She was a patient of 34 who had been paralysed for twelve years in both legs, was emaciated, 5 st. (32 kg.) in weight, would not and could not eat, and had such severe headaches and noises in the head that she could not read, nor listen to the radio, nor meet visitors. The headaches took the form of pressure in the cranium and a "cracking" and "grating" in the occiput, as of a fracture. The noises were described as "Morse sounds" of someone constantly crying, interspersed with someone screaming. She also heard voices in German saying, "Won't eat! I can't go on," etc. These noises and voices were so loud and insistent that she projected them and thought they came from someone crying in an adjoining room or in the street, and often asked that they should be stopped. It is not surprising that on several occasions she attempted suicide, and that her condition was falsely diagnosed as schizophrenia. She also suffered from "fits," and was on occasion found on the floor in the morning unable to move because of her paralysis. These fits were diagnosed as epileptic, and she was given "epanutin" for several years.

She was treated psychologically by the abreaction method (reliving the experiences, releasing the repressed emotion, and readjustment to the situation), and the causes of her symptoms were revealed. It transpired that the cracking and grating sensations in the occiput and the headaches originated in a car accident in which she was thrown on the back of her head on the hard road and suffered "concussion." This accident does not concern us except that it was for the results of this accident that she was first treated medically in Germany and then sent to a psycho-analyst, obviously of the cruder type, whose insistence that she was sexually in love with her father and that she must fall in love with him, the analyst, before she could get better so distracted her that she became much worse and had to be sent to a mental hospital, was diagnosed as schizophrenic, and there received electroplexy in 1938.

This apparatus seems to have been of the somewhat primitive type, and she was warned that on no account must she let the electrode slip. Three or four times the administration was satisfactory, but on the occasion in question, just before the shock was given, she felt the electrodes slipping. She was filled with horror, and yet dared not move to stop it in case it made things worse. The shock was administered, the instruments were smashed, the doctor and nurse also received shocks, and the patient experienced a terrific blow on the head followed by the convulsion, during which, as it transpired, she was quite conscious. But she developed an amnesia for the whole experience. Her symptoms originated from this dissociation; they were in fact a revival of what she had experienced but repressed and forgotten. The so-called "epileptic" fits were a reproduction in detail of the convulsion itself, the "Morse noises" were of her own crying when in the dissociated state of shock, interspersed by a scream when she moved and felt a severe pain in her back, presumably from a compressed fracture. The voices she heard were her own voice saying, "I can't go on," etc., when in the dissociated state. The paralysis was partly due to the previous car accident (for after that she suffered from periods of paralysis) but finally and persistently from the electro-shock. There were of course predisposing causes going back to childhood, as we always find even in traumatic cases, but they do not concern us here.

By the recovery of all these experiences all her symptoms have one by one disappeared as they were analysed, and she has now made an almost complete recovery—she has had no fits for some months, no headaches, and the noises have gone. She is now able to walk on the level, though not yet upstairs without help owing to the disuse of her limbs for 12 years, is eating heartily, and has nearly doubled her weight.

This case supports the view of Janet, Freud, and others that it is not the physical shock alone but the psychic shock, in this case the conscious horror of the experience, which produces the traumatic neurosis. This explains why it is that patients undergoing electro-shock do not always suffer from traumatic neurosis. If traumatic neurosis were the result of physical shock as some maintain (as in the case of shell shock), electro-shock treatment should always end in neurosis. This patient had had three or four previous doses of shock treatment without any effect, bad or good, although the shock was sufficient to make her unconscious. In this last instance she was conscious of the horrifying experience although it was dissociated. This case also reveals the interesting fact that projected voices, although regarded as real by the patient, may be due not to paranoia or schizophrenia but entirely to psychological dissociation.—I am, etc.,

London, N.W.1 J. A. HADFIELD.

Poliomyelitis

SIR,—In the excellent refresher course article on poliomyelitis by Dr. Howlett Kelleher in the *Journal* (September 2, p. 570) very little mention is made of the infectivity of the disease. No advice is given to the G.P. on isolation of contacts, nor of any necessary disinfection of rooms, clothing, etc. These are questions always asked by relatives, and a clear guide to the practitioner would be, I am sure, very generally welcomed. Recently, while doing a locum, I have had a case brought to the surgery, and felt it my duty to close the rooms until they were disinfected by the health authority. Was this necessary? I am, etc.,

Hambrook, Bristol. G. S. KEELING.

*** Some of the points raised here are discussed in a leading article this week. For advice on disinfection in individual cases, medical officers of health should be consulted.—ED., *B.M.J.*

Haematemesis from Leeches

SIR,—The following case was recorded in April, 1950, at a camp for Arab refugees situated in the Jordan valley. It compares with an anecdote about Rhazes (Ar-Razi), the renowned Arabian physician who lived from A.D. 850 to 923, and bears out the aphorism of Rokitansky: "Those about to study medicine, and the younger physicians, should light their torches at the fires of the ancients."

Case Report.—An Arab boy, 7 years old, was brought to the camp clinic by his father, who complained that the boy had vomited blood three times during the preceding two days, but was otherwise quite well, without any pain or nose-bleeding, and, apart from measles and ascariasis, had had no previous illness. The boy vomited shortly after his arrival: the vomitus was not large in quantity and contained fresh blood, together with typical "coffee grounds," mucus, and food residue. On examination the boy was seen to be pale, but of good physique. He was intelligent and co-operative. There was no conjunctival or mucosal pallor, and no signs of dried blood on the external nares. The teeth were in good condition, but the gums were hypertrophic and bled easily (a very common condition among these children). Tongue and fauces were normal, but a small black object was momentarily visible behind the uvula. On further examination with a mirror this proved to be the tail of a large horse-leech, which was firmly attached to the posterior wall of the naso-pharynx. Traction on the leech with forceps failed to remove it, owing to its properties of tenacity and elasticity. With a view to local anaesthesia the throat was then sprayed with 5% cocaine hydrochloride; fortunately this had the additional effect of partially paralysing the leech so that it became easily detachable, and it was removed and identified as a specimen of *Limnatis nilotica*. Needless to say, the vomiting of blood did not recur.

The following anecdote is quoted by Professor E. G. Browne in his FitzPatrick Lectures on Arabian Medicine. It appears in the works of several Arab writers, particularly Qadi Abu Ali at-Tanukhi, whose account is particularly valuable, as he was almost a contemporary of Rhazes.

A young man who had recently travelled from Bagdad was troubled by the vomiting of blood, and he went to visit the famous physician. After careful examination, however, he was unable to explain the cause of his symptoms. The patient was in despair, believing that where Rhazes had failed none other could succeed. The physician, touched by his distress as much as by his faith, then proceeded to question him carefully as to the water he had drunk on his journey, and ascertained that in some cases it had been drawn from stagnant pools. "When I come to-morrow," said he to the patient, "I will treat you and not leave you until you are cured, on condition that you will order your servants to obey me in all that I command them concerning thee." The patient gave his required promise and Rhazes returned the next day with two vessels filled with a water-weed, which he ordered the patient to swallow. The patient, having swallowed a considerable quantity, declared himself unable to take any more, whereupon the physician ordered the servants to hold him on his back on the ground and open his mouth, into which he continued to cram more and more of the nauseous substance until

vomiting ensued. Examination of the vomit revealed a leech, which was the source of the trouble and with the expulsion of which the patient regained his health.

Two further cases of leech infestation were seen during a period of eight months in Transjordan. In one case the creature was attached to the epiglottis, in the second case it was in the pharynx. In neither of these cases was haematemesis the presenting symptom. Such leech infestation is not uncommon in tropical and sub-tropical areas. Manson-Bahr and Stitt, for instance, both describe horse-leeches as being liable to occur in this situation, but the usual presenting features are said to be epistaxis and persistent headache.

It is debatable whether Rhazes had made the diagnosis, and it seems possible that his therapy was based on the magical law of similarity (homoeopathic magic), which is still prevalent at the present day in Arab folk medicine. Muhammad 'Awfi, however, writing in the thirteenth century, gives Rhazes credit for the diagnosis and states that the leech when swallowed in the drinking-water had attached itself to the mouth of the patient's stomach and there remained until induced to transfer itself to the more congenial water-weed.—I am, etc.,

A. CAMERON,
Lately with British Red Cross Commission, Jordan.

Guildford.

An Unusual Foreign Body in the Rectum

SIR,—Although medical literature contains a long list of reports of foreign bodies in the rectum, I consider the following case of sufficient rarity and interest to add to the already formidable list.

A married professional photographer, aged 48, stated that, while reducing his piles following defaecation, he slipped and fell and became unconscious. On recovering he had agonizing rectal pain and then noted the absence of a paste pot which had been standing on the lavatory floor. After feeling the paste pot in his rectum he got on his motor-cycle and rode eight miles to his doctor and a further three miles to hospital. On admission he was in considerable pain, but regarded his accident with a certain amount of humour.

On rectal examination, about ½ in. (1.3 cm.) above the deep sphincter the bottom of a large bottle could be felt, but it was impossible to get beyond it. The sphincters and mucous membrane were grossly dilated and oedematous, but not lacerated. Under general anaesthesia the bottle was found impacted between the bodies of the ischium laterally, the pubis anteriorly, and the lower end of the sacrum posteriorly. A finger could be passed beyond the rim of the bottle on the postero-lateral quadrant, but it could not be moved in any direction. Attempts were made to extract it with various forceps, but without success. A laparotomy was carried out through a left lower paramedian incision, and again it was found impossible to push the bottle out of the rectum from above. The rectum was opened, but the bottle could not be got up out of the pelvis.

It was finally found necessary to break the bottle in the rectum with a hammer and chisel before removing it in pieces. This resulted in some laceration of the rectal mucous membrane, which was repaired. The opening in the bowel was closed and a left inguinal colostomy performed. The pelvis was drained with corrugated rubber and the wound closed in layers.

During the post-operative period he developed some proctitis and a small faecal fistula along the drain (from the pelvis). Sphincter exercises were begun after ten days. The fistula closed and he was discharged from hospital in four weeks. He was readmitted after two months for closure of his colostomy. His sphincter tone and rectal mucous membrane were then normal and he was discharged with a normally functioning bowel.

He has kindly photographed an identical bottle with measurements.

I am indebted to Mr. F. H. Scotson, consulting surgeon, under whose care this case was, for giving me permission to publish.

—I am, etc.,

Manchester, 8. J. B. PRENDIVILLE.

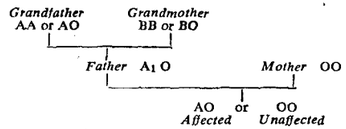
Erythroblastosis Foetalis Following ABO Incompatibility

SIR,—We wish to report an interesting case referred to us by Mr. Rutherford Morison, of Harrogate.

A primipara, aged 28, was admitted to a maternity home on April 4, 1950, being then 26 weeks pregnant (B.P. 180/120, albumin ++). The uterus was much larger than normal for dates. A radiograph of the abdomen showed a single foetus presenting as a breech with extended legs and confirming the age as 26 weeks. No foetal abnormality was seen. On Wednesday, April 5, 1950, her membranes were ruptured and several pints of bright yellow liquor were withdrawn. After being in labour for about 36 hours she was fully dilated but without progress for over two hours. An abdominal palpation, even allowing for the amount of liquor withdrawn from the uterus, gave the age as 34–36 weeks. The foetus and the placenta were removed per vaginam only with the greatest difficulty. The foetus was so oedematous as to be the equivalent more or less of a full-term foetus. Ascites was so marked that the abdomen of the child had to be punctured before it could be delivered. The placenta was mushy and came away piecemeal, in spite of which the amount of post-partum haemorrhage was minimal. There was a second-degree tear. A post-mortem examination was made on the child on April 7, 1950, at the National Blood Transfusion Service Depot, Leeds.

The whole foetus was very oedematous but not macerated. All subcutaneous tissues were waterlogged—the scalp floating on the skull. The brain was oedematous but otherwise normal. The dorsal spine and one thigh had been fractured at delivery. The skin was pale and very slightly jaundiced. At examination there was almost no blood in the child at all. The liver was enlarged, and grossly and visibly degenerated. All other organs appeared normal. These macroscopic appearances suggested haemolytic disease of the newborn in the form of hydrops foetalis.

A piece of the liver was sent to the Pathology Department at Leeds University for histology, which reported:



"The sections of this liver show most extensive extra-medullary haemopoiesis, the majority of the sinusoids containing primitive (marrow) forms of blood cells. There is also a marked degree of haemosiderosis, the iron-staining pigment being dispersed in fine granules within the liver parenchymatous cells. The liver cells show a degree of cloudy swelling but no advanced degeneration. There is no cirrhosis and nothing to suggest congenital lues. The histological appearances are without doubt those of erythroblastosis foetalis."

Meanwhile samples of the mother's blood showed her to be Group O Rhesus-positive, genotype R_1R_1 (CDe/CDe). A Kahn test had proved negative. Setting up the mother's serum against a panel of known Group O cells showed that there were no rhesus antibodies of any kind present about this time—i.e., April 10, 1950. The husband's blood was taken and found to be Group A rhesus negative (r r, cde/cde).

As the serological findings conflicted with all other evidence, further samples of the mother's blood were examined on May 12, and with the following result as regards the alpha titre. It was found that the mother's serum haemolysed the father's red cells to a titre of 1 in 4 and afterwards agglutinated them to a titre of 1 in 16,384 in saline and 1 in 128,000 in albumin. An indirect Race-Coombs test showed a titre similar to the albumin result.

As the child had been born dead no blood was taken from it, but it was presumed to have been Group A (from the father). ABO incompatibility seemed a certainty as the cause of foetal death. It seems possible that the high alpha titre was in part naturally occurring, as the mother gave no history of previous pregnancy in any form, nor of any previous transfusions or injections of blood at any time. A further sample of the mother's blood was taken on May 27, 1950. This showed no change in the alpha titre.

The parents were anxious about the prognosis. Accordingly, in order to find out whether the father was heterozygous, blood samples were taken from the father's parents. Grandmother, Group B; grandfather, Group A. It was calculated as under that each pregnancy produced a 50/50 chance of the infant being affected—and probably dying *in utero*.

Further estimations of the mother's alpha titre will be made.—We are, etc.,

National Blood Transfusion Service, Leeds.

Myeloid Leukaemia and Pregnancy

SIR,—In order to add to the list one more instance of chronic myeloid leukaemia associated with pregnancy, I record the case of a woman who, some fifteen years ago, was admitted in the early days of the puerperium to the Crewe Memorial Hospital as suffering from puerperal sepsis.

She was pyrexial, had localized infection of the breast, vulva, and skin, a large spleen, and cardiac murmurs. Before the blood film was seen, the likely diagnosis seemed to be bacterial endocarditis. Dr. W. H. Grace, of Chester, kindly examined the film and found it to be typical of myeloid leukaemia, from which disease the patient eventually died. In spite of the fact that the leukaemia, which must have been present during the pregnancy, was not treated at that time, I cannot recall any abnormality of the infant. The woman was admitted for a time to the Royal Infirmary at Chester, where I am sure any investigator will find more adequate details than my memory can supply.—I am, etc.,

High Wycombe. G. S. W. EVANS.

Danger of Mixed Anaesthetics

SIR,—It would seem, from a study of some recent articles on anaesthesia and from conversations with colleagues, that the practice of mixing thiopentone and a relaxant in the same syringe prior to administering them as an anaesthetic is becoming widespread. As almost the sole advantage of this technique is its convenience to the anaesthetist, I should like to present the arguments which operate against it. When any drug is exhibited the safest possible method should be used, and only techniques which allow the operator to judge the signs of possible overdosage, and to take steps to prevent it, are admissible. Dr. T. C. Gray and others, whose experience of relaxants is greatest, stress the necessity of a test dose, and while as yet the percentage of subjects sensitive to relaxants is not known, the literature already contains records of deaths which have occurred when this precaution was neglected, to say nothing of other cases which have survived only after prolonged and energetic resuscitation.

When the thiopentone-relaxant mixture is used, the test dose is rarely given, and if given loses most of its value, because, since the cardinal sign of overdosage of either thiopentone or curare is apnoea, each may mask the effect of the other to such an extent that it is impossible to judge the effect of either drug on the patient with any accuracy. Under such conditions overdosage becomes fatally easy. In addition, users of a thiopentone-relaxant mixture are, in effect, acting on the belief that there is an exact thiopentone-relaxant equivalent—e.g., 15 mg. D-tubocurarine chloride ≡ 0.5 g. thiopentone. This is simply not true, as users of these drugs can testify, and the fact that on a number of occasions such a mixture has been successfully used cannot be accepted as upholding that belief, for if the exceptions are as rare as even one in two hundred cases, these should be sufficient to rule it out.

