Commander T. D. GALBRAITH replied that detailed information was not available. He had no reason to think that doctors were prescribing drugs which were not of value when taken under medical supervision, in cases where weight reduction was necessary on medical grounds.

Mrs. MANN referred to a report that £400,000 had been spent on slimming tablets, and asked the Minister to confirm whether the tablets really slimmed or merely curbed the appetite.

Commander GALBRAITH replied that "dextrodine," to which Mrs. Mann referred, was quite an effective drug for slimming when used under medical supervision, and slimming was not the only purpose for which it was prescribed.

Mrs. MANN also asked on February 17 what number of patients had transferred from doctors who refused to prescribe advertised proprietary drugs to others who would do so, and if the Secretary of State would protect doctors from this form of pressure.

Commander GALBRAITH told her that no statistics were available. Various forms of publicity had emphasized that it was for the doctor, not the patient, to decide what was to be prescribed, and he looked to the doctors to support one another in this matter.

Dr. EDITH SUMMERSKILL and Mr. A. BLENKINSOP questioned the Minister of Health on February 19 about the prescribing of proprietary medicines, Dr. Summerskill asking whether the Minister's attention had been drawn to the report of the Comptroller and Auditor-General with regard to the heavy prescribing of expensive proprietary drugs, and what action he proposed to take in order to reduce this expenditure in future.

Mr. IAIN MACLEOD replied that all doctors had been urged to help to keep this cost down by prescribing standard drugs wherever appropriate and by not prescribing proprietary drugs which were advertised direct to the public. In the last resort it was in the power of the doctors themselves to help most in this considerable problem, and he was sure that he could count on them to do so. He was considering what further steps could be taken.

Civil Service M.O.s

Dr. A. D. D. BROUGHTON asked the 'Chancellor of the Exchequer why he had not raised the salaries of Civil Service medical officers to conform with the increase in remuneration granted to general medical practitioners under the Danckwerts award. Mr. J. A. BOYD-CARPENTER, the Financial Secretary, who replied, referred him to Mr. Butler's statement last July, to the effect that Mr. Justice Danckwerts's award was confined solely to the remuneration of general practitioners in the National Health Service and had no wider application.

Dr. BROUGHTON pointed out that these medical officers, who performed their responsible duties very efficiently, had been affected like everyone else by the rise in the cost of living. Would the Treasury reconsider the question of revising their salary scales to bring them into line with their professional colleagues in other branches of medicine?

Mr. BOYD-CARPENTER said the salaries of Government servants were kept under constant review. The present scale of salaries of these officers was that recommended by the Howett Committee, which reported as recently as August, 1951.

Toxic Sprays

Sir RALPH GLYN asked the Minister of Agriculture on February 19 whether he would consider issuing immediate circulars to the county agricultural committees advising that no spraying of weeds or any crops with dinitroorthocresol should be carried out without reference to the committees; and whether he would amend the Agriculture (Poisonous Substances) Act to necessitate obtaining a licence before poisonous sprays could be used on land, in view of the damage that was being done to insects, birds, and animals as the result of the application of these chemical substances to large tracts of agricultural land; and whether he would set up a committee, not altogether composed of chemists, to report on the results, during 1952, of the spraying of poisons to destroy noxious weeds.

Sir THOMAS DUGDALE replied that he had no power to require prior notification of spraying, but he was keeping a careful watch on developments. The long-term solution to the problem was the production of equally effective sprays that were not toxic to wild life. Research into this and other aspects was continuing under the supervision of the Agricultural Research Council. He was asking Professor Zuckerman and his Working Party on Precautionary Measures against Toxic Chemicals used in Agriculture to consider the general question of effects on wild life, when they had completed their present study of possible risks to the consumer.

After the Floods

Mr. T. C. PANNELL commented in the debate on the floods on February 19 on Ministry of Health administration. Many people, he said, had lost spectacles, dentures, and surgical appliances, but there seemed to be no clear knowledge whether there would be free replacement. There was also the question of prescription charges.

Mr. HAROLD MACMILLAN, Minister of Housing and Local Government, referring to this in his reply, said that during the emergency period the Minister of Health had used the Nelson technique and turned a blind eye to the giving of prescriptions without charge, and the supplying of artificial teeth or spectacles, perhaps without authority. It would be wise to leave the matter there.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending February 7 (No. 5) and corresponding week 1952.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

† Includes primary and influenzal pneumonia.
‡ Includes puerperal pyrexia.

Vital Statistics

Births and Marriages in 1951

In England and Wales there were 677,529 live births in 1951, giving a birth rate of 15.4 per 1,000 population.¹ This was a decrease of 0.4 from the rate for 1950, when there were 697,097 live births. The average rate for the years 1936-40 was 14.7 per 1,000. There were 32,771 illegitimate live births, comprising 4.8% of the total number of live births. Stillbirths numbered 15,985; this gave a rate of 23 per 1,000 total live and stillbirths—the same as for the previous three years.

There were 360,624 marriages. This figure gives a rate of 16.4 persons married per 1,000 population. A feature of these marriages was their peak in March. Over 21% of the year's marriages were celebrated in that month. The nearest approach to this was in 1950, also in March, when the figure was 14%. These peaks of incidence are much influenced by the date of Easter and of the end of the income-tax year.

The number of new petitions for divorce rose from 29,729 in 1950 to 38,382 in 1951. (The facilities provided by the Legal Aid and Advice Act, 1949, became available from October 2, 1950.) The number of dissolutions and annulments of marriage made absolute was 28,767. Of these, 2,970 related to marriages of less than five years' duration, 9,063 to marriages of 5 to 10 years' duration, 7,011 to marriages of 10 to 15 years' duration, 4,047 to marriages of 15 to 20 years' duration, and 5,676 to marriages of 20 years and over. In 9,895 cases there were no children of the marriage, in 9,678 cases there was one child, and in 5,197 cases there were two children.

50,339 confinements took place within eight and a half months of marriage, and of these 35,997 occurred within six and a half months of marriage.

Under the Legitimacy Act, 1926, 2,596 births originally registered as illegitimate were re-registered as legitimate on the subsequent marriage of the parents. This is the lowest number in any year since the operation of the Act.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1944-52 are shown thus ————, the figures for 1953 thus ————. Except for the curves showing notifications in 1953, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

¹Registrar-General's Statistical Review, 1951, Tables, Part II. Civil. H.M.S.O. 5s.

Infectious Diseases

In England and Wales during the week ending February 7 notifications of measles increased by 5,034, from 26,460 to 31,494, and acute pneumonia by 309, from 2,029 to 2,338; while decreases of 305 were recorded for scarlet fever, from 1,850 to 1,545; 228 for whooping-cough, from 2,799 to 2,571; and 149 for dysentery, from 435 to 286.

The largest rises in measles notifications during the week were 577 in Surrey, from 908 to 1,485; 358 in Kent, from 1,082 to 1,440; 313 in Derbyshire, from 733 to 1,046; and 235 in Hertfordshire, from 640 to 875. The largest decrease in the incidence of scarlet fever was 44 in Yorkshire West Riding, from 185 to 141. The largest fluctuations in the trends of whooping-cough were a rise of 39 in Yorkshire West Riding, from 239 to 278, and a fall of 48 in Wiltshire, from 63 to 15. 16 cases of diphtheria were notified, 8 fewer than in the preceding week; 4 cases were notified in Wales compared with none in the previous week.

15 cases of paratyphoid fever, 8 more than in the preceding week, were notified. The rise was mainly contributed by Wales, where 11 cases, 10 more than in the previous week, were notified. The chief centre of infection was Caernarvonshire, Bangor M.B., 6.

26 cases of acute poliomyelitis were notified during the week; these were 2 fewer for paralytic and 1 fewer for non-paralytic cases than in the preceding week. The largest returns were Somersetshire 4 and London 3.

The largest returns for dysentery were Lancashire 65 (Liverpool C.B. 19, Oldham C.B. 10); Lincolnshire 37 (Grimsby C.B. 30); London 29 (Chelsea 6); Yorkshire West Riding 24 (Barnsley C.B. 15); Essex 22 (East Ham C.B. 19); and Middlesex 19 (Edmonton M.B. 13).

The deaths from influenza in the great towns numbered 446, being 133 more than in the previous week. 61% of the deaths were registered in London and the south-east region.

Influenza

There were 530 deaths from influenza in the great towns of England and Wales in the week ending February 14. This is an increase of 84 over the previous week's total of 446. The northern half of the country experienced a greater increase than the southern, though the majority of the deaths (274) occurred in London and the south-east. First claims on the Ministry of National Insurance were falling in London and the south, but showed a moderate rise in the north. Since the beginning of the year there have been 1,544 deaths from influenza in the great towns compared with 237 in 1952 and an estimated 6,460 in 1951.

Week Ending February 14

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,515, whooping-cough 2,238, diphtheria 24, measles 32,359, acute poliomyelitis 17, dysentery 320, paratyphoid fever 6, and typhoid fever 4.

The measles notifications constitute the highest weekly total to be recorded since notification was made compulsory in England and Wales in 1940.

Medical News

N.H.S. Estimates.—The cost of the Health Service in Britain for the next financial year (1953-4) is estimated at £416,480,360. This is a reduction of over £22m. on the estimates for the current year.

Royal College of Surgeons in Ireland.—The time-honoured Charter Day Dinner of the Royal College of Surgeons in Ireland was held on February 14 in the Large Hall of the College. Some 180 Fellows and their guests attended. Before the dinner Sir Gordon Gordon-Taylor was admitted to the Honorary Fellowship of the College by the President, Mr. Michael Burke. In presenting Sir Gordon for admission Mr. William Doolin, the Secretary of the Council, described his name as already "almost a legend, intimately associated with certain of the less frequent, more daring, not to say heroic, procedures in modern surgery." They welcomed him, too, as a Scotsman, for that "subtle blend of Celtic qualities which so often puzzle the Sassenach—the high courage and temper of the Highlander and the sentimental humour of the Lowlander." At the dinner, the toast of "Our Guests" was proposed by Mr. Ian Fraser, Vice-President, and was replied to by Sir Gordon in a characteristically graceful speech. The toast of "The College" was proposed by Dr. Edward Freeman, P.R.C.P.I., and was responded to by the President, Mr. Burke.

Surgeons' Hall of Fame.—The International College of Surgeons is planning a Surgeons' Hall of Fame at its Chicago headquarters to commemorate illustrious surgeons and their work. A large mansion has been acquired for the purpose, and a board of 12 trustees, of whom Sir Zachary Cope is one, has been appointed. An electoral college, composed of representatives from all over the world, will decide which surgeons are to be honoured in the Hall. The International College of Surgeons has about 10,000

members, drawn from 71 nations; about half its membership is from the United States. The College was founded in 1935 by Dr. Max Thorek in Geneva, and in 1940 moved to America.

Local Medical Societies.—Recent meetings have included the following: *Manchester Medical Society.*—On January 13 three short papers were read to the Section of Surgery on "Continuous Scoline for Relaxation in Abdominal Surgery" (Dr. M. Swerdlow), "The Effects of X-ray Contrast Media in the Arterial Circulation" (Mr. R. P. Jepson), and "Pneumomediastinum following Block Dissection of the Neck" (Mr. H. F. Smith). On January 14 Professor L. J. Witts read a paper on "Ulcerative Colitis" to the Sections of Medicine and Pathology. During it he referred to an M.R.C. therapeutic trial of cortisone, which it was hoped would eventually settle whether cortisone was indicated in that disease. Hospitals from five regions were co-operating in the trial. *Devon and Exeter Medico-Chirurgical Society.*—On January 15 Mr. C. C. Jeffery gave an address on "The Closed Treatment of Fractures of the Forearm." On February 5 Dr. C. J. Fuller read a paper drawing attention to a small group of cases in which dysphagia is associated with lung complications. There was always an oesophageal anomaly of some kind, and pulmonary infection occurred by spilling over of oesophageal contents. *Liverpool Medical Institution.*—On January 22 a pathological meeting was held. Dr. A. H. Cruickshank described a case of Chiari's disease; Dr. K. McCarthy read a short paper on "Generalized Vaccinia," in which he described a rare and fatal case in a child who had no globulin in her serum, failed to develop neutralizing antibodies, and had a persistent viraemia up to her death seven weeks after vaccination; Dr. M. K. Alexander described a fatal case of the Stevens-Johnson syndrome with fibrinoid necrosis of the arterioles in the stomach, liver, and spleen. On February 12 Mr. Ronald Edwards gave an address on "The Present Position of the Surgery of the Heart and Great Vessels." *Chelsea Clinical Society.*—On February 10 there was a discussion on the importance of leisure, opened by Mr. John Betjeman, and continued by Sir Heneage Ogilvie and Mr. Gilbert Harding. *North of England Obstetrical and Gynaecological Society.*—On February 20 there was a joint discussion in Liverpool with the *North-western Tuberculosis Society* on "Tuberculosis and Pregnancy." The opening speakers were Dr. G. S. Erwin and Dr. S. J. Barr.

Journal of Clinical Nutrition.—The first number of a new international journal on nutrition, the *Journal of Clinical Nutrition*, has now appeared from America. With Dr. S. O. Waife as its chief editor, it numbers Sir Edward Mellanby, F.R.S., and Dr. A. P. Meiklejohn among its corresponding editors. It will be published bi-monthly at a sterling subscription rate of 55s., post free, Messrs. Baillière, Tindall & Cox being the agents for it in the Commonwealth. Success for the new venture probably depends on the journal's ability to live up to its name. Lately, in some journals on nutrition, there has been a tendency for contributions on agricultural subjects to outnumber those with a medical bias. The new periodical could usefully help to restore the balance.

William Hyde Award.—Dr. Richard Scott has recently received the William Hyde Award for 1951, valued at £300, for his work with students at Edinburgh. The award is made from funds provided by the Nuffield Foundation in memory of the late Mr. William Hyde, who played a prominent part in the establishment of the Nuffield Provincial Hospitals Trust. Dr. Scott is physician in charge of the Royal Dispensary, Edinburgh, which is now used as a teaching general practice.

Emergency Bed Service: Applications and Admissions.—During the seven days ending February 23 the number of applications made by doctors to the London Emergency Bed Service for admission of patients was 1,472, of whom 84.29% were admitted. The yellow warning was cancelled from February 19, and the white warning was issued the same day.

Dr. C. E. Dent, reader in medicine in the University of London, is visiting the Universities of Florence and Rome for a week from March 3 under arrangements made by the British Council. He is to speak on chromatography.

Mr. John Foster, senior clinical lecturer in ophthalmology at Leeds University, has been invited to lecture at the University of Barcelona and at the Triennial Congress of Ophthalmology at Buenos Aires in April.

The closing date for applications for the **Anglo-French Exchange Bursaries** described recently in this column (see January 17, p. 169) is March 31.

COMING EVENTS

C.M.F./M.E.F. Physicians Reunion Dinner will be held on March 28 at Simpson's-in-the-Strand, with Dr. D. Evan Bedford in the chair. Further information can be obtained from Dr. A. Willcox, 59, Harley Street, London, W.1.

Laboratory Animals Bureau Congress.—The Sixth Laboratory Animals Bureau Congress is to be held at the Royal Veterinary College, London, N.W.1, on March 27 and 28. The congress, which will consist of three sessions, will be opened by Sir Harold Himsworth, and the chairmen at the three sessions will be Professor S. P. Bedson, F.R.S., Dr. R. Lovell, and Professor R. E. Glover respectively.

NEW ISSUES

British Journal of Ophthalmology.—The next issue (Vol. 37, No. 3) will be available in a week's time. The contents include: CENTRAL AREOLAR CHOROIDAL SCLEROSIS. A. Sorsby and R. P. Crick. CENTRAL SENILE AREOLAR CHOROIDAL SCLEROSIS: A HISTO-PATHOLOGICAL STUDY. Norman Ashton. SPECTRAL SENSITIVITY CURVES AND THE ABSORPTION OF LIGHT BY THE OCULAR MEDIA. R. A. Weale. OCULAR REACTION TO LENS PROTEIN: A PRELIMINARY STUDY. F. W. Law. QUANTITATIVE STUDY OF VISUAL AFTER-IMAGES. C. A. Padgham. MANDIBULO-FACIAL DYSOSTOSIS. A. H. Briggs. SCLERAL RESECTION—LAMELLAR OR PENETRATION? C. Dee Shapland. JOHN DALTON, F.R.S., D.C.L., LL.D., CAPTAIN JOSEPH HUDDART, F.R.S., AND THE HARRIS FAMILY. HISTORICAL NOTES ON CONGENITAL COLOUR BLINDNESS. I. W. Czerar and J. A. Ross. INTRA-OCULAR OPERATIONS IN EGYPT. A. M. Girgis. INJURY SIMULATING CONGENITAL ANOMALY. L. Staddon-Cook.

Issued monthly; annual subscription £4 4s., single copy 8s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

Details in this column are necessarily brief. Further information and tickets where required (marked ●) should be obtained from the institution concerned.

Monday, March 2

INSTITUTE OF NEUROLOGY.—5 p.m., Professor R. W. Russell: Comparative Study of the Effect of Electric Shock Convulsions on Behaviour. **MEDICAL SOCIETY OF LONDON.**—8.30 p.m., Lettsomian Lecture by Dr. E. R. Cullinan: Some Disorders of the Liver and Bile Passages.

Tuesday, March 3

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor E. P. Sharpey-Schaefer: Causes of Hypotension in Man. **INSTITUTE OF DERMATOLOGY.**—5.30 p.m., Dr. S. Thomson: Animal Diseases, etc. **WEST END HOSPITAL FOR NERVOUS DISEASES.**—5.30 p.m., Dr. G. Parsons-Smith: Neurological demonstration.

Wednesday, March 4

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. O. Oliver: Animal Parasites in Dermatology. **INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.**—5.30 p.m., Dr. B. Larsen (Denmark): Occupational Deafness, Including Some Remarks on Auditory Fatigue and Adaptation. **INSTITUTE OF UROLOGY.**—At St. Paul's Hospital, W.C., 4.30 for 5 p.m., Dr. C. Dukes: Pathology of Calculous Disease. **LIVERPOOL MEDICAL INSTITUTION.**—At Manchester University, 5 p.m., joint meeting with Manchester Medical Society. Dr. E. N. Chamberlain: Rheumatic Carditis; Retrospect and Prospect; Mr. J. H. Hughes: Gastroscopy: a Retrospective Evaluation. **MIDLAND MEDICAL SOCIETY.**—At Birmingham Medical Institute, 8.15 p.m., joint meeting with Midland Counties Veterinary Association. Deficiency Diseases in Animals and Man. **OXFORD UNIVERSITY.**—At Radcliffe Infirmary, 5 p.m., Litchfield Lecture by Sir James Larnmonth: Reflections on Portal Hypertension.

Thursday, March 5

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor G. W. Pickering: Natural History of Essential Hypertension. **FACULTY OF HOMOEOPATHY.**—5 p.m., Dr. Grace H. Newell: Homoeopathy in Gynaecological Disorder.

INSTITUTE OF CHILD HEALTH.—5 p.m., Dr. J. A. Fraser Roberts: Genetic Background of the Dull Child. **LONDON UNIVERSITY.**—At St. Mary's Hospital Medical School, 5 p.m., Professor P. Mallet-Guy (Lyons): Les Opérations npathiques dans le Traitement des Pancréatites Chroniques Récidivantes (illustrated). **ROYAL COLLEGE OF SURGEONS OF ENGLAND.**—5.30 p.m., Otolaryngology Lecture by Professor E. C. Dadds: Biochemistry of Endolymph, Perilymph, and Cerebrospinal Fluid. **St. ANDREWS UNIVERSITY.**—At Physiology Department, Dundee, 5 p.m., Dr. G. W. Corner: Embryology of Twins, Triplets, Quadruplets, and Quintuplets. **UNIVERSITY COLLEGE.**—At Physiology Theatre, 4.45 p.m., public lecture by Professor V. B. Wigglesworth, F.R.S.: Chemical Aspects of Insect Physiology.

Friday, March 6

INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. H. J. Wallace. **LONDON UNIVERSITY.**—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor G. F. Martian, D.Sc., F.R.S.: Some Aspects of the Metabolism of the Steroid Hormones. **ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS.**—5 p.m., John Shields Fairbairn Memorial Lecture by Mrs. Ruth Graham (Boston, Mass.): Value of Vaginal Smear to the Gynaecologist. **ROYAL MEDICAL SOCIETY, Edinburgh.**—8 p.m., Mr. J. C. Menzies: Obesity. **ROYAL SANITARY INSTITUTE.**—At Town Hall, Keighley, 10 a.m., Dr. H. M. Holt: Educational Aspects of a Clean Food Campaign; Mr. T. Lindsay: Some Practical Effects of a Clean Food Campaign.

Saturday, March 7

MIDLAND TUBERCULOSIS SOCIETY.—At Chest Clinic, 151, Great Charles Street, Birmingham, Professor Thomas McKeown: Inheritance and Environment in Tuberculosis.

APPOINTMENTS

EAST ANGLIAN REGIONAL HOSPITAL BOARD.—F. J. Hebbert, M.D., F.R.F.P.S., Assistant Physician (Geriatrics), Norwich and East Norfolk Area; G. McD. A. Turner, M.B., Ch.B., Medical Registrar, Newmarket General Hospital. **HENDERSON, WILLIAM GORDON, M.B., Ch.B.,** Junior Lecturer in Bacteriology, London Hospital Medical School. **O'CONNOR, MAURICE F. A., M.Ch., D.P.H., D.L.O.,** Assistant Ear, Nose, and Throat Surgeon, Jervis Street Hospital, Dublin. **SOUTH-WESTERN REGIONAL HOSPITAL BOARD.**—Brenda James, M.B., B.S., D.C.H., Paediatric Registrar, Southmead Hospital, Bristol; Stephanie Saville, M.B., B.Ch., Anaesthetic Registrar, Bath Group of Hospitals; A. Chalmers Fleming, M.B., B.S., Deputy Medical Superintendent, Horsham Hospital, Almondsbury, near Bristol; I. K. Trotter, M.R.C.S., L.R.C.P., D.A. (Part I), Anaesthetic Registrar, Frenchay Hospital, Bristol; W. Lumsden Walker, M.B., Ch.B., D.P.H., D.P.M., Senior Registrar in Psychiatry, Moorhaven Hospital, Ivybridge; C. E. C. Wells, M.B., B.S., M.R.C.P., Medical Registrar, Southmead Hospital; J. N. Hoffman, M.B., B.S., Registrar in Diseases of the Chest, Bristol Clinical Area; S. L. Paton, M.B., Ch.B., Registrar in Orthopaedic and Traumatic Surgery to Mount Gold Orthopaedic Hospital and to Traumatic Centre at the General Hospitals, Plymouth; R. A. Yorston, M.B., Ch.B., Registrar in Ear, Nose, and Throat Surgery to Bath Group of Hospitals.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Gray.—On February 9, 1953, at University College Hospital, London, W.C., to Jean (formerly Leader), wife of Dr. Ian Ramsay Gray, a daughter. **Jennett.**—On February 20, 1953, at the Liverpool Maternity Hospital, to Sheila M. Pope, M.B., Ch.B., wife of Mr. W. Bryan Jennett, M.B., F.R.C.S., a son. **Turner Warwick.**—On January 21, 1953, at the Middlesex Hospital, London, W., to Margaret (formerly Harvey Moore), M.R.C.P., wife of Richard Turner Warwick, F.R.C.S., a daughter.

DEATHS

Brown.—On February 4, 1953, at Woodbridge Hill, Guildford, Surrey, Osmond Hayman Brown, M.R.C.S., L.R.C.P., aged 59. **Browne.**—On February 11, 1953, James M. Browne, M.B., B.Ch., D.O., of North House, Oakley Road, Bromley Common, Kent, aged 83. **Bunting.**—On February 9, 1953, Gerald Lantbery Bunting, M.D., of 16, Pembury Road, Worthing, Sussex, late of Tonbridge and Crowborough. **Cooke.**—On February 3, 1953, at the Radcliffe Infirmary, Oxford, Edward Robert Cecil Cooke, M.C., M.R.C.S., L.R.C.P., of Little Milton, Oxford, aged 66. **Corsellis.**—On February 8, 1953, at Glamis Lodge, Priton-on-Sea, Essex, Ernest Shawe Corsellis, L.R.C.P.&S.I. **Gibson.**—On January 27, 1953, John McCoy Gibson, M.B., B.Ch., D.O.M.S., of Mitcham Lane, Streatham, London, S.W., aged 77. **Grey.**—On February 9, 1953, at Bristol, Harry Grey, M.D., formerly of Edinburgh, aged 83. **Hunt.**—On February 6, 1953, Arthur Douglas Hunt, M.D., of 47, Wellington Road, Bournemouth, and late of Park Grange, Duffield Road, Derby, aged 72. **Jupp.**—On February 8, 1953, at 6, Haven View Road, Seaton, Devon, Edgar Norman Jupp, M.R.C.S., L.R.C.P., aged 77. **Mann.**—On January 30, 1953, in London, Dora Mann (Mrs. Clec), M.D., of 16, Salisbury Place, London, W., and Irwinleigh, Ascot, Berks. **Pain.**—On January 25, 1953, in hospital, Thornhill Coles Pain, L.M.S.S.A., formerly of New Kent Road, London, S.E. **Petty.**—On January 20, 1953, in Buenos Aires, Argentina, Michael Joseph Petty, G.B.E., M.D., F.R.C.S. **Stalkart.**—On January 31, 1953, at Kenilworth, Portsmouth Hill Road, Cosham, Hants, Walter Henry Skinner Stalkart, M.D., F.R.C.S.Ed., Surgeon Rear-Admiral, R.N., retired. **Thornett-Johnson.**—On January 30, 1953, at 22, St. George's Road, St. Margaret's-on-Thames, Middlesex, Marian Thornett-Johnson, F.R.C.S.I. **Wylie.**—On February 4, 1953, at 3, Hillway, Holly Lodge, Highgate, London, N., John Robert Wylie, M.B., B.S., D.M.R.E.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Is Penicillin Alone Enough for Syphilis?

Q.—Is it true that penicillin alone is adequate treatment for syphilis in all stages? If not, what ancillary treatment is advised?

A.—Many series of cases have so far been reported in which penicillin alone has proved to be adequate in the treatment of syphilis. In the small percentage of failures following treatment for primary or secondary syphilis there is much confusion about whether the reappearance of active lesions was due to reinfection or relapse. It is impossible to give a dogmatic opinion at this stage. Most workers in this country continue to give ancillary treatment consisting in one or two ten-week courses of bismuth, or one course of neoarsphenamine and bismuth. The writer gives one course of bismuth only.

The results obtained in neurosyphilis with penicillin combined with fever therapy are no better than with penicillin alone, but better results are claimed in the treatment of interstitial keratitis in young children with the concomitant administration of cortisone.

Diabetic Drivers

Q.—Recent successful police prosecutions of diabetic motor-drivers suffering from hypoglycaemia due to insulin administration have prompted local road haulage depots to enquire whether they should continue to employ as drivers diabetics receiving insulin. (1) What advice should be given to the haulage depots? (2) What is the legal definition of a drug, and is insulin one? (3) What clinical or other criteria should be adopted in deciding whether an individual diabetic should be advised not to drive a car?

A.—(1) Haulage depots should be advised to insist upon a medical examination of applicants for employment as drivers of haulage vehicles; ideally, a periodical re-examination of drivers should form part of the medical arrangements of each firm of contractors. Every applicant for employment as a motor-driver should in the first instance provide evidence from a medical practitioner on his fitness to drive a motor vehicle, and in default should be requested to submit himself to a medical examination by a practitioner nominated by the prospective employer. This examination would be conducted only when the prospective employer was satisfied with the candidate in all other respects: that is to say, the applicant would be appointed subject to passing a medical examination.

(2) There is no comprehensive legal definition of a drug. A drug is regarded as medicine for internal or external administration, and this definition would include insulin.

(3) This question has been to a large extent answered by a recent letter in the *Journal* from Dr. R. D. Lawrence (September 13, 1952, p. 616).

The most important consideration in deciding whether a diabetic is fit to drive a car, is his ability to recognize hypoglycaemia in its earliest stages and to take the necessary steps to remedy it. In addition, he should always take his proper amount of carbohydrate food at the proper time, and never drive without adequate supplies of carbohydrate food in his car. Diabetics who are liable to frequent insulin reactions, and especially those in whom they are liable to occur without adequate warning, should be advised not to drive, both in their own interests and in that of the public.

Chloramphenicol Ointment in Blepharitis

Q.—In the treatment of recurrent blepharitis by chloramphenicol ointment, is there any likelihood of either local sensitivity or drug-fastness developing?

A.—Experience so far has not shown any local reactions to the use of 1% chloramphenicol ointment. As this preparation is not used, and need not be used, for any length of time the possibility of developing drug-fastness hardly arises. There seems to be no valid reason for using chloramphenicol for blepharitis, as this affection is generally due to Gram-positive organisms which respond well to penicillin ointment. No local remedy is completely satisfactory in blepharitis, for the general health is usually unsatisfactory, and recurrences are common unless this receives attention.

Oestrogens for Mumps Orchitis

Q.—Is stilboestrol of value in the prevention and treatment of mumps orchitis? Hoyne, Diamond, and Christian¹ in the U.S.A. originally wrote in favour of it, but Candel² did not seem to think it worth while. Micks³ says of it: "Clinical trials have not yet (1949) been extensive enough to prove or disprove this claim."

A.—Little further work has been carried out on this form of therapy, and none of it is entirely satisfactory. There would appear to be no reason to expect oestrogen therapy to modify the course of a virus infection, and the best preventive measure against orchitis is probably the administration, where available, of convalescent serum or the gamma globulin prepared from it. When orchitis is established, efficient local cooling and support remain the most effective treatment.

Implantation of Hormone Pellets

Q.—What is the technique of subcutaneous implantation of hormone pellets? How are the pellets sterilized?

A.—The pellets are supplied already sterilized and each is contained in a sterile sealed tube between plugs of cotton-wool. With the aid of a file the tube is snapped across one of the plugs, which is removed, thereby withdrawing with it any minute particles of glass which may be present. The pellet should not be removed at this stage. Should the pellet become contaminated it may be sterilized by boiling in water in a test tube. The technique of injection is as follows:

Open or Incisional Method.—An incision 1 to 1½ in. (2 to 4 cm.) in length is made in the subcutaneous tissue of the abdominal wall or of the infrascapular region. Strict asepsis is necessary, for sepsis, apart from its usual disadvantages, causes the pellets to be extruded. A small pocket, ½ to 1 in. (1 to 2 cm.) deep, is made by blunt-dissection in the subcutaneous tissue. The pellet is dropped into the pocket from its container and is gently pushed to the bottom with blunt forceps. If more than one pellet is to be implanted several pockets are made and a pellet is inserted into each. The wound is then closed with sutures.

Injector Method.—The injector is a blunt-ended or sharp-pointed trocar and a cannula of a bore just sufficiently wide to take a cylindrical pellet. The skin is cleaned, with a tenotomy knife a small incision is made slightly longer than the diameter of the cannula, and the trocar and cannula are pushed into the subcutaneous tissue at an angle of about 45 degrees. The trocar is withdrawn, and the pellet is dropped into the cannula from the container and gently pushed home with the trocar. If several pellets are to be inserted the position of the instrument should be changed slightly after each insertion so that they are separated from each other. The incision is closed with a suture.

Elliptical Pupils

Q.—Why are the pupils of some animals oval instead of round?

A.—In photography it is usual to reduce the aperture of the lens when it is required either to improve definition or to increase depth of focus. Usually the reduction of the aperture requires a longer exposure to be given because the image formed by the lens has suffered a loss of brightness. If photographs were being taken of objects the contour of which lay in a horizontal, or nearly in a horizontal, plane, then if increased definition or depth were required the usual method would be to use a smaller circular aperture and to increase the exposure as for normal subjects. There is, however, in this case an alternative method available—namely, to use an elliptical aperture with its long axis horizontal. Thus, suppose this to measure 8 mm. long by 2 mm. high, then the definition and depth for horizontal or nearly horizontal lines would correspond to those of a 2-mm. diameter circular aperture, but the light-transmitting power would correspond to that of a 4-mm. diameter circular aperture, since this has the same area as the ellipse. If photographs were wanted of objects with vertical contours, then the correct procedure would be to use an elliptical aperture with its long axis vertical. Similar reasoning applies to the eye, and those animals, like cats, to whom the outlines of tree trunks and the openings in fencing, etc., are important could with advantage have irises with elliptical apertures, the long axis being vertical. On the other hand, those animals, like cows, sheep, or goats, to whom the lie of the land is important could with advantage have the long axis of the ellipse horizontal.

Toxic Effects of Amphetamine

Q.—What toxic effects may arise from prolonged use of dexamphetamine sulphate? I am particularly interested to know whether there is any risk of blood or hepatic changes, chronic dyspepsia, carcinogenesis, and such-like serious effects.

A.—The actions and toxic effects of dexamphetamine sulphate are similar to those of amphetamine sulphate, but the D-isomer is claimed to be effective in smaller dosage. Both substances have been safely used for lengthy periods in narcolepsy or obesity in doses up to 60 mg. daily. The development of psychoses has been reported, as for example in the man of 49 who had taken 250 mg. daily for five years. Reports have also appeared of damage to bone marrow: pancytopenia occurred in a girl of 21, and acute aplastic anaemia in a man of 26 who took 290 mg. during 19 days. Habituation may also occur, though this is probably not very common. Withdrawal symptoms observed included hallucinations, restlessness, and insomnia. These symptoms, together with anorexia, may be expected to follow prolonged administration in most patients. Many of those receiving amphetamine possess personality defects and may be especially prone to exhibit these side-effects. Tachycardia and hypertension have also been reported, but I am not aware of any evidence of carcinogenesis or liver damage from prolonged use of dexamphetamine.

Benign Prostatic Enlargement

Q.—What is the cause of benign enlargement of the prostate?

A.—The exact cause of benign enlargement of the prostate is not known, but it is probably related to hormonal imbalance. This is suggested by the fact that the enlargement begins to manifest itself most commonly at a period when testicular activity begins to decline. Other indications of the close association of testicular hormones with prostatic disease are provided by clinical evidence of the control of prostatic carcinoma by oestrogens and by castration, and the fact that while prostatic disease is quite common in dogs it does not occur in those which have been castrated.

It seems not improbable, therefore, that prostatic disease in man will eventually be treated, or at least prevented, by hormonal therapy, instead of by surgery, but at the present time the results of both androgenic and oestrogenic treatment are disappointing. We seem to be near the mark, but not quite there.

Khellin in Bronchospasm

Q.—Is oral khellin effective in the treatment of bronchospasm? Are there any dangerous toxic effects which contraindicate its use? Is it safe for children?

A.—One of the pharmacological actions of khellin is a marked bronchodilator effect on guinea-pig bronchi.¹ Its clinical effect on humans is variable, but it can relieve bronchospasm, and its effect and that of adrenaline are, to a certain extent, additive. It is much more effective when given parenterally; the onset of its action is delayed and may be prolonged over 24 hours after a single intramuscular injection. The incidence of side-effects after oral use is only slightly lessened by using enteric-coated tablets, and in a recent trial² nausea, anorexia, and vomiting occurred in a high proportion of patients: nausea occurred in 65%—to a prohibitive degree in 32%, and sufficient to necessitate a suboptimal dose in 22%. The difficulty of maintaining an adequate dosage by the oral route limits the value of the drug, and for this reason it is inadvisable to give it to children.

NOTES AND COMMENTS

Troublesome Cough in a Child.—Dr. M. C. WATKINSON (Blackburn) writes: With regard to your question and answer on this subject ("Any Questions?" February 14, p. 413), troublesome night cough in children is one of the commonest problems I encounter in the baby clinics here, and I have worked out a rather homely method of treatment which rarely fails to be effective and which may help the doctor who made inquiry about the condition. First, I advise the mother to give drinks of lemon and honey (home prepared) to the child throughout the day and a spoonful of honey to be sucked slowly just as the child is going to bed. The bedroom window should be closed at least an hour before bedtime and kept closed during the night. Also, if possible, the room should be warmed by a small electric fire for 45 minutes or so before putting the child to sleep. The menthol rubbing ointments applied to chest and throat after the warm bath are helpful too. With my own children I find that this combination of therapies is usually sufficient, but if we hear the cough start during the night we switch on the electric heater for about half an hour, and as the room warms up again the cough ceases. Where, despite these measures, cough persists and is troublesome, I prescribe syrup of codeine phosphate according to Young's formula and using 2 drachms (7 ml.) as the adult dose. I did this at first with great trepidation after reading the Refresher Course article on "Acute Bronchitis" (*British Medical Journal*, 1951, 1, 827). I find, however, that, as the author of the article stated, codeine is quite well tolerated by even small children. Certainly I should use it in preference to chloramphenicol.

Correction.—Mr. H. K. McCOMB writes: With regard to your report in the medico-legal column (February 21, p. 461) concerning an action for negligence against "the surgical registrar" of Mayday Hospital, I would point out that there is more than one surgical registrar at that hospital.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY MARCH 7 1953

ISONIAZID IN THE TREATMENT OF PULMONARY TUBERCULOSISSECOND REPORT TO THE MEDICAL RESEARCH COUNCIL BY THEIR
TUBERCULOSIS CHEMOTHERAPY TRIALS COMMITTEE*

In February, 1952, the Medical Research Council appointed their Tuberculosis Chemotherapy Trials Committee to plan a clinical trial of isonicotinic acid hydrazide (isoniazid) in pulmonary tuberculosis. Selected hospitals were invited to co-operate, and the first patient started treatment on March 29, 1952. The trial is still continuing and has expanded steadily. The number of participating hospitals now stands at 52, and more than 1,100 patients are undergoing, or have undergone, prescribed courses of treatment and observation.

The trial was designed so that monthly progress reports on each patient could be collected, and the accumulated information reviewed, from week to week. This continual review of results in a large number of patients has not only facilitated early publication of reports, but also enabled the Committee to stop the allocation of some treatments and to introduce others during the course of the trial.

The first report of the Committee was published on October 4, 1952 (Medical Research Council, 1952). It compared the value of isoniazid with that of streptomycin + P.A.S. in the treatment of pulmonary tuberculosis, in a series of 331 patients after three months' observation and treatment. The report suggested that over this period isoniazid lay within the same range of efficacy as streptomycin + P.A.S. It demonstrated, however, a frequent and rapid development of bacterial resistance to the drug and showed that this was a serious problem, since it affected the response to treatment.

The present report studies the effects of streptomycin combined with isoniazid; it compares this treatment with those investigated in the first report—namely, streptomycin + P.A.S. and isoniazid alone. The progress of a total of 364 patients who were treated for three months is now presented. They were divided at random on entry to the trial into three series receiving one or another of the three treatments.

The list of the 40 hospitals which have contributed cases for this analysis, and the names of the co-operating clinicians, bacteriologists, and pathologists, are given at the end of the report. The bacteriologists and pathologists formed a laboratory subcommittee under the chairmanship of Professor R. Cruickshank. The trial was co-ordinated by Drs. Marc Daniels and Wallace Fox, of the Council's Tuberculosis Research Unit; Dr. Fox and Dr. Ian Sutherland (of the Council's Statistical Research Unit) analysed the present results and prepared the report. X-ray assessments were made by

*Members of the Committee: Sir Geoffrey Marshall (chairman), Professor J. W. Crofton, Professor R. Cruickshank, Dr. Marc Daniels, Dr. J. E. Geddes, Professor F. R. G. Heaf, Professor A. Bradford Hill, Dr. J. V. Hurford, Dr. D. A. Mitchison, Dr. W. D. M. Paton, Dr. J. G. Scadding, Dr. Norman Smith, Dr. P. D'Arcy Hart (secretary).

Dr. L. G. Blair. The isoniazid used throughout the trial has been supplied as "nydrazid" by E. R. Squibb and Sons.

1. PLAN AND CONDUCT OF THE TRIAL

The plan and conduct of the trial have already been described in the first report and some points are dealt with more fully there.

1. General

When a patient has been accepted for the trial, treatment is allocated by the Tuberculosis Research Unit from confidentially held prearranged lists based upon random sampling numbers.

After admission to the trial and a preliminary week of observation, all patients are kept under observation for six months. During the first three months the prescribed treatment is followed for every case. During the second three months Group 3 cases (see later description of groups) remain on the same treatment. For other cases the clinician is free to undertake any treatment he wishes.

At the end of the first, second, and third month of treatment, clinical progress reports for each patient on standard forms are sent to the Tuberculosis Research Unit. At six months the clinicians send a final progress report and a full case summary.

The information is scrutinized as soon as it is received, and the most important items from the clinical progress reports are entered on special cards. Information for each patient is thus accumulated, and with these cards regular analyses of results are carried out. Laboratory data are kept separately by the bacteriologists and pathologists, and are called in as required (see Section III of this report).

2. Type of Case

Before acceptance into the trial, basic requirements for all cases were laid down as follows:—At the start of treatment: (1) Tubercle bacilli must have been demonstrated: there must be either a positive direct smear from a sputum specimen taken within the previous two weeks, or a positive culture derived from a specimen taken not more than two months previously. (2) The tubercle bacilli must not, so far as is known, be streptomycin-resistant or P.A.S.-resistant. (3) The patient must not have had more than 15 g. streptomycin and/or 300 g. P.A.S. within the previous three months, and not more than 3 g. isoniazid at any time (this last requirement was added soon after the start of the trial). (4) The patient must not be undergoing pneumoperitoneum, nor have any form of collapse therapy for the lung requiring treatment. (For fuller criteria see the first report.)

Twelve cases (3%) did not conform entirely to the bacteriological requirements, but are nevertheless included in the clinical analysis. In none of these patients was the diagnosis in doubt, and for most of them it had been established bacteriologically either before or after starting treatment, though not within the stipulated period. These cases have, however, been excluded from the bacteriological analysis (see Section III).

Cases satisfying the above requirements were admitted to the trial in one of three main disease groups: (1) acute rapidly progressive pulmonary tuberculosis believed to be of recent origin; (2) other forms of pulmonary tuberculosis considered suitable for chemotherapy; (3) chronic forms of pulmonary tuberculosis expected to make only a limited response to streptomycin + P.A.S.

Under these three headings eight subgroups were defined as follows: (1A) Bilateral lesions; age 15-30. (The definition of this subgroup corresponds to that of cases admitted to the earlier chemotherapy trials, 1946-52.) (1B) Bilateral lesions; other ages. (1C) Predominantly unilateral lesions; all ages. (2A) Chronic cases with a recent exudative lesion. (2B) Primary tuberculosis with manifest recent lesions diagnosed not more than six months previously. (2C) Other forms. (3A) Patients who have previously had, in all, not more than 15 g. streptomycin and/or 300 g. P.A.S. and/or 3 g. isoniazid. (3B) Other patients who have had some chemotherapy, but not more than 15 g. streptomycin and/or 300 g. P.A.S. within the previous three months, and/or 3 g. isoniazid. It was realized that there would be some overlap between Groups 2 and 3, as well as between the subgroups of Group 2.

EVOLUTION OF THE TRIAL

FIG. 1.—The treatments allocated in each disease subgroup from the start of the trial to the present time, showing the period of allocation of each treatment.

3. Intake of Cases

Group 1 cases are selected by a central panel of clinicians; cases in Groups 2 and 3 are, in the main, selected by the clinicians in the co-operating hospitals from the patients already under their care.

4. Treatment

The dosage of each drug used was as follows:—*Streptomycin* (not dihydrostreptomycin): 1 g. daily, in one intramuscular injection. (Children under 15: 15 mg. per kg. of body weight daily, up to a maximum of 1 g.) *P.A.S.*: 20 g. of the sodium salt daily, in four doses, by mouth. (Children under 15: 1 g. per 3 kg. of body weight daily, up to a maximum of 20 g.) *Isoniazid*: 200 mg. daily, in two doses of 100 mg. given 12-hourly, by mouth. (Children under 15: 3 mg. per kg. of body weight daily, up to a maximum of 200 mg.)

5. Evolution of the Trial

The large number of cases and the continual analysis of the results have enabled the Tuberculosis Chemotherapy Trials Committee to introduce new treatments and to stop allocating other treatments during the course of the trial, and so to study fresh problems in the application of isoniazid as they arose. The trial has thus proceeded in several stages. The time-table has been complicated by the fact that for several reasons the new treatments have not been introduced at the same time in each of the disease subgroups of the trial. Subgroup 1A and Group 3 have followed patterns different from those of the other groups. Fig. 1 illustrates this complex time-table, and the following paragraphs should be read in conjunction with this figure.

When the trial began on March 29, 1952, the first problem was to decide whether isoniazid was an effective drug when compared with the best chemotherapy known at that time—namely, streptomycin + P.A.S. Accordingly, two treatments—streptomycin + P.A.S. (SP) and isoniazid (H)—were allocated concurrently, and at random, to cases in all disease groups.

In view of the development of bacterial resistance to other anti-tuberculosis drugs when given alone, it was decided from the outset to study also the results of combining isoniazid with another effective drug. A third treatment, streptomycin + isoniazid (SH), was therefore introduced at the start of the trial in Group 3, in which the cases (by definition) were expected to make only a limited response to streptomycin + P.A.S. In this way fundamental bacteriological information would become available as soon as possible.

As the trial proceeded there was growing evidence concerning the frequent development of bacterial resistance to isoniazid when given alone. The Committee therefore decided to introduce the SH treatment throughout the trial (except in subgroup 1A) from June 1, while continuing a concurrent allocation of cases to SP and H. Although the three treatments were allocated at random as

before, it was arranged, without the knowledge of the clinicians, that rather more patients should be admitted to the SH series than to either of the other two, because of its potential importance.

The cases in subgroup 1A (acute rapidly progressive tuberculosis of recent origin, bilateral and between the ages of 15 and 30) were of special importance since they corresponded by definition to those in all the previous Medical Research Council tuberculosis chemotherapy trials. The aim of the Committee was to have a sufficiently large number of cases in this subgroup to enable a clear-cut comparison to be made between isoniazid alone and each of the treatments allocated in the earlier trials. For this reason the two treatments SP and H were allocated in this subgroup from the start of the trial until September 22, by which date 99 cases had been admitted, and the Committee had decided from the bacteriological information then available that it was unjustifiable to continue to allocate isoniazid alone. From this date onwards, two other treatments were adopted for subgroup 1A—namely, SH and 2O PH (20 g. P.A.S. daily + isoniazid 200 mg. daily). (See Fig. 1.)

By the beginning of September, 1952, the numbers of patients who were on the SP and H treatments in other subgroups were adequate; also, the bacteriological analysis for the first report, although incomplete, suggested that isoniazid resistance was a serious problem affecting clinical progress. From September 5 onwards, therefore, the allocation of cases to SP and H was stopped throughout the trial (except, as stated above, in subgroup 1A). As it was essential to concentrate upon combined therapy with a view to the prevention of drug resistance, three new treatments were introduced in addition to SH (streptomycin 1 g. daily + isoniazid 200 mg. daily)—namely, S2H (streptomycin 1 g. twice weekly + isoniazid 200 mg. daily), 2O PH (20 g. P.A.S. daily + isoniazid 200 mg. daily), and 1O PH (10 g. P.A.S. daily + isoniazid 200 mg. daily). The trial of these four treatments is still proceeding.

The first isoniazid report (Medical Research Council, 1952) compared the progress after three months' treatment of all the SP and H cases admitted to the trial before June 1, 1952. (During this period 38 Group 3 cases were allocated to the SH treatment; but, because this number of very chronic cases was considered to be inadequate for the assessment of clinical results, no comparison was then made with the Group 3 cases allocated concurrently to SP and H.)

The clinical section of the present report analyses the progress after three months' treatment of all the 364 cases which were admitted concurrently to the three treatments SP, H, and SH—that is, all the Group 3 cases allocated between March 29 and September 5, and all cases in the

other disease groups (except subgroup 1A) allocated from June 1 until September 5 (see Fig. 1). The progress of the SH patients is compared with that of the SP and also of the H patients. Direct comparison between the SP and the H patients (numbering more than 500 since the start of the trial) is not made here, but will be the subject of a further report.

The bacteriological section of the present report analyses the tests for tubercle bacilli in the sputum and the development of drug resistance for the same group of 364 cases.

6. Total Number of Patients in the Present Analysis

Table I sets out the number of cases according to treatment, and shows that, of the 364 cases, 102 have been treated with streptomycin + P.A.S., 120 with isoniazid, and 142 with streptomycin + isoniazid. (Of the Group 3 cases, 29 SP and 40 H were included in the first report but appear again in the present analysis, since they were admitted concurrently with 38 SH patients. Subgroup 1A does not appear in the present analysis, since the SH treatment was not allocated concurrently with the SP and H treatments in this subgroup. Consequently, whereas Group 1 of the first report included cases in all three subgroups, Group 1 of the present report includes cases in 1B and 1C only.)

II. CLINICAL PROGRESS

1. Exclusions

Before detailing the clinical exclusions it should be pointed out that Table I and the clinical analysis include approximately 20 patients who were found to have had streptomycin- or P.A.S.-resistant organisms at the start of treatment, although this was not known when they entered the trial. Because their response to treatment may have been affected by this, it would have been desirable to exclude these cases from the clinical analysis. This has not been done because a few P.A.S. sensitivity tests are still pending. A subsidiary analysis has shown no evidence that the conclusions drawn below are in any way affected by the retention of these cases for the time being.

The totals in Table I do not include 39 cases which were admitted concurrently with the 364 but subsequently excluded for the following reasons:

- The 7 cases in Group 2B were excluded (3 SP, 2 H, and 2 SH). This group was too small and too different from the others to justify its retention.
- Five cases were excluded before treatment was started: 1 patient died before admission to hospital (SH); 2 patients refused admission to hospital (1 SP, 1 H); 1 patient refused treatment (SP); 1 patient, although admitted, did not start treatment as no positive sputum could be obtained (H).

TABLE I.—Number of Cases Treated Concurrently with SP, H, and SH

		Treatment			All Cases
		Streptomycin Plus P.A.S.	Isoniazid	Streptomycin Plus Isoniazid	
Group 1: Acute rapidly progressive pulmonary tuberculosis of recent origin	1B. Bilateral; under 15 years and 31 or more	4	7	10	21
	1C. Unilateral; all ages	21	19	27	67
	Total	25	26	37	88
Group 2: Other forms of pulmonary tuberculosis suitable for chemotherapy	2A. Chronic with recent spread	14	13	24	51
	2C. Other forms (excluding primary disease)	24	31	32	87
	Total	38	44	56	138
Group 3: Chronic forms of pulmonary tuberculosis expected to make only a limited response to chemotherapy	3A. Very little previous chemotherapy	12	15	14	41
	3B. Some previous chemotherapy, but not recently	27	35	35	97
	Total	39	50	49	138
All cases		102	120	142	364

(iii) Twenty-seven cases were excluded after treatment had begun:

- 1 patient was found to have had four months' chemotherapy up to within a month of entering the trial (H);
- 1 patient was found to have a carcinoma of the bronchus, proved on biopsy (H);
- 3 patients were given the wrong treatment in error (2 SP, 1 SH), 2 having SP+H for one month, the third having SP+H for two months;
- 6 patients discharged themselves against medical advice (1 in the first month, 3 in the second, and 2 in the third) (4 SP, 1 SH, 1 H);
- 11 patients had severe toxic reactions attributed to streptomycin (6 SH, 5 SP);
- 2 patients had severe toxic reactions attributed to P.A.S. (2 SP);
- 1 patient was found to be pregnant and this was considered by the clinician in charge a contraindication to streptomycin (SH);
- 2 changes of treatment were necessary in the first month—namely, in 1 H case which showed gross spread radiologically and in which streptomycin was added because the patient was considered at risk of death in the absence of this treatment (the radiographic appearances remained unaltered in the next two months), and in another H case which deteriorated clinically but not radiographically and in which streptomycin+P.A.S. was added after four weeks.

It will be seen that there were 13 exclusions because of drug intolerance—11 to streptomycin (5 SP and 6 SH) and 2 to P.A.S. Although many patients intolerant to streptomycin or P.A.S. can be desensitized, these exclusions for drug intolerance must be considered a defect of therapy with streptomycin or with P.A.S. when compared with isoniazid, for in no case was there any interference with the prescribed regime of isoniazid due to toxicity, whether the isoniazid was taken alone or in combination. Against these 13 exclusions there is one exclusion representing a definite failure of isoniazid therapy, and one in which clinical deterioration was reported.

One patient whose treatment was changed from H to SH at the end of the second month has been included throughout as an H patient.

2. Toxicity

Toxicity of Streptomycin and of P.A.S.—Apart from the 13 cases referred to in the previous paragraph, in which

treatment had to be stopped, there were some slighter toxic reactions to streptomycin in patients on the SP and SH treatments and to P.A.S. in patients on the SP treatment. These reactions were sometimes troublesome and worrying, but did not interfere unduly or more than temporarily with the prescribed regime of chemotherapy. Nevertheless, toxic reactions to streptomycin must be accepted as a defect of the combination streptomycin + isoniazid as of the combination streptomycin + P.A.S.

Toxicity of Isoniazid.—There have been no reports of serious toxicity from isoniazid in any of the trial patients, with the dosage used, over a period of three months, and there is nothing further to add, at this stage, to the information presented in the previous report.

3. Condition on Admission

Table II shows the condition of patients before the start of treatment as reflected by their general condition (assessment by the clinician in charge), temperature, sedimentation rate (Westergren 200 mm. reading at one hour), and the extent of cavitation on x-ray film (as estimated by an independent radiological assessor, unaware of the treatment of any case). It can be seen that, judging by the factors listed, the SP, H, and SH cases, both in Group 1 and in Group 3, have a reasonably similar distribution of severe and less severe illness. In Group 2, however, the SP patients appear to have been on the average rather more ill than the SH and H patients. For the totals of all groups the three treatment series are comparable.

4. Results at the End of Three Months

In the following sections, after a general note on the low mortality, a comparison is made between the progress of the patients on streptomycin + isoniazid (SH) and that of patients on streptomycin + P.A.S. (SP). This is followed by a comparison of the progress of patients on streptomycin + isoniazid (SH) and the progress on isoniazid (H) alone.

Mortality.—There were four deaths among the 364 cases (1.1%) during the three months of treatment; two in 102 SP patients, one in 120 H patients, one in 142 SH patients. One SP patient (in Group 3A), who died 14 days after the start of treatment, suffered clinically from chronic bronchitis and emphysema, and cannot be regarded as having died from tuberculosis; the H patient (in Group 2C) died from

* A patient was considered afebrile if every evening temperature in the pre-treatment week of observation was below 99° F. (37.2° C.).
† Assessment on a single film taken before treatment started. Tomograms were not taken into account.

congestive cardiac failure the day after starting treatment. These two cases do not represent a failure of treatment, in contrast to the other two patients—one on SP, the other on SH (from Groups 3A and 3B)—who died of their tuberculous disease 32 days and 22 days respectively after the start of treatment; both were very ill on admission to the trial.

5. The Comparison between SH (Streptomycin + Isoniazid) and SP (Streptomycin + P.A.S.)

General Condition.—Change in the clinical condition was assessed by the physician in charge of the patient. It represents an overall impression of the patient's progress, being based on the clinical observations, the patient's appearance, and his feeling of well-being (or lack of it). Table III shows that on each treatment a considerable percentage of patients improved—87% of 142 SH patients and 75% of 102 SP patients. This difference just attains statistical significance at the 5% level, due mainly to the experience in Group 3. In this group of very chronic cases, 51% of

39 SP patients showed 1-plus (moderate) improvement, and none had 2-plus (considerable) improvement; in the 49 SH patients the corresponding figures are 49% and 22%. In Group 1, the acute rapidly progressive disease, all the 25 SP patients and 36 of the 37 SH patients improved clinically.

Weight Changes.—The weight changes for the three-months period are set out in Table IV, and here the SH patients have benefited strikingly compared with the SP patients. The difference in the average weight gains for the totals (6.1 lb. and 13.0 lb.—2.8 and 5.9 kg.), and also that for each disease group, is statistically highly significant. Of the 136 SH patients, 82% gained 7 lb. (3.2 kg.) or more and 42% gained 1 stone (6.3 kg.) or more. The corresponding figures for the 97 SP patients are 45% and 13%. It is noteworthy that the acute (Group 1) cases on both treatments have fared better than the less acute cases, and that in this group, too, the SH patients have benefited more than the SP patients. Of 36 SH patients 61% have gained 1 stone or more, compared with 32% of 25 SP patients. Of

* For three other SP patients and five SH patients the weight changes are not available. Also two SP patients, one H patient, and one SH patient had died † One patient included here lost 11½ lb. in two months, was too ill to be weighed at three months, and died the following day.
‡ One patient changed treatment from H to SH at the end of two months, and is included here.

the total of 61 acute cases on SP or SH, only 4 (7%) have failed to gain some weight.

Temperature.—In the present analysis a patient was considered to be initially afebrile if the evening temperature was below 99° F. (37.2° C.) on every day of the week of preliminary observation. The same definition applied to the last week of the third month of treatment. Table V sets out the number of patients who were febrile in the pre-treatment week, but afebrile at three months. The patients are grouped according to the initial level of pyrexia. In a total of 88 febrile SH patients, 82% were afebrile at three months, compared with 76% of 63 SP patients. There is also little difference between the three disease groups; the figures for Group 1, the acute cases, were 81% of 32 SH patients and 84% of 19 SP patients. In none of these comparisons is there a statistically significant difference.

Of 53 SH patients who were afebrile in the pre-treatment week (not shown in the table) 6, or 11%, had a low-grade pyrexia at three months (an occasional evening temperature above 99° F.). The corresponding figures for the SP patients were 4 out of 37, also 11%.

Sedimentation Rate.—Table VI sets out the number of patients with an initially elevated blood sedimentation rate (B.S.R., Westergren) which was lowered after three months' treatment. Of 101 SH patients with an initial B.S.R. of 21 or more, 45% fell to normal (10 or less) in three months; the corresponding figure for 73 SP patients was only 21%. This difference is statistically highly significant. When the initial B.S.R. was 51 or more the rates were normal at three months in 18% of 39 SH patients, and in only 5% of 38 SP patients. The B.S.R. rose from an initially normal level in 4 of 19 SH cases and 3 of 10 SP cases (not shown in the table).

Radiographic Changes in First Three Months.—Table VII sets out the radiographic changes at the end of three months' treatment. The assessments were made by an independent reading of full-plate chest x-ray films by a radiologist unaware of the treatment in any case. (Since the radiographic reading was intended as a comparative measure of x-ray change and not as an absolute assessment, it was considered that the readings of a single radiologist could be fairly accepted for assessing the relative merits of

* This patient had 2-minus deterioration at two months, was too ill to be x-rayed at three months, and died the following day.

† One patient included here had 2-minus deterioration at two months, changed treatment from H to SH, and still had 2-minus deterioration at 3 months.

different treatments.) In assessing improvement or deterioration three degrees were allowed—namely: 1-plus, 2-plus, and 3-plus, and 1-minus, 2-minus, and 3-minus. In total, the SH and SP groups both contain 64% who showed radiographic improvement. The improvement was more than 1-plus in 38% of SH patients and in 31% of SP patients. (In Group 1, the acute group, 2-plus or 3-plus improvement was seen in 57% of SH cases and 48% of SP cases.) In all there was radiographic deterioration in 3 patients, and one death on streptomycin + isoniazid, and one deterioration and two deaths of patients on streptomycin + P.A.S. The differences between the two treatments are not statistically significant.

Summary of the Comparison of SH and SP

In general condition the SH patients fared rather better than the SP patients, but only among the chronic cases was the difference more than very slight. It must be remembered that assessment of general condition is to a considerable extent influenced by a knowledge of all the other observations of the patient's progress, such as the B.S.R., weight changes, and temperature. The weight gains in all three disease groups were strikingly better for patients on the SH treatment than on the SP treatment. The SH combination also proved much the more effective in lowering the B.S.R. On the other hand, the two treatments had very similar effects on the temperature, and, most important, there were no significant differences in the radiographic response.

6. The Comparison between SH (Streptomycin + Isoniazid) and H (Isoniazid)

General Condition.—Comparing streptomycin + isoniazid with isoniazid alone, it was found in regard to general condition that the response of the patients to each treatment was very similar. Table III shows that 87% of the SH patients improved, compared with 78% of the H patients. Again the response of Group 1 cases is particularly satisfactory.

Weight Changes.—Table IV shows that the average gain in weight for 136 SH patients was 13.0 lb. compared with an average gain of 12.8 lb. for 119 H patients. In each of the three disease groups the two treatments show little difference. The very chronic cases (Group 3) have, however, fared less well on either treatment than the other two groups. The close similarity in weight gain of the

SH and H patients indicates that the important factor in these striking increases is either the presence of isoniazid or the absence of P.A.S.

Temperature.—Of 88 pyrexial SH patients 82% became afebrile, compared with 68% of 59 H patients (Table V). The greatest disparity is in the very chronic cases of Group 3, where the difference attains statistical significance. In the other groups it is not important.

Sedimentation Rate.—The SH treatment has proved more effective than isoniazid alone in lowering the B.S.R. (Table VI). In 101 SH patients with an initial B.S.R. of 21 or more there was a fall to normal (10 or less) in 45%. For 84 H patients the figure was only 25%, giving a statistically highly significant difference. The difference is apparent in all three disease groups.

Radiographic Changes in First Three Months.—Table VII shows that of 142 SH patients 64% improved radiographically, compared with 54% of 120 H patients. Moreover, 38% of the SH patients showed 2-plus or 3-plus improvement, compared with 22% of the H patients. This superiority of the SH treatment, which is apparent over the whole range of the x-ray assessment, is statistically highly significant. Taking the acute Group 1 alone, 57% of the SH patients showed 2-plus or 3-plus improvement, compared with 38% of the H patients. In total, 3 SH patients deteriorated radiographically and one died, compared with 11 deteriorations and one death on H alone. (All 3 SH deteriorations and 7 of the H deteriorations were slight.) The SH treatment has thus shown itself to be more effective radiographically than isoniazid alone.

Summary of the Comparison of SH and H

The SH treatment was more effective than H in lowering the blood sedimentation rate and also in improving the radiographic appearances, and was slightly more effective in lowering the temperature of pyrexial patients. The two treatments were very similar in their effect on the general clinical condition and on weight, both producing striking improvement.

III. BACTERIOLOGY

The Laboratory Subcommittee (chairman, Professor R. Cruickshank) has been responsible for prescribing uniform laboratory techniques and procedures for the centres. A detailed description and discussion of these procedures will be published later as part of a further report.

The first report on the trial (Medical Research Council, 1952) gave as much bacteriological information as was then available on the presence of tubercle bacilli in the sputum during treatment with streptomycin+P.A.S. and with isoniazid. An analysis of isoniazid-sensitivity tests at one, two, and three months demonstrated that isoniazid resistance developed frequently and rapidly; this resistance was shown to affect clinical progress.

The present section analyses the bacteriology of cases treated, concurrently, with streptomycin+isoniazid (SH), streptomycin+P.A.S. (SP), or isoniazid alone (H). These are the same patients as those reported on clinically in Section II. The bacterial content of the sputum of the patients is compared after one, two, and three months of treatment. The development of bacterial resistance to streptomycin is studied for the patients treated with SH and with SP, and the development of resistance to isoniazid in patients treated with SH and with H. Because of the time needed to obtain results of cultures from sputum specimens and to complete drug-sensitivity tests on those cultures, the present analysis omits results pending at two and three months for a small percentage of cases.

1. Exclusions

For the clinical section of this report, it was decided to retain in the analysis only those patients who completed three months' treatment or who died after starting treatment. The procedure adopted for this bacteriological section has been different from that for the clinical section; the results of all available complete tests at one, two, and three months have been used. Thus any complete tests from the small number of patients withdrawn from the clinical analysis have been included—provided they had been treated for at least one month.

On the other hand, 16 patients whose clinical progress is reported have been excluded entirely from the bacteriological analysis. It was laid down that all cases at the start of treatment must be bacteriologically positive for tubercle bacilli (see p. 521). For 12 cases (4 SP, 4 H, 4 SH) the records show that no tubercle bacilli had in fact been seen or isolated from pre-treatment specimens, although positive results were obtained subsequently on one or more occasions from 4 of them. All 12 have been excluded from the bacteriological tables. It should be emphasized that there was no doubt of the clinical diagnosis, and in

fact for most of these cases a positive bacteriological test had been obtained, though not within the prescribed pre-treatment period.

Four other cases (2 SP, 2 SH), all from one small centre, have been excluded because the recording of the bacteriological information was manifestly unsatisfactory.

2. Bacterial Content of Sputum

Sputum collected during the pre-treatment week, and subsequently at monthly intervals, or more often, was examined by direct microscopy and by culture. Where there was no sputum, material from laryngeal swab or gastric lavage was cultured.

The procedure for taking specimens varied considerably from centre to centre. Many centres adhered simply to the minimum requirements for the trial—namely, a single specimen taken each month; in others, specimens were taken much more often. There was evidence that in some centres examinations were made more frequently for patients on some treatments than on others.

In analysing this varied material two important points had to be observed. One was to assess the results as nearly as possible at one, two, or three months after the start of treatment. The other was to ensure that no apparent advantage or disadvantage accrued to a particular treatment merely because numerous or few examinations had been made on those patients allocated to it.

To meet these requirements it was decided to assess the presence or absence of tubercle bacilli each month from the results of single complete examinations of specimens, one from each patient, collected on a date as near as possible to, or exactly at, one, two, and three months after the start of treatment. A test was regarded as incomplete, and was ignored, unless a culture result was available. No result was included for a given month if the date of collection of the nearest specimen examined lay more than 7 days on either side of the appropriate date. Where there was more than one complete test within this period of 15 days, that on or nearest to the appropriate date was chosen, to avoid bias. Table VIII of the present report is therefore not comparable with Table VIII of the first report, in which the "most positive" of the results obtained at any time during each month was recorded.

TABLE VIII.—Presence of Tubercle Bacilli at Single Examinations made at Monthly Intervals

	Treatment	Total Patients Examined		"Positive" Direct Examination†		"Scanty Positive" Direct Examination**		Direct Examination Negative and Culture Positive; or Laryngeal Swab Positive		Direct Examination and Culture Negative; or Laryngeal Swab Negative	
		No.	%	No.	%	No.	%	No.	%	No.	%
At 1 month	SP	91	99	33	36	14	15	14	15	30	33

	SH	43	100	2		2		8		31	72
Group 3	SP	33	100	9		4		4		16	48
	H	45	100	17		3		15		10	22
	SH	44	100	7		5		6		26	59

All patients were bacteriologically positive before treatment—that is, at least one pre-treatment specimen showed bacilli on direct examination or was positive on culture.

* Defined as follows: only a few clumps of acid-fast bacilli found after five minutes' search.

† Whether culture-positive or negative.

The results at one, two, and three months of the selected single examinations of the sputum for tubercle bacilli are set out in Table VIII. It will be clear from the foregoing paragraphs that, in all the bacteriological tables, each item represents a number of patients for each of whom a single test has been selected (by the method already stated), and not a total of all the tests performed on a smaller number of patients.

The recording of the pre-treatment findings was incomplete and biased, since it favoured positive results. For this reason no comparison is possible with the findings during treatment. The pre-treatment findings have, however, been used to check that the degree of positivity of the three treatment series was comparable at the start of treatment.

For the analysis of data at two and three months results have been included only for the specimens in which at least an eight-week period had elapsed since they were collected (this being the period recommended for the incubation of cultures before regarding them as negative). The results at the second and third months would otherwise have been unduly weighted by "positives," since specimens negative on direct examination and with no culture yet available would not have been included, while specimens directly positive, or with early positive cultures, would have been included.

Results

It will be seen from Table VIII that at the end of one month's treatment the results of the tests were negative both on direct examination and on culture in 33% of 91 SP cases, 22% of 107 H cases, and 32% of 131 SH cases. These differences are not statistically significant.

At the end of the second month the percentages of cases negative both on direct examination and on culture were 49% of 89 SP cases, 29% of 110 H cases, and 50% of 132 SH cases. It will be noted that the percentage had increased under each treatment from one to two months. Further, a definite superiority of the SH and SP treatments over the H treatment had appeared; the benefit to the SH and SP cases when compared with the H cases is highly significant statistically. There is no significant difference between the SH and SP series.

At three months, further increases in the percentages negative both on direct examination and on culture had occurred, the figures being 55% of 83 SP cases, 37% of 101 H cases, and 67% of 117 SH cases; there was by then a tendency for the SH cases to show a benefit over the SP cases, but the difference does not attain significance. The cases on H lagged well behind, the benefit to the SH cases being highly significant. It must again be emphasized that this table presents only findings of single tests and so is not necessarily indicative of "sputum conversion." At the other end of the scale the percentages with a positive direct examination at three months were 19% for the SP cases, 30% for the H cases, and 9% for the SH cases.

3. Sensitivity Tests

Strains isolated from specimens collected before starting treatment, and subsequently at least once a month, were tested for streptomycin sensitivity in the SP and SH patients and for isoniazid sensitivity in the H and SH patients. The technique employed for streptomycin sensitivity was similar to that in previous trials (Medical Research Council, 1948); that for isoniazid sensitivity is outlined later (p. 530).

In addition, as the importance of initial P.A.S. resistance in patients admitted to the SP treatment became apparent, it was laid down that a P.A.S.-sensitivity test should be performed on the earliest culture available (whenever possible from the pre-treatment specimen) for all patients from whom a history of one month or more of treatment with P.A.S. alone was obtained. These tests of P.A.S. sensitivity were performed in two laboratories (see Acknowledgments).

As with the recording of the sputum tests, a sensitivity test for a given month was accepted only if it was performed on a specimen collected not more than seven days before or after the appropriate date. When more than one such result was available the one referring to a specimen taken on or nearest to the appropriate date was selected.

4. Streptomycin Sensitivity

All tests in which the "resistance ratio" is 8 or more are classed as resistant, provided the test organisms grew in 0.5 unit per ml. or more; this latter proviso has been introduced to make allowance for the occasional exceptionally low reading for the standard strain H37Rv (inhibition by 0.06 unit per ml.). Check-tests in the reference laboratory for these few test strains indicated that they were sensitive.

As already stated (p. 521), it was required that at the start of treatment the tubercle bacilli must not, so far as was known, be either streptomycin-resistant or P.A.S.-resistant. The object of this requirement being that if the case was allocated to the SP treatment the effectiveness of chemotherapy should not be hindered by pre-existent resistance to either drug, or, if allocated to the SH treatment, by pre-existent resistance to streptomycin. In fact, for many cases the drug sensitivity was not known until well after the start of treatment, when the results of pre-treatment sensitivity tests had become available. It was then found that in 9 patients (2 SP, 7 SH) the bacilli had been streptomycin-resistant initially. Of these, 7 had a history of treatment with streptomycin, alone or in combination with P.A.S., prior to the trial. The other 2 patients are of particular interest, since neither had had any previous chemotherapy and yet both had initially streptomycin-resistant organisms (ratio 8); they are referred to again in the Discussion. These 9 patients are excluded from the following analysis of the development of streptomycin resistance under the SP and SH treatments. The 7 SH patients are referred to again in the section on isoniazid sensitivity, as it was particularly important to investigate whether their bacilli developed resistance to that drug.

There were 3 other patients (2 SP, 1 SH), in whom the streptomycin-sensitivity tests were equivocal. Although the resistance ratio was 4 in two of them, and only 2 in the third, the test organism was inhibited in a concentration of 2 units per ml. in one case, and had grown in 2 units per ml. in the other two (and was not tested further). There was therefore a suggestion that the strains might be resistant. It did not seem correct to class these strains either as initially sensitive or as initially resistant, and these patients too have been excluded from the analysis. The strains from one of the two "doubtful" SP cases remained doubtfully resistant at both one and three months, with sensitivity tests still showing growth in 2 units per ml. (not tested further). Strains from the other patient were resistant (ratio 8) at one month, doubtfully resistant at two and three months, and resistant (ratio 64) at four months. Both these patients gave a previous history of having had streptomycin alone. The SH patient with a doubtfully resistant test initially had no previous history of chemotherapy and gave a definitely sensitive test at two months.

For almost all (95%) of the remaining patients it was established that the organisms were streptomycin-sensitive at the start of treatment. No information was forthcoming for the remaining 5% (7 SP, 4 SH) for technical reasons, such as failure of the primary culture (despite a positive direct test) or of the subculture to grow; for these cases it has been assumed that the organisms were sensitive to streptomycin. Of these 11 patients, 5 on SP and 2 on SH had never had any previous chemotherapy, and a third SH patient had never had streptomycin previously.

* Defined as the ratio of the lowest concentration of streptomycin completely inhibiting growth of the test strain to the corresponding figure for the standard strain (H37Rv).

Results

It is obviously very important to compare the relative effectiveness of the P.A.S. and of the isoniazid in the SP and SH treatments respectively in preventing the emergence of streptomycin resistance. Table IX presents the results of the streptomycin-sensitivity tests after one, two, and three months' treatment with SP or SH (after excluding patients known to be streptomycin-resistant at the start of treat-

ment). The figures in the column headed "culture positive, no sensitivity result available" usually represent failure of a subculture to grow, contamination of the culture, or overheating (incubator fault). For a few of the cases at two and three months in this column, the sensitivity result was still pending at the time of analysis.

TABLE IX.—Results of Streptomycin Sensitivity Tests in SP and SH Cases, Excluding Those Found to be Streptomycin-resistant on Entry to Trial

	Treatment	Total Patients with Culture Examined (a)	Culture-negative (No Sensitivity Test Possible)	Culture-positive but No Sensitivity Result Available	Patients Culture-positive with Sensitivity Tests				Total Resistant		
					Total Results Available (b)	Sensitive	Moderately Resistant (Ratio 8 to 99)	Strongly Resistant (Ratio 100 or More)	No. (c)	(c) as % of (b)	(c) as % of (a)
At 1 month	SP	86	37	2	47	46	1	0	1	2	1
	SH	124	45	4	75	74	1	0	1	1	1
At 2 months	SP	84	49	4	31	30	1	0	1	3	1
	SH	124	68	4	52	50	1	1	2	4	2
At 3 months	SP	78	53	8	17	13	2	2	4	24	5
	SH	109	82	8	19	17	2	0	2	11	2
By disease group at 3 months:											
Group 1	SP	21	14	4	3	3	0	0	0		
	SH	30	23	2	5	5	0	0	0

	SH	41	30	3	8	7	1	0	1		
Group 3	SP	28	20	0	8	4	2	2	4		
	SH	38	29	3	6	5	1	0	1		

ment). The figures in the column headed "culture positive, no sensitivity result available" usually represent failure of a subculture to grow, contamination of the culture, or overheating (incubator fault). For a few of the cases at two and three months in this column, the sensitivity result was still pending at the time of analysis.

Table IX shows that at one month a streptomycin-resistant culture was obtained in one out of 47 culture-positive SP cases (2%), compared with one out of 75 culture-positive SH cases (1%). At two months the corresponding figures were one out of 31 culture-positive SP cases (3%), and 2 out of 52 similar SH cases (4%). At three months there were 4 resistant cultures from 17 culture-positive SP cases (24%) (2 of them moderately and 2 strongly resistant); the corresponding figure was 2 from 19 positive SH cases (11%) (both moderately resistant). When the incidence of streptomycin resistance is expressed by a percentage of the total number of patients for whom cultures were examined (whether culture-positive or negative—that is, (c) expressed as a percentage of (a) in Table IX)—the figures at three months are 4 out of 78 SP patients (5%) and 2 out of 109 SH patients (2%). None of these differences is statistically significant.

On the main question—namely, the prevention of streptomycin resistance by the administration of isoniazid with the streptomycin (SH)—the figures in Table IX at three months, though small, are highly suggestive. They indicate that the addition of isoniazid in a dosage of 200 mg. a day is highly effective—indeed, of the same order of effectiveness as 20 g. of sodium P.A.S. a day (or, when less was given, as large a dose of P.A.S. a day as the patient could tolerate).

Streptomycin-sensitivity tests are already available, in addition, at four months for 7 SH patients who had continued on the combination, though at a reduced dosage of streptomycin (1 g. three times a week), during the fourth month. All 7 tests showed that the cultures were sensitive. One of the patients had yielded a resistant strain at a low level (ratio 8) at three months.

5. P.A.S. Sensitivity

The figure of 4 streptomycin-resistant strains from 17 culture-positive SP patients with sensitivity tests at three months does not seem to represent the usual experience of strepto-

mycin resistance after this period of treatment with streptomycin 1 g. daily plus P.A.S. 20 g. daily. In the present series this high figure is in part related to previous chemotherapy with P.A.S. alone. Evidence will be presented in a further report, as well as in a detailed article from one of the co-operating centres, to show that the administration of P.A.S. alone for periods of more than a month is an important factor in the development of streptomycin resis-

6. Isoniazid Sensitivity

The technique was in brief as follows: a loopful of bacterial suspension from a young primary culture on egg medium was spread on each of a series of egg-medium slopes containing graded concentrations of isoniazid of 0, 0.2, 1, 5, 10, and 50 µg. per ml.; a culture of H37Rv was treated similarly in parallel. Both sets of slopes were read at two weeks and at four weeks, and each slope was recorded at each reading in one of five categories: "confluent growth," "innumerable discrete colonies," "100–20 colonies," "less than 20 colonies," "nil." The experience gained since the publication of the first report has served to confirm the satisfactory nature of the criteria of sensitivity recorded in that report, and there appears to be no reason to introduce any modification. A small number of colonies continue to be observed occasionally on isoniazid-containing medium bearing cultures of the test organism, both before and during treatment, as well as of the standard organism, even in concentrations of isoniazid of 10 µg. per ml. This occurrence justifies the earlier decision that such sparse growths should be ignored in assessing the emergence of resistance during treatment. Accordingly, in the analysis of isoniazid resistance, readings of "less than 20 colonies" are classified with "no growth." This endpoint has proved very satisfactory from the point of view both of reading the tests and of interpreting the results. A culture is designated "resistant" when growth of 20 or more colonies is observed at four weeks in concentrations of 1.0 µg. isoniazid per ml., or higher, and "of doubtful resistance" in cases of such growth in a concentration of 0.2 µg. per ml., but not more. As before it was found that the development of colonies is often incomplete after two

weeks' incubation, and the results analysed in Table X are derived solely from the four-week reading.

The 7 SH patients known to have streptomycin-resistant organisms at the start of treatment have been excluded from Table X. It was suspected that the behaviour of their organisms in regard to the development of isoniazid resistance under SH treatment might well differ from that of

even more impressive; whereas 33 resistant strains were isolated from a total of 93 H patients (35%), only 3 isoniazid-resistant strains were isolated from 109 SH patients (3%) (growth at 1, 5, and 50 µg. per ml. respectively). Again, the benefit to the SH treatment is highly significant.

There is therefore a striking difference between the incidence of isoniazid resistance in patients on isoniazid

TABLE X.—Results of Isoniazid Sensitivity Tests in H and SH Cases, Excluding Those Found to be Streptomycin-resistant on Entry to Trial

† One of these cultures showed growth at 5 µg. per ml., but was not tested at higher concentrations.

patients with initially streptomycin-sensitive organisms; it is shown below that this was so. In order that Table X should present data for comparable groups, 5 H patients whose bacilli were subsequently found to be streptomycin-resistant before treatment were also excluded, although for these patients there was no *a priori* expectation that resistance to streptomycin would influence the development of resistance to isoniazid under that drug alone. These 5 H cases are also considered separately below.

Results

Table X sets out the results of the isoniazid-sensitivity tests at one, two, and three months in H and SH cases (after excluding patients known to be streptomycin-resistant at the start of treatment). Of 80 isoniazid-sensitivity tests on positive cultures from H patients before treatment, there had been 5 "doubtful" and no "resistant" strains. Examination of 100 SH patients' cultures before treatment also yielded 5 "doubtful" and no "resistant" strains.

At one month, from 73 culture-positive H patients with sensitivity results, 8 resistant cultures (11%) (5 at a level of 10 µg. per ml. or higher) and 7 doubtfully resistant cultures (10%) were obtained; 76 similar SH patients yielded 3 instances of isoniazid resistance (4%, all resistant at the lowest level) and 6 of doubtful resistance (8%). The differences are suggestive, but not statistically significant.

At two months, resistant cultures were obtained from 32 (52%) of 63 culture-positive H patients (half of these growing at 50 µg. per ml.), and another 14 patients (22%) yielded doubtfully resistant strains. The corresponding SH results from 54 culture-positive patients were 5 resistant cultures (9%) and 3 doubtful (6%); again resistance was at a low level (growth at 1 µg. per ml. but not 5). The benefit to the SH treatment is highly significant statistically.

At three months, the proportion of resistant strains from patients on isoniazid alone had increased to 33 (62%) from 53 culture-positive patients, compared with only 3 (13%) of 23 positive SH cultures. When the incidence of isoniazid resistance is expressed as a percentage of the total number of patients for whom cultures were examined (whether culture-positive or negative—that is, (c) expressed as a percentage of (a) in Table X), the difference at three months is

alone and in those having the combination isoniazid + streptomycin. The combination largely prevents the development of isoniazid resistance.

Turning now to the 7 SH patients in whom streptomycin-resistant strains were isolated before treatment, 4 had produced isoniazid-resistant strains at the end of three months. The other 3 were culture-negative at three months, but one was known to have had sensitive strains at two months, and another at both two months and four months. Although the numbers are very small, they suggest that this group of patients is behaving more like a group treated with isoniazid alone than a group treated with the combination streptomycin + isoniazid. In other words, patients with streptomycin-resistant organisms are not protected from the development of isoniazid resistance by the SH treatment.

Of the 5 H patients with streptomycin-resistant organisms initially, the bacilli of 1 were also isoniazid-resistant before treatment. In this case the organisms grew at 1 but not 5 µg. per ml. in the pre-treatment test. The organisms showed the same degree of resistance at one, two, and five months, but at four months growth occurred in the 5 µg. per ml. tube; the culture was negative at three months. This strain was non-pathogenic to guinea-pigs and mice, and therefore appears to be non-virulent (this case will be reported later). Of the strains from the other 4 patients, one was resistant at three months and one sensitive. The other two patients were culture-negative at three months, but had resistant organisms at four months (the culture from one had been doubtfully resistant at one month). The behaviour of these four cases is in keeping with the behaviour of the rest of the H cases.

Isoniazid-sensitivity tests are also available at four months for 8 patients who had continued on streptomycin + isoniazid, in full dosage in one, but with a reduced streptomycin dosage of 1 g. three times a week in 7. Of these 8 patients, 4 had isoniazid-sensitive organisms (including the patient on daily streptomycin), one was doubtful, and 3 were definitely resistant (growth in 5, 10, and 50 µg. per ml. respectively). The strain from one of the 3 resistant cases was known to have been resistant at two months. There were no sensitivity tests available on the

other 2 between one month, when sensitive organisms were found, and the resistant results at four months, and they may well have developed resistance before the fourth month. Clearly this experience beyond three months' treatment with streptomycin + isoniazid indicates the need for a most careful evaluation in the light of further results when they become available.

When the data are complete it will be important to determine whether, when the bacilli of patients on streptomycin + isoniazid become resistant to one of the drugs, they become resistant to the other as well. The results of streptomycin- and isoniazid-sensitivity tests at three months in SH cases given in Tables IX and X have been derived from 23 patients. Results of isoniazid-sensitivity tests were available for all 23, whereas the results of streptomycin-sensitivity tests were available for only 19. No conclusions can be drawn from this limited information, but the findings were as follows:

Isoniazid sensitivity at 3 months	Resistant Doubtful Sensitive	Streptomycin Sensitivity at 3 Months		
		Resistant	Sensitive	Test Pending
1	0	1	16	2

IV. DISCUSSION

In the design of the present trial there were two main departures from the plan of the earlier Medical Research Council trials of chemotherapy in pulmonary tuberculosis. One was the decision to increase the range and scale by including several different types of case, and by enlisting the co-operation of a large number of hospitals. The other arose from the realization that a rapid intake of cases would make it imperative to review the results continually if clinical material was not to be wasted, and if the best forms of treatment were to be introduced without undue delay. A system of monthly progress reports for each patient was therefore set up, and the continual analysis permitted the early publication of a report in which the effects of streptomycin + P.A.S. were compared with those of isoniazid alone (Medical Research Council, 1952).

Even before the publication of this first report it had become apparent that the effects of the combination streptomycin + isoniazid should also be studied, and this treatment was introduced from June 1, 1952, in all three disease groups of the trial, concurrently with the treatments already mentioned. As further knowledge about the effectiveness and limitations of the new drug accumulated, the trial was modified again in order to study exclusively the value of combining isoniazid with other anti-tuberculosis drugs. The trial therefore differs from earlier clinical trials because it has developed on a flexible pattern and has been modified to study fresh problems in the light of information it has itself yielded. This flexibility is one of the most valuable characteristics of the present trial, since it enables much more information to be gained from the available clinical material.

The present observations relate to 364 patients suffering from pulmonary tuberculosis and treated for three months—142 with streptomycin + isoniazid, 102 with streptomycin + P.A.S., and 120 with isoniazid alone. These three treatments were allocated concurrently and at random. The results at the end of three months are summarized in Table XI and also in Figs. 2 to 8. The analysis shows that over this limited period streptomycin + isoniazid is superior to streptomycin + P.A.S. in lowering the sedimentation rate and in increasing body weight, and rather better in improving the

general condition. The two treatments have a similar effect upon pyrexia, upon the presence of tubercle bacilli in the sputum, and, most important, upon radiographic appearances. Streptomycin + isoniazid, compared with isoniazid alone over a three-month period, is found to be considerably more effective in lowering the sedimentation rate, in suppressing tubercle bacilli in the sputum (confirming the findings of Dye, Lynch, and Brees, 1953), and also in improving the radiographic appearances. It is slightly more effective in resolving pyrexia. The two treatments produce equally striking improvements in general clinical condition and in weight.

TABLE XI.—Summary of Comparisons of Streptomycin Plus Isoniazid with Streptomycin Plus P.A.S., and with Isoniazid Alone, at the End of Three Months' Treatment

	Streptomycin Plus Isoniazid %	Streptomycin Plus P.A.S. %	Isoniazid %
General condition:

Resistant	13	—	62

See the text for the streptomycin-sensitivity results, and Figs. 2-8 for the numbers of patients on which these percentages are based.