It is suggested that when it is intended to use a relaxant with thiopentone, or indeed any other anaesthetic agent, the greatest margin of safety is obtained only if (*a*) a test dose of relaxant is invariably given, since at worst no harm is done, and at best, where the patient is sensitive, valuable information is obtained, and (*b*) the full dose of relaxant is administered separately and after the anaesthetic agent, so that the anaesthetist can judge the effect of each on the patient.

Anaesthetists have been called—among other things—"the guardians of sleep." If they use techniques other than the safest, surely their proud motto "In somno securitas" can be called in question and yet another question posed in its place: "Quis custodiet ipsos custodes?"—I am, etc.,

London, W.12. J. ANSTRUTHER SMITH.

Collapse During Spinal Analgesia

SIR,—I read the letter from Drs. E. H. Winterbottom and J. W. Dundee in your issue of August 26 (p. 527) with great interest. The last paragraph, however, gives me cause for thought and great difference of opinion. I agree that there was much argument against the use of spinal analgesia in this case, but why, if general anaesthesia were chosen as an alternative, should it be assumed to be necessary to intubate and use intratracheal methods? Auricular fibrillation could just as easily have been initiated by intubation, as they say, and I can see no reason for thus complicating a general anaesthetic in a case for relief of urinary obstruction.—I am, etc.,

Orpington. ERIC A. SCOTT.

Methyl Bromide Poisoning

SIR,—The case of methyl bromide poisoning reported by Drs. A. C. MacDonald, I. C. Monro, and G. I. Scott (*Journal*, August 19, p. 441) prompts me to record the case of a man who was in my care last year.

The patient was a "spiv" who stole some 200 R.A.F. methyl bromide fire extinguishers from a storage depot. While unloading these from his lorry one went off in his face and he felt temporarily overcome by the fumes. Between two and three hours later he felt his hands shake and then collapsed quite suddenly. He was admitted to a hospital, where he was unconscious for four days. The cause of his collapse was only discovered following police investigations.

After four weeks he was discharged from hospital but complained of weakness and jumping in his arms and legs. Ten weeks later, as there were no discoverable organic causes for his symptoms, he was referred to a psychiatric out-patient clinic, where I first saw him, and he was later in my care in a neurosis unit for some weeks. The symptoms were of a hysterical nature and were susceptible to suggestion, but at first it was necessary to persuade the man to face the police charge that was awaiting him. In court the Recorder said that the patient had already suffered enough, and he was put on probation. Following a slight relapse in his weakness he then improved with superficial psychotherapy and was soon fit for work.

An interesting feature of the case was that while in hospital for treatment of the neurosis he had a typical grand mal seizure. This was witnessed by an experienced male nurse who has observed many epileptics, and I have no doubt that it was a genuine epileptiform convulsion. There was no history of any previous attack (even during the acute stage of the methyl bromide poisoning), and unfortunately the patient took his discharge soon after this so that further observation was denied us.

My attempts at follow-up of this patient have been unsuccessful, but over a year after leaving hospital he was seen by a nurse who had known him in hospital, and he appeared to be maintaining normal health.—I am, etc.,

Co. Durham. JOHN A. EWING.

Pyloric Stenosis in a Premature Infant

SIR,—Congenital pyloric stenosis is regarded as a well-defined entity and has been widely reviewed in the literature. The following case report is of interest chiefly because the patient was a premature infant presenting the classical signs of congenital pyloric stenosis.

In 1925 Weeks and Brooks reported a premature infant with pyloric stenosis weighing 4 lb. (1.8 kg.) at operation. Gallagher, in 1937, reported a case of pyloric stenosis occurring in a coloured female infant which weighed 3 lb. 8¾ oz. (1.6 kg.) at birth. The mother was delivered by caesarean section because of nephritic toxaemia. In this case the infant did well until the 28th day, when vomiting commenced and typical signs of pyloric stenosis were noted. A Ramstedt operation was performed, but the wound did not heal by first intention and resuturing was necessary. Vickers and Conrad

(1940) also reported a case of an infant weighing 4 lb. at birth. Signs and symptoms of pyloric stenosis developed when the infant was one month old. The infant weighed only 3 lb. 12 oz. (1.7 kg.) at operation, which was successfully performed. The wound broke down on the 10th day after operation, but final recovery was complete.

Case Report.—An apparently healthy female infant was born at Staincliffe General Hospital, Dewsbury, on November 24, 1949. The mother had had three previous pregnancies, two of which had resulted in premature births and one in a miscarriage. There was no history of pyloric stenosis in the two living children. With the present pregnancy there was evidence of toxaemia, but delivery was spontaneous and normal. At birth the infant weighed 4 lb. 6 oz. (1.9 kg.) and had a crown-heel measurement of 17 in. (42 cm.). The mother's menstrual history was vague, but it was estimated that the infant was born at about the 36th week of gestation. The infant did well until the 15th day, when she began to regurgitate feeds. Gradually the vomiting became more copious and forceful, and stools became infrequent and dry. She was hungry for her feeds but began to lose weight. On the 19th day a definite abdominal mass with the characteristics of a pyloric tumour was felt, and weak peristaltic waves were visible. A diagnosis of congenital pyloric stenosis was made, and "eumydrin" was given before each subsequent feed. However, she did not improve and vomiting persisted.

On the 21st day a Ramstedt operation was performed. At this time the infant weighed 4 lb. 1 oz. The operation was performed under local analgesia, and a well-marked hypertrophy of the pylorus was found. No particular difficulty was encountered at the operation. Recovery was uneventful and the wound healed well by first intention. She was discharged from the hospital 3½ weeks after operation, when she weighed 6 lb. 13¼ oz. (3.1 kg.).

The Training of Pathologists

SIR,—It was with considerable interest that I read of the recommendations of the committee set up by the Royal College of Physicians "to inquire into the training and recognition of medical specialists in pathology, and to make recommendations concerning this branch of medical practice in the future" (August 26, p. 515). Having been actively engaged in the teaching of pathology for almost twenty years I write to point out a condition which should apply to all pathologists-in-training.

I consider it imperative that the fundamental principles of pathology should be assimilated and inculcated correctly, systematically, and thoroughly from the very outset, and not left, as is implied in the annotation on the report, until the third, fourth, or fifth year when the trainee is in a university or associated department and free from routine responsibilities. As a consequence, the recommended generous provision of posts in hospital laboratories, and in the departments of clinical pathology of universities and teaching hospitals, must be such as to permit candidates specially selected for training to be free or relatively free from routine responsibilities in the first or first and second years of training. This would enable all trainees systematically to acquire considerable competence and experience of laboratory methods in each of the four divisions of pathology within a two-year period, and at the same time to make some study of the four subjects in selected and supervised reading. By this means candidates would receive a good grounding in pathology and be the better able to profit from the three succeeding years of study in which a selected subject or one of special interest could form the basis of individual investigation and study suitable for presentation as the thesis for a higher degree.

This point is stressed because, unless first- and second-year trainees are appointed *supernumerary* to departmental establishment in hospital laboratories selected for training, those in training would be employed mainly or wholly in repetitive routine work and would learn little of the fundamentals of their subject and perhaps only a limited repertory of technical methods. As a corollary, it is important that the medical staff of departments of pathology selected for teaching, in hospitals other than teaching hospitals, should be adequate to allow the senior members time in which to teach all juniors systematically. Such an arrangement would, in the end, more than justify the expense of the salaries paid out for little immediate return, other than, say, resident alternate night duty required of trainees.

When, in the future, conditions become more stabilized it should be possible for the university departments of pathology to be responsible for the initial period of postgraduate training and provide, in a two-year course, a curriculum similar to that at present followed for one year at the Postgraduate School for the Diploma in Clinical Pathology (University of London). The additional year would permit of methods being learned less hurriedly and practised more frequently, and at the same time allow of related systematic reading. Such university postgraduate courses in pathology for all trainees should not be regarded as the ideal and the unattainable, but rather as the best and essentially economic means of providing well-trained pathologists in this country.—I am, etc.,

J. F. HEGGIE.

London, N.18.

Vaccination and Inoculation Certificates

SIR,—In your issue of July 22, p. 215, you publish a letter from Sir Philip Manson-Bahr referring to the inconvenience caused by regulations regarding vaccination and inoculations. This draws attention to an important international matter at present being studied by the World Health Organization. It is proposed next year to replace the various present international sanitary conventions with new international health regulations. An opportunity is thus given to place medical supervision of international trade and travel on a more scientific basis and so reduce the present too frequent obstruction it offers to free international movement. In this respect, however, the draft of the new regulations already circulated to governments for comment is not reassuring. If these regulations are adopted they will still provide nervous or officious health authorities with ample scope for demanding excessive immunization certificates, medical examination, and isolation of passengers and crews, and the holding of ships, aircraft, and land transport, all in the name of disease prevention. It is not possible in a letter to indicate how doubtful many such quarantine barrier methods are as a means of preventing the introduction of disease. My own opinion is that there is scarcely any measure of the quarantine barrier type which is practical or justifies the serious obstruction given to international trade and travel. I have given this view in an article in the *Journal* (1948), **1**, 1092, from which I should like to quote the summary:

Much medical interference in world traffic still exists in spite of the advance in international sanitary legislation. This partly arises out of the increasing demand for travellers to hold vaccination certificates and to submit to medical examinations, and partly to medical interference with shipping and aircraft. Arguments are put forward [in the paper] suggesting that such restrictive quarantine medical practice is of limited value and is dangerous in creating a false sense of security. It cannot guarantee exclusion of infection and is no protection against the recrudescence of endemic disease. It leads to the neglect of more valuable internal measures for improving medical organization and sanitary conditions. It also contributes to inter-territorial friction.

There is thus a need for the international sanitary conventions now being revised to reduce "police" measures, to emphasize national self-reliance and responsibility, and to clear the way for better national health services and world transport less shackled with medical restrictions.

Lung Cancer and Petrol Lighters

SIR,—If the use of petrol lighters is to be considered as a possible cause of lung cancer, as suggested by your correspondent Dr. R. W. Ironside (August 26, p. 529), what about paraffin-impregnated matches?—I am, etc.,

B. R. SANDIFORD.

Birmingham, 3.

Obituary

HERBERT MORLEY FLETCHER, M.D., F.R.C.P.

Dr. Morley Fletcher, consulting physician to St. Bartholomew's Hospital, died at his Sussex home on September 9, in his eighty-sixth year. Although he had lived for years in retirement in the Sussex village of Petworth, Dr. Morley Fletcher will be remembered not only by a host of his Harley Street neighbours and others but by a large number of young and middle-aged members of the medical profession who worked under him as clinical clerks and house-physicians or met him in the examination-room. He was examiner in medicine for Cambridge, Durham, Manchester, Sheffield, and Glasgow Universities, Queen's University, Belfast, and the National University of Ireland, also for the Conjoint Board and the Society of Apothecaries, so that a large proportion of entrants into medicine must have been examined by him. He had the gift of rapidly assessing the quality of an individual and measuring his attainments, and was never misled by pretentiousness or superficial brilliance.

Herbert Morley Fletcher was born in 1864 at Huyton, in Lancashire, the son of Alfred Evans Fletcher and Sarah, daughter of Richard Morley, of Leeds. His younger brother was Sir Walter Morley Fletcher, the first secretary to the Medical Research Council, who died in 1933. Herbert was sent to Mill Hill School, and then to Trinity College, Cambridge, where he took his B.A. in 1887. At Cambridge, like his brother, he shone not only in natural science but also as an athlete. He was elected president of the Cambridge University Athletic Club in 1888, and to a good age he was adept in many kinds of outdoor sport. Few men have kept their youthful appearance and carriage so long after middle life. He received his medical training at St. Bartholomew's, qualifying in 1890, and proceeding M.D.Cantab. in 1893. He completed his studies at Freiburg and Vienna.

Morley Fletcher's reputation as a consultant in general medicine, and especially in children's diseases, quickly grew. In 1904 he was appointed to the staff of his old hospital, St. Bartholomew's, of which in due time he became senior physician and on his retirement in 1929 consulting physician. He was also vice-president of the Medical College. Other hospitals with which he was associated were the East London Hospital for Children, Queen Charlotte's, the Alexandra Hospital for Diseases of the Hip, the Florence Nightingale Hospital, the Infants' Hospital, and the Bushey Heath, Hertford County, and Royal Buckinghamshire Hospitals. He was also a member of the consulting staff of the Convalescent Home for Officers at Osborne, Isle of Wight, honorary physician to the Metropolitan Convalescent Institution, and a member of the Medical Consultative Board of the Navy. In the war of 1914–18 he served as major, R.A.M.C.(T.). In 1933 he was appointed by the Government a member of the Advisory Committee concerned with the administration of the Cruelty to Animals Act.

He was a prominent figure in the Royal College of Physicians of London, becoming eventually Senior Censor. He took the Membership of the College in 1891 and was elected a Fellow in 1900. At one time he was president of the Section of Medicine of the Royal Society of Medicine and at another president of the Section of Diseases of Children. He had also been president of the British Paediatric Association and honorary secretary of the Association of Physicians. The Royal Australasian College of Surgeons made him an Honorary Fellow, and in 1937 Queen's University, Belfast, conferred on him the honorary degree of LL.D. The Marquess of Londonderry, Chancellor of the University, in bestowing the degree, described him as having one of the most acutely critical minds in medicine. "His detection of error is exercised not only on scientific hypotheses but also on conjectures contained in the type of monographs whose utility is most doubted by their authors." This ceremony took place during the British Medical Association meeting at Belfast, where Dr. Morley Fletcher was president of the Section of Diseases of Children. In 1894 he published a translation of C. van Kahlden's *Method of Pathological Histology*. He contributed the article on biliary cirrhosis in Allbutt and Rolleston's *System of Medicine* and on diseases of the peritoneum, liver, and pancreas in Garrod, Batten, and Thursfield's *Diseases of Children*. He was a frequent contributor to the *Practitioner*, and his writings were authoritative and widely quoted.

He was twice married: first to Ethel Frances, who died in 1918, daughter of the late Joseph Crossley, of Halifax, by whom he had two sons and three daughters; one of his daughters of this marriage is the wife of Mr. H. U. Willink, K.C. His second marriage was to Mary Christina, sister of Mr. H. U. Willink, by whom he had two daughters.

A former house-physician writes: "Morley," as we always called him, gave one the impression of being a bit aloof. But to become his house-physician was to become his friend and colleague. It was only after one had left Bart's that one realized how tolerant he had been to youthful arrogance. He treated his house-physicians as equals who were sharing with him the common task of looking after the sick. "It might be worth while trying such-and-such a drug," was his method of instruction: you received the instruction in the form of a consultation, and this was enormously encouraging.

Morley Fletcher was a sound clinician of the older school. He kept himself up to date with recent advances in medicine without ever surrendering his judgment of a case to the compilers of reports on special investigations. He was always courteous and urbane, and to be on "Morley's" firm as clerk and house-physician was a very happy experience. That very remarkable figure in charge of his male ward, Sister Hope (Miss Powell), used to say: "One can get very cross with Dr. Fletcher, but as soon as he smiles you are disarmed at once." One amusing characteristic of him was that once he had made up his mind that certain of your experiences had followed a certain pattern it was difficult to convince him of error in one or two particulars: he held fast to his own version.

About a year ago he said he thought he had shrunk a bit, but he still held his slim, trim figure as erect as ever. Morley Fletcher was a connoisseur in those things that make for the fuller life. To all who knew him well he was a lovable person, and they will hold his memory in great affection.

Dr. ERNEST VILLIERS HUNTER, of the Church Missionary Society, Uganda, died suddenly on July 29 at Nairobi aged 73 years. As a young man he worked as a missionary in India, but after a time he decided to become a doctor, and he qualified in Ceylon in 1903. After qualifying he held a number of medical posts, being at one time in charge of a leper colony in India. At the beginning of the first world war he joined the R.A.M.C. and was posted to Gibraltar. On demobilization he took up general practice in Worcestershire, but two years later he responded to an appeal from the Church Missionary Society for a doctor to work in Uganda. For some years he worked at Ngora, where he founded and built the Freda Carr Hospital. In 1939 he took charge of the Mengo Hospital. During the difficult war years his gifts of resource and practical common sense were of great service to Mengo. He did much to modernize and improve the hospital. On his retirement in 1942 his services to the Protectorate were marked by the award of the O.B.E. He continued to serve the Church Missionary Society in an advisory capacity up to the time of his death. Dr. Hunter was a man who was valued and respected by a wide circle of friends of all races. As a doctor he showed great shrewdness, wisdom, and skill. He was eminently a practical man and could turn his hand to many things. His deeply rooted Christian faith was the mainspring of his entire life and character. The last year of his life was clouded by the death of his wife, who had been so closely united with him in all his aims and activities, and also by the loss of his only son. His own death came at a time when he felt that his life's work was done, and he was buried, as he would have wished, in African soil.—W. R. B.