FIG. 2.—Changes in general condition in the first three months in the three treatment series. Each category of response is expressed as a percentage of the total patients.

FIG. 3.—Weight changes in the first three months in the three treatment series. Each category of response is expressed as a percentage of the total patients weighed.

FIG. 5.—Sedimentation rate at three months in patients with a sedimentation rate of 21 or more pre-treatment. The response is expressed as a percentage of the total patients with initially raised B.S.R.

FIG. 7.—Presence of tubercle bacilli at a single examination at three months. The results are expressed as percentages of the total patients examined.

FIG. 4.—Temperature at three months in patients febrile during pre-treatment week. The response is expressed as a percentage of the total patients initially febrile.

FIG. 6.—Changes in radiographic appearances in the first three months. Each category of response is expressed as a percentage of the total patients.

FIG. 8.—Isoniazid sensitivity in SH and H patients at three months. The results are expressed as percentages of the total patients with sensitivity tests.

Although there has been virtually no toxicity from isoniazid with the dosage used, its combination with streptomycin suffers from the disadvantage of toxic reactions to the streptomycin. In the present series such reactions were severe enough to lead to withdrawal of the patient from the trial in 4% of cases (6 out of 148). On the other hand, streptomycin + isoniazid produces far fewer side-effects than streptomycin with P.A.S. in a dosage of 20 g. daily, and is also less unpleasant for the patient. Summarizing, it may be concluded that over a three-month period streptomycin 1 g. daily + isoniazid 200 mg. daily is clinically the most effective anti-tuberculosis chemotherapy yet investigated in this trial, although its superiority to streptomycin 1 g. daily + P.A.S. 20 g. daily is not great.

An important defect of the use of isoniazid by itself is the frequent and rapid emergence of bacterial resistance to the drug. In the present series of patients treated with isoniazid alone, 11% of cultures positive at one month were resistant, 52% of those at two months, and 62% of those at three months. The corresponding figures for the patients treated with streptomycin + isoniazid were only 4% isoniazid-resistant cultures at one month, 9% at two months, and 13% at three months. Moreover, when, with the combined drugs, isoniazid resistance did develop, the average level of this resistance was much lower than for patients on isoniazid alone. The administration of streptomycin 1 g. daily with isoniazid 200 mg. daily therefore lessens considerably the proportion of cases in which isoniazid-resistant strains, particularly those of high resistance, emerge over a three-month period. The very limited information on isoniazid resistance available at four months for these patients is, however, a little disquieting. If, with larger numbers, a substantial incidence of resistant strains appears, it will be important to assess what part, if any, is played by reducing the dosage of streptomycin in the fourth month.

It must be remembered that an increasing proportion of bacteriological specimens from patients on each of the three treatments studied here was found to be negative on culture as treatment proceeded, and consequently fewer and fewer sensitivity tests could be performed. Because of this, it can be argued that the figures quoted above, expressing the resistant strains as a percentage of the positive cultures on which sensitivity tests were performed, do not give an entirely fair picture of the development of resistance; they omit the culture-negative patients, some of whom will be permanently negative. An alternative presentation of the findings is that at three months 33 resistant cultures were obtained from a total of 93 of the patients on isoniazid alone (35%), compared with only 3 from a total of 109 of the patients on streptomycin + isoniazid (3%). On the other hand, these percentages give an unduly favourable impression of the incidence of resistance at three months, partly because not all the culture-negative patients will be permanently negative, and partly because a few sensitivity tests are still pending at three months. A true measure of the incidence of isoniazid resistance at three months in patients not permanently negative probably lies somewhere between 62% and 35% for those on isoniazid alone, and between 13% and 3% for those on streptomycin + isoniazid.

Of 7 patients on streptomycin + isoniazid whose organisms were initially streptomycin-resistant, 4 yielded cultures resistant to isoniazid at three months.

The behaviour of this small group of patients is more akin to that of patients on isoniazid alone than to that of patients on streptomycin + isoniazid. In other words, if a patient's organisms are streptomycin-resistant initially, the combination streptomycin + isoniazid apparently affords no protection against the risk of the development of isoniazid resistance.

For the patients treated with streptomycin + isoniazid it is also important to know whether the combined therapy prevents the emergence of bacilli resistant to streptomycin. The analysis has shown that this is so. At three months, two streptomycin-resistant strains were isolated from 19 positive cultures (11%); these two strains were obtained from a total of 109 patients (2%). The true incidence of streptomycin resistance at three months in patients not permanently negative probably lies between these two percentages. The corresponding figures for isoniazid resistance in the same patients were 13% and 3%. Thus, the combination streptomycin + isoniazid appears to be as effective for three months in preventing the development of streptomycin resistance as of isoniazid resistance. The very limited information on streptomycin sensitivity available at four months for patients on the combination is satisfactory. However, it will be appreciated that, if isoniazid resistance should prove to be a problem at four months, there is a risk that streptomycin resistance may also emerge after a delay of one or two further months if treatment with streptomycin + isoniazid is continued.

For a period of three months streptomycin + P.A.S. and streptomycin + isoniazid are of the same order of effectiveness in preventing the development of streptomycin resistance. However, evidence, which will be presented later, has emerged in the course of the trial that the administration of P.A.S. alone carries with it a serious risk that P.A.S. resistance will develop; if it does, and the patient is subsequently treated with streptomycin + P.A.S., the combination no longer provides protection against the development of bacillary resistance to streptomycin. These findings are particularly important because the use of P.A.S. alone is still regarded by many clinicians as an acceptable treatment for pulmonary tuberculosis. The conclusion of the Therapeutic Trials Committee of the Swedish National Association against Tuberculosis (1952), that P.A.S. alone "should be given in cases where a moderate effect is wanted for a rather long time," seems unwarranted in view of these bacteriological findings.

The lessons to be learnt from these apparently complicated findings concerning the development of bacterial resistance are simple, and are as follows:

(1) *None of the three drugs, isoniazid, streptomycin, or P.A.S., should be used by itself in the treatment of pulmonary tuberculosis.* Equally, no new drug should at first be used by itself, except in clinical trials carefully planned to ascertain its bacteriological qualities as well as its clinical efficacy.

(2) *To give a combination of two of these drugs to a patient whose organisms are already resistant to one of the two appears to be tantamount to giving the other alone, and so is equally undesirable. It is therefore essential, whenever possible, to test the drug sensitivity of a patient's organisms before a course of chemotherapy is started, so that any unsuitable combination of drugs may be avoided and a potentially effective combination for that patient used instead.*

(3) The procedures for the assessment of drug resistance are at present slow and not always satisfactory, and many clinicians, when confronted with an ill patient, will not wish to risk further deterioration before instituting some form of chemotherapy. *A careful scrutiny of the history of previous chemotherapy, with particular regard to any drug which has been given alone, may warn the clinician of possibly unsuitable combinations, but such information cannot be regarded as a substitute for sensitivity tests, which should always be undertaken as soon as possible.*

(4) Even in newly diagnosed cases it is no longer safe to assume that the tubercle bacilli are fully sensitive; since the start of the present trial 4 out of 279 previously untreated patients whose bacilli were tested for initial streptomycin sensitivity (1%) have been found to have organisms resistant to streptomycin; there is evidence that these cases may have been infected with resistant strains. (A full report will appear later.) With the increasing use of anti-tuberculosis drugs the present low risk of becoming infected with drug-resistant bacilli may well increase. *If, therefore, chemotherapy must be initiated for a newly diagnosed case in the absence of sensitivity results, the clinician should inquire into previous chemotherapy and the results of sensitivity tests in any known contact before deciding upon a treatment combination.*

(5) There is, in fact, a great need for simple, reliable, and speedy techniques both for the culture of tubercle bacilli and for the determination of their sensitivity to chemotherapeutic agents. In the meantime it is recommended that every patient with pulmonary tuberculosis, if still bacteriologically positive on completing a course of chemotherapy, should have further sensitivity tests performed as a routine. This information would then be available if more chemotherapy is required at a later date, or should one of the patient's contacts develop the disease. However, the possibility that a drug-resistant strain may be replaced by a sensitive variant after the cessation of treatment must be kept in mind.

Finally, the Committee has obtained convincing evidence that streptomycin 1 g. daily + isoniazid 100 mg. twice a day is a highly effective combination of drugs when used for a period of three months in the treatment of pulmonary tuberculosis. On none of the clinical or bacteriological criteria was the combination inferior to streptomycin 1 g. daily + P.A.S. 5 g. four times a day over this period; in two respects—namely, in lowering the sedimentation rate and in fostering weight gain—it was decidedly superior. Nevertheless, the slender evidence on bacterial resistance which is available after four months' treatment is not entirely reassuring. In view of the short period of observation it is certainly not yet possible to assess the final place of streptomycin + isoniazid in the chemotherapy of pulmonary tuberculosis. The evaluation will depend to a considerable extent upon the clinical and bacteriological findings in patients treated with this combination of drugs over a longer period of time, in comparison with streptomycin + P.A.S. and other forms of chemotherapy.

The trial is continuing, and at present two different dosages of streptomycin and two of P.A.S. are being used, each in combination with isoniazid. These investigations are indispensable in determining the most effective ways in which isoniazid should be used in the treatment of pulmonary tuberculosis.

V. SUMMARY

As part of a clinical trial of isoniazid (isonicotinic acid hydrazide) in the treatment of pulmonary tuberculosis, 364 patients from 40 hospitals were studied; 142 were treated with streptomycin (1 g. daily) + isoniazid (100 mg. twice a day), 102 with streptomycin (1 g. daily) + P.A.S. (sodium salt, 5 g. four times a day), and 120 with isoniazid (100 mg. twice a day) alone. When submitting a case the physician did not know which treatment the patient would receive, this being determined by random allocation. The present report analyses the results at the end of three months' treatment and observation.

Three main groups were observed: Group 1, acute rapidly progressive disease of recent origin (excluding, from this report, bilateral disease between the ages of 15 and 30); Group 2, other forms suitable for chemotherapy; Group 3, chronic disease considered unlikely to respond to chemotherapy.

On admission, the three treatment series had a similar distribution of patients with severe and less severe illness.

At the end of three months, the general condition of the majority of patients had improved, but in this respect the differences between the three treatment series were small. The average gains in weight during the period were 13 lb. (5.9 kg.) for those on streptomycin + isoniazid (SH), 6 lb. (2.7 kg.) for those on streptomycin + P.A.S. (SP), and 13 lb. for those on isoniazid (H) alone.

The temperature of febrile patients fell to normal in 82% of SH, 76% of SP, and 68% of H cases. In patients with a sedimentation rate of 21 or more before treatment, the rate fell to 10 or less in 45% of those on SH, compared with only 21% on SP and 25% on H.

Changes in radiographic appearances were independently assessed by a radiologist unaware of the treatment of any patient. Two-plus or 3-plus improvement was seen in 38% of SH, 31% of SP, and 23% of H cases. There was little difference, over the whole range of response, between patients on SH and SP, but the patients on these treatments responded better than those on H. There were three radiographic deteriorations and one death on SH, one deterioration and two deaths on SP, and 11 deteriorations and one death on H.

The proportions of patients bacteriologically negative, both on direct examination and on culture, at a single examination at three months, were 67% for the SH series, 55% for SP, and 37% for H.

It is concluded, judging solely from the results at three months, that streptomycin + isoniazid, with the dosages used, is clinically the most effective of the treatments studied, although its superiority to streptomycin 1 g. daily + P.A.S. 20 g. daily is not great. A full evaluation must await a longer period of observation.

Bacillary resistance to isoniazid was found in 62% of culture-positive H patients tested at three months, compared with only 13% for similar SH patients. Bacillary resistance to streptomycin was found in 11% of these SH patients at three months. Thus the combination streptomycin + isoniazid, with the dosages studied, is as effective for three months in preventing the development of streptomycin resistance as of isoniazid resistance. Further, for three months the SH treatment is as effective as the SP treatment in preventing the emergence of bacilli resistant to streptomycin.

Patients with organisms initially streptomycin-resistant were apparently not protected from the risk of development of isoniazid resistance by the SH treatment;

patients with organisms initially P.A.S.-resistant (who had had prior treatment with P.A.S. alone) were not protected from the risk of development of streptomycin resistance by the SP treatment. Thus none of the three drugs, isoniazid, streptomycin, or P.A.S., should be used by itself, nor should two of them be used in combination for a patient whose organisms are already resistant to one of the pair. Whenever possible, the drug sensitivity of a patient's organisms should be assessed before chemotherapy is started, to avoid an unsuitable combination of drugs; and also on its completion, in case more chemotherapy is required later.

There is a great need for simple, reliable, and speedy techniques for the culture of tubercle bacilli and for the determination of their sensitivity to chemotherapeutic agents.

The trial was designed so that it could be modified to study fresh problems in the light of information it had itself yielded; at present the effects of two different dosages of streptomycin and two of P.A.S., each in combination with isoniazid, are under investigation.

ACKNOWLEDGMENTS

The hospitals and the doctors co-operating in the phase of the trial reported here are as follows:

Hospitals.—Aberdeen City Hospital; Aintree Hospital; Bangour Hospital, West Lothian; Black Notley Hospital, Braintree; British Legion Sanatorium, Nayland; Brompton Hospital; Canadian Red Cross Memorial Hospital, Taplow; Clare Hall Hospital, Herts; Connaught Military Hospital; Cumberland Hospital, Surrey; Dumfries and Galloway Sanatorium; East Fortune Hospital, East Lothian; Edgware General Hospital; Edinburgh City Hospital; Foxhall Hospital, Ipswich; Hammersmith Hospital; Heathcote Hospital, Leamington Spa; Inverurie Hospital, Aberdeen; Kettlewell Hospital, Leamington Spa; King Edward VII Sanatorium, Midhurst; King George V Hospital, Godalming; King George's Sanatorium for Sailors, Hants; Lenham Sanatorium, Kent; Llangwyfan Hospital, Denbigh; Mount Pleasant Hospital, Middlesex; North Middlesex Hospital; R. A. F. Hospital, Wroughton; Robroyston Hospital, Glasgow; Romsley Hill Sanatorium, Worcester; Royal Victoria Hospital, Edinburgh; St. Albans City Hospital; St. Helen's Hospital, Ipswich; St. Helier Hospital, Surrey; St. Stephen's Hospital, London; St. Wulstan's Hospital, Worcester; Southfield Sanatorium, Edinburgh; Sully Hospital, Glamorganshire; West Heath Sanatorium, Birmingham; Woodend Hospital, Aberdeen; Yardley Green Hospital, Birmingham.

Physicians.—Drs. P. G. Arblaster, G. P. Bardsley, D. Bell, R. W. Biagi, W. M. Borthwick, L. E. Burkman, J. A. Chamberlin, C. W. Claxson, R. C. Cohen, A. H. C. Couch, Wing Commander I. R. Cran, Professor J. W. Crofton, Drs. V. Davies, V. F. Dawkins, M. K. Dhole, T. A. Watkin Edwards, W. J. Ferraby, H. M. Foreman, P. Forgas, M. A. Foulis, R. Fraser, M. A. Gallagher, J. E. Geddes, J. W. B. Grant, L. J. Hill, P. Hodgkiss, N. W. Horne, J. V. Hurford, G. Penrhyn Jones, R. G. R. W. N. Luntz, Lieutenant-Colonel J. Mackay-Dick, Dr. G. R. McNab, Captain S. Marks, Drs. A. T. Mason, K. Murray, W. A. Murray, I. D. Ross, J. D. Ross, F. A. H. Simmonds, Flying Officer A. Simpson, Dr. J. Morrison Smith, C. J. Stewart, P. Stradling, G. J. Summers, J. Sumner, D. Teare, H. E. Thomas, O. F. Thomas, B. C. Thompson, Sir Geoffrey Wheeler, E. H. Williams, D. van Zwanenberg, and the consultant staff of Brompton Hospital (Registrar, R. N. Johnston).

Bacteriologists and Pathologists.—Drs. C. S. Anderson, D. F. Barrowcliff, G. Blowers, D. M. H. Cogman, R. T. Cooke, J. E. Craik, P. B. Crone, J. C. Dick, Professor A. W. Downie, Drs. J. M. Dunbar, W. J. Godden, T. E. W. Goodier, W. I. Gordon, J. F. Haggie, E. D. Hoare, Captain C. H. Jones, Drs. E. R. Jones, P. Kidd, M. Laidlaw, G. Laws, J. T. A. Lloyd, A. Macdonald, J. Marks, P. H. Martin, A. Messer, D. A. Mitchison, E. Nassau, J. W. Nicholas, W. H. A. Picton, Squadron Leader Robertson, B. R. Sandiford, F. E. T. Scott, A. G. Signy, T. Skeoch, J. M. Smith, P. J. Taylor, W. K. Taylor, A. T. Wallace, R. F. Welch, W. Whitelaw. The Laboratory Subcommittee met under the chairmanship of Professor R. Cruickshank.

Dr. E. H. Bailey, Southern Group Laboratory, supplied culture medium where desired. Dr. D. A. Mitchison's laboratory, Postgraduate Medical School of London, served as reference laboratory for drug-resistance tests. Some of the P.A.S. sensitivity tests for the Scottish centres were undertaken by Dr. A. T. Wallace.

The above cannot be a comprehensive list of all the doctors who have contributed to the results reported here, nor has it been possible to name the many laboratory technicians who have done detailed and valuable work. The Tuberculosis Chemotherapy Trials Committee expresses its thanks to all members of hospital staffs who have assisted in the investigation, particularly for their willing response to the urgent requests for information for inclusion in this report.

The Research Committee of the Scottish Tuberculosis Association has been of considerable assistance in initiating the trial in Scotland. The Edinburgh team is in receipt of a research grant from the Royal Victoria Hospital Tuberculosis Trust. Figs. 1 to 8 were drawn by Miss S. Treadgold and Miss P. Carter of the Department of Medical Illustration, Guy's Hospital.

M. CANIS RINGWORM AND LOSS OF SCHOOLING

BY

BERNARD A. THOMAS, M.D., B.Sc., D.P.H.
Dermatologist, Royal Gwent Hospital

Cases of ringworm of the scalp produced by the two commonest pathogens, *Microsporum canis* and *M. audouini*, continue to be grouped together as one condition from the point of view of treatment. This is unfortunate. *M. canis* ringworm differs from the *M. audouini* type in being amenable to simpler measures of treatment and in being less contagious. Further, it can be demonstrated that there is no valid reason for excluding *M. canis* cases from school. In the treatment of *M. audouini* ringworm, x-ray epilation is unquestionably the correct procedure, and if it is not carried out the child may continue with the complaint until puberty is reached. As the technique of epilation improves, so do the risks inherent in its use diminish.

In common with others treating ringworm of the scalp, I have experienced the following difficulties. There has been an occasional case of incomplete regrowth of hair; cases in which a marked inflammatory reaction resulted, necessitating incision of sterile abscesses (Fig. 1); and cases in which the first epilation failed to eradicate the infection. Occasionally an anaesthetic has been necessary in toddlers. After x-ray epilation a good regrowth of hair has taken six months in boys and up to a year in girls.

Scalp ringworm caused by *M. canis* need never be treated by x-ray therapy, the following measures of treatment being effective in all cases. The scalp is clipped and the hair kept short, a linen cap is worn constantly, and a simple fungicidal ointment is applied daily. The mildest fungicides are effective, and Whitfield's ointment is adequate. Far stronger fungicides and rubefacients are tried from time to time in cases of *M. audouini* ringworm, but, as yet, no completely effective application has been found. There is no justification for their use in *M. canis* ringworm.

Sharp (1951) described his treatment of 120 cases of *M. canis* ringworm of the scalp (*M. audouini* ringworm is extremely rare in Australia). He used fungicidal treatment only, and the average time taken for cure was 13 weeks. In the subsequent discussion it was apparent that many dermatologists still use x-ray epilation in *M. canis* cases simply because by this method it is possible to get the child back to school in about six weeks.

Distinction Between Types

M. canis and *M. audouini* ringworm cases may be distinguished with reasonable accuracy clinically but only with certainty on culture. It is essential to know which type is endemic locally. For many years a focus of *M. audouini* scalp ringworm has existed in the Blackwood area of Monmouthshire, but practically none of this type of ringworm has been encountered in Newport, 12 miles distant. Of the ringworm cases in the Blackwood area, 91 out of 94 cases have been of *M. audouini*, and in the Newport area out of 32 cases only one has been produced by *M. audouini*.

There are other factors which enable one to make a clinical diagnosis of *M. canis* ringworm. Local tissue reactions are usually more pronounced and there may be erythema, papulation, or even kerion. This distinction, however, is not entirely reliable, and, exceptionally, *M. audouini* cases produce inflammatory reactions (Fig. 2). There is usually a history of an infected puppy or kitten

with which the patient has come in contact. The frequency of tinea circinata in *M. canis* ringworm is well known (Fig. 3). Beare and Cheeseman (1951), describing 1,004 cases occurring in Northern Ireland between May, 1949, and July, 1950, refer to greater brilliance and longer duration of Wood's light fluorescence in *M. audouini* infections. By applying these tests they were able to diagnose correctly 97% of their 71 *M. canis* infections before the results of culture were available.

Epidemiology

While there is abundant evidence that *M. canis* infections are caught direct from animals, it is rarely possible to demonstrate direct contagion from child to child. In the 27 cases dealt with in Table I, six animals were known to be responsible for 11 cases. Five of the animals were kittens, which were destroyed.

In other cases some association with a domestic animal was invariable, but this alone is not proof of an animal source of contagion. The possibility of one animal being responsible for multiple cases must not be lost sight of, and

with some reluctance because the disease is of such a long-term nature as to result in the loss of a high percentage of a child's school career. The cases were of the *M. audouini* type, and the average period of absence from school was assessed as 180 days if the treatment was by ointment and manual epilation. If x rays were used an effort was made to have the children back in school in three weeks after irradiation.

Carslaw (1951) treated 208 cases of tinea tonsurans, all mainly *M. audouini* type, and found that the 104 children of school age were able to return to school in an average of 45 days.

It is usual to discuss the period of treatment and surveillance but to overlook the period of absence from school before special treatment is sought. In the children dealt with in Table I this period varied between 1 day and 20 weeks. A variety of excuses, mostly unsatisfactory, were offered, but the fact remained that some children, with either type of microsporiasis, managed to evade both school and clinic, while at the same time mixing with siblings at home and playmates in the street. The mean loss of schooling before attending clinic in these cases was 33 days. This figure must be added to the 91 days of surveillance when estimating the average loss of schooling which would have been entailed by the attack of scalp ringworm had the children been excluded. It would thus have amounted to 124 days. (Holiday periods have not been deducted from these figures.)

National Survey

In order to assess the incidence of scalp ringworm in England and Wales a questionnaire was circularized to 104 major education authorities. The results are summarized in Table II. The following facts emerged.

(a) *Prevalence*.—There was a rise in incidence towards the end of the last war and in the immediate post-war years, but this seems to be subsiding again. That scalp ringworm is a problem only of the minority of regions is shown by the fact that in 63 areas the number of cases occurring annually is now either very low or nil. In Table II the

TABLE II.—Summary of Replies to Questionnaire Received from 91 Major Education Authorities. Both *M. canis* and *M. audouini* Types of Scalp Ringworm are Included

		Exclusion from School		Recent Annual Case Incidence				
		Total	Conditional	0-10	11-20	21-30	31+	
County councils	29	23	6	16	5	3	5	
County boroughs	62	58	4	47	6	4	5	
Total	91	81 (89%)	10 (11%)	63	11	7	10	

figures quoted refer to the last year for which full information was available, and is usually 1951, although 1950 is taken in a few instances. As examples, Bristol had 131 cases, Liverpool 82, Newcastle-upon-Tyne 136, Northumberland 65, Reading 48, Durham 58, and Monmouthshire 42 in 1951.

(b) *Routine Culture*.—Some 42 authorities (46.1%) stated that cultures from infected hairs were taken as a routine. Particulars were not usually available, however, because the patients were dealt with in the dermatological departments of hospitals. Where information was obtainable it was shown that in the county boroughs *M. canis* was predominant in 12, *M. audouini* in 7, and the infections were mixed in 4. In county areas *M. canis* was preponderant only in 2, whereas *M. audouini* was found in 10, 3 areas showing a mixture.

(c) *Exclusion from School*.—This is rigidly enforced for all types of scalp ringworm by 89% of authorities. Four county boroughs and five county councils allow some relaxation of this rule, but in none of these areas is ringworm common. The usual condition insisted upon is that the lesions are capable of being adequately covered by some form of headwear. In one district single cases are excluded, but if several children are infected simultaneously

they are allowed to attend school with head coverings. Exclusion was enforced in all the localities where *M. canis* is the endemic infection.

Present Investigation

The number of *M. canis* cases in Newport was only 14 between 1945 and 1950, but at the end of the latter year the incidence rose sharply. It was decided to allow all children with *M. canis* ringworm to return to school immediately, provided that certain precautions were observed. The precautions consisted in the wearing of a linen covering or a cap, the use of the ointment provided, and the weekly attendance at the ringworm clinic. The school health authorities willingly co-operated in this plan. Few objections were raised from any quarter. Parents were gratified that their children were able to continue at school, and satisfaction was felt at the clinic because regular weekly attendance was ensured. A solitary complaint was expressed from one child, who felt self-conscious about his headgear.

Details of the plan were as follows. At the first visit of the child to the ringworm clinic a decision was made regarding the probable nature of the dermatophyte and a specimen for culture was taken. A printed list of instructions was then handed to the parent with a promise that if clipping was adequately carried out and the other instructions were followed the child would be allowed to return to school. At his next visit to the clinic a certificate was issued stating that the child was suffering from a type of ringworm of low infectivity, that progress was now satisfactory, and that it was perfectly in order for him to continue at school.

The scheme was put into operation in February, 1951, and a careful note made of the school from which any subsequent case came and also of the subtype of *M. canis* involved.

Results

The results of the experiment are set out in Table I. By studying the type of organism, the time lapse between cases, and the school involved, it was possible to determine whether the infection had been propagated to another child. In fact, not one case of direct infection followed the return to school of any of the 24 children. It would have been well within the bounds of possibility for coincidental infections with the same type to occur in a school, but even this seems not to have taken place during the period under review.

Case 14 attended the same school group as Cases 9 and 10, but a different organism was involved. Case 25 was in the same school group as Cases 15 and 19, but none of these children was infected at the same time. No new case in a schoolchild has been reported in Newport for four months.

Discussion

The main consideration in scalp ringworm is the loss of schooling brought about, especially in the scholarship year. With the common childish complaints, such as the acute specific fevers, the period of absence usually is only a matter of weeks, but with ringworm it may be a matter of months. Efforts to avoid this loss of tuition merit serious attention. In localities where *M. canis* is the exclusive dermatophyte there need be no interruption in school attendance because of ringworm.

The possibility of allowing children with active ringworm to attend school has been raised before. In the annual reports of the Chief Medical Officer of the Board of Education (1927, 1933) it is stated that in rural areas where x rays are not available the child's hair must be clipped short, appropriate ointment applied, and a linen cap worn, and in such circumstances affected children may be allowed to attend school. No distinction in types of cases is made here, and, from my survey, little use has been made of this concession, particularly as x rays have become more generally available. Whether it would be profitable to allow *M. audouini* cases in school is a matter of conjecture and one which is being

It is not possible to calculate accurately the number of cases of *M. canis* ringworm excluded from school in one year, but the figure must be high. Apart from the question of contagion, with which I have dealt, there can be no objection to these children being in school, because no subjective illness is produced in ringworm. The risk of child-to-child contagion is slight anyway, and it is virtually impossible if simple precautions are taken.

Summary

The importance and methods of distinguishing between *M. canis* and *M. audouini* scalp ringworm are indicated.

Some epidemiological considerations regarding *M. canis* ringworm are presented.

The role of microsporum ringworm as a cause of loss of schooling is discussed.

The results of a survey of the incidence of ringworm in the areas of the major education authorities of England and Wales are tabulated and analysed.

An experiment, carried out in Newport, where the scalp ringworm is almost exclusively of the *M. canis* type, and in Monmouthshire is described. Twenty-four children were allowed to continue at 19 schools, the exclusion rule being waived. In no case was the infection propagated.

The conclusion is reached that children with *M. canis* ringworm should neither be treated by x-ray epilation nor be excluded from school.

My thanks are due to Dr. David Lawrence, medical officer of health for Newport, for permitting me to carry out this investigation and for co-operating so helpfully. Also to Dr. Jacqueline Walker, of the Department of Medical Mycology, London School of Tropical Medicine and Hygiene, for carrying out the culture and identification of the fungi.

FIELD TRIALS OF NEW ANTIMALARIALS IN WEST AFRICA

BY

LEONARD J. BRUCE-CHWATT, M.D., M.P.H.
D.T.M.&H.

AND

H. M. ARCHIBALD, M.B.E., M.B., Ch.B.
(Malaria Service, Medical Department, Nigeria, B.W.A.)

The value of new antimalarials has not always been assessed in the field in comparison with other similar drugs, and specific claims for one or another of the new compounds are difficult to judge when each has had only a limited number of clinical tests. Differences which are known to exist between geographical strains of malaria parasites justify comparative field trials in many tropical areas.

The present difficulties in carrying out chemotherapeutic tests of new compounds in temperate climates on cases of induced malaria and/or on non-immune

volunteers increase the value of properly designed field trials in areas where indigenous malaria is common.

There has been little investigation, especially in tropical Africa, of the value of "camoquin" and pyrimethamine ("daraprim") in comparison with older antimalarials. The present paper reports on results of a chemotherapeutic trial of these drugs and of two other antimalarials, chloroquine sulphate ("nivaquine") and a new compound of the acridine series named "azacrin."

This last drug is a 2-methoxy-6-chloro-9-(5'-diethyl-amino-2'-pentyl) amino-3-aza-acridine dihydrochloride synthesized recently by Messrs. Ward, Blenkinsop and Co. jointly with Messrs. Howards and Sons, Ltd. The first laboratory tests against *Plasmodium gallinaceum* in chicks and *P. berghei* in mice have shown that this compound, given by the mouth, possesses good schizonticidal activity at a dose of 25 mg./kg. in chicks and at a dose of 5 mg./kg. in mice. Its toxicity for experimental animals was found to be low. No data on toxicity of this drug to man being hitherto available, it was taken as a precautionary measure by one of us before using it in field trials on children. The daily dose of 0.4 g. taken for five days having produced only minor side-effects (nausea), it was decided to use this drug for a field trial.

Present Investigation

The method of investigation was that developed by one of us (Bruce-Chwatt, 1951) and subsequently used in the first field trials of pyrimethamine (Archibald, 1951). This method is based on a preliminary selection of an adequate group of African schoolchildren, 5-10 years of age, all naturally infected with malaria. After the administration of a suitable therapeutic dose of the drug to be tested, daily blood examinations of each child are carried out. The parasite rate, parasite density, and any other malarimetric indices are calculated for each group from the results of daily examinations.

Blood slides (thin and thick film) were stained with Giemsa, and parasite rates and counts were based on the examination of thick films. Parasite counts were made from the parasite leucocyte ratio, and the number of parasites per c.mm. was calculated. No film was declared negative before the examination of at least 200 thick-film fields. Parasite density indices were computed as previously described (Bruce-Chwatt, 1951). The speed of decrease of the initial 100% parasitaemia of each group to the lowest level was used as a criterion of the comparative therapeutic activity of the investigated drug against the specific parasite.

For the purpose of the present trial 120 schoolchildren 5-10 years of age were selected after a preliminary investigation and divided into five groups. The first four groups were treated with chloroquine sulphate, pyrimethamine, camoquin and azacrin respectively. The fifth group was not given any drug and represented the control. The administration of each drug was invariably made under our personal supervision.

In the chloroquine sulphate group the drug was given in two different regimens. One-half received 0.75 g. (3 tablets) in a single dose on D day; the other half received 0.75 g. (three 0.25-g. tablets) on D day as a single dose, followed by 0.25 g. (1 tablet) on each of the two following days. In terms of chloroquine base the total dosage was 0.45 g. and 0.75 g. respectively.

The pyrimethamine group also received two different dosages of the drug. One-half had a single dose of 25 mg. (1 tablet) on D day, and the other half had 25 mg. on D day followed by the same dose on the next day. The camoquin group received one dosage only—0.4 g. (2 tablets) as a single dose on D day. The azacrin group was given 0.2 g. (2 tablets) on D day followed by 0.1 g. (1 tablet) on each of the two following days. The dosage of the four drugs is half the usual adult dose. The average age of the

children was 7.6 years. Apart from the preliminary selective examination every child was examined on D day immediately before the administration of the first dose and then on days D+1, D+2, D+3, D+4, D+7, and D+10. The results of the trial are shown in the Table.

Results of Comparative Field Trials of Four Antimalarial Drugs

Group and Day	No. of Cases	<i>P. falciparum</i>					<i>P. malariae</i>

Discussion

These results show that all four drugs are very good schizonticides for *P. falciparum*. There seems to be relatively little difference between the speed with which in a selected group of African children each drug reduces the parasite rate for trophozoites of *P. falciparum* from 100% to 0 (clearance time).

The comparative clearance time of trophozoites of *P. falciparum* in each of the tested six groups was found to be as follows: chloroquine sulphate (dosage I), 1.78 ± 0.41 days; chloroquine sulphate (dosage II), 1.95 ± 0.39 days; pyrimethamine (dosage I), 1.74 ± 0.26 days; pyrimethamine

(dosage II), 1.77 ± 0.24 days; camoquin, 1.69 ± 0.43 days; azacrin, 1.58 ± 0.42 days.

The clearance time found in this investigation for chloroquine is very close to the 1.80 days found for this drug in one of our first trials (Bruce-Chwatt, 1951). It was thought at first that the clearance time obtained in this type of trial with chloroquine is longer by about half a day when compared with figures quoted by investigators whose reports were based on clinical trials in East Africa (Handfield-Jones, 1949), in Tunisia (Durand, Schneider, and Dupoux, 1949), in Indo-China (Canet, 1950). Our average figures for the chloroquine clearance time of asexual parasitaemia due to *P. falciparum* are, however, almost identical with 1.84 days reported from India by Chaudhuri, Chakravarty, Rai Chaudhuri, and Poti (1952), and very close to 2 days observed by Singh and Kalyanum (1952).

In our present investigation camoquin appeared to have a faster action than any of the other drugs, except azacrin. This was somewhat unexpected, since in Bertagna's (1951) summary of information on camoquin the reported clearance time of asexual parasitaemia due to *P. falciparum* had a range between 24 and 120 hours, with an average duration of 53 hours, or 2.25 days. This is also the figure reported more recently by Mein (1951) from Brazil.

The camoquin clearance time of *P. falciparum* parasitaemia observed by us is slightly longer than 1.25 days reported by Hoekenga (1951) from Honduras, 1.2–1.4 days found in Bolivia (Villarejos, 1951), or 1.4–1.6 days reported by Singh and Kalyanum (1952) from India.

The clearance time for *P. falciparum* obtained with pyrimethamine is 1.74 days. This is close to the results obtained by the French workers in Tunisia (1.25 days) and in Indo-China (1.56 days) (Schneider, Canet, and Dupoux, 1952). In the Gambia, however, work by McGregor and Smith (1952) produced slower clearance times in cases of clinical *P. falciparum* malaria treated with pyrimethamine in doses different from those used in the present investigation. The clearance time in infants treated by them with an average dose of 2–4 mg. was 2.82 days even when two infants who failed to respond to therapy are excepted. In a similar series of young children it was 2.57 days, and in a small series of adults, it was 2.25 days.

None of the four antimalarials is an effective direct gametocide for *P. falciparum*, since the crescents persist in the peripheral blood for at least 10 days after the administration of the drugs and show no obvious and constant morphological changes.

In the camoquin series, in which gametocytes of *P. falciparum* were already present in the blood, there was little evidence of any gametocidal action. The observation supports the results quoted by Bertagna (1951) and by Mein (1951), and is in marked contrast to the findings of Singh and Kalyanum (1952), who found that 40% of their crescent carriers were cleared within six days.

Infections with *P. malariae* were too few and of a generally too-low density to obtain series of malariometrical data comparable with series of *P. falciparum*. Nevertheless it seems that chloroquine and camoquin have a more marked action on *P. malariae* (clearance time 1.2–1.3 days) than either pyrimethamine or azacrin (clearance time 2 days and 3 days respectively).

Two infections with *P. ovale* mixed with *P. falciparum* disappeared within 24 hours after the administration of camoquin and azacrin.

Of the four drugs used in the present trial pyrimethamine was tolerated best and no complaints of headache, nausea, or vomiting were made by any children who took it.

Chloroquine sulphate was also well tolerated, though two children complained of nausea after taking a single dose of three tablets. Four children out of 23 given camoquin complained of headache and nausea within four hours of taking 0.4 g. Azacrin was well tolerated in a single dose of two tablets (0.2 g.), but three tablets caused nausea, pain in the stomach, and vomiting in 7 out of 10 children.

It must be emphasized however, that some children had had little or no food in the morning when the drugs were administered and that the side-effects noted might have been less frequent if the drugs had been given after a meal.

Summary

Field trials with chloroquine sulphate, pyrimethamine, camoquin, and azacrin (an amino-aza-acridine) were carried out on 120 African schoolchildren with a subclinical natural infection with *P. falciparum* and *P. malariae*.

All four antimalarials have proved to be good schizonticides. The clearance time of parasitaemia due to trophozoites of *P. falciparum* was shortest with azacrin (1.58 days) and camoquin (1.69 days) and followed by pyrimethamine (1.84 or 1.77 days) and chloroquine sulphate (1.78 or 1.95 days). None of the four drugs shows any direct gametocidal action.

It appears that chloroquine sulphate and camoquin have a more marked action on *P. malariae* than either pyrimethamine or azacrin.

Our thanks are due to Dr. S. L. A. Manuwa, Inspector-General of Medical Services, Nigeria, for permission to publish this paper.

AN ASSESSMENT OF CHLOROPHYLL AS A DEODORANT

BY

JOHN C. BROCKLEHURST, M.D.

(From the Department of Materia Medica and Therapeutics, University of Glasgow, and Stobhill General Hospital, Glasgow)

Between 1943 and 1950 many claims were made in published articles for the beneficial effect of water-soluble chlorophyll in stimulating the growth of granulation tissue and accelerating epithelization of skin ulcers. The work of Moss and his colleagues (1949) cast doubt on the validity of these claims. In 1951 the Council on Pharmacy and Chemistry of the American Medical Association could find no evidence that water-soluble chlorophyll stimulated granulation and healing beyond the normal rate.

Many reports also noted a deodorant property in chlorophyll when applied to skin ulcers. More recent workers have claimed that the alleged deodorant action of chlorophyll is effective against all kinds of body smells when the substance is taken orally. Such claims have received the widest publicity in the lay press. On the other hand, the *Journal of the American Medical Association* (1951) questions whether chlorophyll does in fact have deodorant properties at all.

The present communication presents the results of a number of *in vitro* experiments designed to determine

the effect of chlorophyll on a number of odours. Some clinical experiences with the drug are also recounted.

Full summaries of the earlier work with chlorophyll have appeared in recent leading articles in the *British Medical Journal* (1952) and the *Lancet* (1952). It is therefore unnecessary to review the literature again here. It may be noted, however, that all published findings of the action of chlorophyll as a deodorant have depended on the olfactory sense of the observer. Not only is the sense of smell notoriously inconstant from one observer to another, it is also apt to fluctuate in the one observer in different circumstances. Of all the human senses the sense of smell is the most easily affected by suggestion.

Chemistry

As there are various types of chlorophyll, a brief comment is required on the chemical composition of the substance used in these experiments.

Chlorophyll is extracted from plants (especially nettles, spinach, and alfalfa) with alcohol or acetone. This substance, which has the formula shown below, is oil-soluble

Chlorophyll formula. R = CH₃ (chlorophyll-a) or CHO (chlorophyll-b). Ester groups indicated by dotted boxes.

but not water-soluble. It has been described (*Lancet*, 1952) as "a system of four pyrrole rings pivoted on a central magnesium atom," and the formula is similar to that of haem, in which the pyrrole rings pivot in similar manner on an iron atom. Treatment of this substance with acid removes the magnesium atom. The magnesium atom is also easily displaced by other metals—for example, copper.

Treatment with alkali (hydrolysis) splits off the two ester groups shown in the diagram. The resulting substance is a salt of the dicarboxylic acid chlorophyllin. The sodium and potassium salts of this acid are soluble in water and constitute the active principles of the so-called water-soluble chlorophylls (Mitchell, 1952). The therapeutic substance called chloresium was defined by the Council on Pharmacy and Chemistry (1951) as consisting chiefly of the copper complex of the sodium and potassium salts of chlorophyllin. This is the substance used in those published trials in which the nature of the chlorophyll was disclosed. More often, proprietary preparations were used, and no information was supplied about their chemical composition.

In the present experiments the substance hereafter called chlorophyll solution A consists chiefly of sodium copper chlorophyllin, and is made up in a solution containing 1 g. in 10 ml. The substance called chlorophyll solution B is a crude commercial preparation of water-soluble chlorophyll intended for use as colouring matter. Solution C is a proprietary preparation intended for use as an atmospheric deodorant, and is exposed to the atmosphere by means of a wick. Solution D is a proprietary water-soluble preparation sold for dispensing purposes. It is reported to contain 12.5% water-soluble chlorophyll.

Experiments

The principle of the first experiments is the same as that used by Alstead (1942) in assessing the deodorant properties of activated carbon. Methylmercaptan gas (one of the substances contributing to the odour of the gas normally present in the lower bowel) is evolved by adding 5N solution of

sodium hydroxide to crystals of thiourea sulphate (Fig. 1). To obtain as near standard conditions as possible in consecutive experiments, constant quantities of the reagents are used (3.5 g. of thiourea sulphate and 5 ml. of 5N NaOH). The flask containing the reagent is kept in a water-bath at a constant temperature of 65° C. Nitrogen is bubbled through the flask at a constant rate of flow so that the inert gas carries mercaptan through the rest of the apparatus. The gas passes through two bell-jars, securely clamped together, where it comes into intimate contact with a screen of filter paper soaked in chlorophyll solution. The filter paper is arranged around a baffle (Fig. 1).

After passing through this part of the circuit the gas bubbles through test-tubes containing N/10 solution of iodine. Any mercaptan passing over combines with iodine to form colourless hydriodic acid. Thus the time taken to decolorize a standard quantity of iodine solution can be used as a measure of the amount of mercaptan passing over. Alternatively, after some, but not all, of the iodine has combined with mercaptan, a back-titration with N/10 sodium thiosulphate solution indicates the amount of iodine remaining unchanged, and by difference the amount of mercaptan which has reacted with the iodine solution.

Experiment 1

The circuit was set up as in Fig. 1. To the filter paper around the baffle was added 2 ml. of either water or chlorophyll solution A. The whole circuit was filled with mercaptan. New reagents were then added for producing mercaptan. The iodine indicator was added and the gas passed across the circuit for 20 minutes. In this way as nearly similar quantities of mercaptan as could be obtained were exposed to water or to chlorophyll. By back-titrations at the end of the experiment the amount of iodine which had been reduced was noted.

The results were as follows: (1) water, 2 ml. on filter paper—12.6 ml. iodine solution reduced; (2) chlorophyll 2 ml. on filter paper—14.6 ml. iodine solution reduced; and (3) chlorophyll, 2 ml. on filter paper—18.5 ml. iodine solution reduced. These findings show at once that chlorophyll has not removed or altered all the mercaptan exposed to it. Indeed, more mercaptan has passed across when exposed to chlorophyll than when exposed to water.

Experimental error is obviously too great to allow of exact quantitative comparison. The source of error was thought to lie in the existence of a large dead space resulting from the use of bell-jars, and accordingly this was eliminated in experiment 2.

FIG. 1.—A and B=Test-tubes containing iodine, used as an indicator.

FIG. 2.—A=Test-tube containing chlorophyll solution, and used as a trap to collect froth from the burette. B=Test-tube containing iodine, used as an indicator.

Experiment 2

The apparatus is shown in Fig. 2. An ordinary 25-ml. burette is filled with the substance to be tested. It is tilted slightly off the horizontal so that bubbles of gas slowly traverse the column of fluid. The gas then passes to the test-tubes. The first test-tube, which also contains a measured volume (10 ml.) of the chlorophyll solution being tested, acts as a trap. Chlorophyll solution has a low surface tension, and bubbles of gas passing through it tend to carry the solution forward as foam. This is caught in the first test-tube. The second test-tube contains 5 ml. of iodine solution. The time taken for decolorization of successive tubes of 5 ml. of iodine is noted.

The reading from the first tube of iodine is always the highest, as mercaptan is soluble in water. The first reading is therefore a measure of the solubility of mercaptan in the solutions used. These were as follows:

Water	..	..	..	34 minutes
Chlorophyll solution A (a)	..	..	..	34 "
" " (b)	..	..	..	35 "
Chlorophyll solution C	..	..	..	36 "

After decolorization of this first tube of 5 ml. of iodine, fresh reagents for production of mercaptan were added and notes were made of the times taken to decolorize a second and then a third test-tube, each containing 5 ml. of iodine. The results obtained on two different days were as follows:

First Test.—Rate of flow of nitrogen carrying mercaptan across=8 bubbles a minute.

Time to decolorize 5 ml. iodine			
Water (i)	..	..	4 minutes
" (ii)	..	..	6½ "
Chlorophyll solution A (i)	..	..	4 "
" " (ii)	..	..	7 "

Second Test.—Rate of flow of nitrogen=4 bubbles a minute. (N.B., reduced rate of flow.)

Time to decolorize 5 ml. iodine			
Chlorophyll solution A (i)	..	..	7½ minutes
" " (ii)	..	..	22½ "
Chlorophyll solution C (i)	..	..	6 "
" " (ii)	..	..	22 "

Thus, regarding chlorophyll solution A as a standard, it will be seen that there is no difference in the time taken for a constant amount of mercaptan gas to pass through solutions of chlorophyll A and C and water. Furthermore, the times taken for such solutions and water to become saturated with mercaptan are the same. It is obvious, therefore, that intimate exposure of mercaptan gas to the action of chlorophyll solution, as described above, did not reduce the volume of the gas.

Experiment 3

This experiment involves the use of very much smaller quantities of mercaptan and of other odorous vapours, and exposes these to chlorophyll for much longer periods. This method depends on the reliability of the observer's olfactory sense and is open to criticism on that account. Such criticism, however, as has already been noted applies equally to all who have made positive claims for the deodorant value of chlorophyll.

The apparatus is shown in Fig. 3. The bell-jar stands on a ledge in a water-bath so that there is a complete water seal. A filling funnel from which N/2 sulphur acid is run in; B is a shallow dish containing N/2 sodium hydroxide saturated with

methylmercaptan. By mixing equal quantities of acid and base methylmercaptan gas is liberated. The filter paper (C) stands clear of the water in a petri dish soaked with chlorophyll or other substance under trial.

FIG. 3.—A=Filling funnel (N/2 H₂SO₄). B=Dish containing mercaptan in N/2 NaOH. C=Filter paper soaked in chlorophyll.

with acid liberates very approximately 30 mg. of methylmercaptan, or 130 ml. of the gas. In two cases tablets of chlorophyll, marketed for oral use, were crushed and suspended in water (one tablet per ml.), and this suspension was exposed to the gas.

Source of Smell	Substance under Trial	Quantity	Duration of Exposure	Result (Smell +/-)
Methylmercaptan: 30 mg. ..	Water (control)	3 ml.	12 hours	+
	"	3 "	13 "	+
	Chlorophyll solution A	2 "	12 "	+
	"	3 "	12 "	+
	"	3 "	14 "	+
	"	3 "	16 "	+
	Water (control)	3 "	14 "	+
	Chlorophyll solution A	3 "	14 "	+
	"	3 "	15 "	+
	Suspension of "chlorophyll tablets"	3 "	12 "	+
Meth-ether: 4 ml. ..	Water	2 "	28 "	+
	Chlorophyll solution A	0.5 "	22 "	+
	"	4 "	47 "	+
	"	4 "	25 "	+
	"	4 "	36 "	+
	"	4 "	36 "	+
Syrup of garlic: 5 ml. ..	Water	1 "	12 "	+
	Chlorophyll solution A	1 "	12 "	+

* In this case the smell of mercaptan was not detected. There was, however, a very strong smell of chlorophyll, which may have masked it.

This experiment, which involved exposure of small quantities of mercaptan, ether, and syrup of garlic in a small enclosed space for long periods of time to filter paper soaked in various chlorophyll preparations, showed a possible complete deodorant effect in only one case, and because of the presence of a strong smell of chlorophyll on that occasion it can hardly be regarded as being significant. It is concluded from this experiment that chlorophyll when exposed in this way to an odour does not remove the odour from the air.

Experiment 4

(a) Three jars were set up containing, respectively, 4 ml. of concentrated solution of chlorophyll; 4 ml. of dilute solution of chlorophyll; and 4 ml. of water. To each was added one drop of perfume. On smelling the jars subsequently no difference could be detected between them. In each case all the liquid evaporated within 14 days. The smell of the perfume persisted strongly in all the jars even after five months. A similar experiment, using slices of onion instead of perfume, showed no difference after 24 hours. The smell was so offensive that the experiment then had to be abandoned.

(b) Stopped test-tubes containing 10 ml. respectively of water, chlorophyll solution A, and solution C were set up for 72 hours, with 10 ml. of a solution of mercaptan in water added to each. At the end of this time there was a strong smell of mercaptan from each tube. It was also noted that the tube containing solution C (a preparation of chlorophyll which is perfumed) yielded the smell of mercaptan after standing for 72 hours, but on being shaken the smell of the perfume emerged and masked the smell of mercaptan fairly effectively. This was noted on several occasions, and suggests that the apparent deodorant property of such a preparation is due to substitution of a smell which is stronger but more pleasant than that which it is desired to eliminate. This experiment was repeated, using a smaller quantity (1 ml.) of mercaptan solution. Instead of adding chlorophyll solutions, however, plugs of cotton-wool were inserted at the upper part of each tube. These were then saturated respectively with (1) chlorophyll solution A; (2) chlorophyll solution A evaporated to dryness; (3) powdered activated carbon; and (4) a control of plain cotton-wool. After 24 hours the smell of mercaptan was perceptible in all the tubes. After a further 24 hours the smell was perceptible from all tubes except that containing activated carbon.

(c) A series of four stopped test-tubes was set up containing (1) 5 ml. of syrup of garlic and 4 ml. of chlorophyll solution A; (2) 5 ml. of syrup of garlic and 4 ml. of chlorophyll solution D; (3) 5 ml. of syrup of garlic alone; and (4) 5 ml. of chlorophyll solution A alone. The smell of garlic was present in all tubes except the fourth whenever the contents were smelled—at intervals from one day to one month after setting up. (The test-tubes were left in an ordinary warm room during all this time.)

Clinical Trial

The following simple *in vivo* tests were performed:

(a) A patient incontinent of urine and faeces was being nursed in a special bed which gathered the excreta direct into a receptacle. This patient was given three-day courses of (1) chlorophyll solution A, 400 mg. daily; (2) proprietary chlorophyll tablets, 400 mg. daily; and (3) periods with no chlorophyll. The days on which particular courses were given were not known to the observer. Each morning the odour of the receptacle containing the night's collection of urine was noted. This characteristic and unpleasant odour of urine was present every day no matter whether chlorophyll was being given or not.

(b) *Asparagus Test.*—It is well known that in many people the urine develops a characteristic odour within an hour or two of eating asparagus. One of the earliest and widely quoted observations on the alleged deodorant action of chlorophyll is one by Westcott (1950), who stated that oral administration of chlorophyll before taking asparagus prevented the appearance of this odour in the urine. A colleague in this hospital who consistently detects the asparagus odour in his urine after eating this vegetable decided to test Westcott's findings. In the 24 hours preceding the meal he swallowed 48 100-mg. tablets of a proprietary water-soluble chlorophyll in doses of 6-12 tablets at intervals of four hours. He then took his meal, which included an average serving of asparagus. Some two hours later the urine which he passed smelled strongly of the volatile substances of asparagus, and the odour was readily

detected in further specimens of urine passed about 12 hours later. It is concluded that, in this observer, chlorophyll in doses at least 25 times greater than those usually recommended was valueless in preventing the characteristic smell of the urine following ingestion of asparagus. It was also noted that the smell of the faeces was unaffected by this large dose of chlorophyll.

I have confirmed these findings in similar manner, and have also found that the oral administration of 800 mg. of chlorophyll daily for a week did not remove the odour of urine, faeces, or axillary perspiration.

So much has been made of the alleged deodorant effect of chlorophyll on the urine of persons who have eaten asparagus that it would be helpful if a large number of doctors would themselves repeat this simple experiment. The experience would be in the best tradition of the advice offered to Jenner by John Hunter.

Conclusions

Exposure of methylmercaptan gas in a closed system to water-soluble chlorophyll did not reduce the amount of gas passing over to an indicator, compared with a control.

Exposure of small quantities of methylmercaptan gas to water-soluble chlorophyll in a closed system for up to three days did not remove the smell of mercaptan.

Mixtures of water-soluble chlorophyll and various strong-smelling solutions did not remove the smell of these solutions even after exposure for one or more months.

Clinical trials are reported in which the smell of urine, faeces, sweat, and of urine after ingestion of asparagus was not removed after taking large numbers of chlorophyll tablets.

I should like to thank Professor J. W. Cook, F.R.S., for the use of many facilities in the Department of Chemistry, University of Glasgow, also Professor Stanley Alstead and Dr. D. Gibson for many helpful suggestions.

The Faculty of Ophthalmologists has for some time been considering the desirability of standardizing reading types used for testing vision. Suggestions from many sources have been studied and the final recommendations of the Council of the Faculty have been embodied in a memorandum by Mr. F. W. Law (*Brit. J. Ophthalmol.*, 1952, 36, 689). The Council's recommendations for a standard test of near vision are that: (1) "Times Roman" type shall be used, with "standard" spacing; (2) suitable passages of literature shall be selected, and a different passage used for each type; (3) specimens of printing in 5, 6, 8, 10, 12, 14, 18, 24, 36, and 48 point type shall be used, starting with the smallest [1 point = 1/72 in.]; (4) a few isolated words in lower-case letters shall be printed in each size; (5) near acuity shall be recorded by the letter N, followed by a number indicating type-face size—for example, N.5, N.8, etc.; (6) the test shall include a facsimile of a Snellen distance chart reduced to 1/17 normal size and used at 35 cm. distance, the result being recorded as a "Snellen equivalent"—for example, N=6/9; (7) the test may also include reproductions or actual portions of familiar types in everyday use; (8) near test types shall be reproduced on sheets about 9 × 6 in. (23 × 15 cm.); (9) the print shall be on dead-white matt-surface cartridge paper or board, and the latter may be varnished to increase durability.

CAPACITY OF A CATIONIC EXCHANGE RESIN ("ZEO-KARB 225") IN VIVO

BY

PAUL FOURMAN, M.D., M.R.C.P.

With the technical assistance of ALISON SHEPHERD and BARBARA SEIBERT

(From the Nuffield Department of Clinical Medicine, Oxford)

Cationic exchange resins are insoluble powders which will exchange cations on the same principle as the familiar water softeners. The exchange obeys the law of mass action, and mixtures of cations combine with the resin *in vitro* in proportions determined by equilibrium constants (MacIntyre and Jordan, 1951). *In vitro* the affinity for monovalent ions follows the order $K > Na > NH_4 > H$. The affinity for divalent ions is greater than for monovalent ions. The resins have been given in the H or NH_4 form to prevent absorption of Na from the bowel in patients with oedema or ascites and in patients with hypertension (McChesney, Dock, and Tainter, 1951; Greenman and others, 1951). The resins give off H or NH_4 in exchange for Na; H or NH_4 is absorbed combined with acid, and Na is excreted in the faeces combined with resin. The resin takes up K and other cations as well, and the depletion of cations may result in acidosis. To minimize these complications the resin has been given partly combined with K.

Most of the information available is on the effects of carboxylic exchange resins. In the course of work on experimental depletion of potassium we have obtained data on the effects of a sulphonated polystyrene resin, "zeo-karb 225," on the absorption of K, Na, Mg, Ca, and P with a normal diet in man. Though these data are incidental to another investigation and give information of limited scope, we think it may be useful to report them now that a pharmaceutical preparation of zeo-karb 225 has become available ("kationium"). Additional information was derived from studies of three patients who were receiving only small amounts of sodium in their diet.

Procedure

There were three experiments—F.1, W., and F.2—on two normal subjects, F. and W. The H form of the resin was given in F.1 and the NH_4 form in W. and F.2. The dose of resin was 60 g. daily for eight days, followed by 90 g. daily for eight days in F.1 and F.2 and 90 g. daily for four days in W. (These doses are two or three times what is likely to be given therapeutically.) The diets contained, per day, Na, 180–220 mEq; K, 31–38 mEq; Mg, 12–22 mEq. The composition of the diet in each experiment was constant. Resin was given with meals; added sodium was given between meals. The faecal excretion of N, P, Ca, K, Na, and Mg and the urinary acidity and ammonia were measured. Other details are available in a previous publication (Fourman, 1952).

In addition three patients were studied: a woman (A.) with intractable cardiac oedema; a man (M.) with cirrhosis of the liver, ascites, and oedema; and a woman (P.) with hypertension but without oedema or other evidence of heart failure. The patients received resin in a dose of 20, 30, or 45 g. daily while taking a diet which contained less than 20 mEq of Na a day. The faecal excretion of Na was measured in periods of seven or twelve days while the resin was given in the NH_4 form and also while it was

given in the NH_4 form with K salts added to the treatment or in the K form as prepared in the laboratory. Potassium salts were given between doses of resin and not with resin.

Effect of Resin on Different Ions

In the experiments the resin took up Na, K, and Mg (Table I), but not Ca (Table II). Absorption of phosphate was possibly enhanced (Table II).

The proportions of Na, K, and Mg in the faeces were remarkably similar for the different doses of resin and in

the different experiments (Table III). The mean ratio of Na:K:Mg was approximately 11:5:1. It seems likely that these proportions represented an equilibrium mixture of Na, K, and Mg for the diet provided, where the intake of Na was liberal. The amount of Na taken up by the NH_4 resin was about 2 mEq/g. and slightly more than twice that of K. The uptake of K exceeded the dietary intake. The amount of Mg taken up was small compared with the two other ions, but constituted a large proportion of the dietary intake.

In the patients who were receiving a low intake of Na, the amount of Na taken up by the resin was small and equivalent to only 0.7 mEq/g. When K was given in addition, either as K salts or as the K form of resin, the amount of Na taken up was even smaller (Table IV). The amounts of Na taken up per g. of resin were again similar for the different doses of resin given.

The number of data is small and the agreement may be fortuitous; but the results suggest that the equilibrium between resin and Na depends on the cation content of the diet and not on the dose of resin, for the range of doses given.

Capacity of Resin in Vivo

The capacity of the H and NH_4 forms of resin *in vitro* differs because the NH_4 form has a lower moisture content (10% as opposed to 30%). Thus, while the same weights of both forms of resin were given, the effective dose of the NH_4 form was about 130% of that of the H form. The following estimates of capacity are based on the weight of resin given.

The capacity of the H resin *in vitro* is 2.5 mEq/g. (*Lancet*, 1950). The capacity of the NH_4 resin *in vitro* was estimated as 3.3 mEq/g. (calculated from the N content, on the assumption that all the N was present as NH_4). An estimate of the capacity of the resin *in vivo* was obtained from the increase in faecal excretions of cations when resin was given. The capacity calculated in this way from data in Table I was 2.4 mEq/g. for the H form and 2.8 mEq/g. for the NH_4 form in both experiments in which this form was given. These are minimum estimates of the capacity of the two forms of resin, because some resin was excreted with cation after the marker for the end of the resin period had appeared in the faeces (cf. Table I), and because not only of the increase in faecal cation but also the cations normally present in faeces may have combined with the resin.

Another estimate of the capacity of the NH_4 resin *in vivo* was given by the change in faecal N when the NH_4 resin was given. In W. there was an increase of faecal N while the resin was given, equivalent to 0.4 mEq of NH_4 per g. of resin; this suggests that 2.9 mEq of NH_4 per g. of resin was exchanged. This estimate corresponds well with the one above of 2.8 mEq/g. In F.2 the faecal N did not increase, so that in this experiment all the NH_4 , or 3.3 mEq/g. of

Medical Memorandum

Jejunal Diverticulitis with Diverticular Concretion

In an exhaustive review of the complications of acquired diverticulosis of the jejunum and ileum, Milnes Walker (1945) pointed out that in no case of jejunal diverticulitis had a concretion ever been found in an inflamed diverticulum, a fact suggesting that such concretions do not predispose to inflammation. I have found only one case of concretion formation reported since 1945, and this occurred in an uninfamed diverticulum. It was reported by Klidjian (1946).

The case recorded below therefore seems unique in that a concretion was found in a jejunal diverticulum which was the site of acute diverticulitis. It is also of interest because simple local excision of the diverticulum was practicable, which is unusual in cases of jejunal diverticulosis.

CASE REPORT

A housewife aged 60 was admitted to hospital on July 18, 1949, complaining of nausea and abdominal pain. The pain had started thirty hours previously as periumbilical colic,

Diagram illustrating the operative appearance. The inflamed diverticulum, with contained concretion *in situ*.

and had been continuously present since, increasing in intensity until it became "as bad as labour pains." It was accompanied by a feeling of abdominal distension, right-sided soreness, and a little lumbar back-ache. No previous history of any abdominal upset could be obtained.

Examination showed great tenderness of peritoneal type above and to the right of the umbilicus, and also high right-sided tenderness on rectal examination. Bowel sounds were present. The temperature was 100.2° F. (37.9° C.). The tongue was heavily coated. Although a provisional diagnosis of acute appendicitis was made mental note was taken that the clinical picture did not seem entirely typical of that condition.

Operation.—A right lower paramedian incision was made under general anaesthesia. Some free fluid was present, and some distance below the duodeno-jejunal flexure there was a hard movable rounded mass, about the size of a golf ball, attached to the mesenteric aspect of the small gut. When withdrawn from the incision the mass proved to be an inflamed solitary diverticulum of the jejunum containing a concretion or enterolith 1 in. (2.5 cm.) in diameter. The diagram shows how this diverticulum presented on the left-hand aspect of the mesentery at a point on the jejunum 2 ft. (61 cm.) below the duodeno-jejunal flexure. In spite of the inflammatory oedema in the related part of the mesentery and nearby jejunal wall, and because of the narrow neck, diverticulectomy and jejunal repair, using two layers of catgut sutures and an omental graft, were easily accomplished without any narrowing of the jejunal lumen. The appendix was removed too, but it looked entirely normal. No other abnormality could be found in the abdomen, and in particular there were no other diverticula.

Convalescence was uneventful, and the patient was discharged home with the wound healed on the ninth post-

operative day. She was seen and re-examined six months after the operation, when she reported fit and well, and said that she had been able to dispense with the laxatives she had previously found necessary.

COMMENT

The diverticulum had only a very thin and tenuous muscle coat, and seemed a typical acquired (rather than a congenital or cyst-like) diverticulum, which lay in close relationship to the left branch of one of the vasa recta. The contained concretion completely filled the lumen. Fusiform in shape, it was about 1 in. (2.5 cm.) long, of hard consistence, and brownish yellow in colour. By a misfortune it was lost on the way to the laboratory and so never came to analysis, but I believe that it probably was a bile-acid enterolith of the type described by Armitage, Fowweather, and Johnstone (1950).

Diverticula of the small intestine are comparative rarities, and those containing concretions are very rare indeed. Orr and Russell (1951) reported a series of 13 cases of jejunal diverticulosis, but they do not record concretion formation in any; nor did Edwards (1939), in his classical series of 16 cases. In addition, in the series of 122 cases of jejunal and ileal diverticulosis reported from the Mayo Clinic, Benson, Dixon, and Waugh (1943) do not mention concretion formation. Milnes Walker (1945) was able to find only four previously recorded cases of concretion formation in jejunal diverticula. In three of these the concretions had caused acute intestinal obstruction. He reported a case in which an inflamed ileal diverticulum had been found to contain a concretion, and noted that several other authors had reported cases of concretion formation in duodenal diverticula. Soon afterwards Klidjian (1946) reported his case, in which severe melaena had been caused by haemorrhage from a jejunal diverticulum containing a large concretion of unspecified type.

It would therefore seem that the present case of jejunal diverticular concretion is only the sixth reported, and in fact it is the only one in which a concretion has been found in an inflamed jejunal diverticulum.

It is a pleasure to thank Mr. D. M. Sutherland, under whose care this case was admitted, for much help and encouragement, and I am indebted to Dr. Robert Ollerenshaw, and Mr. Kilshaw, of the department of medical photography at the Manchester Royal Infirmary, for the illustration.

A new quarantine station will be put into service at Jeddah, the port of Mecca, for the pilgrimage season of 1953 (Year of the Hegira, 1372). The Government of Saudi Arabia is completing its construction and the World Health Organization is helping to equip and staff it. It will replace the old station of Kamaran, situated on an island in the southern part of the Red Sea, where, between the two world wars, up to 100,000 pilgrims were handled during one year (1926-7). The station at Jeddah comprises a quarantine station for the accommodation of persons under observation, a communicable diseases hospital, a general hospital, and a laboratory. On several occasions in the past the pilgrimage to the holy places in the Hedjaz has been the cause of serious epidemics, notably of plague and cholera. At its own request, the Government of Saudi Arabia is responsible for the new station under the International Sanitary Regulations.

Reviews

ABDOMINAL SURGERY

The Management of Abdominal Operations. Edited by Rodney Maingot, F.R.C.S. (Pp. 1,256; 532 illustrations in 328 figures. £6.) London: H. K. Lewis and Co. 1953.

The appearance of this remarkable volume forms an epoch in the history of modern surgery. It records the experiences and the achievements of 33 of the acknowledged leaders in British surgery, set out with lucidity, brevity, and candour. Much that is to-day accomplished with almost routine facility would 20 years or even 10 years ago have been utterly impossible, and it is doubtful if any other art can show such solid and continuous progress.

It is remarkable that just one-third of the book is devoted to considerations which are essentially physiological—a striking contrast to the atmosphere of anatomy in which we surgeons were trained in another epoch. To-day the surgeon must have this knowledge, but the human brain does not expand, and one wonders how long he can carry such a burden and whether we must not in the future achieve some division of responsibility.

The contents of the book are so good and so varied that no review could possibly do them justice. We can only mention the really fine articles by Maingot on the stomach and on the biliary tract, by Norman Tanner on gastric haemorrhage and perforation, and by Borrie on the oesophagus and the cardia. But standing above everything else is the great essay by Gordon-Taylor on abdominal injuries in warfare and in civil life, an essay which really makes history and which only its author could have written.

HENRY SOUTTAR.

HANDBOOK OF OBSTETRICS

A Modern Practice of Obstetrics. By D. M. Stern, M.B., B.Ch.(Cantab.), F.R.C.S., F.R.C.O.G., and C. W. F. Burnett, M.D.(Lond.), F.R.C.S., F.R.C.O.G. Line drawings by Susan M. Robinson. (Pp. 248; 140 illustrations. £1 15s.) London: Baillière, Tindall and Cox. 1952.

This book, intended for medical students, is based on the writers' experiences at the West Middlesex Hospital. It is rather smaller in size than the average undergraduate text-book but is in no way a "synopsis." In order to keep it concise, pure anatomy and physiology have been entirely omitted, while, according to the preface, normal and common abnormal conditions have been emphasized and the rarer complications but briefly mentioned.

The authors have aimed "to write upon the subject from a new aspect" and avoid the repetition of unsubstantiated statements which sometimes "have found their way from the pages of one textbook to those of another." In this they have largely succeeded, although it may be thought that a few clinical myths have in fact been perpetuated, such as the alleged predisposition of the elderly primigravida to the uterine inertia. Again, on some controversial topics the authors' opinions, dogmatically expressed, will not meet with general acceptance. For example, their preference for face-to-pubes delivery with Kielland's forceps in persistent occipito-posterior cases, their view that uterine inertia commonly recurs, their approval of a laterally placed episiotomy, and their condemnation of all mucus extractors are all matters which will provoke criticism.

Because of the omission of the basic sciences the uninitiated student may sometimes be bewildered when confronted with a new term (for example, "diagonal conjugate") without explanation—even though there is an appended glossary of terms. Despite the promise contained in the preface, the balance between common and uncommon conditions is not always well preserved. Most of the normal and important abnormal conditions are adequately described, yet ante-partum haemorrhage—surely

an important subject—receives only a brief description and is altogether oversimplified. On the other hand, space is given to the mention of some rare conditions such as the Chiari-Frommel syndrome.

The book is well written and "readable." It is produced in an unusual format—larger in page size than is the custom and printed in double column—and is a refreshing break-away from the traditional students' handbook. There are numerous line drawings, most of which are clear and explanatory. Each chapter is headed by an apt Shakespearean quotation and clearly divided by subheadings. Pleasing features are the inclusion of an appendix on "Obstetrical Terms Defined" and another (3½ pages of double column) on "Etymology." There are few printers' errors, although page 156 contains a mistake, and on page 189 two diagrams are incorrectly labelled.

Such criticisms as are advanced are not intended to detract from the considerable merits of this book. It is a welcome production and can be recommended to readers wanting a short textbook that is "different."

MOSTYN P. EMBREY.

LOCAL ANALGESIA

Local Analgesia: Abdominal Surgery. By R. R. Macintosh, D.M., F.R.C.S.Ed., D.A., and R. Bryce-Smith, B.M., B.Ch., D.A. Illustrated by Miss M. McLarty. (Pp. 94; 88 figures. £1 2s. 6d.) Edinburgh and London: E. and S. Livingstone. 1953.

The introduction of curare and other specific relaxants of muscle has tended to obscure methods of local analgesia in abdominal surgery, for a single intravenous injection is easy to give and is more rapid in its effects than infiltration and multiple nerve blocks. Nevertheless, as the authors of this excellent monograph point out, local analgesia still has its place, not only for abdominal surgery but in the diagnosis and treatment of many diseases. The recent introduction of lignocaine ("xylocaine") has stimulated interest in local techniques, since this drug has a rapidity of onset and reliability greater than other agents in concentrations of equal toxicity.

The various methods are described in sufficient detail for practical use, and the vagueness so annoying in many books of this nature is avoided. The illustrations are prolific, well drawn, and often in colour—features now associated with publications from the Nuffield Department of Anaesthetics. No mention could be found of the use of hyaluronidase as an aid to the successful blocking of deep nerves, which the reviewer has found valuable (though the authors can justly retaliate by saying that his knowledge of anatomy is not up to the Oxford standard). The printing, paper, and binding are first class, but the price is distressingly high.

C. LANGTON HEWER.

HAZARDS OF ATOMIC ENERGY

Biological Hazards of Atomic Energy. Edited by A. Haddow. Being the papers read at the Conference convened by the Institute of Biology and the Atomic Scientists' Association, October, 1950. (Pp. 235. £1 15s.) Oxford: The Clarendon Press. 1952.

Between these covers will be found a series of papers delivered by experts to their peers. Fortunately for the general reader the experts were of many branches, so that usually the content is not so abstruse as to be really difficult: the wind was tempered for other lambs of the same flock. As for the medical reader, it may be hoped that he will be effectively impressed with the possible dangers of atomic energy, but also with the possibility of escaping them by adopting a technique or ritual no more complicated than that used in aseptic surgery. Pochin's article on the clinical use of radio-iodine is an excellent description of such a technique. Another useful piece of evidence is Marley's report on 51,077 weekly monitoring films at Harwell; only 77 exceeded 0.2 r, and none at all were over 3 r. Clearly, then, safety can be and should be attained, but equally

clearly no one should expose himself or others to any risks at all unless he has learnt in a proper school how to avoid them.

Loutit's article on possibilities of protection against massive doses of ionizing radiation holds out hope that something more than shielding may be attainable when the fundamental action on tissues is better understood. Neary's contribution, which clearly indicates the nature of the hazards associated with the dangerous tools now put into doctors' hands, should certainly be studied. The geneticists have their say, and arrive at results which bear a gloomy aspect; nevertheless, the warning they give should be noted. As Mather says, "It is our plain duty to avoid all unnecessary and unjustifiable radiation of the germ line."

For all those engaged in work with radiation sources this book is one that should always be within reach and constantly consulted.

E. ROCK CARLING.

SEWAGE DISPOSAL

Small Sewage Disposal System (with special reference to the Tropics). By O. J. S. Macdonald, M.D. (Pp. 300; 92 illustrations. 20s.) London: H. K. Lewis and Co. 1952.

As the author of this book points out, there was previously no single volume recording the range of small sewage-disposal systems suitable for rural areas. He therefore describes the methods which he has proved to be satisfactory under ordinary conditions of use in the Tropics. He includes an account of almost every type of latrine or sewage-disposal installation which may be set up in sewerless areas for the individual house or for small communities numbering up to 200 persons, and discusses its advantages and disadvantages.

In the first part of the book the author considers problems of construction and practice. After three general introductory chapters he writes on domestic and communal water-borne systems using septic tanks, the purification and disposal of the effluent, the pour-flush latrine and aqua privy, pit and bucket latrines, and the maintenance of disposal systems. The second part of the book is on the nature of sewage, its biological treatment, and the principles involved in the design and functioning of septic tanks. There are two chapters listing, with descriptions, the many different designs of septic tank and aqua privy which have been adopted by sanitary authorities and experts in various parts of the world.

This is an extremely practical volume which may be strongly recommended to medical officers, sanitary engineers, and sanitary inspectors working in rural areas, particularly of the Tropics. The descriptions are lucid, and are accompanied by nearly 300 drawings in which dimensions and constructional details are given. Bills of quantities prepared by an engineer are provided in the case of the more popular systems, and costs in Ceylon are recorded. In fact, the author has included almost every item of information which anyone may require on the choice, construction, or maintenance of a small sewage-disposal installation.

T. H. DAVEY.

SOCIAL PSYCHIATRY

Social Psychiatry. By Maxwell Jones, M.D., M.R.C.P.(Ed.), D.P.M., et al. (Pp. 186. 18s.) London: Tavistock Publications, Ltd. 1952.

Dr. Maxwell Jones and his six collaborators describe the development and realization of an idea—from its first beginnings in a unit for the treatment of effort syndrome during the war, and later in a unit for the rehabilitation of returned prisoners at the end of the war, to the present Industrial Neurosis Unit at Belmont Hospital. The purpose of this unit, as its name implies, is the treatment of neurotic patients who are partly or completely disabled. In fact, many of them have been unable to work for years, and some have few prospects of returning to work under any but sheltered conditions.

The idea which inspired Dr. Jones, and through him his staff, was that of creating a society in which these social misfits might enter and actively participate. The central problem was morale; merely submissive co-operation on the part of the patient was not enough, and he had to be induced to enter into the spirit of the community life provided for him. This has been the rationale behind the various techniques which have been developed—for example, group discussions to which patients contribute both in providing their own problems and in advising on those of others, and "psychodrama," in which the same themes, in playlets written and acted by patients, receive a more dramatic and stimulating form.

It seems needless to add that there are many other aspects to the work done at this centre at Belmont—investigation along normal psychiatric lines, the testing of intelligence and assessment of employability, a work programme with workshops and physical training, the social study of the patient's private world, and liaison with the rehabilitation officers of the Ministry of Labour. The final aim is to get the patient back into satisfactory working life, and a happier life personally. In view of the fact that the treatment of chronic neurosis is exceedingly difficult and discouraging, a figure of 44% of patients making sound adjustments after discharge must be regarded as very satisfactory.

ELIOT SLATER.

CARDIOVASCULAR DISEASES

Clinical Progress in Cardiovascular Disease. Edited by Herrman L. Blumgart, M.D. Modern Medical Monographs. (Pp. 143. \$4.50.) New York: Grune and Stratton. 1952.

In December, 1950, the American journal *Circulation* started a new monthly feature: "Clinical Progress." These critical reviews of important subjects have been well received, and several of them are now presented together in book form. The subjects chosen include atherosclerosis, the management of acute cardiac emergencies, surgery for mitral stenosis, the management of cardiac patients in relation to surgery, and emotion and the circulation.

The chapter on atherosclerosis, to which Louis Katz, Ancel Keys, and John Gofman contribute, will be widely acclaimed. The relationship of certain classes of serum lipoprotein (Sf 12-100) to atherogenesis can no longer be disputed, and it is clear that the serum cholesterol has only indirect bearing on the disease, depending on its relationship to the lipoprotein classes mentioned. Each of the contributors presents independent evidence that a diet low in total fat influences atherogenic activity favourably, the nature of the fat, whether animal, vegetable, or cholesterol-bearing, being unimportant. But much more than this is discussed—for example, the part played by hypertension, sex, vascular injury, and lipotropic substances. There is little doubt that a vast amount of work on this grave disease is gradually bearing fruit, and it may not be long before atherosclerosis can be in some measure controlled.

The account of the management of acute cardiac emergencies by de la Chapelle and Rose is didactic and practical. The advice is orthodox except in recommending intravenous digoxin in preference to aminophylline in cases of acute left ventricular failure. The surgical treatment of mitral stenosis is discussed by E. F. Bland. He traces the history of this great surgical achievement admirably, but surveys the present situation less well. The management of cardiac patients in relation to surgery is described by A. C. Ernstene, the effect of emotion on the circulation by Mark Altschule. Both these chapters are sound so far as they go.

Just what finally decided the editor to choose these five contributions out of the 20 reviews so far published in *Circulation* is not clear. The reasons given are pertinence to significant problems of current interest and practical usefulness. Personally I should be content, and honoured, with a reprint of the article on atherosclerosis.

LONDON

SATURDAY MARCH 7 1953

STREPTOMYCIN AND ISONIAZID

The series of clinical trials organized by the Medical Research Council to test chemotherapeutic agents in tuberculosis has been notable not only for the results achieved but also for the advance in technique which has enabled questions to be answered in a matter of months that with former methods would have taken years. By analysing the results as the trial progressed it was possible to publish¹ the first report on the use of isoniazid in pulmonary tuberculosis only six months after starting the trial and a second important report, published this week in our opening pages, only five months later. Great credit is due to the many clinicians and bacteriologists who have worked almost anonymously and who have contributed so much. With such widespread team-work it is almost invidious to mention names, but a special tribute must be accorded to Dr. Marc Daniels, the chief co-ordinator of all these trials since their inception. His death earlier this week is a grievous loss to the Medical Research Council and to British medicine.

The present report gives the results of three months' treatment of 364 patients suffering from pulmonary tuberculosis of different degrees of severity. Of these, 142 were treated with streptomycin 1 g. daily and isoniazid 100 mg. twice a day, 102 with streptomycin 1 g. daily and sodium *para*-aminosalicylate (P.A.S.) 20 g. daily, and 120 with isoniazid 100 mg. twice a day alone. Over this period streptomycin and isoniazid, given together, were superior to streptomycin and P.A.S. in their effect on weight gain and blood sedimentation rate, and rather more effective in improving general condition. There was no significant difference in the effect on pyrexia, sputum-conversion, or the radiographic appearances. Comparison of streptomycin and isoniazid with isoniazid alone, over the same period, showed that the combined treatment was much more effective in lowering the sedimentation rate and improving the radiograph. It was slightly more effective in returning the temperature to normal. The effect on general condition and on weight was similar with both treatments.

The tests for sensitivity of the tubercle bacilli to the drugs are as important as the results of the different treatments. Positive cultures from patients treated with isoniazid alone showed drug-resistant

¹ *British Medical Journal*, 1952, 2, 735.

tubercle bacilli in 11% of the cultures after one month's treatment, in 52% after two months', and in 62% after three months'. When streptomycin was added, isoniazid-resistant bacilli were obtained in only 4% of positive cultures at one month, 9% at two months, and 13% at three months. The difference is even more impressive when negative cultures are taken into account. After three months' treatment isoniazid-resistant bacilli were obtained from 35% of patients treated on isoniazid alone, compared with only 3% of patients treated with streptomycin and isoniazid. Naturally it is not known what percentage of patients with negative cultures may be harbouring undetected resistant bacilli. When a comparison was made of the emergence of streptomycin-resistant organisms in the two groups on combined treatment, no great difference was found after one or two months' treatment. Expressed as a proportion of positive cultures, 2% were resistant at one month with streptomycin and P.A.S., compared with 1% for streptomycin and isoniazid; at two months the figures were 3% and 4% respectively. At three months 24% of positive cultures were resistant to streptomycin in the group treated with streptomycin and P.A.S., compared with 11% of cultures in the group treated with streptomycin and isoniazid. Expressed as a percentage of patients treated, this looks less formidable: resistant organisms were isolated from 5% of those treated with streptomycin and P.A.S. compared with 2% of those on streptomycin and isoniazid. The percentage resistant in the streptomycin-P.A.S. group is unduly high. When allowance is made for cultures P.A.S.-resistant before the start of treatment, the figures for streptomycin resistance fall to about 13% of cultures and 2.5% of patients, which are comparable to the results for the streptomycin-isoniazid group.

It is clear from this and the previous Medical Research Council report that isoniazid should no more be used alone than should streptomycin or P.A.S. When any of these drugs is given alone, resistant tubercle bacilli are likely to emerge. Moreover, if in the same patient the relevant drug is later used in combination, it will be found to have lost its capacity to prevent or delay resistance to the other member of the combination. On the other hand, isoniazid 200 mg. daily given with streptomycin 1 g. daily seems to be the most effective combination so far available, even though its proved superiority over streptomycin and P.A.S. is seen only in weight gain and blood sedimentation rate. Isoniazid has the additional advantage over P.A.S. of negligible toxicity in the doses used. When streptomycin and isoniazid are given together, the reciprocal suppression of drug

resistance is of the same order as that of streptomycin and P.A.S. over a three-month period. But the few available figures for isoniazid resistance at four months are less reassuring. Three out of eight positive cultures were resistant, though in most of these patients streptomycin was given only three times a week in the fourth month. Until more evidence is available these results suggest caution in giving streptomycin less often than once daily when it is used with isoniazid, and we do not know that the combination will maintain its clinical superiority when continued for more than three months. The patient being treated with streptomycin and isoniazid is having the advantage of the two most powerful drugs at present available, but if tubercle bacilli emerge which are resistant to one they will probably become resistant to the other; in short, all one's chemotherapeutic eggs are in one basket. In view of this it would seem rational to confine streptomycin and isoniazid to certain types of case. When chemotherapy will probably be the definitive treatment of a patient—for instance, with relatively localized recent disease without cavitation—resistant organisms are less likely to emerge and it is reasonable to risk using the best combination. It is also justifiable if the patient is quite intolerant to P.A.S. or if, because of previous treatment with P.A.S. alone, there is strong possibility that the organisms are P.A.S.-resistant. In patients with cavities or with more extensive disease it is wiser to start with the well-tried streptomycin and P.A.S., keeping isoniazid in reserve in case the bacilli become resistant. Occasionally the patient's bacilli may be resistant to streptomycin but not to P.A.S.; combination of isoniazid with P.A.S. is then appropriate, though we have as yet no evidence on its efficacy. When patients are desperately ill, it is reasonable to give them all three drugs in the first place, but again it may be advisable to withdraw isoniazid into reserve as soon as the most acute phase has been controlled. If, because of resistance to streptomycin and P.A.S., the patient has to receive isoniazid—which has been kept in reserve—its use should be carefully timed to cover a crisis. The last important chemotherapeutic reserve must not be frittered away.

It must be remembered that patients may have been primarily infected with resistant bacilli. The bacilli of four patients in this series were initially resistant to streptomycin, though they had had no previous chemotherapy. Resistance tests on pre-treatment cultures are therefore essential. It may be impossible to defer treatment until results become available, but, as suggested in the report, one should take note of the chemotherapy given to known contacts before deciding on the best combination for the patient.

Clearly therefore every case must be carefully assessed before deciding on the appropriate form of chemotherapy. The possibility of drug resistance should always be borne in mind, and adequate information on drug sensitivity should be available at important stages in the patient's treatment. A culture at the end of the course of chemotherapy (or the last positive culture) should always be tested for drug-sensitivity.

The chemotherapy of tuberculosis is no longer simple. Its very success and diversity are creating ever-changing problems with which everyone who treats the disease must become familiar. The pace of research is such that even the conclusions of the present authoritative report may be out of date in a few months.

EPIDEMIC NAUSEA AND VOMITING

During the past few years many general practitioners and some medical officers of health¹⁻⁴ have been encountering an epidemic infection which, because it is mild and apt to be misdiagnosed, has not attracted much official attention. It is a disease characterized by nausea and vomiting of sudden onset, some initial fever and general aching, and in some cases giddiness, anorexia, and diarrhoea. The syndrome has a variety of synonyms such as epidemic viral gastro-enteritis, winter vomiting disease (because outbreaks occur more often in the winter), epidemic diarrhoea and vomiting, and gastric flu. This last diagnostic title, while apt, is likely to cause confusion if the outbreak of epidemic vomiting coincides with an epidemic of influenza, as has happened this winter. A false clinical picture of the syndrome may thus be obtained, in that respiratory symptoms may appear to be an integral part of the disease. But in school outbreaks, such as those recently reported by Garland² and by Dummer,⁴ respiratory symptoms have been notably absent.

This is no new disease. School outbreaks of a similar nature were reported by Miller and Raven⁵ in 1936, by Gray⁶ in 1939, and by Bradley⁷ in 1943, while some years ago epidemic diarrhoea and vomiting was a prevalent infection in maternity units, affecting both mothers and infants.⁸ However, profuse watery diarrhoea with or without vomiting was the principal symptom in these maternity hospital outbreaks, and it may be that there are two separate clinical entities.

When outbreaks occur in schools some form of food-poisoning is often suspected, but investigation shows that the outbreak has not the explosive character of a food-borne infection and has no close

correlation with the distribution of water, milk, or other foods, while bacteriological examination of stools, vomit, or suspected foods is invariably negative. Certain clinical features also help to distinguish epidemic vomiting from food-poisoning. Thus the sudden unexpected onset of projectile vomiting, most often in the middle of the night, has been an outstanding feature; giddiness has been a fairly common accompaniment, and there is often some general aching, with a frontal headache which tends to come and go. Fever up to 100° F. (37.8° C.) occurs at the onset. Abdominal signs are usually limited to some epigastric discomfort, and there are no colicky pains. The illness usually lasts for one to three days, but relapses may occur about one week after recovery. The nature of the clinical symptoms has suggested some disturbance of the central nervous system, but no direct evidence of its involvement has been described.