Dr. JOHN VINCENT BATES, of West Malling, Kent, died suddenly on August 14 at the age of 58, while attending a meeting at the West Kent General Hospital. Dr. Bates was educated at Highgate School, Pembroke College, Cambridge, where he was a scholar and where he obtained first-class honours in the Natural Sciences Tripos in 1913, and University College Hospital, where he gained the Goldsmid Exhibition. He qualified in 1915 and at once joined the R.A.M.C., serving in France with a battalion of the Black Watch. At the Battle of the Somme, in 1916, he was awarded the Military Cross. He served in France until he was wounded in 1917, when he was posted to the Military Heart Hospital at Colchester. On demobilization he took the M.A. and M.B. and B.Ch. degrees of Cambridge University, and subsequently became house-physician at University College Hospital and house-surgeon at the Leicester Royal Infirmary, finally entering general practice as partner in a large practice at West Malling. In this practice he was medical superintendent of the Malling Isolation Hospital and medical officer to the Aylesford Paper Mills and Holoplast, Ltd., and was the well-loved friend and adviser of a large number of patients, who will mourn his passing. Shortly after coming to West Malling he was gazetted to the 131st (H.C.) Field Ambulance and eventually commanded the unit, retiring with the rank of brevet-colonel. Dr. Bates was a member of the B.M.A. since 1919, was chairman of the Maidstone Division from 1944 to 1947, and was Representative of the Division at the A.R.M. in Cambridge in 1948. He was a member of the Kent and Canterbury Local Medical Committee and of the management committee of the Mid-Kent group of hospitals. He leaves a widow and two sons, both of whom have followed him in the profession of medicine. The sympathy of a large circle of friends and colleagues will go out to his family.

Dr. BERTRAM HENRY BARTON died on August 16 after a long illness at the age of 67 years. He was educated at Chatham House, Ramsgate, and in medicine at St. Bartholomew's Hospital, where he qualified in 1906. He graduated M.B. in 1908 and proceeded M.D. in 1910. After holding house appointments at the Seamen's Hospital, Greenwich, the Royal Hospital, Portsmouth, and the Hospital for Sick Children, Great Ormond Street, he became a general practitioner in Harrow, where he worked until his retirement about three years ago. During the first world war he was in the R.A.M.C., serving in France with front-line troops for a long period. He was awarded the M.C. for his outstanding work in a field-dressing station. As a general practitioner he was much beloved by his patients and held in great esteem by his brother practitioners. He was on the staff of Harrow Hospital for many years as a general practitioner and gave much of his time to giving anaesthetics there. During the second world war he did E.M.S. work at the same hospital. He was a keen member of the B.M.A. from 1910, and chairman of the Harrow Division in 1926–7. In 1941 he represented Harrow at the Annual Representative Meeting in London. By his death the district of Harrow has lost one of its most loyal and devoted general practitioners, for he was a man who devoted his time and attention whole-heartedly to his profession.—H. E. T.

Mr. EDWARD GILLESPIE, for many years a member of the surgical staff of the Prince of Wales General Hospital, Tottenham, died at Bishop's Stortford on August 22. He studied medicine at Glasgow and graduated M.B., Ch.B. in 1900. After working as a house-surgeon at the Western Infirmary he left Glasgow and held a number of hospital posts while studying surgery. He was admitted F.R.C.S.(England) in 1907. Gillespie became surgical registrar at the Prince of Wales Hospital after working there as a house-surgeon. Before long he was elected an assistant surgeon, and thereafter he rose steadily until he became senior and, comparatively recently, consulting surgeon of the much enlarged hospital. He also soon came to be associated with the Enfield Cottage Hospital, which later became the enlarged Enfield War Memorial Hospital. During the first world war he held a number of surgical posts in France and in England: two of the most important were at Tréport and at the Tooting Orthopaedic Hospital. At the beginning of the second world war he joined the E.M.S. and was appointed to the Haymeads Emergency Hospital at Bishop's Stortford. He retired shortly after the end of the war, but continued to live at Bishop's Stortford.

Dr. C. F. Hadfield writes: The announcement of the death of Edward Gillespie may well have escaped the notice of the many hundreds of patients alive to-day who owe their existence to his skill and care. Perhaps the fact that I knew and worked with him for more than forty years may be deemed a valid excuse for attempting an appreciation of a man whom I, with no small experience, regard as one of the most able and skilful surgeons whom it has been my privilege to assist. While studying in Glasgow he came much under the influence of Sir William Macewen. Although anything but a hero-worshipper, and in fact apt to be somewhat censorious of the work of himself and others, he was never tired of praising the abilities of that great surgeon and admitting his indebtedness to his teaching. How exactly he became house-surgeon at the Prince of Wales Hospital, which was to take such a large part in his subsequent life, I do not know, but when I first met him in 1908 he was already surgical registrar there and working under, among others, that fine old type of general-practitioner surgeon, Mr. Hooper May. For very many years quite a proportion of Gillespie's private and hospital work was connected with Enfield, and he became the trusted adviser in more than surgical matters to many of the general practitioners of that neighbourhood. During this period he did not only the routine surgical work of the Enfield Cottage Hospital but also all the emergency operations, and he never seemed to resent the innumerable night calls there from the West End. Another of his appointments was that of surgeon to the Tottenham Hotspur Football Club. In this I was usually associated with him, and I should hesitate to say how many potential football teams we dealt with. I again had the privilege of working in close co-operation with him at the Haymeads Emergency Hospital. At first the staff was a rather shifting one of younger surgeons, some of whom perhaps did not quite understand why their senior should be a surgeon whose name they scarcely knew. It was, however, interesting and even amusing to those of us who knew him to notice how rapidly and without any effort on his part they came to seek his advice and to acknowledge his superior judgment and skill. He quickly attained an outstanding position not only in the hospital but in the surrounding neighbourhood for his surgical skill, his wisdom, and the trust he inspired. It is in fact at the special request of a number of his Haymeads colleagues that I have attempted to write this brief appreciation. During the war years his work at the hospital was twice seriously interrupted by severe attacks of coronary thrombosis, but after each of these he returned to his work with unimpaired abilities and continued to perform gastrectomies and other severe operations with unaltered success. Although a diligent student and critic of surgical literature, he himself wrote little and seldom took active part in formal discussions, though in private consultations his opinions were decided and trenchantly expressed. He was a keen sportsman and in younger days played much tennis. He was fond of golf, and, though never of the first class, he could up to the last usually give points to most of his house-surgeons and colleagues. Though his friends who remain will miss him sadly, we can rejoice that he was spared any long and tedious period of slowly diminishing physical and intellectual activity.

Dr. JAMES FRANCIS BLACKETT, for twenty-five years medical officer of health of the city of Bath, died at his home on August 30 after a brief illness at the age of 69 years. Though on the retired list, he was happily active up to the end, just having returned from doing relief duty for an old friend who had been on holiday. A student of the Bristol Medical School, he graduated M.B., B.S.(London) in 1906, proceeding to the M.D. in 1909. Two years later he also obtained the M.D. of Bristol University. James Blackett was an able student, obtaining the Lady Haberfield and the Clarke and Sanders Scholarships, as well as the committee gold medal of the Bristol Medical School. After a period as house-physician at the Bristol General Hospital he went into general practice for a few years. During the first world war he served as a captain in the R.A.M.C. In 1917 he turned to the public health field, and after obtaining the D.P.H. at Bristol he became assistant medical officer of health in the borough of Swansea. In January, 1920, he was appointed medical officer of health and school medical officer of his native city of Bath, a post which he held until his retirement in 1945. During his term of office Blackett was a pioneer in the development of the health services, being closely associated with the reconstruction of the City Isolation Hospital, the building of the Bath and Wessex Children's Orthopaedic Hospital, and Winsley Sanatorium. For thirty years he was honorary treasurer of the West of England Branch of the Society of Medical Officers of Health, and he was an active member of the B.M.A., representing the Bath Division at the annual meeting in 1923, and serving as chairman of the Division in 1930–1. Few people were privileged to know Blackett intimately, but those who did found in him a loyal friend and interesting companion. Studious and retiring by nature, he had a great interest in many subjects, apart from his chosen profession. Archaeology was a particular hobby, and at week-ends he was frequently to be seen cycling through the byways of Somerset in search of fresh knowledge. After his retirement he was able to enjoy his hobbies to a greater extent, travelling further afield on the Continent. His brain was as active and eager as ever, much of his time being devoted to recording the history of the development of public health services in Bath during the last fifty years. Happily he was able to complete this work, and in 1949 the University of Bristol awarded him the degree of M.A. for his thesis on this subject. Blackett was one of those who possessed in high degree the qualities of loyalty, thoroughness, and integrity—qualities which are so needed in public life to-day. He will be sorely missed by those of his staff to whom he also accorded the privilege of friendship. His wife died in 1941, but he leaves a son and daughter, to whom the sympathies of his friends and colleagues are extended.—B. A. A. W.

The Ministry of Health announces that gifts of blood to hospitals in England and Wales through the National Blood Transfusion Service totalled 125,956 during the first three months of this year—the highest number since the war. Over 23,600 more donors joined the Service in the quarter, bringing the total strength up to 377,704. Another 220,000 donors are needed to keep ahead of the steadily increasing demands of hospitals and to reduce calls on the individual donor.

Medico-Legal

NATIONALIZATION AND CHARITY

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

Another Chancery case recently gave the court an opportunity further to trace the dividing line between charities and State-owned institutions under the National Health Service, and to define the effects of the new legislation on bodies that have hitherto been governed by the principles of equity relating to charitable trusts. It decided that teaching hospitals are still charities and therefore suitable objects of bounty; and also that the Royal College of Surgeons is a charity.

The late Lady Bland-Sutton bequeathed funds to the National Provincial Bank, as executor and trustee of her will, to be applied as follows. The Royal College of Surgeons was to have £300 a year, free of tax, to maintain a Bland-Sutton Research Scholarship in its Bernhard Baron Laboratories, and the residue was to go each year to the Middlesex Hospital for the maintenance and benefit of the Bland-Sutton Institute of Pathology already in existence. But she attached a condition to this gift. If ever the institute should cease to be carried on as a pathological research institution, or if its name should be changed, or if the Middlesex Hospital should become nationalized or by any means pass into public ownership, or if the bank should become unable lawfully to apply the income for those purposes, then it was to transfer the capital and income of the endowment fund to the Royal College of Surgeons absolutely for the College's general purposes. In 1943, when her will was proved, the fund amounted to some £23,000, and down to July 5, 1948, when the National Health Service Act came into force, it was duly applied according to her will. After that date, however, the bank felt doubt concerning the effect of the Act, started to accumulate the income other than that required for the scholarship, and moved the court to determine whether the gift to the College was valid.[1]

Two important points arose for decision: whether the Middlesex Hospital had become nationalized and passed into public ownership, and whether the Royal College of Surgeons was a charity. On the first point, Mr. Justice Danckwerts stressed that the Middlesex is a teaching hospital for the purposes of the Act, and that when the Act came into force the Bland-Sutton Institute of Pathology was part of a medical school. By Section 6 of the Act all the premises and movable property of the hospital were transferred to the Minister of Health free of any trust; but by Section 7 all endowments of a teaching hospital were transferred to the board of governors constituted under the Act, and by Section 8 (1), where a medical or dental school is associated with a hospital which is transferred to the Minister under Section 6, property held solely for the purposes of that school is not affected, and those purposes are not to be deemed to be purposes of the hospital.

This provision seemed to the judge to take the property held for the purposes of the medical school of the hospital, including the Bland-Sutton Institute of Pathology, out of the provisions of the Act transferring property of hospitals to the Minister. By Section 8 (2) the property of a medical school of the University of London is transferred to the school's governing body. By the scheme submitted by the old council of the medical school and approved by the university, the council became incorporated and the property vested in it. The judge took the view that the governing body and the property had neither been nationalized nor passed into public ownership; the Bland-Sutton Institute of Pathology and its work continued in existence, though administered by a differently constituted body, and the bank might lawfully apply the income of the endowment fund for the purposes of the institute.

This ruling disposed of any right of the Royal College of Surgeons to the residue, but before giving it the court went deeply into the question of the legal standing of the College.

The right of the College depended on whether it is a charity at law, and a major obstacle to this view was a previous decision of the Court of Appeal in an unsuccessful claim by the College to be exempted from the tax on corporate and unincorporated bodies.[2,3] The argument before the court on that occasion had proceeded entirely on the question whether the property or income of the College was appropriated and applied solely for the promotion of science; and the court held that this condition was not satisfied.[4] Its reason was that the College had two main objects: promotion of the science of surgery, and promotion and encouragement of the practice of surgery and the interests of those practising or about to practise it; and the second of these objects disqualified it for exemption. The Chancery judge, however, now held that, in considering whether a particular society is a charity for the purposes of a gift in a will, the test is whether the objects of the society are really charitable, notwithstanding that their carrying out might incidentally produce benefits to its members. The motives of the members of a society on joining it are not material. Counsel for the College urged that the art and science of surgery are essentially a practical art and science, and cannot be promoted without practice and experience, which can be carried out only by means of a competent body of practitioners whose labours are intrinsically directed towards the cure or alleviation of the ills of mankind. The judge found great force in that argument, and considered himself free to hold that the real object of the College was the promotion and encouragement of the art and science of surgery and not the interests of surgeons. The earlier decision did not prevent him from so doing, as it concerned a particular statute and was directed to different considerations. This present judgment, though it did not help the College in its immediate object of securing the Bland-Sutton residue, may prove of great help on some future occasion.

Universities and Colleges

UNIVERSITY OF EDINBURGH

The Faculty of Medicine of the University of Edinburgh has announced the following Macarthur postgraduate lectures to be delivered by Mr. Norman C. Tanner, F.R.C.S., Senior Surgeon, St. James's Hospital, Balham, S.W., in the Surgery Lecture Theatre, University New Buildings, Edinburgh, at 5 p.m. on each day: Monday, October 9, "The Indications for Surgery in Peptic Ulcer"; Tuesday, October 10, "Operative Methods in the Treatment of Peptic Ulcer"; Wednesday, October 11, "Treatment of the Complications of Peptic Ulcer." Dr. Philip S. Hench, Mayo Clinic, Rochester, Minnesota, U.S.A., will deliver a Macarthur postgraduate lecture on Friday, October 13, at 5 p.m., in the Anatomy Lecture Theatre, University New Buildings, Edinburgh. His subject is, "The Present Status of Cortisone and A.C.T.H. in General Medicine." Senior students and graduates in medicine are cordially invited to attend these lectures.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

At a meeting the Royal Faculty of Physicians and Surgeons of Glasgow held on September 4, with the Visitor, Mr. Walter W. Galbraith, in the chair, the following were admitted Fellows of Faculty *qua* Physician: J. Colvin, R. J. Cuthbert, J. C. C. Kelly, R. J. McWilliam, S. S. Meighan, jun., J. McC. Murdoch, G. B. Shaw.

SOCIETY OF APOTHECARIES OF LONDON

Dr. Frank Howitt has been elected Master of the society and Dr. G. Roche Lynch and Sir Wilson Jameson Wardens. Sir Cecil Wakeley has been reappointed as the society's representative on the British Postgraduate Medical Federation for a further year.

The diploma of Mastery of Midwifery has been conferred upon Dr. Hugh F. Powell, *honoris causa*.

The following have been granted the diploma of L.M.S.S.A. upon examination: P. A. Van Der Merwe, A. H. R. Hewett-Clarke, W. B. Wright, P. E. E. Kann, M. K. Mangan, M. el K. A. Tarshouby, L. Tippett, C. E. Law, A. J. Rowe, W. C. Snoek, H. C. Killey, N. L. Rowe, D. G. Bluett, D. L. Hadley, T. G. Scott, R. A. Davidson, W. H. Bexon, A. Gordon, P. H. I. Parsons, B. Kay, R. N. Pearson, J. M. Hayman, G. T. Gould, R. E. Hazell.

No. 34

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended August 26.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1950 (a)	(b)	(c)	(d)	(e)	1949 (Corresponding Week) (a)	(b)	(c)	(d)	(e)

Stillbirths	180	22	24			189	14	33		
Rate per 1,000 total births (including stillborn)			28					37		

* Measles is not notifiable in Scotland, and the returns are therefore an approximation only.

† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

‖ Includes puerperal fever for England and Wales and Eire.