The disease is highly infectious, and the attack rate in a susceptible community varies from 10% to over 80% according to intimacy of contact. Outbreaks seem to occur most often in the autumn or winter, but no season is exempt. The incubation period may vary from two to seven days but is usually short, so that the infection spreads quickly through a school community. The epidemiological evidence suggests that the infection is spread by the respiratory route, although indirect spread by contaminated articles or food certainly cannot be excluded. The causative agent is unknown but is believed to be a virus. Gordon and his colleagues⁹ were able to infect human volunteers by feeding them with faecal filtrates or unfiltered throat washings from infected cases, whereas no symptoms occurred after inhalation of the throat washings. Attempts to infect the chick embryo and various experimental animals have been unsuccessful.

Although infectious syndromes of unusual nature may attract attention when they occur in schools or other institutions, clearly if they are of short duration and relatively mild they may be prevalent in the general community yet entirely escape official recognition by the health authority unless the general practitioner of his own accord notifies such cases to the medical officer of health. For example, it is clear from information received through the Public Health Laboratory Service that outbreaks of epidemic vomiting have been occurring among schoolchildren and students in many parts of the country during the past two or three years, yet no records of the prevalence

of this infection are generally available. Much useful information about the clinical features and epidemiology of prevalent but non-notifiable illnesses might be collected if there were some arrangement for doctors in different areas to act as "spotters" of new maladies. Is this another job for the College of General Practitioners?

AGRANULOCYTOSIS

Therapy of some kind is the usual cause of agranulocytosis. It was first described as a clinical entity in 1922, when Schultz¹ reported on six patients presenting with severe sore throat, prostration, and extreme reduction or disappearance of granulocytes from the peripheral blood. The number of reported cases increased steadily during the ensuing decade, largely owing to the use of amidopyrine in analgesic and antipyretic tablets. A few cases were caused by benzene, gold, and organic arsenicals. In 1933 the sale of amidopyrine was made illegal except on the prescription of a registered medical practitioner, and the frequency of cases due to this drug diminished. They did not completely disappear, because physicians continued to prescribe proprietary preparations without realizing that they contained amidopyrine.² During the last decade these older compounds have given way to newer ones as causes of agranulocytosis, and severe or total depression of granulocytes has been attributed to treatment with sulphonamides, thiouracil, tridione, P.A.S., chloramphenicol, isoniazid, and, most recently, "butazolidin."³ While a therapeutic agent is the commonest cause of agranulocytosis, hair-dressing chemicals may not be without blame: Cotter⁴ has reported three cases caused by thioglycolic acid, a substance used in a "home cold-wave" process.

The mechanism by which chemicals cause agranulocytosis remains unknown. Possibly they derange the metabolism of the granulopoietic marrow cells. Often the condition develops suddenly and after only a small dose. This, together with the observation that urticaria, angioneurotic oedema, asthma, and other allergic manifestations may be associated, has led to the belief that some patients have an idiosyncrasy to the drug.

Prevention of agranulocytosis lies in avoiding drugs known to cause the condition, and, when this is impossible, in warning the patients to stop taking the drug and to report immediately if they develop malaise, a sore throat, or any other new symptom. It is doubtful if white cell counts at weekly or longer intervals are of use, for a normal white cell count on one day may be followed two days later by a precipitous fall in granulocytes.

The many treatments recommended bear testimony to the difficulty of obtaining enough cases to test the value of any one therapeutic agent. Indeed, the disease is so

dangerous that usually blunderbuss therapy is given. All workers are agreed that the offending drug must be withheld. The most beneficial single therapeutic measure is to give penicillin as soon as the condition is diagnosed; it must be continued until the granulocytes reappear in the peripheral blood. Marrow function usually returns within seven days, and, if the patient can be protected from infection while the leucocyte defences are down, spontaneous recovery is likely. Attempts have been made to increase the number of circulating granulocytes, and for this pentnucleotide, folic acid, pyridoxine, and liver extract have been recommended, but their value has still to be proved. Fresh blood transfusions have been used, but it is doubtful whether they provide viable leucocytes for a sufficient length of time to be of help to the patient.

Recently cortisone and adrenocorticotrophin (A.C.T.H.) have been tried, partly because they are known to influence allergic reactions and partly because they cause a leucocytosis in normal subjects. In fact the well-known eosinopenia caused by these agents is not so marked as the less well known increase in neutrophilic cells.⁵ The course of agranulocytosis is so variable that it is difficult to assess the therapeutic value of A.C.T.H. and cortisone, and in the reported cases penicillin and other treatment were wisely given in addition. Two cases ascribed to sulphonamides recovered, but one of them showed improvement with early neutrophilic regeneration after treatment with penicillin and pentnucleotide and before the cortisone was given.^{6,7} Virkkunen⁸ reports two patients with rheumatoid arthritis who developed agranulocytosis following treatment with thiosemicarbazone: one had shown no improvement after six days of penicillin and the other after two days. Both appeared to respond promptly to A.C.T.H. Hart and his colleagues⁹ have reported a case due to "novalgin"—a proprietary preparation containing a substance allied to amidopyrine—which still showed depression of myeloid marrow cells 13 days after treatment with penicillin, blood transfusions, and pyridoxine. There was a notable response to A.C.T.H. Although the findings in these cases are suggestive, there is no proof that cortisone or A.C.T.H. was really responsible for the improvement, which may have been spontaneous. Further trials, if possible properly controlled, are required. One note of warning must be sounded. Cortisone and A.C.T.H. increase the liability to infection, and if they are given to patients with agranulocytosis large doses of penicillin are more necessary than ever.

CHLOROPHYLL

We recently discussed the evidence for the statements which continue to be so widely circulated that chlorophyll preparations have a deodorant action.¹ In an effort to credit some of the less unlikely claims, such as that chlorophyll dressings reduce foul odours from wounds, too favourable an opinion may have been expressed. Many of us are inclined to think in a matter

of this kind that there must be something in it, so that mere condemnation is unconvincing. On another page Dr. J. C. Brocklehurst describes some experiments arranged to test the deodorant action in an objective way. He used methylmercaptan as a substance with an unpleasant odour. It is said to be present in the urine after eating asparagus, and its relation, vinylmercaptan, is the substance discharged by the skunk. Dr. Brocklehurst showed that, when methylmercaptan passed a screen of filter-paper soaked in chlorophyll solution, it reduced just as much iodine as when the screen of filter-paper was soaked in water, showing that the methylmercaptan was not destroyed by the chlorophyll. Thus he substituted a quantitative estimate for an olfactory impression. He then bubbled nitrogen carrying methylmercaptan through a chlorophyll solution on the one hand and through water on the other and again failed to observe any difference in the decolorization of iodine. Another series of experiments revealed a deodorant action in one out of 22 trials, though here Dr. Brocklehurst regarded the mercaptan smell as merely being masked by a very strong smell of the chlorophyll solution. Observations were also made on a patient with incontinence of urine and faeces, and on a normal subject who ate asparagus. In neither of these was there any modification of the smell of the urine when large amounts of chlorophyll preparations were taken.

Recently Dr. A. H. Corwin,² head of the department of chemistry at Johns Hopkins University, quoted to the American Chemical Society a report from the National Bureau of Standards which said that "we have no reason whatever to believe that chlorophyll has anything to do with deodorization." It is evident that the wave of credulity which has swept the United States has not overwhelmed everyone, and it is to be hoped that it will not overwhelm too many in Britain. Some who are sceptical of chlorophyll tablets have faith in appliances which allow a substance to evaporate from a wick, the wick standing in a solution which contains chlorophyll; this substance is said to remove odours. Crotonaldehyde has been used for this purpose, and like formaldehyde it renders the olfactory nerve endings less capable of detecting any odour, unpleasant or otherwise.

NEW CORONERS RULES

New Coroners Rules came into force on March 1. They largely embody the B.M.A.'s recommendations, which were submitted to the Coroners Rules Committee of the Home Office in April, 1951.¹

Rule 26 provides that proceedings at an inquest shall be restricted to finding out who the victim was, how, when, and where he died, if the cause of death was murder, manslaughter, or infanticide, who ought to be charged as principal or accessory to the crime, and the particulars required for registration. Neither coroner nor jury is to express an opinion on anything else, except that they may make a recommendation designed to prevent a recurrence of similar fatalities. No rider to any other effect is to be recorded by the coroner. This

should go some way towards eliminating the cross-examination whose real purpose is not to ascertain the cause of death but to prepare the way for an action for damages against someone who may be civilly liable. It is reinforced by Rule 33, which expressly provides that no verdict is to be framed in such a way as to appear to determine any question of civil liability.

If anyone's conduct is likely in the coroner's opinion to be called in question at the inquest, he is to be either summoned to give evidence or given notice of the date, place, and time when it will be held. Further, if in the course of the inquest someone who is not there, and has not thus been given notice, has his conduct called in question on grounds which are substantial and relevant, the inquest must be adjourned to enable him to be there if he wishes. This will prevent anyone from being criticized without having the opportunity to give evidence on his own behalf. By Rule 18 the rule of evidence in legal proceedings both civil and criminal, that no witness has to answer a question tending to criminate him, is expressly applied to inquests. By Rule 28 documentary evidence is not to be admitted without the matter of the document being called, unless the coroner is satisfied that there is a good and sufficient reason why he should not attend; and, once it is admitted, if the coroner or any other properly interested person so requires, the inquest must be adjourned to enable the maker of it to give oral evidence. By Rule 16 the police are entitled to examine witnesses only through the medium of a solicitor or counsel. In all these matters of evidence the tendency of the Rules is to bring proceedings at an inquest more nearly in conformity than they have been in the past with proceedings in court. By Rule 8, although the full B.M.A. recommendation is not met, it is provided that necropsy is not to be carried out in a dwelling-house or on licensed premises, but only in premises adequately equipped for the purpose with running water, proper heating and lighting facilities, and containers for storing and preserving what may be necessary. It is satisfactory to find that these important provisions in the new Rules so largely accord with the Association's recommendations.

THYMECTOMY AND MYASTHENIA GRAVIS

In an article in the *Archives of the Middlesex Hospital* (which has maintained a high standard since its welcome reappearance two years ago), Holmes Sellors¹ has reviewed the treatment of myasthenia gravis by thymectomy and described the results of the operation in 37 cases: 32 of these patients had symptoms of myasthenia gravis. He concludes that removal of the thymus offers the best hope of permanent relief in this disease, particularly if carried out in its early stage. The connexion of the thymus gland with myasthenia, and indeed its function in the normal individual, remain unknown. That the thymus often appears enlarged or may contain a tumour in myasthenic patients was observed at necropsies fifty years ago. Sauerbruch carried out partial removal of the gland in 1911, but no further attempts to relieve the disease in this way were made

until Blalock's work in Baltimore; he published² the results of 20 operations in 1944. Since then the operation has not found as great favour in the U.S.A. as it has in this country, where the results in 155 cases published by Keynes³ in this *Journal* have been most stimulating. Over 90% of the surviving patients in his series were improved.

Most patients with myasthenia gravis have been treated with neostigmine since Walker,⁴ in 1934, reported on the relief of symptoms afforded by this drug. It is usually effective by mouth, but sometimes must be given by injection: atropine may be necessary to neutralize the side-effects, such as abdominal griping. Neostigmine must usually be taken after thymectomy, but often in smaller doses than before, and it becomes more effective. Some patients are so much improved that they dispense with it altogether. Sellors, like Keynes, has found that the operation is most likely to be successful when the history is short, and that, even in patients greatly benefited in other ways, muscles which have been weak for a long time may not recover, so that ptosis, for example, may be permanent. Some patients do not improve at all; unfortunately no way of predicting the likely result in any individual has been found.

About one in ten myasthenic patients has a tumour of the thymus, benign or malignant, though not all thymic tumours are associated with myasthenia. Some may be symptomless, and others may cause mediastinal obstruction. The tumours may be impossible to diagnose before operation, even with careful radiography. Sellors and Keynes have both found that the prognosis is poor after operation in cases of myasthenia with a tumour of the thymus, for the condition is liable to relapse. Occasionally the thymic tissue is ectopic, lying in the first or second intercostal spaces, but usually it is found immediately beneath the sternum, as in the infant, and consists of two lobes united by an isthmus, closely related to the left innominate vein. Surgical access is provided by vertical division of the sternum. All thymic tissue must be removed, and this is ensured by leaving no visible fatty tissue in the anterior mediastinum. If there is a tumour, adjacent pleura or pericardium should be excised: with controlled respiration by endotracheal anaesthesia no harm results, but wound closure must be airtight. Post-operative pulmonary complications can be dangerous, since muscular weakness may make coughing or even breathing difficult. Neostigmine should be continued, and it is wise to have an artificial respirator, such as a Drinker's apparatus, to hand. A watch should be kept for pneumothorax, and aspiration or bronchoscopy may have to be carried out if secretion of mucus becomes excessive or if atelectasis occurs. Some patients improve immediately after operation, others improve gradually. In its natural course the disease fluctuates in severity and there may be long remissions. These must be allowed for in assessing results of treatment, but, even so, Sellors's report confirms the value of operation.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

MEDICAL ASPECTS OF AIR TRAVEL—I. ENVIRONMENT AND IMMUNIZATION REQUIREMENTS

BY

Sir HAROLD E. WHITTINGHAM, K.C.B., K.B.E., LL.D. F.R.C.P.

Director of Medical Services, British Overseas Airways Corporation

Now that travel by air has become so commonplace general practitioners are consulted more and more by their patients on its medical aspects. The points on which information is often wanted are the medical contraindications to flying, how babies and the elderly react to long flights, what facilities are available for invalids, and what are the immunization requirements.

First, it is desirable briefly to consider the environment, particularly the limitations of space and other facilities on an airliner, and the effects of speed, altitude, noise, and vibration, as these are all factors of importance in the care and comfort of invalids who contemplate travelling long distances.

Space and Facilities for Invalids

The space allotted to each passenger is relatively small, even in the most luxurious airliners, and is virtually limited to a seat. Under the best conditions reclining seats are in pairs, with an arm-rest between them, arranged in rows on either side of a narrow gangway 18 to 20 in. (46 to 51 cm.) in width. Each pair of seats is pitched some 39 to 46 in. (99 to 117 cm.) from the next pair, so that there is just room to get in and out past one's neighbour. In some aircraft a number of sleeping berths can be made up at night. There is, of course, an extra charge for these, as there is also for any stretcher space needed; in the latter instance the charge is usually double fare, as two seats are occupied.

FIG. 1.—Diagram showing anatomical points in aircraft seats. (A) Adjustable support for head and neck. (B) Padding to support small of back. (C) Compression of seat cushion should not exceed 1 in. (2.5 cm.). (D) Feet must reach floor to take weight off lower thighs. A footstool damps vibration. (E) Avoid pressure on main veins and lymphatics and so prevent swelling of feet and ankles. (F) Position prevents abdominal muscles being too relaxed and so lessens pooling of blood in large veins of abdomen and helps to avoid flatulent distension of the gut.

Comfortable seats are essential on long flights of six to twelve hours at a stretch, otherwise passengers cannot rest properly, become unduly fatigued, and suffer from discomfort in the small of the back and from postural oedema of the feet, especially if they have poor circulation. This oedema is largely the result of the seat being too soft and

FIG. 2.—Stretcher cot suspended between two chairs and fastened to floor.

too long in the pan, so causing widespread pressure on the veins and lymphatics of the buttocks and underside of the thighs. The backache is due to insufficient support in the back of the seat to maintain the proper curve of the lumbar spine, with the result that the ligaments and muscles concerned are overstretched. Nowadays many aircraft seats are constructed on sound anatomical and physiological principles (Fig. 1), with padding in the right places and tilting devices to enable passengers to adjust their position from upright to reclining and with feet raised enough to prevent oedema. In addition, footstools and soft cushions are available to give further support where required and to suit individual peculiarities of build.

Where necessary or advisable, the airline's medical department recommends acceptance of certain types of invalids as stretcher or sleeping-berth cases only. Special seats are then allotted for the purpose, so that a stretcher can be accommodated or a lie-down constructed by bridging the gap between two facing seats and covering this with a mattress (Fig. 2). Curtains are available to screen off these invalids, particularly those requiring dressings or special attention during the flight.

Toilet facilities in a 40 to 60-seater aircraft are limited to a small "powder room" with two wash-basins and one closet for ladies, and a lavatory with two or three wash-basins, a urinal, and a closet for men. Hot meals are served in flight or at stopping places *en route*, and special diets can be provided for invalids if notification is given in advance.

Speed and Smoothness of Flight

Speed is not felt in the cabin type of aircraft so long as it is uniform and there are no visual cues, such as passing-by objects like clouds. Alterations in the speed or direction

of the aircraft, however, are felt: the greater the degree of change the more the sensation. Commercial passenger-carrying aircraft are flown so as to cause little or no sensation of speed; in fact, the only time when speed may be appreciated at all is at take-off and during ascent and descent, and even then it is no greater than that experienced in a carefully driven motor-car. Some motion may be felt in "bumpy" weather conditions, especially when flying through cloud, and this may cause airsickness in predisposed individuals. Bad-weather clouds frequently extend up to altitudes of 15,000 to 25,000 ft. (4,600 to 7,600 metres) in temperate zones and to 40,000 ft. (12,000 metres) or more in the Tropics. Modern airliners have therefore been specially designed to fly smoothly and speedily (up to 500 m.p.h.—800 km.p.h.) at altitudes between 15,000 and 40,000 ft. (4,600 and 12,000 metres)—that is, 3 to 8 miles high—and to do this the aircraft has to be "pressurized."

Effects of Altitude

Oxygen Lack or Anoxia

Although the air has the same percentage composition of its component gases at any altitude within the earth's atmosphere, it becomes progressively rarefied with increasing altitude above sea-level in accordance with Boyle's law. At 18,000 ft. (5,500 metres) the air has half the density it would have at sea-level, and at 40,000 ft. (12,000 metres) about one-fifth. This gives a rough idea of the corresponding reduction in the partial pressure of the oxygen available in the air inhaled at different altitudes. Healthy individuals are less affected by lack of oxygen than are the non-robust. The onset of anoxia in flying is insidious, and the symptoms are very similar to those of alcoholism: the individual is oblivious of the fact that he is suffering from lack of oxygen, and, like the inebriated, feels that he is "on top of the world" even when "half under the table." The first symptoms of oxygen deficiency of relatively minor degree occur after a stay of over an hour at an altitude of 10,000 ft. (3,000 metres), but normal individuals and most invalids, if more or less sedentary, can remain in the atmosphere of an altitude of 8,000 ft. (2,400 metres) for ten to twelve hours without suffering anything more than the ennui and fatigue experienced in most modes of travel. Aircraft are therefore pressurized to a degree adequate to compress the air in the cabin (even when the aircraft is flying at an altitude of 40,000 ft.—12,000 metres) to a density of the air at an altitude of 8,000 ft. (2,400 metres) or lower and to maintain it constantly at that density. When invalids are carried, however, the precaution is taken to provide special oxygen sets in case of need, but in practice it has been found that these are seldom required.

Air and other gases contained in the body spaces—for example, the middle ear, the paranasal sinuses, and the alimentary tract—naturally are also subject to Boyle's law, and therefore expand and contract with decrease and increase of the atmospheric or cabin pressure.

Ventilation of the Middle Ears

Normally, the air pressure on either side of the eardrums is equalized automatically by the expanding air escaping from the middle ears by way of the Eustachian tubes during ascent and by being drawn in during descent. This ventilation of the middle ears is apt to fail if the Eustachian tubes are even only partially occluded by nasopharyngitis or some other condition affecting their apertures, especially during a rapid descent, as the continuing contraction of the air imprisoned in the middle ears tends to draw together the walls of the Eustachian tubes. Consequently the tympanic membranes may result (acute otitic barotrauma). The immediate symptom is acute earache, followed by some loss of audibility and sometimes by tinnitus and vertigo. These symptoms may persist for some hours after ventilation of the ears has been re-established by the Valsalva technique or, in severe cases, by puncture of the safe area of the

tympanum with a fine needle. It follows, therefore, that those suffering from acute nasopharyngitis or sinusitis should be advised not to fly until they have recovered; if they do fly with a head cold they should inhale amphetamine or some other vasoconstrictors to help clear their Eustachian tubes.

Descents in airliners or alterations in their cabin pressure are usually made very gradually to permit proper ventilation of the middle ears, even if the passengers are sleeping. Young children may get airlocks in their ears: this makes them cry, an act which immediately relieves the condition by opening their Eustachian orifices. Mothers with babies should be instructed to give them a feed or a dummy to suck during ascent and descent. Persons about to travel by air for the first time, and who are apprehensive of their ability to ventilate their middle ears, should be advised to suck a sweet, chew gum, or practise the Valsalva technique during ascent and descent. In fact, this is a wise precaution for all to take, and it is the custom for cabin attendants to hand round to every passenger boiled sweets or chewing-gum at appropriate times.

Gases in the Alimentary Tract

Expansion of gas in the gut usually causes no trouble, except the embarrassment of passing flatus. It may, however, create painful distension in those with lax abdominal walls, and may even be dangerous on account of haemorrhage or perforation in cases of active ulceration or after major operations on the stomach or intestines. The general rule, therefore, is not to accept for air travel cases of appendicectomy or herniotomy for ten days after operation, and those who have had gastrectomy or a perforation or haemorrhage of the stomach or intestines (except for haemorrhoids) for at least two months after the event. Colostomy cases are usually not acceptable in the confines of an aircraft, owing to the odour from escaping faeces and flatus. Distension of the stomach and intestines may embarrass those with certain heart and lung conditions by interfering with diaphragmatic movements. Usually, however, alimentary tract distension is automatically relieved by the passage of flatus. It is in the interests of those prone to flatulence to ensure a good evacuation of the bowels before flight, to abstain from gas-producing foods (legumes and excess of carbohydrates), to avoid overeating during the journey, and to absorb some of the gas by means of charcoal biscuits.

Noise and Vibration in Aircraft

Noise and vibration of certain frequencies and intensities if continued are disturbing, induce fatigue, and contribute to the onset of airsickness, all of which are apt adversely to affect invalids. Most of the noise and vibration experienced when flying is derived from the engines, though some is from aerodynamic turbulence over the skin of the aircraft. Modern airliners are designed to reduce these defects as far as practicable by using sweeter running engines, by efficiently muffling and orientating exhausts, and by sound-proofing cabins. These measures have proved most effective in jet and turbo-jet aircraft, especially in the former, owing in part to the absence of propellers and pistons and in part to the fact that the engine noise is mainly of high pitch, which is more readily damped down or cut out by sound-proofing than is the lower-pitch noise of the piston engine. Cotton-wool is handed out in all aircraft so that those susceptible to noise can plug their ears; alternatively, passengers can provide themselves with rubber ear-plugs, but these are no more effective than moistened cotton-wool. Such plugs are not really needed in jet and turbo-jet aircraft, which are as quiet as most saloon cars.

Airsickness

It is appropriate now to consider airsickness, or motion-sickness, as a number of predisposing factors have already been mentioned—namely, bumpy weather, oxygen want,

fatigue, flatulence, noise, and vibration. Airsickness is rare in pressurized aircraft, which fly above the weather; in fact, the incidence is about 0.6% of all passengers carried, and even then it is usually only a temporary occurrence during ascent and descent when flying through cloud or regions of changing air temperatures in warm climates. It is important, however, to safeguard invalids against airsickness, particularly diabetics, pregnant women, and those with gastro-intestinal lesions such as ulcers and post-operative conditions.

Fortunately, airsickness can be prevented in most cases by the simple expedient of swallowing 1/100 gr. (0.65 mg.) of hyoscine hydrobromide half an hour before the time of take-off. Children under 15 years of age should be given half this dose. (Incidentally, hyoscine has been proved by the U.S. Air Force to be more efficient as a preventive of airsickness than the antihistaminic drugs.) It is rarely necessary to repeat the dose, as acclimatization to aircraft motion develops quickly in most instances, especially if steps are taken to minimize other predisposing factors. It is advisable, therefore, for invalids to be well rested before and during the journey, to obtain a good evacuation of the bowels before flight, to keep comfortably warm, and to plug their ears with cotton-wool to lessen noise.

Motion is felt less near the centre of the aircraft than towards the tail, so seats for invalids are specially allotted. Those who are particularly susceptible to travel-sickness should relax, lie back in their seats, and look upwards, so as to prevent over-stimulation of the labyrinths.

Immunization Requirements

In accordance with the International Sanitary Regulations of the World Health Organization, which came into force on October 1, 1952, passengers undertaking international air travel have to be in possession of certain immunization certificates, depending on the place of departure, the countries of transit, and the destination. For most journeys the would-be traveller must have been vaccinated against smallpox within three years, and, if it is intended to pass through or leave a yellow fever zone, immunized within six years against that disease. When travelling from or through cholera endemic areas, inoculation with anti-cholera vaccine is necessary within a period of six months. The immunizations done must be recorded on the international vaccination certificate form prescribed by the World Health Organization, dated* and signed by the doctor doing the inoculations, and in the case of yellow fever vaccine its origin and batch number must be stated.

Each certificate must then be authenticated and stamped by an authority approved for the purpose by the health administration of the particular country—that is, the Ministry of Health so far as England and Wales are concerned. The approved authenticating authority in England and Wales is the health officer of the town council, urban district council, or rural district council in whose area the doctor practises. These certificate forms are obtainable from the airline company or travel agency concerned or from the Government health department, except those for yellow fever vaccination, which are held at certain recognized centres. Details of immunization requirements can be obtained from the medical or traffic department of the airline concerned, or from the embassies, consulates, or other Government representatives of the countries to be visited. It is most important that travellers should have these certificates completed in all details and have them available with their passports throughout their journey, otherwise they are liable to be subjected to delays, compulsory vaccination, or surveillance, detention in quarantine, or to a fine.

Vaccination against smallpox and yellow fever should not be done at the same time, especially primary vaccination, as this increases the risk of encephalitis. Vaccination against yellow fever should always precede that against

*The date should be written thus, 3/X/52, to prevent misunderstanding, as in some countries the month is recorded in front of the day.

smallpox, because if primary vaccination were done first there would have to be an interval of twenty-one days before giving the yellow fever vaccine. A convenient scheme of inoculations, when all are needed, is as follows: First day: vaccination against yellow fever, cholera, and typhoid group (first T.A.B.); fourth day: vaccination against smallpox; seventh to ninth days: second dose of T.A.B. vaccine, after reading and recording the result of primary vaccination.

If it is decided that it is best for medical reasons not to give a required vaccination, the doctor concerned must certify the fact. It must be appreciated, however, that such individuals may be refused entry into certain countries or be detained in quarantine, and that the airline carrying such persons may have to remove them from the country at its own expense or pay a fine, and the aircraft may be detained. In any case a form of indemnity must be signed by a person who proposes to travel without any necessary certificate of vaccination: this is required to free the airline from any liability if the passenger meets with difficulties or expenses en route or on arrival. Conscientious objectors to vaccinations are treated in the same manner as those without valid certificates.

[Part II will appear in our next issue.]

Nova et Vetera

AN EARLY CASE OF HAEMOLYTIC JAUNDICE OF THE NEWBORN

During the last few years light has been shed on the condition whereby newborn infants used to perish in a deeply jaundiced state within a few days of birth; before the discovery of the Rhesus factor in the blood and its significance for the infant the occurrence of fatal jaundice which started soon after birth was a sad and hopeless problem. Lately, in searching through some letters written to Sir Hans Sloane and now preserved in the British Museum, one was found which is of historical significance and which, by the kindness of the authorities of the Museum, I am able to reproduce here. It was written to Sir Hans by Dr. George Cheselden, of Leicester, probably a distant relative of William Cheselden. It is dated Leicester, February 25, 1729, and runs as follows:

"At the request of a patient of mine (the bearer) I give you the following short account. The case of the gentlewoman has been very extraordinary. She has had the misfortune to lose 3 fine boys who came into the world with very healthful symptoms for the first 2 days and then the strongest signs of an icterus appear'd the epidermis being all over tinctur'd alike which bad symptoms prov'd most certainly mortal in a few days medicine being of no service to the infants.

"The mother for the generality has good health even when with child only, give me leave to observe that a few days after her quickening her water changed into a true jaundice colour as high as possible and so continues till she is deliver'd, and then as well as usual. Evacuations of all kinds we have made use of in vain alteratives chalybeates and advis'd to no purpose. Last year I advis'd to Scarborough with no better success.

"The last child to all outward appearance was a healthful one excepting the febrile disorder. I therefore importuned the parents that I might examine the Vesica Fell. Ductus Communis in which we found nothing amiss, all the viscera intirely perfect the liver not larger nor harder than common no stone nor obstruction any where nor decay in any part nor any part emaciated. The mother's habit of body you'll be better able to judge than I can represent in any letter. I hope that you'll be so good as to put the lady into a more successful method which I do assure you will give a great deal of satisfaction to

sir, your most obedient and humble servant

GEORGE CHESelden

"P.S. One line will be esteemed a favour."

There is no record of the reply from Sir Hans Sloane but it is to be feared that it would not have contained any solution for the problem propounded.

V. Z. C.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Assistance for Doctors in Flood Areas

SIR,—You kindly published my letter in the *Journal* (February 14, p. 399) in which I appealed to members of the profession to send donations to the Sir Charles Hastings Fund in order that the Trustees might give some immediate assistance to those doctors who have suffered in the recent floods. The response to my appeal has been most gratifying, and through the generosity of certain local medical committees and many individual members of the profession a sum of £1,200 has been received. In addition, through the Canadian Medical Association, our colleagues in Canada have most generously sent a splendid gift of \$1,000. Furthermore, the Trustees of the General Medical Services Defence Trust have very kindly decided to make available to the Trustees of the Hastings Fund moneys for immediate assistance up to £5,000 as and when necessary. As a result of this response the Trustees have been able to make gifts to certain doctors who have sustained considerable loss and whose houses have been severely damaged as a result of the flood waters.

The Trustees are anxious to give all further assistance that may be needed and hope that all doctors who have suffered on account of the floods, or anyone knowing of their difficulties, will not hesitate to write to the secretary to the Trustees. The question of long-term arrangements with regard to individual practices in these areas is already under discussion between representatives of the General Medical Services Committee and the Ministry of Health.

May I repeat that contributions should be sent to the secretary of the Fund at B.M.A. House, Tavistock Square, London, W.C.1, cheques being made payable to the Sir Charles Hastings Fund, and the envelopes marked "Flood Relief."—I am, etc.,

E. A. GREGG,
Chairman of Council.

London, W.C.1.

Ciba Foundation's Colloquia on Endocrinology

SIR,—In his pleasant review of four volumes of the Ciba Foundation's *Colloquia on Endocrinology* (February 21, p. 440) Dr. C. L. Cope commented that "it is disturbing to find that about two years have elapsed between the holding of many of these colloquia and their appearance in book form. . . . Speedier methods of publication must be found if these reports are adequately to serve the purpose for which they are intended."

In fairness to our publishers, I should like to explain that the unfortunate delay in some of these instances was due in part to my failure to anticipate the demand for publication of the earliest informal meetings, in part to my inexperience in having the whole of the proceedings of these first conferences electrically recorded, with all that meant in later transcription—a hard lesson—and in part to the fact that, when meetings are held of people from distant parts of the world, texts of the general discussions and proofs of papers have later to be sent equally far afield for correction—one contributor alone has held up publication of a volume now in the press for four months. Further, I should mention that the first of the volumes reviewed by Dr. Cope was published ten months ago.

So far as "speedier methods of publication" are concerned, I should point out that it is never intended that the conferences held at the Ciba Foundation should provide occasions for the announcement of completed research; rather we prefer to discuss problems in current research,

and any value in the subsequent books is mainly due to the collection within one cover of facts and thoughts published, or about to be published, elsewhere, but scattered throughout the world's literature.

The time taken over some of the volumes now in the press will, we believe, compare not unfavourably with the delay in publication of articles in some of the best-known special journals. The fact that our book *Isotopes in Biochemistry* was published in less than seven months shows how excellently our publishers, J. & A. Churchill Limited, carry out their side of the business when given the chance.—I am, etc.,

London, W.1.

GORDON WOLSTENHOLME,
Director, Ciba Foundation.

The Backward Child

SIR,—I agree with Dr. Brian H. Kirman (February 7, p. 334) that as a rule it is undesirable to classify pre-school children as "ineducable." Moreover, where an occupation centre is not available, as in many parts of the country, and the child is attending the infants' class of a school, and the teacher is satisfied with his behaviour, classification and notification are not indicated either.

The terms "educable" and "ineducable" do not separate children into watertight compartments, but must be interpreted not only in the social setting but in the light of advances in psychology and education. The latter is clearly veering away, although slowly, from a mechanistic philosophy. Theoretically, at least, secondary education is conceived not as a separation of the "superior" and "inferior," but as a differentiation into qualitatively different cultures.

In Glasgow, where I practised for some years, the term "special" has been abandoned in the designation of schools for "educationally subnormal" children. Since the modern "occupation centre" provides a wide range of stimulus patterns for the varied interests and levels of insight of relatively retarded children, whose response to adequate stimulation is obvious, it merits *par excellence* the generic title of an educational establishment—that is, school.—I am, etc.,

Perranporth.

D. JACKSON.

Christmas Disease

SIR,—Dr. Rosemary Biggs and her colleagues are to be congratulated for their excellent article (December 27, 1952, p. 1378). In this important paper it is pointed out that two individuals, both exhibiting clinically indistinguishable evidence of haemophilia, may actually lack two quite different substances from their plasma. The methods used and the results obtained are the same as those reported earlier in 1952 by Schulman and Smith.¹ The purpose of this letter is to protest against the name "Christmas disease" which has been adopted by Biggs *et al.*, because this name suggests a holiday rather than a haemorrhagic blood dyscrasia.

Since the patients exhibit a syndrome having haematological, clinical, and genetic features identical with those of classic haemophilia, it is not clear why the diagnosis of haemophilia is not applicable to these patients as well. As the authors point out, at least two substances exist in the plasma, a deficiency of either of which can give rise to a haemorrhagic disease. If these substances are designated by the numbers I and II, respectively, then the two corresponding haemorrhagic diseases could be designated as haemophilia I and haemophilia II, the former referring to the more commonly occurring type. Since at least two varieties of haemophilia exist, there is a possibility that there may also be a third or a fourth variety. This simple terminology, which is similar to that used by Schulman and Smith in their article, would allow for possible expansion should this become necessary as a result of future investigations. In the letter by Dr. Biggs and her colleagues (January 24, p. 221) the possibility of names such as haemophilia A and haemophilia B (or haemophilia I and haemo-

philia II) is discussed but rejected. The authors argue that the designation should emphasize the differences in the disease. However, all advances in scientific knowledge have always depended on the discovery of universal laws governing seemingly dissimilar phenomena, and, in fact, biological classifications are based primarily on similarities rather than on differences. Probably haemophilia I and haemophilia II (or haemophilia A and haemophilia B) are transmitted by corresponding allelic sex-linked genes (h^A and h^B). In this connexion it is of interest to notice the appearance of an article containing evidence of still another allelic form (h^m) of haemophilia.⁷

These remarks must not be misconstrued as evidence that the undersigned considers differences unimportant. In fact, two important sciences, genetics and blood grouping, arose entirely from the study of individual differences. In the designations haemophilia A and haemophilia B the existence of differences is clearly indicated by the letters, and at the same time proper emphasis is placed on the fact that these are both haemorrhagic blood diseases. In the name "Christmas disease," on the other hand, any emphasis is completely misplaced.—I am, etc.,

Brooklyn, New York.

Mental Hospital Service

SIR,—The Minister of Health is reported (*The Times*, February 6) to have said at the annual conference of the National Association for Mental Health that 8,000 persons, including a large number of children, are awaiting admission to mental hospitals. It is not possible to be sure how many patients are awaiting admission to mental hospitals proper, but it is certain that the majority of mental hospitals are overcrowded, some grossly so, and that many potential voluntary patients are being denied the help that in-patient treatment could give. There are many reasons for this. The poor facilities for the proper classification of patients due to overcrowding and out-of-date buildings are one important reason. Cases of psychoneurosis are too often mixed with psychotics in the same ward. Perhaps the most telling reason of all must be the inability of the average medical and nursing staff of a mental hospital to deal with any great number of voluntary patients suffering from neurosis or psychoneurosis. Psychiatrists know that the starting of a vigorous out-patient department soon greatly increases the number of voluntary admissions—a measure of a state of great and still largely unrelieved mental suffering in the community. Providing for the treatment of great numbers of early psychotic and neurotic patients requires careful consideration and planning if we are not to make serious mistakes.

The clinician working in a mental hospital is faced with two main clinical problems; first, the care of a large population of chronically mentally ill patients, most of whom will never leave the hospital, and, secondly, the active treatment of the new cases, usually at the rate of some hundreds a year. The way to avoid overcrowding and the frustration of being overwhelmed with both chronic and acute patients is not necessarily to provide still larger and more elaborate buildings. The two things that would do more than anything else to lessen the problem of mental illness would be to pursue an energetic programme of clinical treatment to prevent patients becoming chronic, and to provide adequate domiciliary and aftercare services for patients who have left hospital. We are convinced that the number of chronic patients being produced every year can be greatly lessened. It requires only the right sort of will and the necessary time and skill. Pinel managed it 150 years ago, with no "modern forms of treatment" (Pinel, P., *A Treatise on Insanity*, 1806).

We would submit some suggestions for improving the present state of affairs. In the hospitals themselves it would be better to spend money on providing more psychiatrists, particularly those skilled in psychotherapy and group therapy, rather than on providing new buildings and more beds. Junior staff are just as important, and every mental hospital should have its own registrars and carry out its own psychiatric training. In connexion with this, far more regional facilities for taking the D.P.M. are required. Occupational therapy should be developed towards

providing active rehabilitation for acute and recent cases rather than for providing occupation for chronic patients. The services of social workers need to be vastly extended, and their training should be based on the mental hospitals, so that psychiatrists can have the kind of service from them that they really need. Outside the hospitals, training centres exclusively for ex-patients and out-patients are greatly needed, as also is the need for group therapy at out-patient clinics. Perhaps the greatest single need is for psychiatric out-patient clubs, not run as a means of recreation for chronically mentally infirm patients, but staffed by one or more psychiatrists and a team of social workers and designed as active treatment units. Such clubs would, in our opinion, greatly reduce the number of readmissions—those dismal evidences of our failure who lower morale among both patients and staff.

A final word about "neurosis centres." These could be cheaply built on the lines of the many wartime hutted hospitals. The psychiatrists who oppose neurosis hospitals do so on the grounds that the mental hospitals will then only receive chronic patients. This difficulty could be overcome if the neurosis units were administered by the medical superintendent. This control could extend to neurosis beds in general hospitals. Every mental hospital would then have, in effect, three types of admission wards—one for the neurotic and early psychotic patients, the second for disturbed psychotics, and the third for elderly psychotic and demented patients. If neurosis centres are not allowed to become independent, nobody need fear that all the interesting and recoverable cases will pass out of the hands of the mental-hospital psychiatrist.

Our problem is, and will be for a long time to come, that there are already far too many patients for us to have time to treat properly. We would suggest that the Minister should consider the setting up of a small national committee to design a plan for the future of the mental hospital service.—We are, etc.,

Worcester.

R. A. SANDISON.
A. M. SPENCER.

The Metric System

SIR,—Dr. C. Langton Hewer's purist (February 21, p. 450) would be quite correct to speak of his blood count as 5 million per cubic millimetre, and at the same time to hold up his hands in horror if one referred to, say, his output of urine in cubic centimetres. This is because the volume of diluted blood in the haemocytometer chamber is based on linear measurements and so is correctly expressed as a unit of length cubed, whereas measures of volume like the litre are not.

The original idea of the French Government was to have all measures of length, volume, and mass based on a natural standard or metre—the ten-millionth part of a polar quadrant passing through Paris. Difficulties, however, led to an artificial standard metre being adopted and then an artificial standard of weight, the kilogram, not based on the metre. The unit of volume or litre was defined as the volume of a kilogram of water. As this kilogram is not strictly related to the metre the thousandth part of a volume of water of equal weight is not related to the metre either. It is not a cubic centimetre but is called an ml. (Incidentally the word "mil" is an engineering term for the thousandth part of an inch, now generally referred to as a "thou.")

Dr. Hewer's objection that 3.55 ml. per 6.35 kg. is hard to remember is not really a serious one. Surely doses are not so strict as all that and an expression in terms of the nearest ml. and round kg. would serve.—I am, etc.,

Enfield.

C. ALLAN BIRCH.

SIR,—With reference to your leading article on the metric system (February 7, p. 320), may I say that the older system is actually very safe and convenient in practice; that Professor W. C. W. Nixon and Mr. T. D. Whittet (p. 327) very much underestimate the difficulties in making a complete change; and that, so far as I know, the Association has never committed itself to the policy you advocate.

I am, however, much more concerned to point out what the older system of weights and measures actually did. In the days when counting was not so common as it is to-day different names were given at small intervals for the

measures most commonly in use, with units above and below these at much wider intervals. This holds broadly for weights, and measures of length and capacity. In fact, though many intermediate measures such as ell, gill, etc., were used, our forefathers had produced something like a logarithmic scale on either side of the common mean. This may not suit the age of comptometers and mechanization, but it was adapted to the needs of the time, it was a fumbling after something even more advanced than decimalization, and it minimized the chance of errors (which are very serious with decimal points). It ill becomes doctors to forget that measures were made for man and not men for machines.

The change-over may be inevitable, but let us credit our ancestors with possessing a sense of proportion which your article and that of your contributors signally fail to show when they compare the change-over in helm orders—which from the nature of the case had to be done universally at a given time—with a change which entails the re-marking or scrapping of most of the weights, measures, and containers in most of the dispensaries and chemists' shops in this country.—I am, etc.,

Winsford, Cheshire.

W. N. LEAK.

The General Practitioner and Mass Radiography

SIR,—May I correct any false impression that it is universal practice to disallow general practitioners direct access to x-ray departments for the radiological investigations of their patients? The services of the x-ray departments under my charge have been available to general practitioners for the past five years. In the case of simple chest skiagrams, patients are x-rayed and reports reach the practitioners within a few days of the request being made. This is the routine practice, but where it is indicated that a more urgent examination is required suitable arrangements can be made to meet the needs of the case. In addition to the above service one of the hospital x-ray departments is also providing facilities for the x-ray examination of every case referred to the chest clinic, since the latter is housed in the main hospital building and has no independent radiography unit of its own. The area concerned has a population of 200,000.

Before, therefore, embarking on the scheme proposed by Dr. F. A. Nash and his colleagues (February 7, p. 304) consideration should be given to the possibility of getting freer use, for all interested parties, of the facilities which the main x-ray department of the hospital can provide. This service would, of course, be additional to the periodic surveys of the mass radiography unit.—I am, etc.,

Halifax.