¶ Primary pneumonia no longer notifiable in Eire.

EPIDEMIOLOGICAL NOTES

Poliomyelitis

Notifications of poliomyelitis in the week ending September 2 were: paralytic, 302 (369); non-paralytic, 189 (220); total, 491 (589). The figures for the previous week are shown in parentheses. The total decrease compared with the preceding week was 98, of which 67 were paralytic and 31 non-paralytic. Non-paralytic cases in the week under review comprised 38.5% of the total. The uncorrected notifications for the corresponding week in 1947, 1948, and 1949 were 657, 73, and 308 respectively.

The only counties showing more than average increases for the week under review were Kent and the West Riding of Yorkshire—10 and 7 respectively more than in the preceding week. Material decreases in notifications occurred in London 12, Kesteven (Lincs) 15, Middlesex 7, Surrey 14, Warwick 9, Worcester 7, and East Riding of Yorkshire 7.

The following county areas have notified no cases in the four weeks up to September 2—Cambridge, Suffolk West, Cardigan, and Radnor. In the same period the following contributed 1 case only: Isle of Ely, Soke of Peterborough, and Anglesey.

Discussion of Table

In *England and Wales* a decrease occurred in the number of notifications of measles 1,252, whooping-cough 214, and acute pneumonia 56, while a rise was reported for acute poliomyelitis 39, scarlet fever 21, and diphtheria 10.

A further large fall occurred in the incidence of measles, and the number of notifications are now less than one-half what they were six weeks ago. The largest declines during the week were in Lancashire 219, Lincolnshire 185, Middlesex 84, and Yorkshire West Riding 81. The largest fluctuations in the local trends of whooping-cough were a rise of 38 in Hertfordshire and a fall of 38 in Southampton. The only variation of any size in the incidence of scarlet fever was a rise of 24 in the number of cases notified in London. The chief features of the local returns of diphtheria were rises of 3 in London and Kent.

The largest returns of dysentery were from Lancashire 36 (Southport C.B. 11, Oldham C.B. 8); Yorkshire West Riding 19 (Bradford C.B. 10); Durham 15; and Leicestershire 14 (Leicester C.B. 13).

The main centres of acute poliomyelitis were Lancashire 44 (Liverpool C.B. 11, Manchester C.B. 14); London 42 (Hackney 5, Islington 4, Lewisham 4, St. Pancras 4); Warwickshire 39 (Birmingham C.B. 22, Coventry C.B. 5, Sutton Coldfield M.B. 4); Gloucestershire 38 (Bristol C.B. 24, Sodbury R.D. 4); Yorkshire West Riding 38 (Leeds C.B. 8, Bradford C.B. 6, Sheffield C.B. 5); Lincolnshire 32 (East Kesteven R.D. 18); Durham 31 (Hebburn U.D. 5, Boldon U.D. 4, Stockton-on-Tees M.B. 4); Middlesex 24; Staffordshire 21 (Lichfield R.D. 4); Essex 19 (Romford M.B. 4); Kent 9 (Bromley M.B. 4); Leicestershire 18 (Leicester C.B. 15); Northumberland 18 (Newcastle-upon-Tyne C.B. 7); Glamorganshire 15 (Cardiff C.B. 4); Worcestershire 15 (Dudley C.B. 4, Bromsgrove R.D. 4); Sussex 13 (Brighton C.B. 4); Dorset 13; Yorkshire East Riding 11 (Kingston-upon-Hull C.B. 6); Devonshire 10; Yorkshire North Riding 10 (Middlesbrough C.B. 5); and Norfolk 10.

In *Scotland* increases were recorded in the number of notifications of scarlet fever 43, acute poliomyelitis 21, and whooping-cough 18, and decreases were reported for cerebrospinal fever 17, and dysentery 13. A rise in the incidence of scarlet fever occurred in most areas. The chief centres of acute poliomyelitis were Glasgow 20, Dundee 9, Fife county 7, Lanark county 7, Ayr county 6, Aberdeen county 4, and Greenock 4. The largest returns of dysentery were from Glasgow 45, Edinburgh 14, and Dundee 8.

In *Eire* the notifications of measles were 21 fewer than in the preceding week, while the notifications of whooping-cough were 19 above the previous week's total. A fall of 18 in the notifications of scarlet fever occurred in Dublin C.B., while a rise of 11 occurred in the remainder of the country.

In *Northern Ireland* the trends of infectious diseases remained practically constant. The largest returns of acute poliomyelitis were from Down county 8, Antrim county 6, and Belfast C.B. 4.

Week Ending September 2

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 715, whooping-cough 3,671, diphtheria 51, measles 3,413, acute pneumonia 235, acute poliomyelitis 491, dysentery 156, paratyphoid fever 6, and typhoid fever 7.

Medical News

Lecturing in North America

Sir Geoffrey Jefferson, C.B.E., F.R.S., Professor of Neurosurgery at Manchester University, will be making a lecture tour in North America next month. He will be giving the Sommer Memorial Lectures at Portland, Oreg., October 3–5; the Opening Address to the California Academy of Medicine, San Francisco, October 14; the Balfour Lecture, Toronto University, October 18; and the Martin Lecture to the American College of Surgeons, Boston, October 23.

Medical Studentship in Experimental Psychology

The Medical Research Council invites applications from men or women recently qualified in medicine and with one or two years' experience in hospital appointments for a studentship for training in methods of experimental psychology. The studentship will be tenable at the Psychological Laboratory, University of Cambridge, for a period of not less than one year. It will carry a stipend at the rate of £500 per annum (not expected to be liable to income tax); tuition fees and laboratory expenses will be met in addition. The award will be made with a view to future opportunities for research in medical problems of psychology, but no promise of employment after the expiry of the studentship can be given. The selection will be made as soon as possible after October 1, and applications should be lodged before then with the secretary, Medical Research Council, 38, Old Queen Street, London, S.W.1 (Telephone: Whitehall 4884), from whom forms for the purpose can be obtained.

British Epilepsy Association

At a meeting held on September 5 at Mansion House, Portland Place, London, W.1, it was decided to form a society known as the British Epilepsy Association, with the objects of bringing before the public the special needs of epileptics and of promoting their welfare generally. Lady Cynthia Colville was elected chairman, Miss Irene Gairdner honorary secretary, and a provisional council was formed. At a Press conference Lady Colville said that the association, which had the support of the medical profession, would carry out educational and propaganda campaigns to create a proper understanding of epilepsy.

Animal Experiments

The Fight Against Disease, which since 1921 has been the official organ of the Research Defence Society, has been renamed *Conquest*. Since the war only two issues per annum have been published; it is intended to publish *Conquest* quarterly, or even bi-monthly, and to include in it authoritative papers demonstrating important advances in prophylaxis, diagnosis and treatment, the relief of pain, and the prolongation of life which have resulted from experiments on animals. The first number of *Conquest* includes a brief history of the society and a statement of its aims and objects.

Dutch Medical Journals

Acta Brevia Neerlandica, which since 1931 has published Dutch contributions to physiology, pharmacology, and microbiology, is to combine with *Archives Néerlandaises de Physiologie de l'Homme et des Animaux* to form a new quarterly entitled *Acta Physiologica et Pharmacologica Neerlandica*. Papers in the new journal will appear in English, French, or German.

To Visit Greece

Mr. St. J. D. Buxton is visiting Greece for the third time on the invitation of the Greek Recovery Programme Committee from September 17 to October 5 to advise on rehabilitation of the wounded and sick and on the development of a national service for the care of cripples.

Wills

Mr. Thomas A. Hindmarsh, of Newcastle-upon-Tyne, left £59,950; Dr. Edmund R. Boyd, of Blythe Bridge, Staffs, £15,430; Dr. Edward Somerset, of Newbury, Berks, £17,464; Dr. Theodore H. Waller, of Bedford, formerly head surgeon of Chelmsford Hospital, £12,339; and Dr. J. K. Cumming, senior consultant surgeon to the Royal Infirmary, Blackburn, and senior consultant surgeon to the Blackburn District Hospitals Group, £9,207.

COMING EVENTS

Royal Free Hospital School of Medicine

The inaugural address at the opening of the 1950–1 session of the Royal Free Hospital School of Medicine will be delivered by Professor Lillian M. Penson, Vice-Chancellor of the University of London, at B.M.A. House, Tavistock Square, London, W.C., on Friday, September 29, at 3 p.m.

King's College Hospital Medical School

Sir Lionel Whitby, Regius Professor of Physic in the University of Cambridge, will deliver the inaugural address at the opening of the 1950–1 session of King's College Hospital Medical School at the school, Denmark Hill, London, S.E., on Friday, September 29, at 2.30 for 3 p.m.

Contraceptive Technique

A lecture and demonstration (on living models) on contraceptive technique will be given by Dr. Marie C. Stopes at the Mothers' Clinic, 108, Whitfield Street, London, W., on Thursday, October 5, at 2.30 p.m. Tickets must be obtained in advance, as space is limited.

St. Thomas's Hospital Dinner

The St. Thomas's Hospital Old Students' Dinner will be held at Claridge's Hotel, Brook Street, London, W., on Friday, October 20, at 7 for 7.30 p.m., when the chair will be taken by Mr. J. P. Hedley. The price of the dinner, exclusive of drinks, is 30s. Dress, dinner jackets. Tickets may be obtained from the honorary secretaries, St. Thomas's Hospital, S.E.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Wednesday

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE, 28, Portland Place, London, W.—September 20, 3 p.m., "*Modern Anaesthesia in France and its Developments Related to Cardiac Surgery*," Bengué Memorial Award Lecture by Dr. Nadia du Bouchet (Paris).

Thursday

CHADWICK TRUST.—At St. Mary's Hospital Medical School, Norfolk Place, Praed Street, Paddington, London, W., September 21, 4.30 p.m., "*The Public Health Aspects of Venereal Disease Control*," Malcolm Morris Memorial Lecture by Professor J. Earle Moore, M.D. (Johns Hopkins University).

ROYAL SANITARY INSTITUTE.—At Winter Gardens, Malvern, September 21, 10 a.m., papers: "*Water Supplies—An Unusual Case of Copper Poisoning*," by Dr. A. J. B. Griffin; "*Malvern Miscellany*," by Mr. C. C. Judson, B.Sc. Afternoon: visits will be made.

Friday

BIOCHEMICAL SOCIETY.—At Derby Hall, University of Liverpool, N. Mossley Hill Road, Liverpool, 18, September 22, 11 a.m., 289th meeting. Symposium: "*The Biochemistry of Fish*."

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES, 11, Chandos Street, London, W.—September 22, 8 p.m., general meeting. "*The Treponemal Immobilization Test in Relation to Biologic False Positive Tests for Syphilis*," by Professor J. Earle Moore, M.D. (Johns Hopkins University). A discussion will follow.

APPOINTMENTS

ANNING, STEPHEN TOWERS, M.D., M.R.C.P., Assistant Dermatologist (Consultant), the General Infirmary at Leeds.

BREMNER, ALAN E., M.B., Ch.B., F.R.C.S.Ed., Associate Orthopaedic Surgeon, Royal Victoria Infirmary, Newcastle-upon-Tyne, and Consultant Orthopaedic Surgeon to Gateshead Group of Hospitals.

COLLINS, MICHAEL JOSEPH, M.B., B.Ch., D.P.H., Medical Officer of Health, Hucknall Urban District, and Assistant County Medical Officer, Nottinghamshire County Council.

COOK, J. B., M.D., M.R.C.P., Senior Registrar, Neurological Department, the General Infirmary at Leeds.

CRAMOND, JAMES, M.B., Ch.B., D.P.H., Deputy Medical Officer of Health, Borough of Barking, Essex.

EUSTACE, ANTHONY, M.B., B.Ch., D.P.H., County Medical Officer of Health, Donegal, Eire.

KORVIN, H. G., F.R.C.S., Orthopaedic Surgeon to Mayesbrook School Clinic and Newbury Hall Clinic, Ilford, Essex.

POWELL, K. J., M.B., B.S., D.A., Consultant Anaesthetist, Exeter Clinical Area.

PRICHARD, JOHN STOBO, *M.C.*, M.B., B.Chir., M.R.C.P., Neurologist, Hospital for Sick Children, Toronto, Canada.

ROBINSON, MARGARET M. F., M.D., D.P.H., Assistant Medical Officer of Health for Maternity and Child Welfare, Derby.

SMITH, GEORGE W., M.R.C.S., L.R.C.P., House-surgeon, St. Helier Hospital, Carshalton, Surrey.

SOUTH-WESTERN REGIONAL HOSPITAL BOARD.—*Consulting Obstetrician and Gynaecologist in North Gloucestershire Clinical Area*, S. A. Bond, M.B., Ch.B., F.R.C.S., M.R.C.O.G.; *Consulting Radiologist in South Somerset Clinical Area*, D. R. F. Bertram, M.B., B.S., D.M.R.

STEPHEN, J. D., M.B., Ch.B., Pathologist, Regina General Hospital, Regina, Saskatchewan, Canada.

TATTERSALL, WILLIAM H., M.D., Consultant Chest Physician to the Bournemouth Area, South-west Metropolitan Regional Hospital Board.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Fergusson.—On August 27, 1950, at 9, Grosvenor Street, Edinburgh, to Elizabeth (formerly Brouton), wife of Dr. R. S. C. Fergusson, a son.

Shield.—On August 21, 1950, at Lyndhurst, Hants, to Margie (formerly Wood), wife of James B. Shield, F.R.C.S.Ed., a daughter—Pamela Joan.

MARRIAGES

Blend—Imerdauer.—On September 5, 1950, in London, David Blend, M.B., B.S., to Martha Imerdauer.

Donaldson—Wilson.—On September 2, 1950, at Jesmond Parish Church, Newcastle-upon-Tyne, Dr. Richard Gordon Donaldson to Dr. Ann Kenya Wilson.

Tompkins—McCoshim.—On August 28, 1950, in Glasgow, Arthur B. Tompkins, M.B., D.C.H., to Sheena E. McCoshim, M.B., Ch.B.

DEATHS

Cochrane.—On May 25, 1950, Stanley Cochrane, L.R.C.P.&S.Ed., L.R.F.P.S. Glas., of Mitcham, Victoria, Australia.

Ferguson.—On September 7, 1950, at a nursing-home, Edinburgh, Peter Joseph Henry Ferguson, M.B., C.M., of 4, Oxford Terrace, Edinburgh, late of 9, Windsor Street, Edinburgh.

Fletcher.—On September 9, 1950, at Burton Corner, Petworth, Sussex, Herbert Morley Fletcher, M.D., LL.D.(Hon.), F.R.C.P., aged 85.

Gillespie.—On August 22, 1950, at 29, Hockerill Street, Bishop's Stortford, Herts, Edward Gillespie, M.B., F.R.C.S., late of Weymouth Street, London, W.

Gunson.—On June 6, 1950, in Australia, Edward Burton Gunson, M.D., F.R.C.P.

Henry.—On July 13, 1950, Claude Dawson Henry, M.D., of Lower Hutt, New Zealand.

Hudson.—On August 26, 1950, at 6, Castleview Road, Rochester, Kent, Osborne Henderson Hudson, M.R.C.S., L.R.C.P., aged 90.

Kirkpatrick.—On August 19, 1950, William Alexander Kirkpatrick, M.B., B.S., of Skelton-in-Cleveland, Saltburn, Yorks, aged 47.

Kirwan.—On August 29, 1950, at a Croydon nursing-home, John Francis Kirwan, M.B., B.Ch., aged 50.

Lyons.—On September 1, 1950, the result of an accident, Harold Michael Lyons, M.R.C.S., L.R.C.P., of Bishop's Corner, The Bishop's Avenue, London, N., late of Didsbury, Manchester.

Milton.—On August 29, 1950, at Passey's House, Eltham, London, S.E., Edward Farminer Milton, M.D., aged 68.

Murison.—On September 8, 1950, at 4, Olden Lane, Purley, Arthur Alexander Murison, L.R.C.P.&S.Ed., L.R.F.P.S.Glas., late of City Chambers, Glasgow.

Palmer.—On September 2, 1950, at Nottingham, Charles James Palmer, L.S.A., J.P., of Longdale Lane, Linby, Notts, formerly of Mansfield Woodhouse, Notts, aged 81.

Pim.—On August 24, 1950, at Holcombe, Bath, William Ferguson Pim, M.D., formerly of Foxrock, Dublin, aged 83.

Pott.—On September 7, 1950, at Upham, Hants, Francis Henry Pott, M.R.C.S., L.R.C.P., of 81, Cornwall Gardens, London, S.W., aged 89.

Rivaz.—On September 3, 1950, Percy Montgomery Rivaz, M.D., Surgeon Captain, R.N., Ret., of 23, Vanbrugh Park, Blackheath, London, S.E.

St. Johnston.—On August 29, at an Eastbourne nursing-home, Sir Thomas Reginald St. Johnston, K.C.M.G., M.R.C.S., L.R.C.P., late Governor of the Leeward Islands.

Tucker.—On September 2, 1950, at St. Helier Hospital, Carshalton, William Marwood Tucker, B.M., B.Ch., of Gisborne, New Zealand, aged 33.

Wight.—On August 26, 1950, at Wangford, Beccles, Suffolk, Cecil Harold Wight, *M.C.*, M.R.C.S., L.R.C.P.

Wolff.—On August 28, 1950, at Bears House, Hingham, Norwich, Ernest Douglas Wolff, M.R.C.S., L.R.C.P.

Woodcock.—On September 5, 1950, at 23, Burton Crescent, Headingley, Leeds, Herbert de Carle Woodcock, M.D., F.R.C.P.Ed., D.P.H., aged 89.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Varicose Vein Injections

Q.—*Can you tell me something of the nature and frequency of unpleasant sequelae resulting from the injection of sclerosing agents into varicose veins—assuming that the technique has been properly carried out? One is struck by the contrast between the great care and forethought we give to antecubital venous injections and the comparative recklessness we show when we are injecting sclerosing agents into the varicose veins of our patients. Ought we not, for example, to test a patient's urine before we subject him to the somewhat hazardous business of "intravenous phenol therapy"? Do soaps injected intravenously become hydrolysed, and, if so, is there not a potential danger of oleic or morrhuic acids so formed giving rise to oil embolism?*

A.—Unpleasant sequelae occur after the injection of varicose veins in a small number of cases, and the ideal sclerosing agent is yet to be found. Prevention of complications is assisted by avoiding injections in cases of previous severe spontaneous thrombophlebitis, ischaemic conditions of the leg, gross secondary skin changes, and in patients who are not ambulant. A very severe local reaction may lead to an injection ulcer and cause sufficient pain to keep the patient still during the following day, thus encouraging the spread of thrombosis to the deep veins. Sudden collapse following the injection and delayed urticaria are severe enough complications to warrant the cautious use of sclerosing agents, particularly sodium morrhuate and monoethanolamine at the first session. Haematuria and pulmonary embolism are very rare complications. The safest substance to use is probably 30% saline, but it is extremely painful when injected in quantities sufficient to produce good thrombosis, and general anaesthesia is usually necessary. Monoethanolamine is used in many clinics, but very rarely an attack of urticaria is encountered with this synthetic soap, which is included in the *British Pharmacopoeia*. Sodium morrhuate has fallen into disrepute following frequent reports of reactions after its use. There is some experimental evidence (*Proc. R. Soc. Med.*, 1948, **41**, 631) that not more than 2 ml. of sclerosing agent should be injected into a varicose vein at a time, owing to possible damage to the valves in the deep veins. With the patient lying down, 2 ml. of radio-opaque solution has been shown to stay in the superficial veins until the leg is exercised, when it is rapidly dispersed in the general circulation and diluted so much that no distant effects are produced.

Sterilization of the Male

Q.—*Would you kindly let me know the immediate, permanent, and any late effects of sterilization of a healthy male aged 30 by vasotomy? Under effects I include those on libido, sexual functions, mentality, physical organs, and any other known changes. Is vasotomy 100% certain, if carefully performed, to prevent any danger of insemination?*

A.—Vasotomy has no ill-effects of any kind, either immediate or remote. Occasionally there is a little temporary swelling and discomfort for 48 hours after the operation, but even this is unusual. Libido is not affected. A few patients notice that the amount of fluid ejaculated is a little less than previously, but this does not spoil their pleasure, which is more likely to be enhanced by the elimination of all anxiety on the score of a possible conception. Atrophy never follows, and there is no increased risk of developing a testicular neoplasm. The operation is sometimes carried out as a rejuvenating measure (Steinach's operation), so it is not likely to precipitate premature old age. If the operation is properly carried out and the possibility of recanalization guarded against it is 100% successful, but contraceptive measures must be continued until the spermatozoa beyond the ligated and divided vasa have been eliminated: half a dozen ejaculations should be sufficient to secure this, but it is safer to examine the semen microscopically and to be certain that it contains no spermatozoa before discarding these measures.

Ankylosing Spondylitis

Q.—*What are the causes of ankylosing spondylitis? On what points does the diagnosis rest and what is the treatment? Is it possible that the condition could result from, or be aggravated by, any of the well-known tropical diseases? Could living conditions in a country such as Iraq have any special bearing on it?*

A.—The cause of ankylosing spondylitis is unknown. It is considered by some to have an infective origin, but no specific infective agent has been proved. Others have suspected an endocrine basis, but again there is little evidence to support the hypothesis. The relationship between ankylosing spondylitis and rheumatoid arthritis is also uncertain.

The diagnosis is made from a consideration of the clinical, radiological, and serological findings. Clinically, the disease begins typically in young (17–30) male adults. There is deep pain first localized across the sacro-iliac area, later spreading upwards towards the lumbar and dorsal spine. At the same time there is increasing stiffness of the spine. In progressive cases the cervical spine and sometimes the hips are involved. In the typical established case the main features found on examination are gross rigidity of the spine (often excepting the upper cervical region) and markedly diminished chest expansion on respiration (often as little as half an inch). Radiologically the first changes (always bilateral) are seen in the sacro-iliac joints. There is loss of the sharp outline of the joint margins, which have a fuzzy appearance. Later, bony ankylosis of the joints occurs. As the disease progresses changes of a similar nature are seen in the lumbar, dorsal, and often in the cervical spine. There is destruction and obliteration of the facet joints and bridging of the vertebral bodies by ossification of the longitudinal ligaments. In cases with hip involvement there is progressive narrowing and, later, bony ankylosis of one or both joints. It is important to note that the stiffness of the spine, as observed clinically, is in advance of the radiological changes; thus a large part of the spine may be almost completely rigid when the radiological changes are confined to the sacro-iliac joints. The blood sedimentation rate is much raised during the active stage of the disease.

Treatment may be considered under four headings: relief of symptoms and arrest of the disease; prevention of deformity; maintenance of maximum function; and reconstructive or corrective operations in the late stage. Deep *x*-ray therapy is the most effective method of relieving the symptoms, and it is thought that it often leads to arrest or delays the progress of the disease. The marked tendency to flexion deformity of the spine is prevented mainly by sleeping on a hard flat mattress in the supine position, with not more than one pillow. Flexion deformity is almost inevitable if the patient sleeps on his side with spine, hips, and knees flexed. Occasionally, in the active stage, a plaster bed is advisable. Maintenance of maximum function depends upon adequate supervision by a physiotherapist to ensure that all movable joints are used to the full extent and that the muscles controlling them retain their full power. Special exercises for this purpose are advisable. In the later stages, if marked crippling or deformity has occurred, certain reconstructive operations may be advisable. The most useful are arthroplasty of the hip (for pain or ankylosis) and corrective osteotomy of the spine (for fixed flexion deformity).

Since the cause of ankylosing spondylitis is unknown it is difficult to say with certainty whether its incidence or course is likely to be influenced by living conditions or disease in other countries. Though some observers gained the impression during the war that ankylosing spondylitis did seem to occur unusually frequently in troops stationed overseas, the writer knows of no statistical evidence to support the impression.

Vaccination Failing to Take

Q.—*I should be glad of your advice concerning a child, now aged 2, who has been five times vaccinated, with negative results, by three different doctors. On the last occasion special lymph was obtained in view of the four previous failures. Bearing in mind the letter by Colonel W. Strelley Martin in the "Journal" of May 13 (p. 1142), can you suggest any further measures? Is intradermal injection of lymph ever employed in resistant cases? The child's father has lived in the East and has a friend with a similar history of unsuccessful vaccination in infancy; he subsequently developed severe smallpox.*

A.—It is most unusual to find a young child completely refractory to primary vaccination. It is not stated at what age the unsuccessful attempts were made in this case, but if they were done in the first few months of life it is possible that the infant still had enough antibody by passive transfer from the mother to interfere with a successful vaccination, particularly if the mother had been vaccinated within a year or two of the child's birth. A further attempt at vaccination should be made now with vaccine lymph used as soon as possible after it is received, since vaccine quickly loses potency if not kept in the refrigerator. Intradermal injection is not likely to be more effective than inoculation by scarification or multiple pressure. The suggestion that the British vaccine lymph used in the Middle East during the late war was ineffective was thoroughly investigated and refuted by an expert committee.

Lichen Planus

Q.—*What is the modern treatment for lichen planus? A male patient aged 55 has had this condition for two years. He has a rash on the glans and the body of the penis, with mucous patches in the mouth. He has been treated with various salicylate creams and bismuth injections weekly. Arsenic causes a severe skin irritation.*

A.—No specific cause for lichen planus has been demonstrated, though a great deal of work has been done on the influence of constitutional and psychological disturbances and on the part played by drugs in precipitating this disorder. These factors are probably of major importance and should receive due attention and treatment. There is no specific remedy, and none of the modern drugs has shown any particular merit in treatment. Rest and holidays are important; the old-fashioned treatment with mercury as liquor hydrarg. perchlor. dr. 1 (3.5 ml.) t.d.s., or by weekly injections of mercuric salicyl arsonate gr. ½ to gr. 1 (32–65 mg.) intramuscularly to a total of gr. 6, may help in some cases. In this particular patient arsenic appears to be contraindicated. *X*-ray therapy directed over the enlargements of the spinal cord, as suggested by Pautrier or as modified by Hellier (*Brit. J. Derm. Syph.*, 1943, **55**, 11), is sometimes effective. Painting with thorium X has been advocated by some authorities, as has the administration of calciferol in large doses, but none of these remedies is significantly successful. Rest and attention to psychological factors seem to be of much more importance.

Rectal Thiopentone

Q.—*I see in the "Journal" of July 1 (p. 21) an article on rectal thiopentone for minor surgery. Would this be a safe method of giving an anaesthetic for minor surgery in one's consulting-room—for circumcisions, for example—if one has a colleague available to control the anaesthetic and apparatus for administering oxygen in an emergency?*

A.—With the dose usually advised—e.g., 1 g. per 50 lb. (22.5 kg.) body weight—rectal thiopentone cannot be relied upon to produce anaesthesia of sufficient depth and duration for an operation like circumcision. Lorber (*British Medical Journal*, July 1, 1950, p. 21) pointed out that the child might even react to a stimulus like lumbar puncture and that local anaesthesia would be necessary if any incision of the skin was to be made. He also mentioned that the child is only relaxed in the absence of painful stimuli. Rectal thiopentone is an excellent method of inducing sleep in children prior to general anaesthesia. The rather prolonged recovery time, which may last for one to three hours, probably precludes the use of this method, even as sedative, in a consulting-room, unless there are facilities for watching the child throughout the recovery period. A more satisfactory technique for anaesthesia for circumcision in these circumstances would be a small dose of pentobarbital sodium given well ahead of the operation, followed by ethyl chloride and open drop ether as the main anaesthetic.

Trichlorethylene for Dental Operations

Q.—*Is trichlorethylene useful for anaesthesia for dental extractions? If so, how should it be administered? Are there any special intranasal techniques?*

A.—Trichlorethylene is a very useful supplement when dealing in the dental chair with robust patients who are difficult to anaesthetize with nitrous oxide alone. Any simple vaporizer, such as Marrett's bottle, Rowbotham's chloroform bottle, or any ether bottle, is plugged into the apparatus between the nitrous oxide cylinders and the patient. The merest trace of trichlorethylene will smooth out an otherwise difficult anaesthetic. If more than this trace is used the patient may feel "heavy" for some little time after the extraction. No alteration in the usual methods of nasal administration of gas and oxygen is necessary when trichlorethylene is added as a supplement. Trichlorethylene provides excellent general analgesia for cavity preparations, and details of two methods will be found in *Recent Advances in Anaesthesia* (L. Hewer, 6th ed., London, 1949, p. 259).

Antihistaminic Drugs and Diabetes

Q.—*A diabetic patient on large doses of insulin is sensitive to bee-stings, which provoke an alarming reaction. Is there any contraindication to the administration of antihistaminic drugs in such a case?*

A.—"Benadryl" would probably cause a small increase in the insulin requirements, but this would be very small in comparison with the increase in insulin requirements which occurs as a result of severe reaction due to bee-stings. It is certainly worth while trying whether the benadryl or other antihistaminic drug will prevent local reaction, since the diabetic condition would then be much less upset.

Duodenal Ulcer, Obesity, and Hypertension

Q.—*Would you suggest a suitable reducing diet for an obese hypertensive patient who is suffering from an active duodenal ulcer? He has had one bout of bleeding about a year ago.*

A.—It is difficult to devise a diet for the synchronous treatment of peptic ulceration and obesity. It is not clear from the question whether the patient is at present in bed undergoing intensive medical treatment for the former; if so, the obesity should be disregarded and every effort made to induce the ulcer to heal. For this purpose the usual regime of multiple meals should be prescribed, but the quantities reduced to lower the daily intake of calories to 1,200. Aluminium hydroxide should be given after each meal and at night; olive oil and other fats should be avoided. If the ulcer heals satisfactorily an ordinary reducing diet should be taken with plenty of aluminium hydroxide to control gastric activity. It is obviously ill-advised to try to reduce the patient's weight and to heal his duodenal ulcer at the same time.

PHARMACOLOGICAL ACTION OF ANTIHISTAMINE COMPOUNDS*

BY

J. H. BURN, M.D., F.R.S.

Professor of Pharmacology, University of Oxford

We owe the development of a specialized group of compounds known as "antihistamine compounds" to the Swiss pharmacologist Daniel Bovet, who worked in the Institut Pasteur in Paris. Although he recorded preliminary observations in 1937, his first full paper was published in 1944 (Bovet, 1944). There are three highly active substances present in the body—adrenaline, acetylcholine, and histamine—and antagonists to the first two of these have long been known. Some of the ergot alkaloids and synthetic compounds such as "priscol" are anti-adrenaline compounds, while atropine and synthetic compounds like "trasentin" are anti-acetylcholine compounds. Bovet's contribution was to devise tests by which antihistamine compounds could be recognized, and to foresee that the more highly active substances would have a clinical application in allergic states like hay-fever and urticaria.

The pharmacological work which has been carried out on antihistamine compounds in the last few years has shown that these are not highly specialized substances with unusual properties as has been commonly believed, but that they share properties with well-known drugs like atropine, procaine, quinidine, and pethidine, and that these substances in their turn can exert an antihistamine action. I propose to describe briefly how this work has developed and its practical consequences, and to suggest the basis which underlies the results.

In 1945 Dr. G. S. Dawes was working in my laboratory to find substitutes for quinidine, and made the important observation that several substances having a quinidine action on cardiac muscle were also local anaesthetics (Dawes, 1946). Thus cocaine, procaine, and amethocaine were among these substances. This observation recalled the fact that quinine and quinidine are both local anaesthetics, and thus it appeared there was a close relation between power to prolong the refractory period of cardiac muscle and local anaesthetic action. This was not all. Dawes then observed that various substances used as spasmolytics to relax smooth muscle, such as atropine, papaverine, trasentin, and "syntropan," also had a quinidine-like action on the heart. All these substances were also known to have local anaesthetic action. Finally, he examined the analgesic substance pethidine, and found that it exerted a quinidine-like action on the heart and possessed a local anaesthetic action. Thus Dawes's work suggested that the power of lengthening the refractory period, local anaesthetic action, spasmolytic action, and analgesic action were related to one another in many compounds.

*Read in opening a discussion in the Section of Medicine at the Annual Meeting of the British Medical Association, Liverpool, 1950.

Anthisan and Histostab

In 1946 we obtained a specimen of the antihistamine substance "neoantergan," as Bovet called it, or "anthisan," and it occurred to me that we should examine it to see if it fell in the category of these substances. Would it have a quinidine-like action, prolonging the refractory period of cardiac muscle? My colleagues Dews and Graham (1946) found that it did; indeed, they found that neoantergan was twice as active as quinidine. Would it have a local anaesthetic action like procaine? It was found that it had this action also, being three times as effective as procaine when injected into the skin of a guinea-pig. Would it have an analgesic action like pethidine? It was found that it possessed not only an analgesic action but a general narcotic action, though the dose required was as large as 100 mg./kg. Thus its analgesic action was weak, for pethidine produced analgesia in a dose of 5 mg./kg. We were thus able to demonstrate that neoantergan was not only an antihistamine substance, but that it possessed properties in common with quinidine, procaine, atropine, papaverine, and also pethidine.