R. I. LEWIS.

SIR,—I was pleased to see prominence given recently to routine diagnostic chest radiography services for general practitioners, both in the article by Dr. F. A. Nash, Mr. B. Benjamin, and Dr. T. J. Lee (February 7, p. 304) and in your annotation (p. 322). In particular the conception of relatively minor symptoms possibly representing early pulmonary tuberculosis is of considerable importance and can always bear repetition. Diagnostic delay is still all too common because radiographic action is not taken on symptoms alone, as it should be. Accepting that routine radiography on suspicion can go a long way to improve this position, the problem is how to provide the necessary radiographic facilities. In many areas a service similar to that described is being provided by the chest clinics in spite of the increased work thrown upon them by the shortage of sanatorium beds and the increased use of the clinics by practitioners for routine consultation on pulmonary problems. This suggests that the chest clinic fulfils a very real need, and in my opinion the time has come to consider whether the population (often 200,000–300,000) served by individual chest clinics is not very much too big.

The modern chest clinic is providing important and widely appreciated facilities which are becoming increasingly used. This service could be much more efficient were the popula-

tion served by each clinic (as at present constituted) considerably smaller—certainly not larger than 100,000 in urban areas. It would then also be possible for routine diagnostic radiography for general practitioners to be undertaken more easily. There is a much greater "recall" rate with such schemes than with routine mass miniature radiography as at present practised, and it is logical that chest clinics should undertake the work in such circumstances. Odelca camera units in chest clinics would facilitate this, and they have already been installed with considerable success in a number of clinics. Existing mass miniature radiography units could thus be used for the larger scale mass surveys in "black" areas which are still needed. Later, or at present if local conditions dictate, such units could undertake part of the work involved in routine radiography of practitioners' cases.

May I now correct two small errors? In referring to my work, Nash, Benjamin, and Lee state that the cases investigated were seen at Hammersmith Chest Clinic. In fact the particular investigation referred to was undertaken at Willesden Chest Clinic. Furthermore, the article reference is incorrect; it should read *British Medical Journal*, 1948, 2, 832. The *Lancet* reference given is my letter to the editor on another tuberculosis problem.—I am, etc.,

London, W.12.

PETER STRADLING.

Cortisone and Tuberculosis of the Lung

SIR,—Dr. T. M. Ball (February 14, p. 404) and Mr. D. Chalmers (January 17, p. 159) inquire whether any work is being undertaken in this country on the combined use of A.C.T.H. (or cortisone), streptomycin, and P.A.S. in pulmonary tuberculosis. I described a case so treated at the Oxford Conference on Diseases of the Chest in July, 1951 (*British Medical Journal*, 1951, 2, 296), and in November, 1952, I reported upon 10 further cases at a meeting of the British Tuberculosis Association. It is hoped that these results will shortly be published.—I am, etc.,

Harefield, Middx.

L. E. HOUGHTON.

Lung Resection for Pulmonary Tuberculosis

SIR,—Dr. F. H. Young (February 7, p. 287) has given us a very valuable account of his views of the present status of lung resection for pulmonary tuberculosis based on a long and extensive experience of this disease. One is surprised, however, to read the opening statement of his paper in which he says, "In few conditions is there such a difference in the point of view of physicians and surgeons as in the treatment of pulmonary tuberculosis." With the development of fully organized services for the treatment of this disease this divergence in view must be progressively diminished, as in the conjoint conferences of sanatorium physicians, area chest physicians, and surgeons any major difference in opinion becomes ironed out by the general discussions and presentations of successes and failures. The mythical side of the treatment of pulmonary tuberculosis rapidly becomes eliminated by frank inquiry and particularly by the long-term observations of the area chest physicians, which supplement the views put forward by those who work only in the hospital or sanatorium.

The concept that Dr. Young suggests some of us in Liverpool hold, that pulmonary tuberculosis is a localized disease, has not been interpreted correctly by him. In the stage of primary invasion by the tubercle bacillus, when the lymphatic system is wide open, a bacteraemia is usual, but in the later stages or in the stage of reinfection it is likely that the disease remains confined in most cases to the lungs. Occasionally we do see evidence of a bloodstream spread at this stage, but it is unusual. There is a general reaction of the body to this relatively localized disease, producing antibodies, white cells, etc., and cellular changes occurring in various organs due to circulation of toxins. It can be compared to a boil on the back of the neck in its general reactions, yet this is a condition which I would still call a localized disease. It is customary to state in most articles on pulmonary tuberculosis that "of

course we must never lose sight of the fact that pulmonary tuberculosis is a generalized disease." I would like a fuller explanation of this statement.

Dr. F. H. Young asks the most interesting question: "Why did the patient get the diseased area which has been removed?" He does not vouchsafe an answer to this. Does he believe that these are usually reactivation of some remnant of the primary infection? Although this not infrequently does occur, the history of most cases would suggest that exogenous reinfection is the main responsible factor.

I agree that bronchial stenosis, whether of the main bronchi or the lesser bronchi, is an important indication for resecting the affected area. Its presence can be assumed by the examination of serial radiographs in many cases, but in our experience (and we do some 300-400 bronchoscopies a year in tuberculous cases) it is relatively rare to find any evidence of permanent stenosis in the bronchoscopically visible bronchial tree. Dr. Young is most kind and complimentary to us in Liverpool on the low mortality rate of the operation of resection in our hands. I do not think the type of material varies greatly from that operated upon elsewhere, but the timing of the operation does, and this is the factor of importance. It is only by the very closest co-operation between physicians and surgeons that the timing of the operation can be accurately gauged in the best interests of the patient.

In a conjoint paper published recently (*Thorax*, 1952, 7, 310) we, both physicians and surgeons, laid down our guiding principles for submitting cases to resection, and it would be of interest to recall these: (1) Resection is undertaken of (a) an area which remains persistently active despite bed rest, chemotherapy, and simple relaxation therapy, and (b) an apparently "quiescent" area which experience indicates may reactivate with stress or intercurrent infection. (2) Resection is only undertaken when the body defences are fully mobilized. (3) The maximum localization of the disease is obtained by simple means before resection is undertaken. (4) Treatment as above usually leaves one or more areas of confluent disease and small scattered foci. The confluent areas are assessed as to likelihood of healing and resected if doubtful. The scattered small foci are unlikely to reactivate if hyperexpansion is not permitted. (5) Primary lesions only require excision if activity persists after all other forms of treatment. (6) The continued activity of a caseous pneumonia following gland rupture may require removal of that area. (7) Resection under 16 is only carried out after long activity owing to the recognized better tendency of children to heal their tubercle. (8) Between 16 and 20 the disease is unstable and resection is only carried out in these age groups on the clearest indications. (9) Hyperexpansion of remaining lung tissue must not be allowed. (10) Resection is not carried out through an area of active tuberculous endobronchitis.—I am, etc.,

Liverpool.

F. RONALD EDWARDS.

Intra-arterial Injection of Thiopentone

SIR.—I read with interest Dr. J. W. Dundee's letter (February 14, p. 402). He suggests that where thiopentone has been accidentally injected into the brachial artery the correct treatment would be to induce a brachial plexus block with 1% procaine, at the same time blocking the stellate ganglion and then injecting 40 mg. of papaverine into the subclavian artery. Kinmonth¹ has pointed out that sympathetic nerve fibres are responsible for neither the initiation nor the maintenance of spasm in the large arteries and paravertebral sympathetic blocks, or such procedures as blocking the brachial plexus have no place in the treatment. I can confirm Kinmonth's observations and conclusions from personal experience.

The most effective way of treating arterial spasm is to inject a vasodilator drug (and of these papaverine appears to produce the best results) either into or around the affected artery. It is pointless to attempt to inject a vasodilator

drug into the subclavian artery when the same effect can be obtained more speedily and much more easily by injecting it into the needle which is already in the brachial artery. I have not, fortunately, had the need to test the efficacy of intra-arterial injection of papaverine in order to counteract the results of thiopentone, but, in association with Dr. H. S. Pemberton, I have confirmed its almost miraculous power in relieving spasm due to other causes.—I am, etc.,

Liverpool.

J. B. OLDHAM.

REFERENCE

¹ *British Medical Journal*, 1952, 1, 59.

SIR.—Dr. J. N. Fell (January 10, p. 95) and Dr. J. W. Dundee (February 14, p. 402) both make it clear that the risks of accidental intra-arterial injection of thiopentone are ever with us.

In order to prevent the occurrence of this event, which may have serious consequences for the patient, is it not time that the teaching of the technique of venepuncture was altered? Practically every textbook where the technique is discussed recommends the use of veins in the antecubital fossa for withdrawal of blood or for intravenous injection. Your own expert in "Any Questions?" (January 10, p. 115) recommended this site for the former purpose. So long as the area on the anterior surface of the forearm is recommended as the situation of choice for venepuncture then reports of accidental intra-arterial injection will keep on occurring in the literature. I suggest, therefore, that an alternative site be used as the standard site for intravenous injection for three reasons: (1) Cohen, in a masterly paper (*Lancet*, 1948, 2, 361 and 409), states that high division of the brachial artery occurs in one out of ten arms, and that the vasa aberrantia are found on the anterior surface of the forearm. (2) The most usual drug for anaesthetists to inject intravenously is thiopentone, and a 2.5% solution of this drug in water has a pH of 10.4 to 10.6 by the glass electrode method. An alkali may be injected intravenously with impunity, but not so into an artery, where the intima is particularly sensitive to solutions of high pH, and, in any case, the superficial aberrant arteries on the front of the forearm, like other superficial arteries, have a fuller nerve supply than deeper branches, so they are more readily thrown into spasm. (3) To perform venepuncture in the antecubital fossa the forearm must be fully supinated, the arm partly abducted, and the humerus laterally rotated. With the upper limb kept in this position so that antecubital fossa veins may be used with a Gordh-type needle for repeated injections of various drugs during anaesthesia, the risk of producing a brachial plexus palsy in addition is greatly increased. To take an unjustifiable risk is folly, and venepuncture at the bend of the elbow exposes the patient to the very real twofold risk of arterial puncture and brachial plexus palsy.

The veins on the dorsum of the hand, however, are not likely to be accompanied by arteries, and successful venepuncture here can be accomplished only with the hand flexed and fully pronated, so the risks of both arterial puncture and of brachial plexus palsy are avoided. Further, the veins here are virtually constant in position from earliest infancy onwards, and they are so large that a transfusion needle or a Gordh-type needle may be inserted into them with ease, even in very small children. Venepuncture here is no more and no less painful than it is anywhere else. The disadvantage of this site is that, on withdrawal of the hollow needle, unless firm pressure is applied over the vein distal to the point of puncture, blood may flow out of the puncture hole as it may in any other site. On the dorsum of the hand ecchymosis, however caused, is more noticeable to the patient and his family than at the end of the elbow, but ecchymosis is a small price to pay for freedom from the effects of arterial spasm.—I am, etc.,

London, N.W.5.

JOHN HENDRIE.

Methorphan in Anaesthesia

SIR.—In reply to the letter of Dr. R. J. Whiting (January 31, p. 271) following the publication of my paper on methorphan as a supplement to nitrous oxide and oxygen anaesthesia (December 20, 1952, p. 1331), in my experience nausea occurs in about 5% of cases, but on one occasion only has it been prolonged or severe. I was interested to

note that Drs. J. H. Crawford and Rex Binning (January 31, p. 272) have had to administer larger dosage, but I can only confirm my previous statement that in my experience the dosage I recommended was adequate.—I am, etc.,

Dartford.

A. K. BROWN.

Sensitivity to Antibiotics

SIR.—As a physician with a special interest in allergic diseases I am impressed by the increasing numbers of cases of contact sensitivity to the antibiotics occurring in the medical and nursing professions. Penicillin and streptomycin are the major offenders, mainly owing to the fact that a trained person is required for each administration. Medical practitioners are fortunate on the whole, since they are able, once their sensitivity is recognized, either to take detailed precautions when handling the material or, more simply, to delegate the injection to someone else. Nurses are in a less privileged position, and this is particularly the case with district nurses, who in the course of their domiciliary duties find that a great proportion of their work consists in giving such injections.

Symptoms are frequently mild at first, involving only the interdigital or peri-orbital areas, and may pass unrecognized for a time; but with recurring contact the condition spreads and may become very severe indeed. No satisfactory method of hyposensitization has yet been devised, and once a serious degree of sensitivity has been acquired a minimal contact with the antibiotic may produce a widespread reaction of great severity and long duration. When such a reaction has once occurred it seems unlikely that the individual will ever again be able to return to normal routine duties, and this may mean the end of a career to which many years have been devoted. The condition is not as yet regarded as an occupational hazard.

It would appear that while more and more strains of bacteria are becoming antibiotic resistant, more and more human beings are becoming antibiotic hypersensitive. In my opinion, the following precautions represent the minimal efforts which should be made to combat this tendency, which may soon reach serious proportions: (1) Rubber gloves and a face-mask with "cellophane" visor should be used while filling a syringe, giving the injection, and cleansing the syringe. (2) Syringes used for this purpose must fit perfectly and there should be no leak round the piston or at the head of the needle. (3) In hospitals or clinics where penicillin and streptomycin are largely and constantly used (chest units, V.D. clinics, etc.), or on the district, patch tests should be performed on each nurse at the time of appointment, after three months' service, and again at regular intervals of, say, three to six months. Subclinical hypersensitivity might thus be demonstrated in time to forestall the outbreak of the rash by partial or complete avoidance of contact. (4) If symptoms do develop in a nurse, the advice given to her must depend on circumstances. At probationer level she would be well advised to give up nursing entirely: if partly or fully trained, she should be guided into administrative duties or encouraged to train as a health visitor; in the case of a district nurse, the local authority should be urged to make every effort to arrange her duties so that she need never handle a syringe again. (5) The occurrence of severe clinical hypersensitivity should be regarded as an occupational hazard.—I am, etc.,

Liverpool

D. BLAIR MACAULAY.

Export of Antibiotics to China

SIR.—Press reports¹ and questions² in the House of Commons have stated that an order placed in this country by the China National Import-Export Corporation for £500,000 worth of sulphonamides and antibiotics (including streptomycin) could not be met because export licences were not granted. We are not concerned with the effect of the embargo on British trade, but we are concerned with its effect on international medical relations. According to the Secretary for Overseas Trade³ the export of streptomycin "is not prohibited, but it is limited to normal civil require-

ments," and, in answer to a later question, he stated⁴: "The permissible export by the United Kingdom to meet China's normal civilian requirements of antibiotics and sulpha drugs has been estimated by reference to our exports to China and Hong Kong of these drugs in the first six months of 1950." Direct inquiry to the Board of Trade, so we are informed, indicated that no streptomycin was exported to China or Hong Kong in that period, and it would appear, therefore, that there is a complete embargo on the export of streptomycin. In contrast, the need is immense, and it has been variously estimated that there are 30 million cases of tuberculosis in China and that the annual civil requirements may be of the order of 50 million grammes. Even in time of war many doctors have not satisfied themselves that it is proper to withhold supplies needed for the medical treatment of enemy wounded. That this country, which is not at war with the Chinese people, should deliberately withhold a drug which is recognized as a specific for certain particularly fatal forms of tuberculosis and which—in combination with sulphonamides—is the standard treatment for plague, is inexcusable.—We are, etc.,

"Lente" Novo Insulin

SIR.—The publication by Drs. R. D. Lawrence and Wilfrid Oakley (January 31, p. 242) of a preliminary trial of lente insulin is a contribution to the ideal of one dose of one insulin per day, and it is to be hoped that the absence of a substance such as protamine or globin may allow a more uniform rate of absorption from the subcutaneous space. Hitherto a single dose of protamine zinc insulin has been satisfactory in a limited number of cases, while globin insulin given alone has been more widely useful. In 1948 I published a series of blood sugars of 21 in-patients¹ which may be compared with the lente series of 11 patients.

	Average Blood Sugars in mg. %				
	6 a.m.	8 a.m.	Noon	6 p.m.	9 p.m.
11 patients on lente insulin	128	131	168	162	167
21 " " globin "			151	158	

These averages are worked out from the figures given in the two papers; the variations are not great. Lawrence and Oakley (excluding case 8 on the smaller dose of lente): minimum 67 mg. %, maximum 260 mg. %. Wauchope: minimum 62 mg. %, maximum 256 mg. %.

The real test is, of course, the ambulant treatment of out-patients, for which we must wait till lente becomes available for general use. But meanwhile globin does pretty well. I have gone through the notes of 180 patients—20 young people (ages 5 to 20), 55 men (ages 21 to 65), and 105 women of the same age. They are not selected except by the accident of initial and have all been on globin insulin for at least one year since my last survey in 1948. I have excluded the large number of people over 65 who are generally stable on any insulin.

The doses of globin insulin are as follows:

	Units			
	Under 20	21 to 40	41 to 60	61 to 86
Young people aged 5 to 20		3	7	10
Men 21 to 65	21	16	15	3
Women 21 to 65	23	47	29	6
Total	44	66	51	19

Stability is judged by wellbeing and ability to work, constant weight, absence of insulin reactions, polyuria, or ketosis. These criteria have been maintained in the great

majority with reasonable noon blood sugars and little sugar in the morning urine tests. There are three groups where the balance is not good: (a) One young man and one middle-aged man who reported polyuria at night and are now taking a single dose of P.Z.I. with success. (b) Those who report minor insulin reactions and/or alternating bouts of thirst and polyuria. Their blood sugars vary from about 60 mg.% to about 300 mg.%. Changes to other insulins, even to two doses of soluble insulin, do not produce a lasting balance. There are two men, three women, and two children in this group. (c) A group of one man, six women, and two children who have been brought into hospital in a severe insulin reaction or in ketosis or coma. They have been re-stabilized, sometimes more than once, and other insulins have been tried, but they remain unstable. In all about 10% have not been really well balanced on globin insulin, and I fancy this does not differ much from the records of patients of this age on any of the present methods of insulin therapy.

These notes may serve as a yardstick to assess lente insulin when it becomes available, and it is to be hoped that the management of diabetes will become more simple and that some at least of the present "strengths" and varieties of insulin will be eliminated.—I am, etc.,

Hove.

The Catheter and the Prostate

SIR,—Is it seemly to interject among the pundits, "That depends upon the catheter"? An F.B. that fills frets the urethra. If trouble follows, do we ban the simple device or discriminate by deftly passing a loose-fitting No. 6/E Tieman catheter? For this tip—when immediate prostatectomy is imprudent—I am indebted to a general-practitioner colleague. The alternative suprapubic needle is not taboo in my department.

Mr. Arthur Jacobs (January 24, p. 217), quoting Mr. B. H. Page (December 27, 1952, p. 1415), notes that transurethral resection has the lowest mortality despite the use of catheters and largest-bore urethral instruments. May not the fact that the operator stops short of the anatomical line of cleavage used by the enucleating surgeon, and so avoids opening up inflammable cellular tissues in which the vasa and vesiculae are also embedded, be far more decisive than instrumentation?

Mr. J. A. Lloyd-Davies's figures (January 31, p. 257) on pre-operative infection of urine are illuminating, but they will be more cogent, and we more grateful, if he will supplement his research by tests on a similar series about a week post-operatively.—I am, etc.,

Bristol.

A. WILFRID ADAMS.

SIR,—I was interested to read that Mr. J. A. Lloyd-Davies (January 31, p. 257) has found fine polythene tubing useful for temporary suprapubic drainage of the bladder in retention of urine, and I feel sure that this method is preferable to leaving a long needle in the bladder.

I would like to point out that polythene tubing can also be used successfully for continuous urethral drainage in selected cases. The open end can be closed and rounded off in the flame of a spirit lamp, and the tip can be given a suitable curve after softening in the same way. Several small holes are then cut near the end of the tube, using a razor blade. Care must be taken to avoid weakening the tubing, and the edges of the holes can be strengthened by the momentary application of the flame. Using such an improvised catheter (size 3, Allen & Hanburys), I have found it possible to keep the urine sterile for up to a fortnight, even without the use of chemotherapy or antibiotics. Urethritis is absent or minimal, and the tube does not become blocked if the urine is initially clear and infection avoided. This method has obvious advantages in the treatment of the paraplegic bladder, but it can also be

applied to prostatic cases when the patient is unfit for immediate operation, and especially when transurethral prostatectomy is planned.—I am, etc.,

Liverpool.

NORMAN GIBBON.

Smoking and Lung Cancer

SIR,—Professor R. D. Passey (February 14, p. 399) may be quite right that the evidence on the aetiological relation of smoking to lung cancer is not conclusive, but it would not serve the interest of the public or that of the profession if we belittle or distort the available evidence.

In view of the work that has been done on necropsy protocols covering periods up to 50 years (to mention at random only two, Steiner, P. E., *et al.*, *J. Nat. Cancer Trust*, 1950, 11, 497, and Leschke, H., *Virchows Arch. path. Anat.*, 1952, 321, 101), which show the absolute increase of cancer of the lung, the "immeasurably greater ability to diagnose and far greater opportunities for diagnosis of this condition to-day" is an argument which cannot be accepted without some reservations. I am not sure whether Professor Passey really meant his analogy of breast cancer, which might have been related to the bone and metal supports of the corsets of the Edwardian days, to be taken seriously, but, if so, I would be very glad if he would quote one work on this subject which in its scientific conception, thoroughness, and magnitude is comparable with the work carried out by the Medical Research Council on the possibility of smoking being an aetiological factor in cancer of the lung.

One could argue with Professor Passey's interpretation of the evidence on every point he mentions, but it is his final conclusion which is the most surprising, because it is a direct contradiction of the traditions and history of our profession. It would be impossible to estimate the unnecessary loss of life if, for instance, Jenner, Semmelweis, and Lister had waited to put their theories into practice until they were "sure of their evidence." As a matter of fact, as medicine is not an exact science, our responsibility as a profession always has been, and still is, a greater burden to carry than the responsibility of any other learned profession, because more often than not we have to take the most far-reaching decisions according to our conscience, on insufficient evidence, and it will always be to the everlasting credit of our profession that we have never shirked this responsibility.—I am, etc.,

Colchester

FRANCIS KELLERMAN.

The College of General Practitioners

SIR,—The undersigned general practitioners met informally on January 14 to discuss the implications for Irish doctors of the report of the General Practitioner Steering Committee (*Journal*, December 20, 1952, p. 1321) and the subsequent foundation of the College of General Practitioners in London. It was unanimously agreed that these developments were of considerable importance and that a meeting representative of all general practitioners should be called in the near future in order to have the fullest discussion on the subject and to decide upon a unified line of action. Through the courtesy of the authorities of University College, Dublin, this meeting will be held in the College at 11.30 a.m. on Sunday, March 15.

This promises to be the most important meeting ever held in this country in relation to general practice. We hope that it will be attended, no matter what the personal inconvenience, not only by all those already working in this branch of medicine, whether as dispensary doctors, private practitioners, or in any other circumstances, but also by the newly qualified men and women intending to make general practice their career. It may be useful for those attending if some of the points raised at the preliminary discussion are mentioned here.

Irish practitioners have four choices in relation to the new college: (a) individuals having the necessary qualifications may join as members or associates; (b) an Irish faculty

of the new college may be formed (the method of doing this is being investigated); (c) an independent Irish college may be formed; or (d) they may do nothing.

The signatories of this letter feel that some definite step must be taken to ensure that Irish general practitioners may be enabled to secure full reciprocity with their opposite numbers in England, and that nothing should be neglected which would tend to maintain the status of the general practitioner. It is scarcely necessary to point out to readers that the field of medicine embraced by the term "general practice" has narrowed very considerably in recent years, and that many general practitioners find themselves dealing only with the clinical trivialities, while patients whom they could well treat gravitate elsewhere. In the opinion of most general practitioners there is room for great improvement in the training of medical students. While the great majority are destined to enter general practice, rarely if ever see the run-of-the-mill cases which make up a general practitioner's round, and are first introduced to the general practitioner's facts of life the hard way—hard alike for the newly qualified medico and his patients.

There is no intention among the undersigned that any new group, college, or faculty formed shall be a competitor or rival of existing institutions, but rather that it shall be or equal partner with the object of improving the professional status of the general practitioner secondary only to the maintenance of high ethical and clinical standards in the profession as a whole. We appeal most earnestly for a full attendance of our colleagues at the meeting on March 15.—We are, etc.,

SIR,—A College of General Practitioners certainly fills a gap the existence of which most of us have been too busy to notice. Other branches of medicine have their headquarters, the general practitioners had not. The usefulness of such a college must appear qualitatively and quantitatively to each of us in a different light, and it must therefore be conceded that the demand for such a college and the principles of its foundation can at the moment represent no unified opinion of general practitioners. I look upon the College's foundation with enthusiasm and pleasure, because it has a potentially important part to play in research and medical education, in both of which subjects I am deeply interested. If the prestige of general practitioners is increased by the work of the College, so much the better, but I do not put that as a reason for its foundation.

A deal of argument has arisen about the credentials necessary for a general practitioner to become a member of the College. Once a specialist or consultant has the necessary qualifications to practise his specialty, he automatically becomes a member of the Royal College of Physicians or Surgeons. Surely, then, when a doctor has obtained his qualification to practise as a general practitioner, he should become automatically a member of the College of General Practitioners? The specialist has no need to show evidence of continued good work to remain a member of his College, so why should a general practitioner? A specialist can be elected to a fellowship in the Royal College of Physicians, and a general practitioner could similarly be elected to a higher grade, if the idea is thought to be a good one. But, as I have mentioned, the general practitioner has much to contribute to medical research and education, and without a body such as a college to represent him he has little means of contribution. There are many questions which could be readily answered from the records of general practitioners. There are so many empirical forms of treatment that could easily be placed on a surer foundation. One simple example occurs in the treatment of shingles. Does liver extract help? I have not seen sufficient cases to be able to decide. A research department of the college could collect enough cases in a year to answer this question. And there are a

horde of other problems, stimulating to those of us who are young enough in mind to be interested in their solution.

The education of the medical student is in the hands of specialists, and, however hard they try to give a fair share of instruction to the needs of general practice, they can for the most part act only on hearsay evidence, having no first-hand information on the subject. A College of General Practitioners can provide the needed information and take its rightful share with the other colleges in the education of the student, which is the most important problem in medicine.

I think it a point of no small moment that those groups of our profession and its ancillaries which were represented by a college or similar body—physicians, surgeons, dentists, opticians, pharmacists—came to just agreements with the Government in negotiating the new Health Service, while the general practitioners made a bad bargain from which they have had to be rescued.—I am, etc.,

Leeds.

R. A. MURRAY SCOTT.

Intercourse after Syphilis

SIR,—The reply of your expert (February 7, p. 348) to Dr. T. E. Osmond's and my criticism (February 7, p. 348) of his answer to a question under the above heading would not prevent me from doing all I could to dissuade any girl—a daughter, for example—in whose welfare I was interested from marrying a man with a history of a syphilitic infection the treatment of which was completed six months or less ago. The objection that the articles by the authorities I quoted appeared before "salvarsan" was invented is beside the point. No treatment yet invented has afforded 100% success with the course prescribed at the outset before the patient is placed under observation, and, moreover, it is reasonable to believe that the more efficient the treatment, short of being completely successful, the longer is likely to be the clinically latent period before relapse is detected. Consequently, until a 100% cure has been evolved, the observation following any treatment must be longer than the longest known to have been followed by relapse. Your expert's observation respecting his failure to note any relapse more than six months after completion of treatment cuts no ice with me; it is easy to ascribe to reinfection an inconvenient (for statistical purposes) return of signs of the disease, and what American writers do in this matter does not influence me in the least. The failure of others to confirm the observations of Kertesz and of Warthin should be regarded with great caution, having regard to the experience of reliable experimental syphilographers in the difficulty of being certain that an inoculation with material suspected of containing *S. pallida* has failed. The quotation from Stokes *et al.* regarding infection of the ovum with *S. pallida* is not understood. Surely nobody now thinks that transmission of syphilis to the foetus is mostly by infection of the ovum?—I am, etc.,

London, N.W.10.

P. A. CLEMENTS.

The Dangers of Blood Transfusion

SIR,—The letter of Dr. S. H. Waddy (February 21, p. 454) should not go unanswered. Obviously the potential donor of blood should be treated with every consideration. He should not be bled without a knowledge of his haemoglobin level, and not bled at all if it is abnormally low; his blood film should also be examined. He should be bled by a skilful bleeder, and should be regarded as one deserving the thanks of the community, which should be expressed by one of those present at the bleeding session. Further points in the care of the donor could be added. If reasonable precautions are taken, little or no harm results to him.

But even if a very occasional donor is the worse for giving blood, there is much to be set on the other side. Many lives are saved annually in the practice of obstetrics by blood transfusion, and obstetrics is but a small section of the whole field of medicine. The results in the treatment of post-partum haemorrhage have been revolutionized by

ANDREW M. CLAYE.

MARY EVANS.
WILFRID GAISFORD.
A. HOLZEL.
M. L. THOMSON.
NESTA H. WELLS.

Daniels was frequently called upon by other bodies for his knowledge of epidemiology and tuberculosis control. In 1947, with Dr. D'Arcy Hart, he visited the British Zone of Germany and Berlin at the request of the Foreign Office, to investigate the prevalence of tuberculosis, which was alleged to be rising rapidly. Their report (1948) concluded that these fears were unfounded, and were due largely to the sad state of German morbidity statistics; they gave an optimistic forecast of the tuberculosis trends, which has since proved correct. In 1951 and 1952 he investigated the tuberculosis situation in displaced persons' camps in Trieste, on behalf of the U.N. High Commissioner for Refugees and W.H.O., and recommended improvements. He visited Poland and Yugoslavia for the British Council.

Into the short 15 years of his medical career, Daniels thus crowded a host of valuable activities. He worked with tremendous intensity, coupled with strict accuracy—"ruthless objectivity" a colleague once described it. A somewhat spartan approach to life helped him in many situations, not least in his illness. His enthusiasm extended beyond his work; he was a discriminating critic of painting and the theatre, and himself acted, photographed, and modelled with skill, and even took up the flute. He was not easy to get to know intimately, but those who did recognized his charm and warmth and the variety of his interests. Children were attracted to him and he loved their company. Daniels had been a sincere socialist for many years, and his abhorrence of the effects of war led him to join the Medical Association for the Prevention of War. He married, first, Anne Burgess in 1940, and there are two daughters, aged 8 and 11; in 1949 he married Kay Graw, who had been a fellow-worker in Unrra.

We are indebted to Professor A. BRADFORD HILL for the following appreciation: In a leading article, published in the *British Medical Journal* nearly five years ago, commenting upon the Medical Research Council's first controlled trial of streptomycin in pulmonary tuberculosis, it was suggested that the plan then adopted "may well serve as a model in this field." The prediction was right. Many therapeutic trials, not only in the field of tuberculosis, have been founded upon this early essay, and much of the credit for its success must go to Marc Daniels. I came to know him well at this time, and through his shy and diffident manner there stood out very clearly the characteristics that led to that success—an urge for perfection and accuracy, a patience and capacity for hard work that enabled him to seek that perfection in every detail, and an intellectual honesty that made him interested in nothing but gaining the truth. To this he added an organizing ability which kept the trial running smoothly in many different centres. It was the ideal combination of characteristics. He had also, I found later as we continued to work together, a very large share of that statistical "common sense" which is anything but common, and an outlook upon the ethical problem which made him pause and reflect at every step in a controlled trial. With all his eagerness for the experimental approach, no one could have been more humane than Daniels, more careful of the patient's well-being. He never resented criticism; he would argue the point quietly but effectively, and if he concluded he was wrong he would cheerfully start his project or the writing of a report all over again. He wrote concisely and dryly, in keeping with his character. He was too self-effacing and retiring ever to talk about himself, and so was a difficult person to get to know well. Indeed, after five years of friendship I knew practically nothing of his life. Yet his honesty of purpose was so apparent as to command one's admiration—as indeed did his courage in these last weeks—while his quiet shy smile and constant friendliness in discussion inevitably drew one's warm regard and affection. His death at an early age is a serious loss to British experimental medicine.

Sir LOUIS GREIG, K.B.E., C.V.O., M.B., Ch.B.

A friend of royalty and of other high personages, Group Captain Sir Louis Greig died at his home at Richmond Park on March 1 at the age of 72. He underwent a serious operation last December, and had recovered from its effects sufficiently to be able to spend Christmas at home with his family, but he recently suffered a relapse.

Louis Leisler Greig was born on November 17, 1880, the son of Mr. David Greig, of Glasgow and Fife, and was educated at Merchiston Castle School, Edin-

burgh, and at the University of Glasgow, where he graduated M.B., Ch.B. in 1905. Entering the Royal Navy as a surgeon lieutenant in the following year, he saw service in H.M.S. *Hibernia* and *Cumberland*, and at the Royal Naval College, Osborne, and the Royal Marines Depot, Deal. It was while at Osborne that he first met Prince Albert, later King George VI, and thus began a friendship which was ended only by the death of His Majesty last year. After Prince Albert's serious illness in 1917 Greig did much to restore him to health, and by example and encouragement he played his part in moulding the Prince's character.

Greig was serving with the Royal Marines Brigade when he was taken prisoner by the Germans in October, 1914, but, under the arrangement for the exchange of naval prisoners of war, he was repatriated in September, 1915, in time to witness the Battle of Jutland from the crow's nest of Jellicoe's flagship. In April, 1918, he transferred to the Royal Air Force with the rank of major, later becoming group captain. After the war Greig was Comptroller to the Duke of York, as Prince Albert had now become, from 1920 to 1923, and he was Gentleman Usher in Ordinary to King George V from 1924 to 1936 and Extra Gentleman Usher to King George VI from 1937 until His Majesty's death. Greig's services to royalty were recognized by his appointment as C.V.O. in 1917, and he was created K.B.E. in 1932, in which year he was appointed Deputy Ranger of Richmond Park. The recipient of a number of foreign honours, Greig was a Chevalier of the Légion d'Honneur and of the Ordre de Couronne of Belgium, and he was awarded the Belgian Croix de Guerre, the Dutch Order of Orange-Nassau with Swords, and the Legion of Merit of the U.S.A. In the last war he served as personal air secretary to the Secretary for Air from 1940 to 1946. He was appointed a Deputy Lieutenant for London in 1948.

As a young man Greig played Rugby football for Scotland, and was captain of the national fifteen several times. He was also a tennis enthusiast, and played the game often with the late King. In 1920 they won the men's doubles in the R.A.F. championships, and six years later they appeared together in the doubles at Wimbledon in the All-England championships. On that occasion, however, they were eliminated in the first round, but history was made, for it was the first time that a member of the Royal family had appeared in the championships. Greig was chairman of the All-England Club and of the Not-Forgotten Association; he was also a governor of Westminster Hospital and formerly of Guy's. He married Phyllis, daughter of Mr. J. Walter Scrimgeour, and had one son and two daughters.

HAROLD BALME, O.B.E., M.D., F.R.C.S.

Mr. H. W. S. WRIGHT contributes the following memoir of Dr. Balme, whose death we recorded in these columns last week:

The death of Harold Balme will leave a void, not only among his more intimate friends, but in the minds of doctors and students and medical administrators in widely separated parts of the world. When he had obtained the F.R.C.S. and D.P.H. he went to China as a missionary, and worked for some years in the interior at Tai Yuan Fu, where among other things he learnt something of the educational needs of provincial China. Later he went to Tsinanfu, the capital of Shantung, where he played a distinguished and critically important part in building up a modern medical school, starting with the building of a large, well-designed mission

hospital. This subsequently became a part of a university with faculties of arts, theology, and medicine. Its degrees were recognized by McGill University, and were registered in Canada. Balme was first professor of surgery and dean of the medical school, and then president of the university. It was at one time a centre for a research project of the Royal Society on the transmission of kala-azar, and it had a translation bureau which was partly responsible for the translation of standard textbooks into Chinese and the publication of a Chinese medical journal. Harold Balme's major contribution to this not inconsiderable achievement was his insistence that scientific education in China should be under any circumstances be used to produce half-educated medical assistants and teachers for mission hospitals and schools, but that their standards should be comparable with those of western universities. Further, his experience had shown him that at least one of the four universities should teach in Chinese. These rather obvious ideas were at the time the subject of acute and sometimes acrimonious controversy.

With Harold Balme, once a notion had been clarified it was never left to fade gently away and disperse with the tobacco smoke which had attended its birth. He persuaded mission boards and the Rockefeller Foundation to make it live in bricks, mortar, and personnel. To teach science, a method born of the Greek way of thinking, in a language adapted to expressing a very different set of ideas to very different cultural values, is in itself a formidable task. People who knew their subjects well enough and who were prepared to learn Chinese, adapting it to their needs as they went along, were not easy to find. Still, it was done, and in the years that followed this co-operative effort made a useful contribution to educational progress in North China. If for the medical side of it credit should go to some more than others, Samuel Cochrane, Harold Balme, and Roger Green of the China Medical Board deserve it.

About 1927 Balme felt that he had to go home, and went into general practice in Kent. Not having done any degree of medicine for about 10 years, he proceeded to the question of M.D., a feat which he regarded as merely a question of organization easily dealt with. It was the best and most successful general practice I have known. Every case had notes which would not have disgraced any hospital. He was not a born clinician and never became a remarkable one, but he knew how to find out what was the matter with people and how to organize their recovery. It is characteristic of him that during this period he wrote a book on pain related to its treatment in general practice. This practice he had to abandon on account of a long and trying illness which brought with it some disability.

After his work in the E.M.S. during the war, his major interest was rehabilitation, which he regarded more as an attitude of mind than as an affair of gymnastics, important as the latter are. He organized the Ministry of Health branch of rehabilitation and was their consultant adviser till 1951. He was also director of the welfare services of the British Red Cross Society, and as such he travelled widely all over Europe, advising on rehabilitation centres. In 1950 Balme's work on rehabilitation was enlarged by his appointment as adviser to the United Nations and World Health Organization, and also to the World Veterans Federation. This wide field took him on many laborious journeys to the United States, Egypt, and all over Europe. The setting up of international plans and action for the relief of all kinds of disability owed much to his contributions. Treatment for handicapped children was his special concern. In the last year of his life, although he was in constant pain, he organized study courses for experts from war-devastated countries, and he accomplished his final journey in Sweden, Finland, and Denmark last autumn, and was able to see his work successfully concluded.

Many of the last years of his life were a weary tale of suffering serenely borne. He was unable to survive an extensive operation, and he died on February 13, leaving behind him a widow, two sons, and two married daughters. They assuredly have the vivid and understanding sympathy of many friends. His life, whether as a missionary or as

an administrator, developed a consistently clear behaviour pattern. He early realized that creative ideas, of whatever kind, be they religious or secular, have in themselves a dynamic of their own, and his task, as he conceived it, was to crystallize them out in terms both of functioning institutions and human endeavour. This was his ideal, and in its practice he was supremely successful.

We are indebted to Dr. JOHN D. KERSHAW for the following appreciation:

As chief of the rehabilitation unit in the United Nations Secretariat in 1951-2 I was one of Dr. Harold Balme's closest professional colleagues in the last phase of his work, and I feel that some fuller comment upon it should be made in his obituary notices. He joined U.N. as a consultant at an age when most men are retiring from active professional work. U.N. and its Specialized Agencies had all been finding themselves engaged on problems of rehabilitation of the handicapped, and it was necessary to integrate their separate activities into a co-ordinated whole. As chairman of the joint working party of U.N. and the Agencies, Balme's special qualities of experience and personality made him the perfect catalyst, and the great measure of unity which was achieved between 1950 and 1952 was largely due to him. In the more active task of expert adviser to some of the less highly developed countries he combined a realistic outlook with unbounded enthusiasm, and several U.N. projects which are now in operation owe much of their success to him.

The work was exacting and probably hastened his death, but he never spared himself. Even those working with him did not always realize that he sometimes came straight to the conference table from a sick-bed to which he would return as soon as the meeting adjourned. I have, at his request, taken difficult problems to him in a hospital ward and found him as alert and helpful as if he were well and in his office. The Report on a Co-ordinated International Programme for the Rehabilitation of the Handicapped, which was presented to the U.N. Social Commission last year, and which is likely to form the basis of future developments in this field, was largely Balme's work, and in its fulfilment he will have a fitting memorial.

A. H. NORRIS, C.B.E., M.C., M.R.C.S.

Dr. Arthur Herbert Norris, C.B.E., M.C., who was chief inspector of the Children's Branch of the Home Office from 1918 until his retirement in 1940, died at Dawlish, Devon, on February 20 at the age of 77. The son of the late Rev. C. E. Norris, vicar of Falings, Rochdale, he was born in 1875 and educated at Ellesmere, Shropshire, Manchester University, and St. Thomas's Hospital, where he qualified in 1906. He obtained the D.P.H.(Vict.) in 1910 and the special certificate in school hygiene the following year. At Manchester he held a number of appointments, including senior medical officer of the Manchester Children's Dispensary. He was an assistant medical officer of health and school medical officer of the Berkshire County Council for some years, and shortly before the outbreak of the first world war he was appointed to the post of medical inspector of the Children's Branch of the Home Office. When war broke out he was called to the colours and served overseas as a battalion medical officer of the Manchester Regiment, being awarded the Military Cross. He was demobilized in 1917 to enable him to return to his post at the Home Office at a time when the health of the children in the industrial and reformatory schools was causing serious concern. In the same year he was appointed chief inspector of the Children's Branch in succession to Charles Russell, and his influence was rapidly felt. He served in 1927 on the departmental committee on the Treatment of Young Offenders, which culminated in the Children and Young Persons Act of 1933. In 1931 he was honoured with the C.B.E. Dr. Norris had a dynamic and genial personality, a remarkable memory, and an original mind. He did much to humanize the regime of the industrial and reformatory

Influenza

Graphs of Infectious Diseases

PNEUMONIA

NUMBER OF CASES

Highest 1944-52

1953

Lowest 1944-52

WEEKS

Infectious Diseases

530 deaths were registered from influenza in the great towns; these were 84 more than in the preceding week. The rise in mortality occurred in the northern section of the country, while in the southern section it remained constant. The deaths in London and the south-east formed 52% of the total, compared with 61% and 64% in the two preceding weeks.

Industrial Accidents and Disease

The number of work-people (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in January was 100, compared with 137 in the previous month and 130 (revised figure) in January, 1952. The number of cases of industrial disease reported was 30, including 9 from lead poisoning, 3 from anthrax, 10 from epitheliomatous ulceration, and

Week Ending February 21

Medical News

"no" reply on this point.

"B.P., 1953."—The *British Pharmacopoeia*, 1953, which becomes official on September 1, has just been published. It has been completely revised. There are 64 new monographs, and 150 outdated ones have been deleted. The last edition was in 1948, with an addendum in 1951. The most outstanding change is the use of English instead of Latin for the main title of the monographs, which has necessitated a new alphabetical order. The metric system, being that normally used for chemical and pharmaceutical processes, is adopted throughout, although where dosage has been by custom in Imperial units these are also given. The B.P. is published under the direction of the General Medical Council. It costs 50s. net.

Nuffield Gerontological Research Fellowship.—The Nuffield Foundation, as part of its programme for the care of old people, is prepared to offer a Nuffield Research Fellowship, of professorial status, for research on the scientific aspects of ageing, or alternatively one or more fellowships of less senior status. Applications for both types of fellowship are invited, and appointment will be made by a committee representing the Royal Society and the Nuffield Foundation. The fellowship, which may be tenable at any university in the United Kingdom, will be open to applicants of either sex—usually not more than 45 years of age—who are of high merit and whose ability fits them for the conduct of original scientific research. Appointment to the senior award will normally be made for a period of five years and may be renewed for further periods of five years. The value will not be less than £2,000 per annum plus superannuation and child allowance. Research expenses will be met by the Foundation, including such provision for research assistants, apparatus, and technicians as the committee may think appropriate. In the event of one or more less senior workers, instead of one senior, being appointed, the period of appointment will be three years in the first instance. The value will be £1,000 to £1,500 per annum plus superannuation, child allowance, and research expenses. Applications must be received before June 1 by the secretary, the Nuffield Foundation, Nuffield Lodge, Regent's Park, London, N.W.1, from whom full particulars and application forms can be obtained.