An extension of this investigation to other antihistamine substances was later carried out by my colleague Dutta (1949b). He compared "histostab" (also known as "antistin") and "benadryl" with procaine as local anaesthetics, and found that histostab was 2.3 times and benadryl 3.2 times as potent as procaine. He compared the same substances with quinidine for power to prolong the refractory period of the auricle, and found that each was about twice as active as quinidine. He showed that, like procaine and quinidine, histostab and benadryl reduced the action of acetylcholine on the heart and on skeletal muscle, both in the frog and in the rat. He showed a similarity of action on the perfused superior cervical ganglion.

The observations thus made have greatly clarified one aspect of drug action, since they have shown that many substances used for quite different purposes in medicine and hitherto thought to have quite dissimilar modes of action have many common properties, and that among these substances are the antihistamine compounds.

Side-actions of Antihistamine Compounds

The first practical consequence of this conclusion so far as antihistamine compounds are concerned is that it is clear that they will all cause side-actions. Since benadryl, for example, has properties in common with atropine, we must expect that benadryl will cause some dryness of the mouth. Since benadryl has properties in common with the analgesic pethidine, we must expect that benadryl will cause some degree of central depression and mental confusion.

What applies to benadryl must apply to a greater or less extent to all the other antihistamine compounds, and none will be free from side-effects in sensitive persons.

The second practical consequence of this conclusion is that antihistamine compounds will have many other actions than those in which they obviously antagonize histamine.

I have pointed out that they resemble atropine, but since they combine a power to dry up secretions with central depression it would be more correct to say they resemble atropine's near relation hyoscine. It can therefore be said at once that antihistamine compounds should be of value in sea-sickness, as during the war hyoscine was demonstrated to be the best available remedy for that condition. The substance of which benadryl is the hydrochloride when united to chlorotheophylline is known as " dramamine," and that has been shown to be effective in all forms of travel sickness, sickness due to pregnancy, sickness following irradiation, and sickness after operation on the labyrinth. What we do not know at the present time is whether dramamine is better than hyoscine, and whether its side-effects, when taken over a period of days, are more or less severe. The point is important, because dramamine is very much more expensive than hyoscine. The only comparison so far made is that by Chinn and Oberst (1950), which indicates that hyoscine is more effective in controlling air-sickness. Another consequence of the resemblance of antihistamine compounds to atropine and hyoscine is that they are useful in Parkinsonism, in which they relax the spasm of skeletal muscles.

The action of antihistamine substances in aborting the common cold if given early enough has been believed to indicate that the initial phase of the cold is an allergic reaction due to histamine. It is, however, possible that this is also an atropine-like action, for atropine appears to abort some cases of common cold when given early.

I have pointed out that the antihistamine compounds resemble quinidine and quinine in their action in prolonging the refractory period of heart muscle. There is no doubt that benadryl, anthisan, antistin, and other compounds could be used to restore a normal rhythm in patients with auricular fibrillation. So far as I am aware this has not been tried, but it is a reasonable deduction from the pharmacological evidence that the trial would be successful. They have, however, been used in a condition which can be regarded as similar, which arises in skeletal muscle. That is to say, they have been used in myotonia, a disease in which the contraction of the muscle is prolonged, so that in shaking hands, for example, there is much delay in releasing the grasp. There is an abnormal stream of impulses from the motor end-plate which maintains the contraction unduly. The usual treatment is to give quinine, which is thought to act as it acts in auricular fibrillation, by prolonging the refractory period, and so renders the stream of impulses ineffective. My former colleague Dr. Lawrence Bussell (1949) has described the relief of the symptoms of myotonia with benadryl and also with anthisan, thus providing clinical evidence of their similarity to quinine.

If the antihistamine compounds resemble in their properties substances like atropine, pethidine, procaine, and quinine, then, conversely, these latter substances should exert an antihistaminic action. My colleague Dutta (1949a) has shown that they have such an action when tested on the guinea-pig for their power to depress the bronchoconstrictor action of histamine. He found that atropine and pethidine had more than one-tenth the activity of histostab or benadryl; procaine and quinidine were much less active, having only 1/100 and 1/400 of the potency of histostab. The observations bring to mind the recent use of intravenous procaine for the release of bronchial spasm in man. They suggest that intravenous pethidine would be much more effective than intravenous procaine. Procaine is, however, a safe substance for intravenous use, since it is rapidly destroyed in the body, *p*-aminobenzoic acid and diethylaminoethanol being formed by cleavage; larger amounts are, however, required than would be required of a substance like pethidine.

The Properties of Acetylcholine

What is the explanation of the similarity of the properties of so many medicaments? Dawes furnished a hint to explain the similarity between quinidine, procaine, and quinine, for he pointed out that in all forms of muscle—skeletal, cardiac, and smooth—they were antagonists of acetylcholine, and their common properties might depend on this antagonism. Elio then examined a series of other substances which had a quinidine-like action, and found that they too antagonized the action of acetylcholine on different forms of muscle, including the muscle of the blood vessels. Stephenson (1948) added to the list the alkaloid conessine and its isomers; they acted like quinidine on the heart, were local anaesthetics, and antagonized the action of acetylcholine in all forms of muscle. Dutta and I (1948) then showed that a selection of these substances which included atropine, benadryl, pethidine, procaine, and quinidine, when examined on the blood vessels of the rabbit ear, inhibited the action not only of acetylcholine but of adrenaline and of histamine as well.

We are so accustomed to look upon acetylcholine and adrenaline as antagonists and of histamine and adrenaline as antagonists that it is difficult to think of these three as related substances linked to one another in their actions. But as long ago as 1930 Dale and Gaddum (1930) showed that in denervated skeletal muscle the action of acetylcholine could be either potentiated or inhibited by the action of adrenaline. It is this kind of relation which now appears to exist in many tissues of the body.

There is evidence that in the heart, in the intestine and other smooth muscle organs, and in the central nervous system the synthesis of acetylcholine proceeds continually and may be responsible for the activity of the organ. Thus in the auricles of the heart the synthesis seems to be responsible for maintaining the rhythmic contractions. There is evidence of a similar synthesis in blood vessels, where it may be responsible for vascular tone. We commonly think of vascular tone as due to nervous impulses, forgetting that, though tone is lost when the nerves are cut, it is rapidly regained in a few days, although the nerves degenerate. It may be that the acetylcholine synthesis is the basis of the normal function in all these tissues, and that the effect of the acetylcholine so produced is modified, being either potentiated or inhibited, by histamine and adrenaline, which may also be synthesized, or possibly are liberated by the nerves.

Thus the conception forms in our minds of acetylcholine, adrenaline, and histamine acting as local hormones and governing tissue activity in many organs. We then begin to see why substances such as anthisan, which inhibit one of them, in some degree inhibit all of them, and why such substances have many properties. They may prolong the refractory period of the heart muscle, neutralize the action of histamine in the nasal mucous membrane and in the skin, and exert a depressant action on the vestibular apparatus in the central nervous system. For in all these and other functions substances like anthisan, procaine, and quinidine are inhibiting the effect of the local hormones.

Summary

Many substances used medicinally as local anaesthetics, as analgesics, and as spasmolytics have common properties, among which is included the ability to act like quinidine on the heart. Antihistamine compounds also belong to this large group of drugs. The side-effects they produce are therefore to be expected. They can also be used for other purposes—as local anaesthetics, as quinidine substitutes for fibrillation, as quinine substitutes for myotonia, for travel sickness, and to relieve pain. Similarly, local anaesthetics such as procaine, or analgesics such as pethidine, have an antihistamine action which is considerable.

The basis of these common properties is that the substances which possess them depress the effects of acetylcholine, histamine, and adrenaline; these substances control activity locally in many tissues.

CONGENITAL HEART DISEASE*

A REVIEW OF ITS CLINICAL ASPECTS IN THE LIGHT OF EXPERIENCE GAINED BY MEANS OF MODERN TECHNIQUES

BY

PAUL WOOD, O.B.E., M.D., F.R.C.P.

Director of the Institute of Cardiology (National Heart Hospital); Physician in Charge of the Cardiac Department, Brompton Hospital

[WITH SPECIAL PLATE]

PART II

Atrial Septal Defect

There were 35 cases of A.S.D.—12 male and 23 female. Their ages ranged from 5 to 61, eight being under 14, six being adolescent, and 21 adult. There were no symptoms in 20, and only slight breathlessness or difficulty in keeping up with others in 10. Of the remaining five, two had Lutembacher's syndrome and were in congestive failure; one had severe hypertension resulting from polycystic kidneys, and two had considerable limitation of cardiac reserve. Only one had haemoptysis.

The physical signs included a small or normal pulse, a normal or high normal jugular venous pressure without exaggeration of the *a* wave, a tapping cardiac impulse, a lifting right ventricular outflow tract, visible or palpable pulsation of the pulmonary artery, a pulmonary systolic murmur with or without thrill, a pulmonary diastolic murmur, and wide splitting of the second heart sound at the pulmonary area without accentuation of the pulmonary element.

A thrusting hyperdynamic cardiac impulse, as described by Roesler (1934), simulating the left ventricular thrust of patent ductus or V.S.D., was felt in five cases and was attributed to a grossly overfilled right ventricle forming the apex beat of the heart. A lifting right ventricular outflow tract or palpable right ventricular conus could be appreciated in the third and fourth intercostal spaces to the left of the sternum in most cases, and explained the precordial bulge of the chest wall that might be seen in this situation. Visible or palpable pulsation of the pulmonary artery in the second left space was also common; but neither this nor the palpable conus was well documented. Precise figures for their incidence are therefore not given.

Although the systolic murmur was classed as pulmonary, being usually best heard in the second space, it was maximal in the third space in six instances. It was accompanied by a thrill, usually rather faint, in nine. In four cases there was a loud mitral systolic murmur and in eight a mitral diastolic murmur; but only two of these had other evidence of Lutembacher's syndrome. Nevertheless, all mitral murmurs in A.S.D. were attributed to mitral valve disease, presumably rheumatic.

Functional pulmonary incompetence occurred in half the cases. In respect of the size of the shunt there was no difference between those with a Graham Steell murmur and those without.

Noticeable splitting of the second heart sound was characteristic and was heard in practically all cases. The split was usually distinctly wider in A.S.D. than in normal controls, but there was some overlap between the two. The intensity of the pulmonary element was commonly normal, not accentuated. The wide split was attributed to right bundle-branch block or to delay in the emptying-time of a grossly overfilled right ventricle.

The electrocardiogram showed the pattern of partial or well-developed right bundle-branch block in all but two cases, and the S wave in Lead V_1 was never conspicuous (under 5 mm.). The secondary R wave in Leads V_1 or V_2 was rarely very tall. The only case that showed a really high R wave had a considerable degree of pulmonary hypertension.

Skiagrams revealed right ventricular enlargement, dilatation of the pulmonary artery, and pulmonary plethora in varying degree in all cases, as described by Roesler (1934) and by Bedford, Papp, and Parkinson (1941). Skiagrams in the antero-posterior view were often difficult to distinguish from those of V.S.D. or patent ductus; but in the second oblique position the chamber responsible for the enlargement could usually be recognized.

Cardiac catheterization was undertaken in 25 cases (Table IV). The mean pulmonary artery pressure was

* Increased pulmonary resistance. d = Diminished pulmonary resistance.
(No attempt to enter the pulmonary artery was made in 5 cases; these have been omitted from the Table).

*Conclusion of the St. Cyres Lecture delivered on June 13 at the Royal Society of Medicine under the auspices of the National Heart Hospital. Part I appeared in last week's issue.

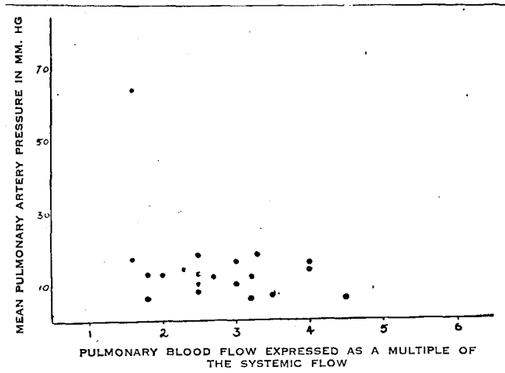

FIG. D.—Graph showing the relationship of the pulmonary blood flow to the pulmonary artery pressure in A.S.D

usually normal or nearly so, and the peripheral resistance in the lungs was usually diminished (Fig. D). This explains why the right auricular pressure does not rise, why the clinical and electrocardiographic signs point to right ventricular dilatation rather than hypertrophy, and why the pulmonary element of the second heart sound is not accentuated.

The pulmonary blood flow was two to three times the systemic flow in 10—that is, about 10 to 15 litres a minute. In five cases it was a little less, and in eight cases more.

Reversal of the shunt was not demonstrated in any case in this series. But the stage was set for such a development in two patients. One of these had considerable pulmonary hypertension for no known reason, and one had slight pulmonary hypertension associated with severe emphysema. Two other cases, not included in this study, came to necropsy with central cyanosis and lowered arterial oxygen saturation. Both had reversed interatrial shunt resulting from the effects of pulmonary hypertension associated with emphysema in one case and with cystic disease of the lungs in the other. It is believed that reversal of the shunt in A.S.D. is rare in uncomplicated cases, even when the heart fails; it is suggested that an increased peripheral resistance in the lungs is more likely to be responsible, and that this is an accidental association, not even an indirect consequence of the shunt. Such pulmonary hypertension may operate not only by raising the right auricular pressure but also by lowering the left (see under Eisenmenger's syndrome).

Differential Diagnosis

Pulmonary hypertension, especially when complicated by pulmonary incompetence, is too often confused with A.S.D., and with too little reason. There are many points of difference. In pulmonary hypertension the jugular venous pressure tends to be raised and the *a* wave may be conspicuous; the second heart sound is split, but not widely so, and the pulmonary element is grossly accentuated; the electrocardiogram usually shows a prominent P pulmonale and tall R waves in Lead V_1 without widening or much notching; skiagrams do not show pulmonary plethora, but merely dilatation of the pulmonary artery and its two main branches. Again, cyanosis always favours cor pulmonale, and, even if a reversed interatrial shunt is responsible for it, cor pulmonale is still likely to be present, as explained above.

The distinction between A.S.D. and V.S.D. has already been discussed.

Idiopathic dilatation of the pulmonary artery, with pulmonary incompetence causing dilatation of the right ventricle and the electrocardiographic pattern of right bundle-branch block, may cause real difficulty; but pulmonary plethora is absent.

Simple mild pulmonary stenosis with dilatation of the pulmonary artery, normal but well-filled pulmonary vessels, and noticeable splitting of the second heart sound is often confused with A.S.D. But these mild cases are usually associated with a normal left ventricular cardiac impulse and with a normal electrocardiogram. Moreover, the pulmonary artery is always impalpable.

Finally, a normal heart with clockwise rotation (due perhaps to slight scoliosis), unusual prominence of the pulmonary artery, a functional pulmonary systolic murmur, noticeable splitting of the second heart sound, a rather tapping type of cardiac impulse (left ventricle displaced posteriorly), a secondary R wave in Lead V_1, and well-filled pulmonary vessels may resemble mild A.S.D. very closely. The clinical diagnosis depends chiefly on the degree of the changes enumerated. There are very few cases of A.S.D. that are mild enough not to show something beyond the range of normal variation.

Pulmonary Stenosis

No form of congenital heart disease has caused so much confusion and muddled thinking as pulmonary stenosis. First, apart from Fallot's tetralogy, it was considered rare (Abbott, 1932; Taussig, 1947); more recently it has been realized that it is not so rare (Currens, Kinney, and White, 1945; Allanby and Campbell, 1949), and in fact it is common. Secondly, the presence or absence of cyanosis, whether it is peripheral or central, and what determines it still need clarification. Thirdly, certain titles used in modern papers to describe various forms of pulmonary stenosis, while obviously acceptable at their face value, are not acceptable when used to define recognizable clinical entities: thus Selzer *et al.* (1949) used the title "the syndrome of pulmonary stenosis with patent foramen ovale" to describe cyanosed cases of pulmonary stenosis with reversed interatrial shunt; and Allanby and Campbell (1949) used the title "congenital pulmonary stenosis with closed ventricular septum" to describe, apparently, any form of pulmonary stenosis that was not Fallot's tetralogy. As is shown later, neither of these descriptive titles covers the facts that they are meant to convey. Fourthly, no satisfactory description of the clinical features of pulmonary stenosis has yet been published.

There were 61 cases of pulmonary stenosis in this series (excluding pulmonary atresia), of which 23 could be classed as "simple," 5 as pulmonary stenosis with reversed interatrial shunt, and 33 as Fallot's tetralogy. Several different types of "simple" stenosis were encountered, depending on: (1) the state of the pulmonary artery—whether aneurysmal, dilated, normal, or small; (2) whether the stenosis was valvular or subvalvular; (3) whether the stenosis was mild or severe; (4) whether the ventricular septum was closed or patent; and (5) whether the auricular septum was closed or patent.

These variables are not academic, but have a profound practical influence on the clinical features of the condition. To avoid too much repetition the classical picture of severe valvular stenosis with closed septa will be described first, and then the effect of each of the variations on this picture can be discussed.

Simple Pulmonary Valvular Stenosis (Severe) with Closed Septa

Five cases were studied. They were characterized by many constant features.

1. Cyanosis, when present, was peripheral. When the cardiac output was low, cyanosis might be increased by compensatory polycythaemia, and the facies was sometimes bloated.

2. Breathlessness developed in childhood or adolescence, and was progressive. Angina pectoris and syncope occurred in one.

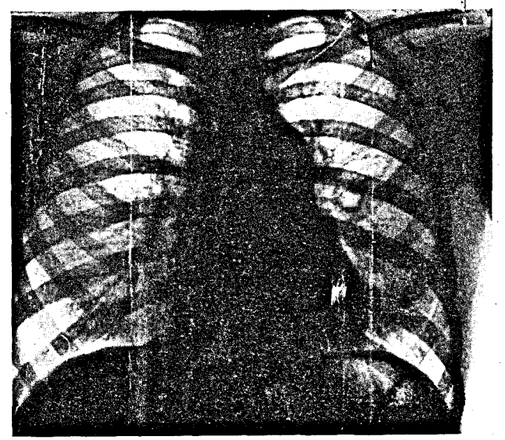

FIG. 5.—Skiagram in a case of moderately severe pulmonary stenosis.

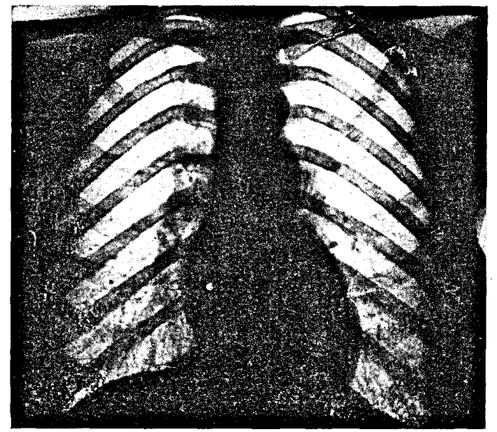

FIG. 6.—Skiagram in a case of mild pulmonary stenosis.

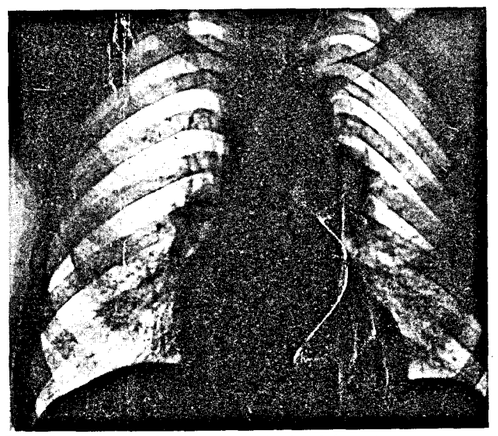

FIG. 7.—Aneurysmal dilatation of the left pulmonary artery associated with pulmonary stenosis.

FIG. 8.—Angiocardiogram of the same case as Fig. 7 (second oblique position).

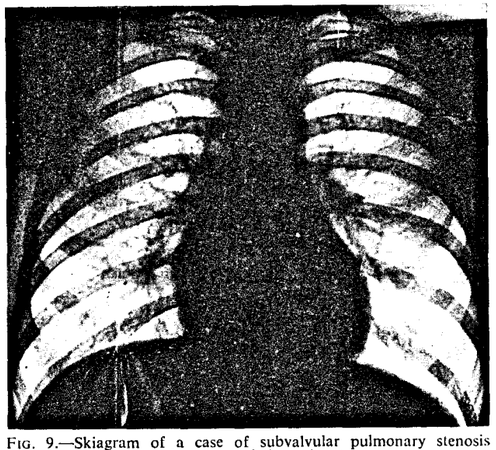

FIG. 9.—Skiagram of a case of subvalvular pulmonary stenosis showing no dilatation of the pulmonary artery.

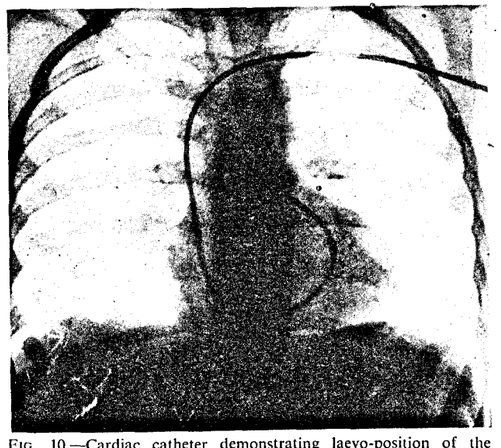

FIG. 10.—Cardiac catheter demonstrating laevo-position of the pulmonary artery in a case of Fallot's tetralogy.

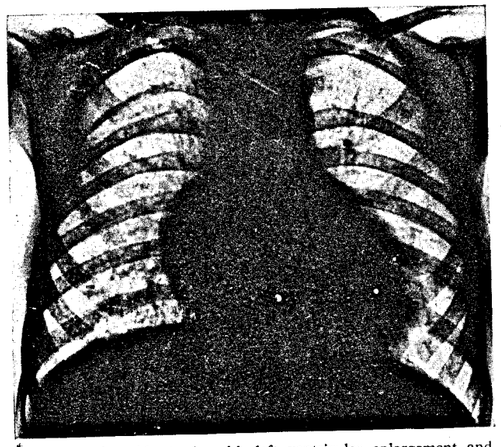

FIG. 11.—Tricuspid atresia with left ventricular enlargement and bronchial vessels supplying the lungs.

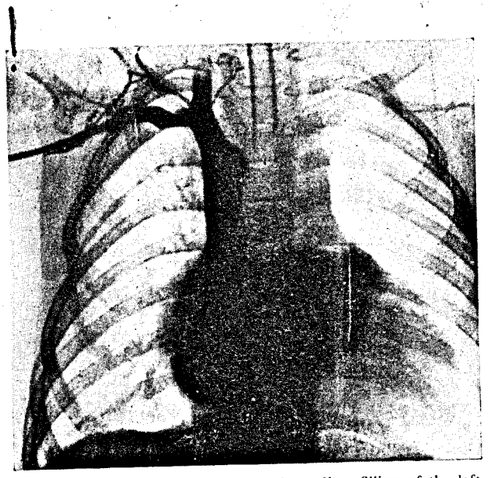

FIG. 12.—Angiocardiogram showing immediate filling of the left auricle in a case of tricuspid atresia (note L.A. appendix).

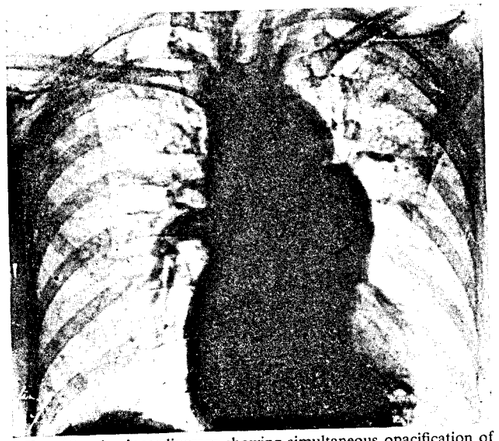

FIG. 13.—Angiocardiogram showing simultaneous opacification of the aorta and pulmonary artery in a case of pulmonary hypertension with reversed aorto-pulmonary shunt due to patent ductus.

FIG. 14.—Angiocardiogram showing simultaneous opacification of the aorta and pulmonary artery in a case of true Eisenmenger's complex.

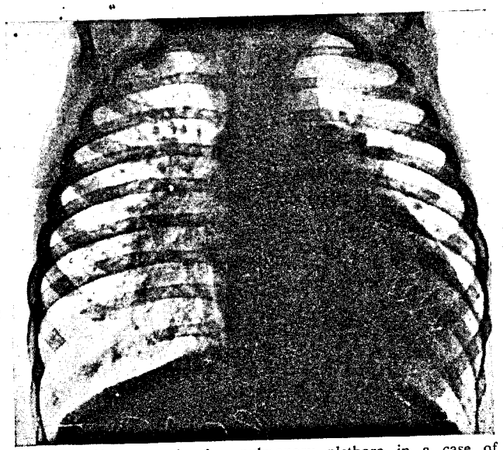

FIG. 15.—Skiagram showing pulmonary plethora in a case of transposition of the great vessels.

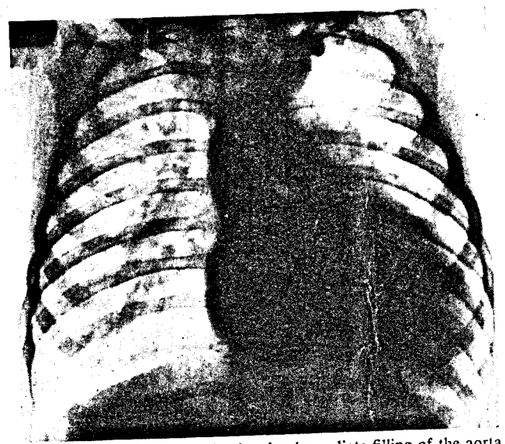

FIG. 16.—Angiocardiogram showing immediate filling of the aorta from the right ventricle in a case of transposition of the great vessels.

Death from congestive failure is expected in all of these before long, unless pulmonary valvulotomy saves them.

3. The pulse was small or on the small side of normal.

4. The jugular venous pressure was usually raised, and in at least two cases giant *a* waves were seen in the neck. This presystolic venous pulse was most conspicuous, towered above the *c* and *v* waves, was abrupt and collapsing in quality, so that it came to be called a "venous Corrigan," and was transmitted to the liver.

5. The cardiac impulse was tapping, the right ventricular outflow tract lifting, and the pulmonary artery pulse invisible and impalpable.

6. All had a high systolic murmur and thrill maximal in the second or second and third left spaces.

7. The second heart sound was invariably single at the pulmonary area.

8. The electrocardiogram showed prominent sharp P waves and strong right ventricular preponderance without right bundle-branch block. The R waves were very tall and the T waves were sharply inverted in right ventricular surface leads or their equivalents (Fig. E). The U waves were also inverted in these leads in some of the cases.

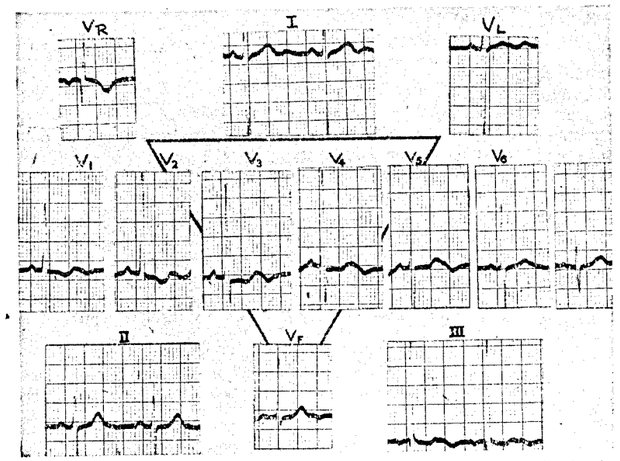

FIG. E.—Electrocardiogram in a case of severe pulmonary stenosis showing almost monophasic R waves, inverted T waves, and inverted U waves in right ventricular surface leads.

9. Skiagrams showed enlargement of the right ventricle, often considerable, and dilatation of the pulmonary artery. The peripheral vascular shadows were normal or rather light (Plate, Fig. 5).

Cardiac catheterization revealed an extremely high mean pressure in the right ventricle (over 35 mm. Hg), and a low pressure in the pulmonary artery (under 8 mm. Hg). Samples from the pulmonary artery, right ventricle, right auricle, and superior vena cava were similar.

Penetration of the pulmonary artery may be dangerous in this condition, for if the catheter blocks the pulmonary valve there is no other way for the blood to escape.

Severe Pulmonary Stenosis with Reversed Interatrial Shunt

Five cases were studied in this series. Three were cyanosed from birth. This is inevitable in the most severe cases, because the low left auricular pressure and raised right auricular pressure must keep the foramen ovale open. But cyanosis certainly increased in childhood or adolescence, and was markedly accentuated by effort. Angina pectoris and syncope occurred in one case. The onset of cyanosis may have been delayed in the other two, as described by Allanby and Campbell (1949). Such cases are presumably not quite so severe at birth but tighten up later. When this occurs reversed interatrial shunt can develop only if the foramen ovale happens to be patent—that is, in about a quarter of the cases.

The physical signs were similar to those of severe stenosis without shunt, with the addition of cyanosis, clubbing, and polycythaemia.

Skiagrams always showed diminished pulmonary vascular markings beyond the dilated pulmonary artery.

Cardiac catheterization (in three cases) revealed extremely high mean pressures in the right ventricle (over 45 mm. Hg) and low pressures in the pulmonary artery (below 5 mm. Hg). Pulmonary venous samples were normal; samples from the left auricle, left ventricle, and femoral artery were similar, and contained a large proportion of venous blood shunted from the right auricle. In a typical case the systemic blood flow was 4.3 litres a minute, and the pulmonary flow 1.4 litres a minute; the shunt was therefore 2.9 litres a minute.

Angiocardiography shows immediate filling of both auricles and simultaneous opacification of both ventricles and of the aorta and pulmonary artery.

Differential Diagnosis.—Severe pulmonary stenosis without cyanosis is difficult to confuse with any other condition. Pulmonary stenosis with reversed interatrial shunt may be distinguished from Fallot's tetralogy by the history, by greater cardiac enlargement, and by the presence of a dilated pulmonary artery. A low murmur or absence of a thrill favours Fallot's tetralogy. Doubt may be resolved by means of cardiac catheterization or angiocardiography.

Treatment—Pulmonary valvulotomy (Brock, 1948) is the treatment of choice for all severe cases of pulmonary stenosis with or without reversed interatrial shunt.

Mild Valvular Stenosis with Closed Septa

Seven cases were investigated, and these differed radically in nearly all respects from the severe type. (1) None had peripheral cyanosis; indeed, they all looked healthy. (ii) There were no symptoms; one patient was an athlete. (iii) The pulse was normal. (iv) The venous pressure was normal, and large *a* waves were not seen. (v) The cardiac impulse was usually a normal gentle left ventricular thrust, and there was little evidence of right ventricular enlargement. (vi) All had a high pulmonary systolic thrill and murmur. (vii) The second heart sound was usually split in the normal fashion, the pulmonary element being soft or of average intensity. (viii) The electrocardiogram showed normal P waves and virtually normal QRS complexes, although the R wave in Lead V_1 was a little high in three of them. (ix) Skiagrams showed no cardiac enlargement, a dilated pulmonary artery, and normal peripheral vascular markings (Fig. 6).

Cardiac catheterization revealed a normal mean pulmonary artery pressure (over 8 mm. Hg) and moderate elevation of the right ventricular pressure (15–30 mm. Hg). Samples from the pulmonary artery were similar to those from the right ventricle, right auricle, and S.V.C., and were normally unsaturated.

Similar mild cases have been described by Mannheimer *et al.* (1949), at Stockholm, and by Dexter *et al.* (1950).

The differential diagnosis is from the normal heart with prominent pulmonary artery and functional pulmonary systolic murmur, from mild atrial septal defect, and from the "maladie de Roger."

No treatment is required.

Pulmonary Stenosis with Aneurysmal Dilatation of the Pulmonary Artery

Only one such case was seen. The clinical features were those of mild pulmonary stenosis, and the *x*-ray appearances (Fig. 7) were a surprise. The mean pressure in the pulmonary artery was 11 mm. Hg, in the right ventricle 22 mm. Hg. Angiocardiography confirmed the nature of the hilar shadows (Fig. 8).

Idiopathic dilatation of the pulmonary artery without pulmonary stenosis (Greene *et al.*, 1949) may be complicated by pulmonary incompetence, enlargement of the right ventricle, and right bundle-branch block. Two such cases were encountered in this series. In both, the pulmonary artery and right ventricular pressures were normal.