Psychiatric Research in America.—The creation of a large fund for research in psychiatry was announced last week by the president of Yale, according to the *New York Times*. The fund consists of a grant of \$6m. provided by the Social Research Foundation of New York. The

Human Behaviour.—Another large and recent American benefaction for research on human conduct is the Ford Foundation's appropriation of \$3.5m. to cover the first six years' programme of a new Centre for Advanced Study in the Behavioral Sciences. The funds will be used principally to permit 50 top-flight scholars and scientists to assemble for study and collaboration at the Centre each year. So far the location of the Centre has not been settled, but a board has been appointed to direct the work. The chairman of the board is the president of the Columbia Broadcasting System.

Société Belge de Droit International Médical.—With Professor René Sand as president a new society has been formed in Brussels to study the medical aspects of international law. The aims of the society, which includes both doctors and lawyers among its members, are : to study international medical law and work for its development ; to ensure close collaboration between doctors and lawyers, particularly where international law impinges on medical ethics ; to give help with the problems inherent in conventions on human rights, and in general to have regard to the impact of international law on medicine. There is a similar society in France.

Index Ophthalmologicus.—At the XVIIth International Congress of Ophthalmology, New York, 1954, a new edition of the "Indicia" will be issued under the title *Index Ophthalmologicus*, and the Ophthalmological Society has been asked to prepare the section covering Great Britain. Any ophthalmologist who is not a member of the Ophthalmological Society of the United Kingdom or the Faculty of Ophthalmologists, and who wishes to be included in this Index, is asked to send his name and address to the honorary secretary, Ophthalmological Society of the United Kingdom, 45, Lincoln's Inn Fields, London, W.C.2, before March 31.

Register of Chiropodists.—The 1952 *Register of Chiropodists* has now been published, and can be obtained by medical practitioners free on request to the Secretary and Registrar, Board of Registration of Medical Auxiliaries, B.M.A. House, Tavistock Square, London, W.C.1. Chiropodists are classified on a geographical basis, and, besides address and telephone number, information is given on qualifications, hospital appointments, and whether private practice is undertaken.

Health Education.—In a praiseworthy attempt to provide authoritative information to those who are interested in health education in its broadest aspects, the Central Council for Health Education is publishing an "Information Digest" twice yearly. This contains extracts from and abstracts of reports and papers which have a bearing on a particular topic selected by the editors, Dr. A. J. Dalzell-Ward and Miss Priscilla Milton. In the issue dated January, 1953, the main headings of the separate sections are "School Health," "Whooping-cough," "The M.O.H. Reports," "Accidents in the Home," and "Health Education Programmes in Local Authorities." The papers selected for abstraction are not necessarily of very recent publication, but they do give a general view of current thought. The "Information Digest" is at present varityped, but future issues will probably be printed.

Dr. H. B. May, director of the clinical laboratories at the London Hospital, will succeed Dr. A. E. Clark-Kennedy as Dean of the London Hospital Medical College on October 1. Until then he will be Vice-Dean.

Mr. C. J. Cellan-Jones, honorary surgeon to the Swansea General Hospital, has been appointed a Deputy Lieutenant of Glamorgan.

Dr. Ludwig Guttman, director of the Ministry of Pensions Spinal Injuries Centre at Aylesbury, has been invited

to speak at a three-day symposium on stress which is being held from March 16 to 18 at the Army Medical Service Graduate School in Washington, D.C.

Emergency Bed Service: Applications and Admissions.—During the seven days ending March 2 the number of applications made by doctors to the London Emergency Bed Service for admission of patients was 1,302, of whom 86.5% were admitted. The white warning was cancelled from March 3.

COMING EVENTS

Institute of Psychiatry.—Details of the lectures to be given to postgraduate students in psychiatry at the Maudsley Hospital during the term beginning on April 13 are now available from the secretary of the Institute, Maudsley Hospital, London, S.E.5.

Ergonomics Research Society.—The third annual conference of the Ergonomics Research Society will be held at the Department of Human Anatomy, Oxford University, from April 13 to 16. The Chairman of the conference will be Professor W. E. Le Gros Clark, F.R.S., and the main subject for discussion will be "Human Performance: Its Measurement and Limitations." Those wishing to enrol as members of the symposium are asked to communicate with H. Murrell, Spinneys, Marlpit Lane, Headless Cross, near Redditch, Worcs.

Research on Micro-organisms.—The first Marjory Stephenson Memorial Lecture will be given by Dr. D. D. Woods, F.R.S., at the Royal Institution, Albemarle Street, London, at 6 p.m. on April 13. The title will be "The Integration of Research on the Nutrition and Metabolism of Micro-organisms," and all those interested are invited to attend. The Marjory Stephenson Memorial Fund is administered by the Society for General Microbiology.

NEW ISSUES

Abstracts of World Medicine.—The next issue (Vol. 13, No. 3) will be available in a week's time. The contents include abstracts of papers selected from the medical literature of the world on all aspects of clinical medicine and surgery and the allied sciences.

Issued monthly; annual subscription £4 4s., single copy 8s. 6d.; a specimen will be sent free on request. Obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

Details in this column are necessarily brief. Further information and tickets where required (marked ●) should be obtained from the institution concerned.

Monday, March 9

EDINBURGH UNIVERSITY: FACULTY OF MEDICINE.—At University New Buildings, 5 p.m., Dr. Pierre Mallet-Guy (Lyons): Manometric and Radiographic Control of Biliary Surgery.

INSTITUTE OF PSYCHIATRY.—5.30 p.m., Dr. E. Stengel: lecture-demonstration for postgraduates.

LONDON UNIVERSITY.—At Bedford College, 5.15 p.m., Professor S. Bergström (Lund): Intestinal Absorption of Fats.

MEDICAL SOCIETY OF LONDON.—8.30 p.m., Lettsomian Lecture by Dr. E. R. Callinan: Some Disorders of the Liver and Bile Passages.

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN.—7.30 p.m., Professor J. H. Burn, F.R.S.: Progress in Biological Standardization.

Tuesday, March 10

CHELSEA CLINICAL SOCIETY.—At South Kensington Hotel, 8.30 p.m., discussion to be opened by Mr. W. V. Gibson and Sir Hugh Griffiths: Medical Aspects of Road Accidents.

EDINBURGH UNIVERSITY.—At University New Buildings, 5 p.m., Professor A. Meyer: Anatomical Aspects of Neurosurgery in Mental Disorder.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. G. Cochrane: Leprosy.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Oliver-Sharpay Lecture by Dr. Clifford Wilson: Renal Factors in the Production of Hypertension.

WEST END HOSPITAL FOR NERVOUS DISEASES.—5.30 p.m., Dr. T. Rowland Hill: neurological demonstration.

Wednesday, March 11

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. G. Cochrane: Histopathology of Leprosy.

INSTITUTE OF UROLOGY.—At St. Paul's Hospital, W.C., 4.30 for 5 p.m., Dr. A. H. Harkness: Non-gonococcal Urethritis.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.—At Royal Free Hospital School of Medicine, 8.30 p.m., annual general meeting.

Presidential address by Miss Diana Beck: Management of Head Injuries in General Practice.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—3.45 p.m., Erasmus Wilson Demonstration by Mr. V. E. Negus: Protection of the Respiratory Tract. (On the Evidence of Comparative Anatomy.)

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Dr. W. C. Harvey: Food Hygiene.

Thursday, March 12

ALFRED ADLER MEDICAL SOCIETY.—At 11, Chandos Street, W., 8 p.m., Drs. Donald Blair, A. R. Redfern, and E. Weissmann: Three Difficult Cases Treated by Adlerian Methods.

INSTITUTE OF CHILD HEALTH.—5 p.m., Dr. R. E. Hope Simpson: Epidemiological Research in Children under 15 Years of Age.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Mycology—Pathology of Mycotic Infections.

LIVERPOOL MEDICAL INSTITUTION.—8 p.m., Dr. J. G. Benstead: Antarctic Observations of Comparative Interest in Hygiene and Forensic Medicine; Dr. A. A. Miller: Case of Concomitant Endometrial Adenocarcinoma with Squamous Metaplasia and Endometrial and Tubal Tuberculosis.

LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—At Dorchester Hotel, 6.30 p.m. to 1 a.m., annual dinner-dance.

LONDON UNIVERSITY.—At Bedford College, 5.15 p.m., Professor S. Bergström (Lund): Formation and Interconversion of Bile Acids.

ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Mr. R. Llewelyn Davies, M.A., A.R.I.B.A.: Modern Trends in Hospital Architecture.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Oliver-Sharpay Lecture by Dr. Clifford Wilson: Renal Factors in the Production of Hypertension.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor J. B. Wyman: The Use of Pentamethonium and Hexamethonium Salts in Major Surgery.

ROYAL SOCIETY.—11 a.m., discussion to be opened by Professor J. Z. Young, F.R.S.: Function and Location of Enzymes in Cells.

ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Sir James Spence: Methods of Clinical Teaching.

UNIVERSITY COLLEGE.—At Physiology Theatre, 4.45 p.m., public lecture by Professor V. B. Wigglesworth, F.R.S.: Chemical Aspects of Insect Physiology.

FRIDAY, MARCH 13

INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. R. G. Cochrane: Leprosy.

OXFORD UNIVERSITY.—At Department of Human Anatomy, 12 noon, Professor G. W. Corner (Washington): Application of Scientific Methods to the Study of Sex and Reproduction.

SATURDAY, MARCH 14

NORTH OF ENGLAND OTOLARYNGOLOGICAL SOCIETY.—At Hull Royal Infirmary, 2 p.m., meeting.

APPOINTMENTS

BLACK, DORIS JEAN, M.B., B.Ch., Assistant Divisional Medical Officer to the Chorley, Adlington, and Coppull areas of Division 4, Lancashire County Council.

CULLINGTON, D. E., M.B., B.Chir., D.P.H., D.C.H., Medical Officer of Health, Barking, and Area Medical Officer and Divisional School Medical Officer.

DAVIES, J. B. M., M.D., D.P.H., Deputy Medical Officer of Health and Deputy Port Medical Officer, City of Liverpool.

HOSPITAL FOR SICK CHILDREN, Great Ormond Street, London, W.C.—Catherine N. McRobert, M.B., B.S., Resident Medical Officer at Tadworth Court; Ruth E. Trilling, B.M., B.Ch., D.C.H., Assistant Resident Medical Officer at Tadworth Court.

MORRIS, NORMAN F., M.D., M.R.C.O.G., First Assistant in Obstetric Unit, University College Hospital, London, W.C.

RAFTERY, J. D., D.Phil., F.R.C.S., Visiting Senior Orthopaedic Surgeon to King Edward VIII Hospital, Durban, and Part-time Assistant in the Department of Anatomy, Faculty of Medicine, University of Natal, Durban, South Africa.

VICKERY, K. O. A., M.D., D.P.H., Medical Officer of Health and School Medical Officer, County Borough of Eastbourne.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Evershed.—On February 5, 1953, at the Liverpool Maternity Hospital, to Elizabeth, wife of Squadron Leader T. A. Evershed, M.B., B.Chir., R.A.F., a son.

Heller.—On February 19, 1953, at St. Mary's Hospital, London, W., to Betty wife of Dr. Michael Heller, a son—Simon Richard.

Solomon.—On February 9, 1953, at the Bearded Memorial Hospital, London, N., to Vera (formerly Apt), wife of Dr. Terence Solomon, M.B., D.Obst.R.C.O.G., a son—Stephen Maxwell Ernest.

Walwyn-Jones.—On February 24, 1953, to Margaret (formerly Pemberton), wife of Dr. E. O. Walwyn-Jones, a son.

Winter.—On February 28, 1953, at the Gordon Road Nursing Home, Cardiff, to Mollie, wife of George Winter, M.B., Ch.B., a sister for John.

DEATHS

Joscelyne.—On February 11, 1953, Edward Walter Joscelyne, M.D., of 13, Stoke Grove, Westbury-on-Trym.

Kerr.—On February 10, 1953, at Grimsby, James Arthur Kerr, V.R.D., M.D., D.P.H., Surgeon Commander, R.N.V.R., aged 54.

Pickard.—On February 9, 1953, at Rusholme, Stratham Drive, Exeter, Ransom Pickard, C.B., C.M.G., M.D., M.S., F.R.C.S., Colonel, A.M.S., T.A., retired, aged 85.

Reid.—On February 10, 1953, at Walsall, Gordon Campbell Kinloch Reid, M.B., Ch.B.

Shears.—On February 5, 1953, at Beckenham Hospital, William Shears, late of Bromley Road, Catford, S.E., and 1, North Dene, Beckenham, Kent, aged 84.

Smith.—On February 13, 1953, at his home, Rodborough Grange, Aylth Road, Bournemouth, Hants, Alfred Tennyson Smith, O.B.E., M.D., aged 83.

Stewart.—On February 8, 1953, at Olney, Sandy Lane, St. Paul's Cray, Kent, Ian James Allan Stewart, M.B., Ch.B., aged 50.

Thompson.—On February 13, 1953, at Ashford Hospital, Hubert Gordon Thompson, M.D., F.R.C.S., of "Bennetts," Appledore, Kent, formerly of China, aged 74.

Turner.—On February 9, 1953, Reginald George Turner, C.M.G., D.S.O., F.R.C.S., Colonel I.M.S., retired, of Ardmore Road, Lower Parkstone, Dorset, late of Clevedon, Somerset.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Chilblains in Women

Q.—Why do women get chilblains more frequently than men?

A.—It is true that chilblains occur rather more frequently in women than in men, though they chiefly affect children and young adults. The individual predisposition appears to rest upon a vasomotor sensitivity which in turn is subject to emotional and endocrine influences. Over and above these considerations, which would favour an increased susceptibility in the female, is the question of clothing. The body temperature to some extent controls the vascular tone in the extremities, and it is desirable that body and limbs should be maintained at an even and adequate temperature by suitable clothing to prevent perniosis. In the matter of clothing the female is usually more adventurous than the male.

Foot-drop after Delivery

Q.—I have encountered two cases of foot-drop following delivery, in one of which there was sciatic pain and muscular wasting. It has been suggested that this was due to prolapse of an intervertebral disk. Is this a recognized complication of pregnancy or labour?

A.—Peroneal palsy is a well-recognized, although fortunately not very common, complication of childbirth. It may be bilateral but is mostly unilateral. The degree of paralysis varies from slight weakness of the dorsiflexors of the foot and toes to inability to move the leg. The affected muscles are flaccid and wasted. Sensory loss is a more variable finding. Sciatic pain and paraesthesiae in the foot may, or may not, be present.

This condition affects primiparae more than multiparae. It may follow normal labour, but seems more common after prolonged labour and difficult forceps deliveries. The first evidence of it may arise during labour or immediately afterwards, but sometimes it is not apparent for several days or weeks. When there is such an interval the injury is probably still attributable to labour, but may have been slight and overlooked. The older and traditional view about its aetiology is that it arises as the result of injury to the lumbosacral cord as it crosses the pelvic brim to the sacral plexus. The injury is said to arise either by direct pressure of the foetal head or forceps blade, or by traction on the relatively fixed nerve root. A more recent explanation¹ is that the paralysis is the result of a slipped disk—usually the disk between L.5 and S.1. This view has been widely but not universally accepted. Some times it is suggested that the mechanism of production may not be the same in all cases.

The prognosis is good in that the muscular wasting and weakness nearly always clears up in time—although it may take many months: it is usually said that recovery is invariably complete, and it is for all practical purposes. In fact, however, special tests often reveal some weakness in one or more groups of muscles many years afterwards. Moreover, if in after life the subject of such an injury is ever confined to bed for a long period, this weakness shows up temporarily.

If the best result is to be obtained, the management of the case is important and should be in the hands of an orthopaedic specialist. Usually the treatment is the same as for any flaccid paralysis of muscles—massage, galvanic stimulation, and the prevention of stretching of the muscles and permanent deformity by suitable splints or plaster. If

there is evidence of disk protrusion it may be necessary to keep the patient at rest in bed for several weeks, and operative treatment might have to be considered in the very severe case. Little can be done to prevent this injury, but if a patient complains of severe sciatic pain during labour it should be regarded as a warning not to proceed with vaginal delivery unless it is reasonably certain that there is no mechanical difficulty at all, and that there will be no need for the application of forceps.

The above comments are based on the assumption that paralysis due to regional analgesia, or to pressure on the peroneal nerve by any appliance used to maintain the lithotomy position, has been excluded.

Diagnosis of Polycythaemia Vera

Q.—What criteria are necessary to establish a diagnosis of polycythaemia vera? Is there any test which will exclude or confirm the presence of the disease beyond question? I have a patient who complains of vertigo, "headiness," "oppressive feelings," and tinnitus, whose R.B.C. count is 6,500,000 (Hb 117%). Are the symptoms likely to be related to the blood picture in this case?

A.—Polycythaemia requires for its diagnosis a persistently raised erythrocyte count and an increase in the packed cell volume; there is, naturally, an accompanying elevation of the haemoglobin level in most, but not all, instances. The upper limit of normal given by Wintrobe (*Clinical Hematology*, 3rd ed., 1951, Kimpton, London, for the red cell count is 6,200,000 per c.mm. for the male and 5,400,000 per c.mm. for the female, and for the packed cell volume 54% and 47% respectively. Most authorities would agree that red cell counts above 7,000,000 per c.mm. and packed cell volumes above 55% were always abnormal. The next step in diagnosis is the exclusion of such causes of secondary polycythaemia as cyanotic congenital heart disease and emphysema. Given their exclusion, a diagnosis of polycythaemia vera can then be accepted; it is made more certain by the presence of splenic enlargement and by a neutrophil leucocytosis with an increase in the platelet count. These remarks are sufficient to show that there is no single test which alone will "exclude or confirm the presence of the disease beyond question."

In the instance cited, the red blood cell count is perhaps just above the upper limit of normal; the symptoms, although not of specific significance, are those experienced by many polycythaemias; splenomegaly and leucocytosis would suggest that this patient has, in fact, polycythaemia vera. These symptoms are usually to be noted in the older patients and it seems likely that the combination of arterial degeneration with unduly viscid blood is responsible for them.

Prevention of Scale in a Sterilizer

Q.—What is the best way of preventing the deposition of scale in a sterilizer?

A.—From the wording of the question it is assumed that the sterilizer is one in which instruments are submerged in boiling water as distinct from their being enveloped in steam.

If this is the case, there are two methods of avoiding the deposition of scale. The more obvious method is to use softened water instead of hard water. At the same time it should be observed that even softened water should be rejected and replaced from time to time, for, with constant re-use and replenishment to make up for evaporation, excessive alkalinity or even a deposit will eventually be encountered. If softened water is not available the trouble can generally be avoided by adding a small quantity—the amount is not critical—of "calgon" (sodium hexametaphosphate) to the water. Here again, periodical rejection and replacement of the water is necessary if it is constantly re-used and topped up.

Crystalline or Procaine Penicillin

Q.—Which is the better preparation of penicillin for routine parenteral use—crystalline penicillin or a procaine penicillin? I have heard that the likelihood of the side-effects from the procaine in the procaine penicillin outweighs its advantages.

A.—Arguments about the relative merits of the two preparations are usually based on theoretical considerations rather than on any observed difference in therapeutic potency. After an intramuscular injection of 600,000 units of procaine penicillin a bacteriostatic level in the blood is maintained for 24 hours as a rule, whereas after an injection of the same dose of crystalline penicillin the concentration in the blood rises to a much higher peak, but rapidly declines to a level which is too low to be assayed. The ability of procaine penicillin to maintain a significant blood-concentration over a prolonged period would suggest that it was the preparation of choice for prophylactic use—for example, as a protective screen for the patient with valvular disease of the heart who requires dental extraction. On the other hand, in the treatment of established infections the high initial concentration of penicillin in the blood achieved with the crystalline salt may facilitate penetration of the antibiotic into the diseased tissues, where high concentrations may be found many hours after the blood level has fallen to zero. In practice the injection of 500,000 units of crystalline penicillin twice a day gives satisfactory therapeutic results. Reports of alarming, even fatal, responses to the administration of procaine penicillin (probably due to inadvertent intravenous injection) should be viewed against the background of the millions of injections that have been given without mishap; the incidence of dangerous side-effects is far too low to justify condemnation of procaine penicillin on this score.

Papaverine

Q.—What are the actions of papaverine? Is it useful clinically in the treatment of disorders such as angina pectoris and essential hypertension? If so, please indicate dosage.

A.—Papaverine is a feebly analgesic and narcotic alkaloid of opium which has a relaxing action on smooth muscle. The official preparation is papaverine hydrochloride, but it is also available as a sulphate and a nitrite. The usual dose is from 0.12 to 0.25 g. orally, but there are reports of as much as 1 g. being given intravenously without ill effect. Papaverine has been used extensively, especially on the Continent, in the treatment of angina, hypertension, and peripheral vascular disorders, but the effect is of short duration and the reports on its use are conflicting. It cannot be said to have any proved value in the treatment of these conditions.

Alcoholic and Traumatic Amnesia

Q.—Is it possible to differentiate between the amnesias due to head injury and alcoholic excess by the use of thiopentone or methylamphetamine?

A.—It should be possible to go some way towards clearing up an amnesic gap by investigation under intravenous thiopentone; and in some cases intravenous methylamphetamine might be tried as an alternative, though with much less prospect of success. Ordinary hypnosis will also sometimes succeed. Such measures should be completely successful in an amnesia solely due to hysterical dissociation, unless the patient is uncooperative. But with organically caused amnesias, though some forgotten events may be recalled, an irreducible minimum of amnesia usually remains. In this case it is presumably desired to explore the amnesia as a differential diagnostic method, to decide how far it might be caused by trauma or by alcohol. If the patient was in a deep alcoholic stupor he would be just as unconscious as after a severe concussion. In both cases, therefore, there might be equally good reasons for a permanent

and irreducible amnesic gap. The principal prospect of thiopentone investigation would then be to fill in the stor as far as possible, and in the light of a better knowledge of the circumstances so gained it might be possible to decide whether alcohol or trauma was implicated.

NOTES AND COMMENTS

Allergic Rhinitis.—Dr. MORRIS CUTNER and Dr. B. S. SWEETMAN (Chelsea, S.W.3.) write: May we supplement the answer under the above heading ("Any Questions?" February 7, p. 347) by quoting our experience? During the past 18 months or so we have submitted seven patients suffering from this condition to a course of histamine ionization. Of these, three have apparently been cured, two have been markedly improved, one (who incidentally has been relieved of her asthma) has not yet responded favourably, and one did not benefit. The numbers are small, but the clinical impression is significant. The only snag is that as each treatment aims at a general reaction it should (as in our cases) be carried out only by a competent therapist under direct medical supervision. As the patient in question derives some benefit from antihistamine drugs she would very likely benefit by this therapy. We hope to submit an article shortly giving clinical and other reasons for this belief.

OUR EXPERT writes: I have no personal experience of histamine ionization, but zinc ionization will help about half those with allergic rhinitis.

Night Starts.—ANOTHER DOCTOR writes: I was interested to read your correspondent's account of night starts in his legs following transverse myelitis (February 14, p. 414). I too have a spastic paralysis of both legs from a transverse myelitis. I observe that the degree of spasticity in my legs varies with the state of my large bowel. If I allow myself to become constipated the legs become much worse; if, on the other hand, the bowel is irritated with too much laxative the spasticity increases also. There is no doubt in my mind that these "kicks" of the legs are the result of an incoordination of large bowel peristalsis causing localized sections of the bowel to become dilated with flatus, and that they are motivated through a spinal reflex arc, the inhibitory impulses of the cerebral cortex having been cut off by the pyramidal lesion at the level of the myelitis. It is probable that air-swallowing during sleep is a factor in producing pockets of gas in the incoordinated large bowel. If I avoid flatus-forming foods the severity of the spasticity diminishes and vice versa. Weather conditions also have a very noticeable effect on the spasticity and "kicks," and it may well be that the lowering of the atmospheric pressure produces increased intra-abdominal pressure from the expansion of the flatus contained in the bowel.

Corrections.—In the obituary notice of Dr. Harold Balme (Journal, February 28, p. 511) we mistakenly recorded that he had only one son. In addition to Mr. David Mowbray Balme, Principal of the University College of the Gold Coast, Dr. Balme had another son, Dr. Harold Wykeham Balme, and two daughters.

In the appreciation of the late Sir William Douglas in last week's Journal (p. 513) he was wrongly described as Parliamentary Secretary to the Ministry of Health. Sir William's post was that of Permanent Secretary.

Dr. M. H. ARMSTRONG DAVISON writes: At the recent R.S.M. meeting on "Hypotension in Anaesthesia" (see February 28, p. 504), I stated that there had been only one death "on the table" in the last 60,000 anaesthetics given at the Royal Victoria Infirmary, Newcastle-upon-Tyne. I have subsequently discovered that there were in fact two such deaths.

The dose of L-thyroxine given in the second paragraph of the summary of the paper by Russell Fraser and M. Wilkinson in our issue of February 28 (p. 484) should read 0.1 mg. thrice daily, and not 1 mg.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 4499. TELEGRAMS: *Atiology, Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad. EASY AND
PLEASANT TO
ADMINISTER
TO CHILDREN
OF ALL AGES

**SUSPENSION****CHLOROMYCETIN®
PALMITATE**

The introduction of Suspension Chloromycetin Palmitate is an important advance in Chloromycetin medication. Pleasantly flavoured and containing a tasteless derivative of Chloromycetin (chloramphenicol, Parke-Davis), it is extremely acceptable to children of all ages and to those unable to take capsules. Physicians everywhere acclaim this antibiotic suspension.

Indicated in the treatment of many bacterial, viral and rickettsial infections, including:

PERTUSSIS · PRIMARY ATYPICAL (VIRUS)
PNEUMONIA · BACTERIAL PNEUMONIA
INFANTILE GASTRO-ENTERITIS · LARYNGO-
TRACHEO-BRONCHITIS · SEPTICÆMIA
MENINGITIS · SALMONELLOSIS · DYSENTERY
URINARY INFECTIONS · SURGICAL
INFECTIONS

Supplied in 60 c.c. bottles.

Each teaspoonful (4 c.c.) contains the equivalent of 125 mgm. Chloromycetin

Now you can prescribe symptomatic relief that offers many chronic asthmatics the return to a happy, useful life. With NORISODRINE, a quick-acting bronchodilator, the asthmatic has effective relief as near as pocket or purse. Administration is easy and inconspicuous. The patient uses the compact little AEROHALOR, Abbott's convenient inhaler. When a bronchospasm is impending, the asthmatic simply takes three or four inhalations of the powder and the attack usually subsides at once. Similar in action to adrenaline—but more effective—NORISODRINE is indicated in both mild and severe asthma. It has relatively low toxicity. With proper administration, side-effects are few and usually minor. There is little evidence of "fastness." NORISODRINE has proved effective in many asthmatic patients who are "adrenaline fast" and in those who could not obtain relief from such drugs as theophylline, iodides, or ephedrine. Before prescribing quick-acting NORISODRINE, however, please be very familiar with certain techniques and precautions discussed in available literature. *May we send you a copy?*

CHANGING CONCEPTS OF HEALTH AND DISEASE, WITH PARTICULAR REFERENCE TO "PSYCHOSOMATIC MEDICINE"

BY

R. R. BOMFORD, D.M., F.R.C.P.
Physician to the London Hospital

I do not think anything I shall say is new; much of it has been better said before, and some of it is very old—so old indeed that there always is a chance it may be mistaken for new. But I am encouraged to hope that, even so, it may fulfil the terms of the Bradshaw Trust, which states simply that a lecture shall be given in memory of Dr. William Wood Bradshaw on a subject connected with medicine or surgery.

As a starting-point I propose to try to put into words some ideas about the nature of disease which seemed to be taken for granted in the medicine I was taught to be taken for granted in the medicine I was taught nearly twenty-five years ago. It was assumed, so far as I could see, that there were things or entities called diseases which could be studied and treated as such. Some of these arose in and affected the mind, and were the province of psychiatrists. Others arose in and affected the body, and were the province of physicians, surgeons, and various specialists.

Diseases with physical manifestations could be divided into organic and functional. Organic diseases were regarded as real, objective, and the proper object of study by scientific medicine. They had physical causes, which either had been or would be elucidated as a result of increasingly thorough study by physical, chemical, and bacteriological methods. In the investigation of a disease the object was to find "the cause" and to deal with it. There was little or no interest in functional disorder. Functional symptoms seemed usually to be regarded either as invented or imaginary or as rather mysterious and discreditable states which in some way affected inferior personalities.

I do not think, as a student, I heard the word "psychosomatic," which is not surprising, for this actual word was apparently first used in 1926. Within a few years, however, it was suggested that certain physical diseases for which no satisfactory cause could be found, and which were becoming increasingly noticeable in nature, were becoming increasingly noticeable in nature. These sources of disability, were psychosomatic in nature. This appeared to mean that the structural changes found in the body were caused by a disordered mind. This possibility was eagerly seized on by a few, but denied or ignored by the many who believed that real organic disease had little or nothing to do with the mind and

would ultimately yield its secrets to the methods of physics, chemistry, and bacteriology.

Though stated baldly and perhaps oversimplified, I believe that is a fair summary of some of the main ideas about disease which were more or less taken for granted in the medicine I was taught. If any of my teachers should say they took nothing of the kind for granted, I can only say that this was what an average student gathered, not so much perhaps from what they said as from what they did not say. One saw, of course, that many of one's teachers did treat their patients as persons rather than as mere vehicles of disease, but I believe this was more an expression of humanity than an indication that they accepted such an approach as necessary to the understanding of disease.

Ideas Still Taken for Granted

I believe that some at least of the ideas I have outlined are still taken for granted by many persons engaged in academic medicine, by which for the purpose of this lecture I mean medicine as taught in undergraduate teaching schools. I will not waste time in defending this latter statement at length, but would refer to two recent articles by eminent teachers in undergraduate schools.

The one lists what he calls the five common causes of disease: inborn and inherited abnormalities; excess of a chemical agent in the environment; deficiency of a chemical substance; infection or infestation by viruses, bacteria, fungi, or animal parasites; and physical trauma. He thinks it possible that the important diseases of unknown aetiology, such as the rheumatic diseases, peptic ulceration, and ulcerative colitis, will turn out to be due to these same causes, acting singly or in combination, but entertains the "possibility that there exists a group or groups of diseases the causation of which we do not comprehend, or comprehend but dimly." His statement of what he calls the psychosomatic hypothesis—which is at least commendably brief—is that it "attributes disease to certain abnormal states of the mind." This hypothesis is then immediately dismissed along with that of focal sepsis as unworthy of serious consideration by scientific medicine. "The small amount of critically established fact," he says, "on

*The Bradshaw Lecture delivered before the Royal College of Physicians of London on November 6, 1952.

which these two hypotheses were based can probably be accounted for on the fact that the condition of any patient suffering from a chronic disease deteriorates when there is superadded infection or disturbance of the mind" (Pickering, 1950).

The other, speaking of the place of psychotherapy in the treatment of peptic ulcer, says: "In this connexion it should be recognized that, while many neurotics invent digestive disturbances, the ranks of genuine ulcer cases contain no higher proportion of neurotics than does the population at large. Most ulcer patients, indeed, are the reverse of neurotic. They may be anxious and worried, but they never invent symptoms, generally make light of their suffering, and rarely give up work unless the pain is intolerable" (Illingworth, 1952).

I would like to assure the authors of these in many ways admirable lectures that I have picked on theirs out of many others I could have chosen, not from any personal animosity, but simply because they happen to illustrate my thesis that certain ideas which seemed implicit in what I was taught are still current in academic medicine to-day.

I believe these ideas are almost without exception open to serious objections. I shall now examine some of them further, and in doing so review in an admittedly eclectic manner some papers which seem to me to illustrate changing ideas. In particular I wish to examine a common misapprehension that there is something called the psychosomatic hypothesis, which holds that abnormal mental states can cause physical disease. This will involve at least some reference to the idea of diseases as entities, to the idea of cause in medicine, and to the problem of the relationship between mind and body.

Diseases

It was and often still is assumed that there are entities called diseases which can be studied and treated as such. But, if we think about it, it seems obvious that we cannot observe diseases: we can only observe diseased persons during life or the mortal remains of diseased persons after death. Nosological classification may be a necessary convenience for purposes of orderly description, but we have come to think and often to act as if the states it describes exist as entities which can be studied and dealt with apart from the person who is diseased. One might almost feel one had to apologize for mentioning something so apparently trite and obvious were it not that much current teaching and action appears to be based on the opposite assumption.

Cause in Relation to Medicine

I have already said that it seemed to be assumed, when I was a student, that organic diseases had physical causes, and by this there was often implied a single cause. The cause of lobar pneumonia was the pneumococcus. The cause of cirrhosis was alcohol, and so on. The business of diagnosis was to find the cause of the disease, and the object of rational treatment was to remove it. When the cause was unknown, only symptomatic or empirical treatment was possible. I have perhaps laboured these illustrations to show that we really did seem to think in terms of single causes, though we cannot have gone very far in considering the implications of this view.

The idea of cause is a complicated one, and many people much better qualified to do so than I have written about it in relation to medicine. Howe (1934), for instance, speaking of the kind of examples of cause and effect I have just mentioned, says: "However, not one of these examples is truly a case of cause and effect. Not only is the effect produced in each case by the interaction of at least two

antecedent events, but each of these antecedent events is produced by the interaction of another two. If we are to be accurate we must then recognize not 'a cause' but an endless multiplicity of causation, which is extremely confusing. There never is, in fact, 'a cause' but always 'a relationship.' And a little later on he says: "It is to-day generally agreed in theory, although not always recognized in practice, that disease is essentially an interaction between seed and soil, in both of which there is a convergence of a sequence of related events, from the association of which the effect is developed."

What we can observe, he says, is a series of events connected and related through the medium of time, stretching back into the past and forward into the future. If a bus runs over my leg I may say that the impact of the bus is the cause of the fracture of my femur. More accurately, the event may be described as the intersection of two time-sequences in which the bus time-sequence crosses the leg time-sequence. "If we seek causes we find two causal time chains: what caused the bus to be where it was, and what caused the driver of the bus to do as he did; what caused the leg to be where it was, and what caused the leg eventually to heal. These are not truly to be regarded as being causes, but as a series of related time-effects."

Recently Strauss (1952) devoted the first of his Croonian Lectures to a discussion of causality in medicine. I am afraid that many of the ill-educated generation to which I belong may have found his philosophical arguments difficult to follow. But we cannot fail to appreciate his criticism of rigid causal relationships in medicine and to be convinced of the inadequacy of our search for single or "specific" causes of disease. I cannot, however, resist one or two comments.

"It is arguable," says Strauss, "that a pure paired cause-effect relationship exists at two levels only: the ethical and the mechanical." Of the pure paired cause-effect complex at the mechanical level he gives two examples: a person swallowing a large amount of arsenic by mistake—the cause—leading to acute gastritis—the effect; and a second example, a personal experience of his own, of the sudden protrusion of a lumbar intervertebral disk—the cause—leading to severe pain in the back and complete immobilization below the waist—the effect.

These examples of simple cause and effect at a mechanical level are then contrasted with an account of the possible factors—bacteriological, constitutional, sociological, and psychological—concerned in the development by a particular person of the mode of morbid behaviour which we call pulmonary tuberculosis. The contrast is instructive, but one is compelled to ask whether in the two examples cited the effect can really be attributed to a single mechanical cause. I would like, for instance, to know how the "mistake" (which Strauss agrees is an over-simplification) of swallowing the arsenic occurred, and I would suggest the effect might have been different had the subject by some odd but not impossible chance been a habitual arsenic eater with a tolerance to the drug, such as has apparently been observed in Styrian woodcutters. Should not the effect in this case again be regarded as resulting from the convergence of two sequences of events—what caused the arsenic to be where it was and to be swallowed, and what caused the person who took it to be susceptible to its effects?

A Personal Experience

The second example interests me, also on account of a personal experience. I too suffered from a pain in my back—in this instance a chronic pain over many years—severe enough to be a nuisance at times, but never incapacitating or bad enough to make me do anything about it. In the earlier years I supposed it was due to fibrositis, whatever that is, and encouraged my dentist to look for a source of focal sepsis, which he did not find. Some years later, when it was particularly troublesome in a humid

tropical climate, I supposed that constantly damp clothes and bedclothes had something to do with it. Later, after reading about psychogenic backache, I concluded this must be the whole explanation. Some months ago an x-ray film of the spine showed, I am told, conclusive evidence of an old and considerable protrusion of a lumbar intervertebral disk. Here, surely, was another example of direct mechanical cause and effect, and incidentally a vindication of the importance of searching for a single demonstrable cause for a symptom or group of symptoms, rather than indulging in the vague speculations of multiple aetiology.

But I am not so sure, for I believe that the protrusion of my disk was not entirely an accident; and, further, I have to account for the fact that I have for some time been practically free from pain, though I am assured that the actual disk lesion is unlikely to have altered.

Briefly—and if you will forgive some personal details—I believe the protrusion of my disk can be traced back to two what might be called parlour tricks. The first was to challenge my fellows to put their hands flat on the ground in front of them without bending their knees. This, the only faintly distinctive physical achievement I had, used to give me satisfaction, and was probably harmless. Unfortunately some years later, though I had never been able to jump anything, I discovered I could do what is known in gymnastic circles as a "neck roll." This consists in diving over some object, turning a somersault on a cushion or mat, and landing on one's feet again. It was a great success at Army mess nights and similar occasions. Unfortunately it involved a sharp flexion of the lumbar spine, and after a year or two I had to abandon it on account of increasing pain and stiffness in my lower back. I have little doubt this eccentricity was an important factor in the protrusion of my disk, and, of course, the story could easily be pursued further by inquiring why a clumsy and rather obese physician should have found it necessary to perform "neck rolls" at an age when such an accomplishment is not generally considered necessary—but I do not intend to follow it further on this occasion. I have said enough to indicate that I am fairly sure the protrusion of my disk was not a simple mechanical accident.

Once it was discovered I was given some back-extension exercises and advised to wear a lumbo-sacral support. This contrivance supports nothing except any abdominal protrusion which may be present, but is effective because it makes bending so uncomfortable that one ceases to bend. I persevered with the belt and the exercises for at most a week or two. I was virtually free from pain within a few days and have now learnt that I can remain so without the aid of the support or the exercises, so long as I do not habitually slump in chairs and car seats. When I do so slump, I get a slight return of pain. I have no doubt that for me "slumping," as I have called it, is a physical expression of certain emotional attitudes.

I have troubled you with this rather long personal anecdote because it seems to me to illustrate clearly the inadequacy of the idea of single causes. For you will see that if you were to ask me what was "the cause" of the pain in my back I should find the question difficult to answer.

What we call the cause of an illness is never strictly the whole cause, though it may be a necessary factor in causation in the sense that one would not have that particular illness without that particular factor. I would not have had the particular kind of pain in my back if I had not had a protrusion of an intervertebral disk. But the protrusion of the disk was simply one link in a chain of causation, and the pain, once it was understood, was relieved by fairly simple measures, which presumably left the disk lesion *in situ*.

It is worth noticing, perhaps, that the main difference between these two examples of the protrusion of a disk is that the first might be described as an acute illness and the second as a chronic. This is probably an example of a

general difference, to which attention has often been drawn, as for instance by Ryle (1942). Whether or no the search for single or specific causes is ever justified on philosophical grounds, it has been more productive of results in acute than in chronic diseases. Medicine's greatest successes have been in connexion with acute disease and particularly acute infections. Where partial success has been achieved in the treatment of chronic diseases, as in myxoedema, diabetes, and pernicious anaemia, one must note that in each instance the patient is not cured, and our knowledge of the aetiology of the condition is still quite incomplete. Our ability to deal successfully with most chronic diseases has advanced much more slowly than in the case of acute ones, and it is possible that this is due, at least in part, to our undue preoccupation with single specific causes and direct mechanical cause and effect.

Aetiology in Relation to Medicine

Aetiology is defined in the *Oxford Dictionary* as "the science or philosophy of causation" and in *Dorland's Medical Dictionary* as "the sum of knowledge regarding causes." Strauss has described the substitution of the term "aetiology" for "cause" as no more than a resort to the magic of semantics in an attempt to escape from the fetters of rigid causality. But I believe that the change in words can be something more than semantic juggling, and may represent a change both in ways of thinking and in ways of acting, which is to be encouraged even though we are still far from a satisfactory concept of aetiology.

Ryle (1942), after quoting the definitions I have mentioned, continued: "It is well to insist on such definitions, for the discovery by Pasteur and the great pioneers in bacteriology of specific microbic agents of disease, and the recognition by others of specific chemical agents and specific deficiencies, have, until quite recently and contemporaneously with their immense benefits to medicine, had a peculiarly limiting effect upon the vision and the practice of many medical men, not excluding teachers. They have, in fact, compelled a neglect of the associated causal factors without which no disease can have its being. They have also fostered a belief in or search for single determining causes where none exist."

A paper by Halliday (1943) seems to me of particular value in that, though some difficult matters are perhaps oversimplified, the author outlines a concept of aetiology which seems to avoid obvious pitfalls and to provide a reasonable system of thought on which medical action can be based. In the space available I can do scant justice to this paper, which could with profit be read, pondered, and re-read by every teacher of medicine.

Cause in medicine, says Halliday, has usually been regarded in one of two ways; and he calls them the "mechanistic" and the "biological."

Mechanistic Cause

The word mechanism refers to a system of mutually adapted parts working together as a machine. Given the requisite preceding movement, the ensuing movement follows necessarily upon it, provided the machine is in working order. During the last three centuries, knowledge of the human organism in terms of mechanism increased progressively and the organism came to be regarded as if it were a machine. If it failed to function properly, in actual fact a machine. The primary concern of medicine was to identify the cause of the breakdown was similar to that of a machine—that is, a fault in one or more of the component bits and pieces. The primary concern of medicine was to identify the fault, which might be viewed by any technique—for example, gastric ulcer, a structural fault; acidosis, a chemical fault; or hypertension, a physical fault—and to take appropriate action by interfering with the mechanism.

Some of the implications of mechanistic aetiology Halliday summarized as follows: (1) The human organism

is a machine composed of mutually adjusted parts working together. (2) Illness corresponds to breakdown in the machine. (3) The cause of illness (provided the patient has adequate food, air, and water) is something wrong—a fault, disease, lesion, imbalance, or abnormality—in one or more of the parts. (4) Medical action is confined to interfering with the mechanism by what is known as the appropriate treatment.

This mechanistic attitude has, of course, brought great advances. The criticism of it is not so much that it is wrong as that it is not enough. In particular it gives little or no guide to action in the prevention of disease, for it is concerned with how a patient is ill rather than why he is ill. One might add that while few doctors now take a purely mechanistic view, most patients do, hence the very great difficulty of giving them any reasonable explanation of functional symptoms. Say what we will, the patient believes there must be a fault in the mechanism somewhere—"the cause"—and an appropriate means of dealing with it—"the cure." One might also point out that the mechanistic idea of disease allows of no definition of health other than the absence of disease, which is plainly inadequate, for there is a great difference between "no disease" and health.