Subvalvular Stenosis

In two cases simple pulmonary stenosis appeared to be subvalvular on cardiac catheterization and angiocardiography. Both were characterized by absence of the common post-stenotic dilatation of the pulmonary artery (Fig. 9) and by a relatively low systolic thrill and murmur which were readily appreciated in the third left space. Otherwise the findings were the same as for valvular stenosis. They happened to be moderately severe (P.A.P. 11 and 8; R.V.P. 44 and 31 mm. Hg respectively). When mild, these cases may easily be mistaken for the "maladie de Roger," or for subaortic stenosis.

Since completing this series a third case has been seen, in which a separate infundibular chamber was demonstrated.

Pulmonary Stenosis with V.S.D. (or A.S.D.)

Four such cases were revealed as a result of cardiac catheterization. Two had been diagnosed as pulmonary stenosis, and two as "maladie de Roger."

The stenosis was valvular in all four. It was severe in one (P.A.P. 5; R.V.P. 37 mm. Hg), moderate in two (P.A.P. 17 and 32; R.V.P. 40 and 40 mm. Hg respectively), and mild in one (P.A.P. 10; R.V.P. 16). Despite the stenosis the pulmonary blood flow was at least twice the systemic flow in two of the cases.

Clinical diagnosis may be puzzling, for the signs of pulmonary stenosis and V.S.D. may be combined. As a rule, however, one or the other dominates the picture and determines the course. The association is important for several reasons: (1) it shows that the notation "pulmonary stenosis with closed ventricular septum" cannot be used clinically to distinguish "simple" pulmonary stenosis from Fallot's tetralogy, because the presence or absence of V.S.D. may be impossible to determine clinically, and may not interfere with the clinical features or course of the pulmonary stenosis; (2) it offers further evidence of the clinical confusion between mild pulmonary stenosis and the "maladie de Roger"; and (3) it is probable that similar cases occur in which the stenosis is very tight—reversal of the shunt might then occur and the case would come to resemble Fallot's tetralogy (but without a riding aorta).

Since completing the series a similar type of case was investigated, but the left-to-right shunt proved to be interatrial and resulted from A.S.D. The stenosis was mild (P.A.P. 8; R.V.P. 31; infundibulum 18 mm. Hg). Left auricular samples were 93% saturated, and the pulmonary blood flow was twice the systemic flow. Considerable pulmonary plethora was present radiologically.

Pulmonary Stenosis with Patent Foramen Ovale

That this is not synonymous with pulmonary stenosis with reversed interatrial shunt is obvious, and if there is no cyanosis the presence of patent foramen ovale is unsuspected. Unlike pulmonary stenosis with A.S.D., there is no left-to-right interatrial shunt.

One such acyanotic case was discovered in this series. This was that of a girl of 14 without symptoms and with typical signs of moderate pulmonary valve stenosis. The catheter slipped through a patent foramen ovale, and left auricular samples were 96% saturated with oxygen. The mean right auricular pressure was 4 cm. of saline, the left 5.5 cm. The pulmonary artery pressure was 8 mm. Hg, and the R.V. pressure was 32 mm. She is clearly liable to develop a reversed interatrial shunt if the situation deteriorates.

Patent foramen ovale in mild pulmonary stenosis should remain functionless indefinitely.

Fallot's Tetralogy

There were 33 cases of Fallot's tetralogy and 3 of pulmonary atresia (Fallot type) in the series. The clinical features are too well known to justify more than a few minor comments:

1. The jugular venous pressure was very rarely raised, and no case was seen in failure. Accentuation of the *a* wave was uncommon and never great.

2. The systolic murmur was maximal high in the second space in one-third of the cases, and low in the third or third and fourth spaces in the remainder. A thrill was present in half of them, and was as frequently high as low.

3. The second heart sound was invariably single, and usually rather loud. This is attributed to absence of the pulmonary element and to the proximity of the root of the aorta to the anterior chest wall.

4. A continuous murmur was heard in three out of four cases of pulmonary atresia in the series, but not in Fallot's tetralogy. Necropsy in three of these cases showed that the murmur depended upon a broncho-pulmonary anastomosis at a fairly high arterial level, not upon a patent ductus. Since these figures were completed two more cyanotic cases with continuous murmurs have been examined and diagnosed as atresia partly because of these murmurs. Cardiac catheterization was not, therefore, undertaken, and angiocardiography proved that both diagnoses were correct. The murmur was left-sided in two of these cases, mainly right-sided in two, and bilateral in one. Clinically it is impossible to distinguish pulmonary atresia from a persistent truncus arteriosus unless well-formed pulmonary arteries arise from the root of the aorta, or unless the latter is obviously much enlarged. Angiocardiograms are also similar in all other respects.

5. Cardiac catheterization was carried out in 21 cases of Fallot's tetralogy. The mean pulmonary artery pressure was under 8 mm. Hg (−1 to +7) in all but one of 15 cases in which that vessel was entered. The right ventricular pressure ranged from 22 to 55 mm. Hg, and was commonly around 40. Samples from the P.A., R.V., R.A., and S.V.C. were usually very unsaturated and were similar in all but two cases: in those two the pulmonary artery samples were less unsaturated. No explanation for this can yet be offered.

6. The catheter was passed through a patent foramen ovale in two cases. It was interesting to be able to demonstrate the absence of reversed interatrial shunt in both instances, the left auricular pressure being higher than the right, and left auricular samples being normally saturated with oxygen; and this despite mean right ventricular pressures of 44 and 37 mm. Hg and a pulmonary artery pressure of 6 mm. in one of them. It seems that the right ventricle is able to accommodate itself to work against the systemic blood pressure without difficulty, and does not suffer from the extremely high pressure generated on effort in cases of pure pulmonary stenosis. This also suggests that reversed interatrial shunt depends more upon elevation of the right auricular pressure than upon the lowering of the left.

7. Both during cardiac catheterization and on inspecting the angiocardiograms, laevo-position of the pulmonary artery was often noticed. This was usually more convincing than dextroposition of the aorta (Fig. 10).

Tricuspid Atresia

This is the only cyanotic form of congenital heart disease with a diminished pulmonary blood flow associated with left ventricular enlargement and a rudimentary right ventricle. The cardiac impulse, *x*-ray appearances (Fig. 11), and electrocardiogram (Fig. F) usually make

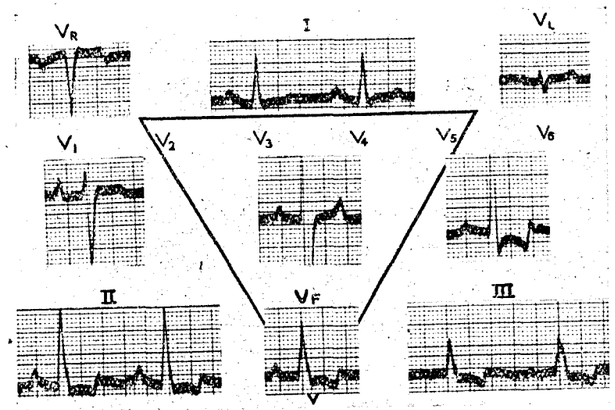

FIG. F.—Electrocardiogram of a case of tricuspid atresia showing the "P mitrale," and left ventricular preponderance (vertical heart).

the diagnosis easy. If not, angiocardiography provides convincing evidence (Fig. 12).

Cardiac catheterization is unsatisfactory, because failure to enter the right ventricle may be due to technical difficulty and cannot be attributed to tricuspid atresia with any surety. However, a reversed interatrial shunt can be demonstrated, and under the clinical circumstances this confirms the diagnosis.

Eisenmenger's Complex

The majority of cases in which a diagnosis of Eisenmenger's complex was suggested turned out otherwise; only three were finally accepted after full physiological and angiocardiographic studies, and subsequent necropsy disproved one of them.

The Eisenmenger's syndrome consists of central cyanosis, tapping cardiac impulse, lifting conus, visible and palpable pulsation of the pulmonary artery, a systolic murmur and thrill in the third left space, normal splitting of the second heart sound with accentuation of the pulmonary element, an electrocardiogram showing right ventricular preponderance, and *x*-ray appearances characterized by right ventricular enlargement, dilatation of the pulmonary artery and its two main branches, and poorly marked peripheral vascular shadows.

Cardiac catheterization reveals a raised pressure in the pulmonary artery and right ventricle, a similar degree of unsaturation in samples from the pulmonary artery, right ventricle, right auricle, and S.V.C., and normally saturated samples from the pulmonary veins and left auricle (if obtained through a patent foramen ovale). The arterial oxygen saturation is reduced.

Angiocardiography shows simultaneous opacification of the aorta and pulmonary artery from the right ventricle, no dye entering the left auricle initially.

Differential Diagnosis

Clinically, advanced idiopathic pulmonary hypertension may closely resemble Eisenmenger's syndrome at any age, differences being largely a matter of degree. Thus there is usually less cyanosis, and the small pulse and cold extremities suggest that some of it is peripheral; breathlessness is more severe, and there may be angina or syncope; the jugular venous pressure is higher and the *a* wave more conspicuous; there is no thrill at the base, and if there is a murmur it is unimpressive; the electrocardiogram nearly always shows a conspicuous P pulmonale and stronger right ventricular preponderance; and the heart looks larger radiologically. Physiological studies reveal higher pressures in the pulmonary artery and right ventricle, and pulmonary venous samples (if they can be obtained) show the same degree of unsaturation as arterial samples. No shunt can be seen in the angiocardiogram.

Idiopathic pulmonary hypertension with reversed interatrial, interventricular, or aorto-pulmonary shunt is the usual explanation for most cases of "proved" Eisenmenger's syndrome. The clinical features resemble those of pure idiopathic pulmonary hypertension as described above; but cyanosis and clubbing are more conspicuous, and the angiocardiogram shows simultaneous opacification of the aorta and pulmonary artery.

The absence of a thrill and murmur favours reversed interatrial or aorto-pulmonary shunt, and both cardiac catheterization and angiocardiography should demonstrate an interatrial shunt; but reversed interventricular shunt is clinically Eisenmenger's syndrome itself. At necropsy, however, the aorta is not overriding.

One of the accepted cases of Eisenmenger's syndrome included in this series (Fig. 13) proved to be pulmonary hypertension with reversed aorto-pulmonary shunt through a patent ductus. This case is being reported in detail by Dr. Maurice Campbell.

The question is constantly being asked whether there is really any such thing as Eisenmenger's complex; whether it is possible to be sure of an overriding aorta at necropsy when the pulmonary outflow tract is normal. One case in the series seems to provide a positive answer to this question.

This was that of a girl aged 7, with considerable effort dyspnoea, squatting, moderate cyanosis and clubbing, slight polycythaemia, a normal rather than small arterial pulse, a normal venous pressure and pulse, a tapping cardiac impulse, lifting conus and visible pulmonary artery pulsation, a systolic murmur and thrill in the third left space, and a normally well-split second heart sound with accentuation of the pulmonary element. Her electrocardiogram showed normal P waves and slight to moderate right ventricular preponderance. Skiagrams showed no obvious enlargement of the heart, but the pulmonary artery was dilated and the peripheral vascular shadows diminished. On cardiac catheterization the pressure was 39 mm.

Hg in the pulmonary artery, 19 in the right ventricle, and +2 in the right auricle, samples from these positions being the same (66–69% saturated). The arterial sample was 71% saturated. Angiocardiography showed simultaneous opacification of the aorta and pulmonary artery without early filling of the left auricle (Fig. 14).

It is clear in this case that the pressures are not high enough to warrant a diagnosis of pulmonary hypertension with reversed interventricular or aorto-pulmonary shunt, and an overriding aorta must be postulated.

Transposition

Two patients with transposition were investigated, girls aged 3 and 12. The clinical diagnosis is usually easy, and depends on the recognition of pulmonary plethora in an obviously cyanotic case (Fig. 15). The rest of the findings closely resemble those of Eisenmenger's complex.

The catheter was passed down the aorta as well as into the pulmonary artery in both cases studied. The mean right ventricular pressure was of course high, 31 and 41 mm. Hg; the pulmonary artery pressure 11 and 64 respectively (aortic 74 and 69). Samples from the pulmonary artery were considerably more saturated with oxygen than samples from the aorta, and this proved the diagnosis. Venous blood entered the lungs from the right ventricle via a ventricular septal defect in both cases, and pulmonary venous blood escaped from the semi-closed pulmonary circuit via an atrial septal defect in the first case and presumably via bronchial and azygos veins in the second. The pulmonary blood flow was greatly increased, being three times the systemic flow in both patients. Angiocardiography also confirmed the diagnosis (Fig. 16).

The elder girl with atrial septal defect was less cyanosed and less breathless than the other; indeed, she was remarkably well. The creation of an artificial atrial septal defect or of a pulmonary-azygos venous anastomosis would seem to be justified.

Classification

In the light of these findings a new clinical classification of congenital heart disease is offered (Table V).

TABLE V.—*Classification of Congenital Heart Disease*

No Shunt		
General	Left-sided	Right-sided
Dextrocardia Idiopathic hypertrophy Von Gierke's disease Heart-block Familial cardiomegaly	Coarctation of the aorta Right-sided aortic arch Complete or incomplete aortic rings Bicuspid aortic valve (or supernumerary cusps) Aortic or subaortic stenosis Left coronary artery arising from pulmonary artery	Idiopathic dilatation of the pulmonary artery Simple pulmonary stenosis (with or without patent F.O.). Ebstein's disease

With Shunt	
Acyanotic Left-to-right Shunt (Pulmonary Plethora)	Cyanotic Right-to-left Shunt
Left ventricular enlargement: Patent ductus Ventricular septal defect (with or without mild pulmonary stenosis) Perforated aortic sinus into P.A. or R.V. (or R.A.) *Right ventricular enlargement:* Atrial septal defect (with or without mild pulmonary stenosis). Anomalous pulmonary veins joining S.V.C. or R.A.	*Diminished pulmonary blood flow:* Low P.A. pressure: 1. Left ventricular enlargement: Tricuspid atresia 2. Right ventricular hypertrophy: Fallot's tetralogy Pulmonary atresia (Fallot type) Persistent truncus Pulmonary stenosis with reversed interatrial shunt High P.A. pressure: Eisenmenger's complex Pulmonary hypertension with reversed aorto-pulmonary, interventricular, or interatrial shunt *Pulmonary plethora:* Transposition

Summary and Conclusions

A fresh account of congenital heart disease is presented in the light of a series of 200 cases proved by means of cardiac catheterization, angiocardiography, thoracotomy, or necropsy.

The technical difficulties of cardiac catheterization are discussed.

The clinical incidence of the more common or well-recognized anomalies is given.

The physical signs of congenital heart disease are reviewed and revalued. Particular attention has been paid to the jugular pulse, the cardiac impulse, the right ventricular outflow tract, functional mitral and pulmonary diastolic murmurs, and the second heart sound.

New facts concerning most forms of congenital heart disease are presented.

The left-to-right shunts with pulmonary plethora usually have a normal or low pulmonary resistance. When the pulmonary resistance is high the shunt is diminished and is in danger of being reversed; an acquired Eisenmenger's syndrome results. This pulmonary hypertension does not depend on the duration of the shunt, but on some inherent predetermined factor, and operates early.

It is suggested that the term "maladie de Roger" should be limited in its meaning, and should be used only to describe uncommon cases of V.S.D. characterized by nothing more than a Roger thrill and murmur. The majority of cases of V.S.D. present a very different picture.

Many types of pulmonary stenosis are described, the chief of which are: (1) severe pulmonary stenosis (usually valvular) with closed septa; (2) severe pulmonary stenosis (usually valvular) with reversed interatrial (or interventricular) shunt; (3) mild pulmonary stenosis (valvular or infundibular) with or without functionless patent foramen ovale; and (4) pulmonary stenosis with left-to-right shunt through an associated V.S.D. or A.S.D. Pulmonary stenosis with late reversed interventricular shunt was not encountered with certainty, but must occur; it would closely resemble Fallot's tetralogy, but there would be no overriding aorta.

Eisenmenger's complex should be diagnosed under appropriate clinical circumstances only when the pulmonary artery pressure is not high enough to cause reversed aorto-pulmonary, interventricular, or interatrial shunt, through a patent ductus, V.S.D., or A.S.D. Pulmonary hypertension with reversed aorto-pulmonary, interventricular, or interatrial shunt might be called acquired Eisenmenger's syndrome, because it is clinically indistinguishable from Eisenmenger's complex.

A new classification of congenital heart disease is offered.

I wish to thank my colleagues on the staff of the National Heart Hospital for allowing me to investigate some of their cases and to make use of material so obtained. I also wish to thank Mr. Latham, our senior technician, for carrying out the blood-gas analysis.