Biological Cause

Halliday explains what he calls the biological idea of cause as follows. "Illness is regarded, not as a fault in the parts, but as a *reaction*, or mode of behaviour, or vital expression of a living unit in response to those forces which he encounters as he moves and grows in time. Cause is therefore *twofold* and is to be found in the nature of the individual and the nature of his environment at a particular point in time." The environment, the totality of exterior circumstances, may be investigated by a variety of techniques—physical, chemical, bacteriological, psychological, and so on—and in this way split up for convenience into separate components which we may call factors.

That an aspect of cause is found in the individual person may not at first sight seem so obvious. It may be illustrated by pointing out that when two persons encounter the same environmental factor the behaviour of each depends on his characteristics. Suppose, for instance, that a weight of 2 st. falls equally on the legs of a man aged 30 and of his father aged 80. The son will probably develop a superficial bruise, and the father a fracture of both legs. Two men swallow water containing virulent typhoid bacilli. One who gives no previous history of typhoid fever responds ten days later by a morbid reaction whose features include fever, prostration, diarrhoea, etc. The other, who does give a history of previous enteric fever, shows no evident morbid behaviour. When an SOS is broadcast several million people may be quite unaffected, while one man falls down in a faint. In each of these imaginary but quite possible examples the environmental factor was certainly not the whole cause. An aspect of cause was present in the persons affected.

Some of the implications of biological aetiology were summarized by Halliday as follows: (1) The human organism, although composed of parts, may also be regarded as an integrated unit or living person. (2) Illness represents a vital reaction of a person to factors of the environment which he meets as he moves in time. (3) The cause of illness is therefore twofold—certain characteristics of the person and certain factors of the environment. (4) Medical action is concerned primarily with measures designed (a) to alter or prevent characteristics of the person known to be causal, and (b) to alleviate or remove factors of the environment known to be causal.

This biological attitude is, as Halliday points out, a *sine qua non* for effective prevention of disease and may be very important in treatment. One might add that it does make possible a reasonable explanation of functional symptoms, the reaction of a particular personality to factors in the environment, and it does make possible a concept of health

other than in terms of "no disease." Halliday then summarizes the ideas underlying the phrase "the cause of the illness" as follows:

"(a) As regards the *illness*, the fields of observation and discourse are the features (signs and symptoms) of a mode of behaviour of an individual.

"(b) As regards the *cause*, the fields of observation and discourse are three—namely:

"(1) *The field of the person*. Under this heading are put the observations on the characteristics of the person before he became ill. These are innumerable, and may be noted in terms of any technique. They include, for example, age, sex, weight, height, bodily habitus, history of previous illnesses, history of illness in the family, blood pressure, menopause, intelligence, etc. The problem is to distinguish which of these characteristics may be regarded as relevant and causal.

"(2) *The field of the environment*. Under this heading are included observations on the factors of the environment which the person met at, or shortly before, the time he fell ill. The observations may be made in terms of any technique—e.g., physical (trauma, heat, cold, light), chemical (diet, poisons), bacteriological, and psychological (death of a loved person, failure or promotion, etc.). Such factors are innumerable, and the problem again is to determine which of them may be regarded as relevant and causal.

"(3) *The field of mechanism*. Under this heading are put observations on the 'bits and pieces' (structural, physical, chemical, psychological, etc.) which are set into action by the encounter and which ultimately bring about the particular mode of behaviour. The problem is to distinguish which of these are primarily involved."

And the three questions which he suggests one should attempt to answer about any illness are, of course, now quite well known: (1) What kind of a person was this before he took ill?—that is, which characteristics of the person are relevant and causal? The field of the person. (2) Why did he become ill when he did?—that is, which factors of environment are relevant and causal? The field of the environment. (3) Why did he become ill in the manner he did?—that is, which part contacted the factor and which bits and pieces by preceding movement and ensuing movement finally made manifest the particular mode of behaviour? The field of the mechanism.

It seems at least, from this brief review of what is meant by cause or aetiology in medicine, that we can never strictly think in terms of a single or specific cause of a disease. On this ground alone it appears unsatisfactory to suggest that abnormal mental states can in themselves cause physical disease.

Body-Mind Relationships, with Reference to the "Psychosomatic Hypothesis"

It was assumed, and I think still is, that diseases can arise in and affect the mind on the one hand, or can arise in and affect the body on the other; and we argue then whether disturbance in the mind may cause disease in the body. My excuse for venturing, with some trepidation and in however superficial and amateur a fashion, on a subject which has puzzled some of the best minds of every generation for well over two thousand years, must be that I believe it is impossible to practise or teach medicine without making some kind of assumption or taking for granted some kind of hypothesis about the relationship between what we call mind and what we call body. Many people do not, of course, consciously make any such assumptions. They take them over ready-made from teachers and textbooks. I should put it rather, perhaps, that our attitude to disease and our manner of dealing with patients must involve some hypothesis of body-mind relationships, whether we are aware of it or not. Fortunately the problem I want to discuss is a fairly limited one. It is simply to ask, have we any right to divide diseases into physical and psychological, in the sense that they arise in the body or arise in the mind, and have we any right to talk about events in the mind causing disease in the body?

Monism

Victorian materialism regarded matter as real and objective, and mind simply as some kind of a by-product of matter. Though, so far as can be seen from their medical writings, this is the view to which many medical scientists still adhere, others adopt some kind of psycho-physical parallelism or some form of monism, which regards mind or conscious states and brain states as different aspects of the same events. As Russell Brain (1951a) explained one form of this hypothesis: "What we call events in the physical brain are happenings about which we may have indirect knowledge inferred from our perception of other people's brains and what they tell us about their experiences; but we have direct awareness of the physical events in our own brains and when we thus perceive them we find them to be thoughts, sensations, feelings, and so on."

According to this hypothesis there is thus only one kind of events, but they appear different to us because we have knowledge of our own minds in terms of perceptual symbols and knowledge of the physical world, including other people's brains, expressed in conceptual symbols.

If for the moment we accept this hypothesis, then it seems to me that the questions I asked have little meaning. Brain states and mind states are two aspects of one series of events which appear different only because we perceive them in different ways. One cannot then imagine purely physical disease or purely psychological disease, and it makes no sense to ask whether mental states can cause physical states. If one asks whether emotions like anxiety or anger can cause physical disease—what one is really asking is whether mind-brain states like anxiety or anger can cause physical disease elsewhere in the body. If, indeed, we watch someone losing his temper, can we really say that this is something in the mind—something purely mental—causing something in the body? And I do not think it makes much difference to the argument if we suppose that brain states and mind states are different events, but events moving, so far as we know, exactly in parallel.

Common-sense Dualism

I would like to ask those who talk about physical diseases arising in the body and psychological disorders arising in the mind, and who argue whether disorder in the mind can cause physical disease in the body, to explain to what kind of a hypothesis of body-mind relationships they are subscribing? So far as one can see, it must be a so-called common-sense dualism, which conceives of an independent immaterial mind in some mysterious way interacting with a material brain and body. But I suspect that this popular dualism again depends on the two kinds of knowledge to which Russell Brain (1951b) has drawn attention. We have difficulty in equating events in our own minds which we perceive directly as thoughts and feelings with events in brains of which we have only indirect knowledge by inference, and we therefore regard our thoughts and feelings as more or less independent things, without pausing to consider the implications of this view.

But whatever ultimate belief or philosophical hypothesis we may entertain, so far as our observation can go, a person is surely a body-mind unity. We have no experience of mind separate from body in ourselves, and we cannot imagine such a state of affairs in anyone else. So far as our own observations and the inferences we can make from them go, a person is a body-mind unity; body and mind are in some way inseparable aspects of a person.

It would seem, therefore, that we must regard all diseases as states or modes of behaviour of a person who is a body-mind unity, and it follows, surely, that all disease must be regarded as psychosomatic, in the sense this word is generally used. All disease must affect in some degree both body and mind. We have no right, then, to divide diseases into physical and psychological, in the sense of that which arises in or affects the mind and that which

arises in or affects the body, nor to say that something happening in an entity mind can cause something else to happen in an entity body.

But we can study diseased persons by different methods. If we study them by methods which provide information in physical terms, we obtain information in physical terms. If we study them by methods which give an answer in psychological terms, we obtain information in psychological terms.

What we can do then is to group disease states roughly into those in which most of the relevant and useful information seems at present to be obtained by physical methods; those in which most of the relevant and useful information seems at present to be obtained by psychological methods; and those in which both methods supply relevant and useful information. The last group corresponds, of course, to what are often now referred to as the psychosomatic disorders.

But even this division can be no more than a rough and temporary grouping for the sake of convenience. For I believe it is true that the more diseased persons are studied by both physical and psychological techniques, the more disease states we find in which both methods produce relevant information.

Literature of "Psychosomatic Medicine"

The literature of so-called psychosomatic medicine—I shall come back to that term later—is already considerable, and I shall not attempt to review more than a very little of it, partly because such an attempt would need to occupy at least several lectures, and partly because I believe it would be unprofitable. For I suspect that a person's attitude to what may be called the psychosomatic method in medicine depends less on an intellectual evaluation of the literature than on his attitude to neurosis. Just as an overtly neurotic patient tends to arouse irrational feelings in most of us, so does the suggestion that illness, needless to say in ourselves as well as in our patients, can be fully explained only when psychological and physical factors are taken into account. We resist this suggestion as applied to ourselves, and we tend to deny it in our patients.

Earlier I quoted an article by Pickering (1950) in which he dismissed what he called the psychosomatic hypothesis in a few lines on the ground that the small amount of critically established fact on which it was based could be explained in other ways. But in doing this he makes an assumption: he assumes, it seems to me, that a satisfactory account of the causation of disease states, or some of them, has been, or can be, given in purely physical terms; and that it therefore behoves those who are interested in the so-called psychosomatic hypothesis to prove their case by providing critically established fact.

But this is a big assumption, and I would ask those who make it to consider carefully in how many chronic diseases can they give a satisfactory account of the aetiology in purely physical terms? We come nearest to giving such an account, I suppose, in nutritional deficiencies and in certain chronic infections, where again one factor in the environment is of particular importance. But is that factor, even in these instances, the whole story? A great deal is known, for instance, about the tubercle bacillus; but can we really explain on humoral grounds why some people become ill with tuberculosis while others do not, and, of those who do become ill, why in some the process is arrested while in others it is not? I doubt if we can, and I believe that studies of personal factors which may be concerned in the onset and course of tuberculosis such as those of Wittkower (1949) and of Day (1951, 1952), even though they do not amount to "critically established fact," are still of great interest and importance in this connexion.

I would like to suggest that we may equally, and indeed with much more reason, start from the historically older and philosophically more satisfactory assumption that illness

is a state of the whole man—in the sense that it is a state of a body-mind unity, and ask those who doubt the importance of psychosomatic method to establish their case by giving a satisfactory account in purely physical terms of the aetiology of even one of the chronic conditions which are at present described as of unknown aetiology. Peptic ulceration, ulcerative colitis, hypertension with all its sequels, rheumatoid arthritis, and asthma, to name but a few, await such an explanation.

But, it may be said, since rheumatoid arthritis can now be dramatically if not completely relieved by supplying the substance cortisone, we can surely regard rheumatoid arthritis as a purely physical abnormality, curable by physical means. And doesn't this make the complicated and difficult psychosomatic approach unnecessary?

Those who use this kind of argument are confusing mechanism with aetiology. The discovery of cortisone and A.C.T.H. has brilliantly illuminated, or bids fair to illuminate, the physico-chemical mechanism of rheumatoid arthritis amongst other things, but it has brought us no nearer being able to answer the question why a given person is taken ill with rheumatoid arthritis or how this illness can be prevented—just as the discovery of insulin and vitamin B₁₂ has led to very great advances in our knowledge of the physico-chemical mechanism of diabetes and pernicious anaemia without telling us why some people develop these conditions or how they may be prevented.

Medicine in undergraduate teaching schools, as Halliday put it, has shown hitherto a distinctly mechanistic bias, in the sense that it has devoted enormous energy to the explanation of the mechanism of disease in physico-chemical terms, relatively less to the environment, and still less to the person. But there are signs that this is changing. There have been, for instance, numerous psychological studies of personality types in different illnesses, notably the very extensive contributions of Dunbar (1943), and her colleagues from the psychiatric and medical divisions of Columbia University. My own feeling is that these and other personality studies, though of great interest, are somewhat inconclusive in that they seem to depend so greatly on the subjective interpretations of the observer, and it remains to be seen whether independent observers will always find the same personality types or range of types in the same illnesses. At the same time a start has been made on the more accurate study of physical types by means of Sheldon's method of somato-typing (Tanner, 1949).

To my mind the outstanding recent contribution to the study of man, rather than mechanism, has been the work of Wolf, Wolff, and their colleagues at Cornell University Medical College, over the last 10 to 15 years.

For details of their methods and results one must read at least their two monographs (Wolf and Wolff, 1943; Grace, Wolf, and Wolff, 1951). Very briefly, one patient with a gastrectomy and four with prolapsed colonic mucosa were studied over considerable periods. The rate of blood flow, as judged by colour changes in the mucosa, and secretory and motor activity of the stomach and colon were measured in a variety of circumstances, and notes made on the effect upon them of ordinary physiological stimuli, of drugs, of the patient's particular life situation, and sometimes of emotionally coloured happenings, either occurring spontaneously or provoked deliberately during the course of the experiments.

I believe these are important studies for several reasons. They were performed on man, and intact man, except for the accident by which either gastric or colonic mucosa was visible. Instead of trying to standardize the conditions of their experiment by avoiding the complication of using conscious human subjects, or by what might be called eliminating the human factor, these observers standardized all the other conditions of their experiments so far as possible, and deliberately set out to study, among other things, the effects on the stomach and colon of human situations and emotions.

What emotion the subjects were actually experiencing in the different experimental situations had, of course, to be inferred. But, given that the authors' inferences were substantially correct, their results are of the greatest interest. I would like to mention one or two points which seem particularly relevant to my lecture. In an animal preparation the actions of a drug are usually constant and predictable. In these observations on man there are several instances where this was not so, and where the actual effect of a drug appeared to depend not on its pharmacological action but on the meaning of its administration to the particular subject. This is seen most clearly in the account of the effects of the intravenous administration of atropine on the colon in three of the subjects with colostomies. In two subjects who were thought to be in a state of relative security and relaxation the injections were accepted with apparent equanimity, and their effect was a profound decrease in motor activity of the colon and some blanching of the colour of the mucosa, as would be expected on pharmacological grounds. In a third subject, who resented the experiment, the same intravenous dose of atropine was followed by a great increase in motor activity and in the colour of the mucosa—changes which had been found previously in states of anger—and, though the atropine produced its expected effects on the salivary secretion and circulatory system, at no time was there any pallor or diminution in the motor activity of the colon. It appears that in this instance the physiological effect of the resentment aroused by the injection of the drug predominated over its expected pharmacological effect.

This observation is in fact a particular instance of something which appears throughout these studies—namely, the important and often predominant effect on the subject's gastric and colonic function of the relationship existing at the time between the observer and the subject or, in more general terms, the physician and the patient.

Another point I would like to mention is the authors' finding that the colonic changes in anger and hostility were greatest in the two of the four patients who had conspicuous difficulty in expressing their feelings (and these incidentally were the two of the four patients who suffered from ulcerative colitis). This again only confirms what has long been held by psychiatrists, but the demonstration that the actual changes in the colon were greatest in those who appeared to be suppressing their anger is new and impressive.

I believe this study is important not only for its content, but because it represents a new departure—the measurement changes in function in the organs of man, in health and disease, in relation to life situations and emotional states. It may well be the beginning of a new chapter in our understanding of illness.

Health

It seems inescapable that sooner or later we shall come, or indeed we shall be driven by the economic pressure of the cost of sickness, to regard the prevention of disease and promotion of health as more important than the curative or more often palliative medicine to which at present we devote so much more attention. One of the main difficulties seems to be that we have no clear idea of what constitutes health. So far as I can remember, health was not mentioned when I was a student. The mechanistic view of disease which was then the rule left no room for a concept of health, other than in terms of no disease. Just as a machine which was in working order ran, so the body was regarded as healthy so long as there was no breakdown or disease. But good health is something more than no disease, and we can all recognize it when we see it, even though we cannot say just what constitutes it or how to go about getting it. I believe it is our profession's lack of a concept of health, other than as a state of no disease, that leaves the way open for widespread exploitation of the average person's natural desire to enjoy as good health as he can.

My object in raising this question is not to attempt to settle the meaning of health. We are asked to believe, indeed, that this has already been done by the World Health Organization, which has laid it down in most authoritative and uncompromising terms that "health is a state of complete physical, mental, and social well-being; and not merely the absence of disease and infirmity." Here, adds its Director-General, as a kind of warning to meddling intruders, is one word concerning the meaning of which the dictionaries will not have to worry from now on (Brock Chisholm, 1949). I need not spend time on this definition (with its necessary implication that all of us are sick, since none of us enjoy complete physical, mental, and social well-being), because it has already been ably examined and criticized by Curran (1952). With all deference to the Director-General of the World Health Organization, I believe we are still far from a satisfactory idea of what constitutes health.

The *Oxford Dictionary* defines health first as "soundness of body; that condition in which its functions are duly discharged," and gives as a further meaning "spiritual, moral, charged," and gives as a further meaning "spiritual, moral, or mental soundness." I imagine it would be generally agreed that health cannot be fully explained in physical terms, and, whatever opinion we hold about disease, health is certainly psychosomatic.

One of the most interesting discussions of health and disease I know of occurs in a small book by Crew (1949) on *Public and Personal Hygiene*. After pointing out that the individual must be capable of adjusting himself to the conditions and circumstances of his external physical and social worlds, he defines health "as that state of the individual in which harmony exists between the various component parts of himself and between the individual as a whole and the circumstances and conditions of his external world."

This definition is a distinct advance, but does not seem entirely satisfactory for at least two reasons: first, no one enjoys complete harmony either in himself or with his external world; and, secondly, health is not so much a state of harmony as the product of a process of continuous adaptation or adjustment, by which a reasonable degree of harmony is maintained. The nearest I can get to an explanation of health—I would not say a definition—is that a person's health depends first on the constitution he is born with, and then on the success he has in constantly adjusting either himself to his environment or his environment to himself, so that a reasonable degree of harmony is maintained both within himself and between himself and the social and material world in which he lives.

But my object in raising this question was not to attempt to settle the meaning of health. It was to point out the need for such a concept, and some of the difficulties in formulating it—difficulties which are, I believe, intimately connected with the questions that I have been discussing. It is no accident that academic medicine has no concept of health; for the mechanistic idea of disease leaves no room for one, other than in terms of no disease, which is clearly inadequate.

Discussion

I would now like to try to pull together some of the apparently disconnected threads of my discursive and eclectic review of some changing concepts in medicine.

Thinking in medicine seems too often to be based on unexamined or insufficiently examined assumptions. It seems often to be taken for granted, for instance, as I have tried to point out, that we can usefully study diseases rather than diseased persons; that all disease or most diseases can be explained in terms of direct mechanical cause and effect; and that diseases can be divided into physical and psychological, with the implication that so-called physical diseases can be studied and treated satisfactorily by exclusively physical methods. In general these individual assumptions add up to a main one, that disease—no one seems to have worried much about health—can be explained in mechanistic or physico-chemical terms.

The rise of so-called psychosomatic medicine, which in America appears already to have assumed very considerable proportions, can best be regarded in a social sense as a revolt against this main assumption; and it is significant that this revolt has coincided with a growing tendency among some physical scientists to question how much their methods can be expected to explain. Strictly, as I have also tried to emphasize, there can be no such thing as psychosomatic medicine or a psychosomatic disease, for these terms involve a confusion between the methods of examination and the objects of study. Health and disease are necessarily psychosomatic, so there cannot be a part of medicine or some diseases which are psychosomatic. What the psychosomatic method does insist—or rather reiterate, for its teachings are as old as medicine—is that in health and disease man must be considered as a whole, and diseased persons must be studied by both physical and psychological methods. It is perfectly true that, in some, much information may be given by physical and little by psychological methods, and in others much by psychological and little by physical methods; but we must not be tempted to conclude from this that there are physical diseases and psychological diseases.

It is often assumed that there is an antithesis of some kind between science and art in medicine. If one were to hazard a guess, a time will come when this too will be regarded as having been a mistaken assumption. When this has happened we shall recognize sciences of pathology, pharmacology, experimental medicine, and so on (for many aspects of disease are explicable in terms of mechanism); and possibly a science of psychology. But strictly clinical medicine will, I believe, be regarded neither as an art nor as a science in itself, but as a special kind of relationship between two persons, a doctor and a patient. It will be recognized that this relationship is the essential feature of clinical medicine; and that the degree of success that it has depends, as in other human affairs, on the skill with which both science and art are called to its aid.

Australia's greatest pest, the rabbit, is rapidly being brought under control by the planned introduction by the Commonwealth Scientific and Industrial Research Organization of the virus disease myxomatosis. The disease is spread among rabbits by mosquitoes, and in the last three years has gained such ground that the Lands Department of Victoria now estimates that more than 90% of the rabbits have been destroyed in large areas of the State. Similar destruction is reported from many parts of New South Wales, South Australia, and Southern Queensland, with the result that farmers and graziers report a phenomenal increase in the carrying capacity of their pastures. The Minister for External Affairs, Mr. Casey, who is also in charge of the C.S.I.R.O., said that if the gains won at such low cost were maintained Australia's carrying capacity would increase by the equivalent of 10,000,000 sheep. However, he warned that in many districts rabbits were showing an increased resistance to the disease, and that in a very few more seasons myxomatosis might have lost most of its killing power.

THE ANTI-CURARE AGENTS

BY

A. R. HUNTER, M.D., F.R.F.P.S., D.A.

Anaesthetist, Royal Infirmary, Manchester

It is a truism to say that the only safe remedy for respiratory depression due to curarizing drugs is artificial respiration. It is, however, often very inconvenient to control a patient's breathing until such time as full spontaneous respiratory activity returns. Fortunately there has long been available in "prostigmin" (neostigmine, B.P.) an adequate and effective antidote drug. A few years ago, however, several fatalities were recorded shortly after the administration of this agent (Macintosh, 1949; Clutton-Brock, 1949; Hill, 1949). Lately the drug "tensilon" (3-hydroxyphenyl-dimethyl-ethyl ammonium iodide) has been adopted as an anti-curare agent in the United States. It has been investigated in Britain (Doughty and Wylie, 1952; Hunter, 1952) and found to be free from the dangers of

excessive parasympathetic stimulation inherent in the action of neostigmine. Unfortunately, tensilon has a very short action, and relapse into partial curarization may occur within some 10 minutes, especially in the deeply curarized subject. Neither antidote is thus completely satisfactory. However, since neostigmine is undoubtedly the more effective of the two, it seemed a matter of some importance to try to elucidate further the dangers of its administration and the methods available for their elimination.

The Investigation

Neostigmine was given to a series of 50 patients who had been curarized with various substitution myoneural blocking agents. All cases had been anaesthetized with nitrous oxide and oxygen and a supplement. It is generally agreed that the primary danger of neostigmine administration is cardiac inhibition. The pulse rates of the patients to whom the drug was given were therefore counted repeatedly at short intervals in order to obtain information on four points: (a) the pattern of the response of the pulse rate to neostigmine given with atropine; (b) the effect on this of giving the atropine some minutes before; (c) the modification induced by giving a sympathomimetic drug with the

FIG. 1.—Pulse-rate changes after neostigmine, 1 to 1.5 mg., with atropine, 1/100 gr. (0.65 mg.).

FIG. 2.—Later pulse-rate changes after neostigmine and atropine (doses as in Fig. 1).

FIG. 3.—Pulse-rate changes after administration of neostigmine, 2.5 mg., with atropine 1/50 gr. (1.3 mg.).

FIG. 4.—Pulse-rate changes after atropine 1/100 gr. (0.65 mg.), followed some minutes later by neostigmine, 1 to 1.5 mg. The time of administration of the neostigmine is indicated by the change from a broken to a solid line in the graph.

atropine and neostigmine; and (d) the appropriate amount of atropine required to make the ordinary doses of neostigmine safe.

Pattern of the Response of the Pulse Rate

The obvious danger of the administration of neostigmine is cardiac inhibition. With this in view, the pulse rates of patients to whom this drug was given with atropine were counted every 15 seconds after the injection had been completed (Fig. 1). It will be seen, however, that in every instance such change as did appear was in fact an acceleration and not a slowing. Presently it became apparent that bradycardia developed later in some cases. The pulse rates were therefore counted every minute for as long as possible after the injection of the drugs. In every instance it was found that there occurred a progressive slowing of the pulse rate to a minimum during the first 5 to 10 minutes after the injection had been given. Typical results are shown in Figs. 2 and 3. The slowing in some cases amounted to 60 beats a minute. The ultimate rate attained was related to the initial heart rate. In patients with a tachycardia of

FIG. 5.—Pulse-rate changes after atropine, 1/50 gr. (1.3 mg.), followed some minutes later by neostigmine, 2.5 mg. The time of administration of the neostigmine is indicated by the change from a broken to a solid line in the graph.

FIG. 6.—Immediate pulse-rate changes after administration of neostigmine, atropine, and a vasopressor drug. Doses: neostigmine, 1 to 1.5 mg.; atropine 1/100 gr. (0.65 mg.); ephedrine 30 mg. or methedrine 10 mg.

120 or more at the time neostigmine and atropine were given the rate tended to slow to speeds between 70 and 100 a minute. In those whose pulses were relatively slow there was a tendency to obvious bradycardia, and rates of 40 to 50 were sometimes seen.

Effect of Giving Atropine before Neostigmine

The work reported in the previous paragraph had suggested that in the anaesthetized human subject no initial period of slowing followed the administration of atropine intravenously. None the less, as the view is widely held that atropine slows the pulse by medullary stimulation before its peripheral accelerating mechanism develops, it seemed desirable to obtain direct evidence on this point. The pulse rates were therefore followed in patients to whom atropine was given at varying periods before the neostigmine. Neither with 1/100 gr. (0.65 mg.) (Fig. 4) nor with 1/50 gr. (1.3 mg.) (Fig. 5) was there any evidence of an initial bradycardia. Further, the pulse rate accelerated apparently immediately on the arrival of the drug at the heart. There was no change in the pattern of the response to the subsequently administered neostigmine even in a case in which 19 minutes elapsed between the injection of the two drugs.

Effect of Vasopressor Drugs

In the very early days of curarization in anaesthesia one of my cases became completely pulseless after the injection of neostigmine alone. For some years after that incident it was my habit to inject either 30 mg. of ephedrine or 10–20 mg. of methedrine with the neostigmine and atropine. Patients so treated were investigated in exactly the same way as those already described. It was found that the addition of a vasopressor to the antidote mixture produced a rather greater initial cardio-acceleration (Fig. 6). The pattern of the subsequent slowing of the pulse rate, however, remained unaltered (Fig. 7). There was some suggestion that the minimum pulse rate in these cases was a little higher than those in patients to whom no vasopressor had been given. The differences were

FIG. 7.—Later pulse-rate changes after neostigmine, atropine, and a vasopressor drug. Doses as in Fig. 6.

Dr. Bibley, of New York, writing to Dr. Merriman, says: "In no case where it [ergot] has been used, has haemorrhage occurred, and in natural labour when haemorrhage does occur, it has been given with great advantage" (Merriman, 1820). In 1840 Wardleworth wrote: "As a prophylactic ample experience justifies a reliance on its powers in suppressing haemorrhage. . . . We have repeatedly witnessed its good effects when given to women, some 10 or 20 minutes previous to the delivery." Berry Hart (1912) used intramuscular injection of a liquid extract of ergot as a routine. He wrote: "When the child is born, it is a good plan to give a hypodermic of ergot into the patient's upper hip. . . . I advise that it should be given in all cases after the head is born, and that one should not wait for haemorrhage before injecting it." But the indiscriminate use of ergot in the second stage has probably done more harm than good, and such abuse has earned it an evil reputation.

Chassar Moir, working at University College Obstetric Hospital, was the first to extract the oxytocic factor from crude ergot and to name it ergometrine (Chassar Moir, 1932; Dudley and Chassar Moir, 1935). Since this description, a number of authors (see Table III) have acclaimed

TABLE III

Author	Dose	Time Given	No. of Cases	Post-partum Haemorrhage Rate	Manual Removal of Placenta Rate
Reich (1939)	0.2 mg. i.v.	With shoulders	154	24.0%	0.3%
Davis and Boynton (1942)	0.2 mg. i.v.	" "	1,020	0.3%	0.8%
Diddle (1942)	0.2 mg. i.v.	" "	1,960	4.0% (over 500 ml.)	0.5%
Roberts (1942)	0.2 mg. i.v.	After birth	400	2.1% (over 500 ml.)	2.5%
O'Connor (1944)	0.2 mg. i.v.	With shoulders	900	1.0% (over 500 ml.)	1.7%
Quigley (1947)	0.2 mg. i.v.	On crowning	430	6.5%	1.4%
Léon (1949)	0.2 mg. i.v.	With shoulders	639	(500 ml. and over) 1.0%	1.7%
Vant (1950)	0.2 mg. i.v.	" "	4,204	4.3% (over 600 ml.)	?
Lister (1950)	1 mg. i.v.	On crowning	835	0.5% (20+ oz. (568.2 ml.))	1.6%
Daley (1951)	0.5 mg. i.m.	" "	490	9.2% (20 oz. and over (568.2 ml.))	3.5%
Snaith (1951)	0.125 mg. i.v.	Often after birth of baby	187	2.1% (20+ oz. (568.2 ml.))	6.9%

its merits in the prevention of haemorrhage. Many of them are enthusiastic, and the routine use of ergometrine with the birth of the baby would seem to be an increasingly popular procedure in the United States. In England its use is not so widespread. This may be due to its condemnation by Munro Kerr and Chassar Moir (1949), the equivocal findings of Linton Snaith (1951), and the modest claims of Daley (1951). Yet Lister's (1950) results are striking: using 1 mg. of ergometrine intravenously with the crowning of the head in 835 selected cases, she reduced the haemorrhage rate from 16% to 0.4%. Manual removal was neither more frequent nor more difficult, and the injection produced no ill-effects. She concludes that the routine employment of ergometrine in all cases would probably reduce the incidence of post-partum haemorrhage in hospital practice to at least one-tenth of its present level.

Ergometrine (0.5 mg. intramuscularly) was used at University College Obstetric Hospital by Flew (1947) in 500 cases in 1935. There was no constriction ring and no manual removal in this series, but the results were not impressive enough for the routine to be continued.

Some authors (Grimes *et al.*, 1948; Priver *et al.*, 1949) have reported side-effects from using intravenous ergo-

metrine. These include nausea, vomiting, headache, and a slate-coloured cyanosis. We have noticed no such complications.

Present Investigation

At an obstetric staff conference at University College Hospital under the direction of Professor W. C. W. Nixon in April, 1951, it was decided that all cases of vaginal delivery in the hospital should be given intravenous ergometrine (0.5 mg.) with the crowning of the baby's head. The present report deals with the first 1,000 cases so treated, and results are compared with a consecutive series of 1,000 cases taken from the years 1950 and 1951. The comparison is between the conservative and the active treatment of the third stage. All deliveries, except the instrumental ones, were done by medical students under supervision. Blood from vagina and perineum was collected in a kidney dish and measured. Episiotomy under local analgesia was performed if a perineal laceration seemed imminent.

In the "control" group the third stage was conducted in the following manner. Delivery of the baby's shoulders and trunk was not hurried. When the umbilical cord had been cut, the patient's abdomen was uncovered sufficiently for the fundus uteri to be observed. It was not handled.

So long as bleeding was slight the patient was left untouched until signs of separation of the placenta were obvious. Fundal pressure on the contracted uterus was used to assist delivery of the placenta from the vagina. Ergometrine, 0.5 mg., was then given intramuscularly, and bleeding checked by fundal stimulation.

If excessive bleeding occurred before the placenta was delivered or if, after waiting 20 minutes, separation had not taken place, pressure was applied to the contracted fundus uteri and the house-surgeon was called. In the absence of bleeding, preparations for manual removal were started after one hour. The house-surgeon was sometimes allowed to attempt one Credé expression. If there was haemorrhage he gave ergometrine, called the member of the staff on duty, took blood for cross-matching, and prepared for a manual removal.

In the ergometrine series the routine was as follows. Ergometrine, 0.5 mg., was given intravenously by a student with the crowning of the head. The shoulders and body of the baby were delivered slowly. To deliver the placenta a hand was placed on the fundus uteri, which was gently squeezed at the time of the first contraction while traction was applied to the umbilical cord. On completion of the third stage an intramuscular injection of ergometrine, 0.5 mg., was given. If the placenta was retained longer than 15 minutes, or if there was haemorrhage, the house-surgeon was informed.

Results

The control series is made up of 1,090 consecutive vaginal deliveries, of which 101 were forceps deliveries. From this series 36 cases have been excluded for various reasons, chiefly because the data required were incomplete, and three of these had haemorrhages. One of them was a case in which maternal death occurred from haemorrhage following a prolonged labour and forceps delivery. A further 54 cases were excluded because ergometrine was given with the birth of the baby, and all were forceps deliveries. In the remaining 1,000 cases the results were:

Primary post-partum haemorrhage (blood loss of 20 oz. (568.2 ml.) or more) . . . 131 cases (13.1%)
Secondary post-partum haemorrhage (excessive loss in the puerperium) . . . 3 cases (0.3%)
Manual removal of the placenta . . . 11 cases (1.1%)
Blood transfusion . . . 18 cases (1.8%)

Comparative figures in the ergometrine series were:

Primary post-partum haemorrhage . . . 12 cases (1.2%)
Secondary post-partum haemorrhage . . . 8 cases (0.8%)
Manual removal of placenta . . . 30 cases (3.0%)
Blood transfusion . . . 5 cases (0.5%)

This series consists of the first 1,000 cases given ergometrine intravenously, and comes from a group of 1,221

consecutive vaginal deliveries. In 176 (14.4%) ergometrine was not given either because the student failed to get the needle into the vein as the head crowned or because he was not present at delivery. (This failure rate was reduced to 10% in the last 500 cases.) In 42 patients the ergometrine was given intramuscularly, and in three cases the required data were not available. There were 19 primary haemorrhages and 1 secondary haemorrhage in the 221 excluded cases, and this figure includes two concealed accidental haemorrhages in which most of the post-partum loss was clot formed before birth.

A comparison of the blood loss in the two groups is seen in Table IV. The difference in the mean blood loss of the two groups is significant at the 1% level, and the conservation of blood in the ergometrine group is considerable.

TABLE IV

Amount of Blood Loss	% In Control Series	% In Ergometrine Series
0-9 oz. (0-255.7 ml.)	64	89.2
10-19 " (284.1-539.8 ml.)	22.9	9.6
20-29 oz. (568.2-823.9 ml.)	7.8	0.7
30-39 " (852.3-1,108 ml.)	3.0	0.3
40-49 " (1,136.4-1,392.1 ml.)	1.4	0.2
50 oz. (1,420.5 ml.) and over	0.9	—

Post-partum Haemorrhage

The haemorrhage rate of 13.1% in the control series is higher than stated in the annual report of the hospital because deliveries by caesarean section are excluded and all losses of 20 oz. (568.2 ml.) are included.

The time of administration of pethidine and the weight of the baby were studied in the 131 post-partum haemorrhages and the findings compared with 131 random cases. It could not be shown that pethidine administration increased the haemorrhage rate as Barnes (1947) showed in her report from this hospital. Large babies—over 9 lb. (4.1 kg.)—were significantly more frequent, as Reich (1939) reported. Any tendency towards heavy bleeding in forceps deliveries was due to loss from lacerations, although inexpertly administered or prolonged anaesthesia is a well-recognized cause of increased blood loss.

Delayed haemorrhage some hours after delivery (as reported by Lister, 1950) was not a feature of our treated series.

Secondary post-partum haemorrhage occurred in three cases in the control group and in eight in the ergometrine group. All three in the control group and four in the ergometrine group had a retained placental cotyledon. In the remaining four only fragments of placental tissue and decidua were removed at curettage.

Manual Removal

There were 41 cases of manual removal of the placenta in the 2,000 cases—30 in the ergometrine series, and 11 in the control group. The indication for the operation is seen in Table V.

TABLE V

	Manual Removal	
	For Retained Placenta	For Post-partum Haemorrhage
Ergometrine series	23	7
Control series	2	9

In the present series placental retention is increased (statistically significant at the 1% level) by the use of intravenous ergometrine. Out of the group of 23 cases in Table V there were five in which the injection of the ergometrine was given too late, and one breech delivery. In each of these cases the uterus did not contain the foetal body when it contracted—a situation which predisposes to

placental retention. It has been a recent practice of some operators to remove the placenta manually after a forceps delivery if it does not show immediate signs of separation, and this accounts for a further 6 of the 23 cases. The operation performed under such circumstances in a fit patient is safe, and, in our opinion, is not made more difficult by the use of ergometrine. In two cases in the ergometrine series the placenta was incompletely removed, resulting in a primary and a secondary haemorrhage, both avoidable.

Haemoglobin Level and Blood Loss

A haemoglobin estimation by Haldane's method is done on all patients on the fourth or fifth day of the puerperium. The results in the 2,000 cases are given in Table VI.

TABLE VI

Haemoglobin	% In Control Group	% In Ergometrine Group
Below 60%	2.5	1
60-64%	3.6	2.4
65-69%	6.7	5.6
70-74%	12.7	11.7
75-79%	13.8	13.7
80-84%	24	22.7
85-89%	13.1	17.7
90-94%	13.9	15.2
95-99%	4.4	6.1
100-104%	3.9	3.3
105% and above	1.4	0.6

The standard deviations of the two groups are significantly different at the 1% level. The means of the two groups are not significantly different, but blood loss may occur without affecting the haemoglobin level; for the latter is dependent on haemodilution, which occurs in some cases and not in others (Dyson, Plaut, and Vaughan, 1943). The mean haemoglobin in the control group is 82%, and in the ergometrine group 83.4%. This difference, though small, is probably due to the greater blood loss in the first group, as there is a tendency for large blood loss to be associated with a low haemoglobin. This can be seen from the fact

Post-partum haemoglobin in the 2,000 cases of the series compared with that reported by the Medical Research Council (1945) in married women.

that 37.4% of those who lost more than 20 oz. (568.2 ml.) had haemoglobin values below 70% (49 out of 131), while only 9.1% of the remainder were below this value (79 out of 869). Among the ergometrine group those with a haemoglobin under 70% were 58.3% (7 out of 12) of patients with blood loss greater than 20 oz. (568.2 ml.) and 8.5% of the remainder (84 out of 988).

In the Chart the post-partum haemoglobin in the 2,000 cases is compared with that reported by the Medical Research Council (1945) in married women in this country. The numbers have been combined for this purpose, since the difference between the two sets of 1,000 is small compared with the difference between married and puerperal women. This report also stated that in the last trimester of pregnancy 9% of women had haemoglobin values under 70, and 37% had values under 80. The corresponding figures in our post-partum series are 12.8% and 39.3% in the control group, and 9% and 34.4% in the ergometrine group.

Length of Third Stage of Labour

There is no doubt that ergometrine reduces the length of the third stage, as Table VII shows. In the ergometrine series it was less than 20 minutes in 94% of cases.

Davis and Boynton (1942) noted that there was a direct relationship between blood loss and length of the third stage—an observation which is confirmed in our treated cases.

TABLE VII

Length of Third Stage	% In Control Group	% In Ergometrine Group
0-4 minutes	1.5	50.3
5-9 "	9.0	33.6
10-19 "	51.5	10.4
20-29 "	28.0	1.1
30-39 "	6.4	1.2
40+ "	3.6	3.4

Discussion

Intravenous ergometrine, if given with the crowning of the foetal head, causes a striking reduction in blood loss in the third stage of labour and a marked lowering of the post-partum haemorrhage rate. It also shortens the length of the third stage. These facts seem indisputable. Those authors who are not wholly in favour of using ergometrine, such as Roberts (1942) and Snaith (1951), admit that the timing of the injection was not accurately made, or else, like Daley (1951), they gave the ergometrine intramuscularly. We consider timing a most important point: intravenous ergometrine acts within a minute of injection, causing a tonic uterine contraction and placental separation while part of the baby still occupies the uterine cavity. Placental expression should be carried out as soon after the birth of the baby as possible. To facilitate this, cord traction is a useful and safe procedure. In a firmly contracted uterus the only danger of cord traction is the theoretical risk of causing acute inversion of the uterus, but, as Picton (1951) points out, before inversion can be initiated uterus and cervix must be relaxed.

In our series there was an increased incidence of manual removal of the placenta when ergometrine was used (3% as compared with 1.1% in the control series). The higher rate of this complication is used by some as an argument against intravenous ergometrine therapy. As we have pointed out, there is a tendency in this hospital towards a more frequent use of this procedure, particularly after instrumental deliveries. Recognition of the value of cord traction would possibly result in fewer manual removals, as might digital exploration of the upper vagina described by Graber (1950), revealing a placenta trapped in the cervix and therefore easily removed without anaesthesia. Smellie (1754) recommended both pulling on the cord and digital exploration to feel the placenta.

It would be wrong to claim that post-partum haemorrhage is eliminated by using ergometrine. The drug has

no effect on bleeding from cervical or vaginal lacerations. Occasionally the uterus fails to contract after 0.5 mg. of intravenous ergometrine, and there are other factors which may cause bleeding, such as an abnormal coagulation mechanism (Reid, 1951).

There is the disadvantage that an assistant must be available to give the injection at the right moment. In hospital this should not be too difficult to arrange. In domiciliary practice it is far less easy. This is a strong argument for teaching midwives the technique of intravenous injection.

We conclude by advocating a more widespread use of this technique, in the belief that it would prevent much puerperal morbidity and some maternal deaths.

Summary

Intravenous ergometrine, 0.5 mg., was given to 1,000 patients in the second stage of labour with the crowning of the foetal head. The results are compared with 1,000 control cases.

The use of ergometrine has shown: (1) A reduction in the primary post-partum haemorrhage rate from 13.1% to 1.2%. This is significant at the 0.1% level. (2) A reduction in the amount of post-partum anaemia. (3) A shortening of the third stage of labour. (4) A significant increase in the rate of manual removal of the placenta from 1.1% to 3%.

We are indebted to Professor W. C. W. Nixon for his help and advice; to the students and midwives who have made this investigation possible; and to Mr. N. W. Please, of the Department of Statistics, University College, London, for his suggestions and the statistical data.

HAEMOGLOBIN LEVELS IN A GROUP OF ELDERLY PERSONS LIVING AT HOME ALONE OR WITH SPOUSE

BY

W. HOBSON, M.D., B.Sc., D.P.H.
*Professor of Social and Industrial Medicine,
University of Sheffield*

AND

E. K. BLACKBURN, M.D., F.R.F.P.S.
Consultant Haematologist, Royal Infirmary and Hospital,
Sheffield

Wintrobe (1951a) stated, "there are few satisfactory data for the blood in old age." Some studies of haemoglobin levels—for example, by Olbrich (1947) and Howell (1950)—have been carried out on old persons living in hospitals or institutions or under especially favourable conditions. Relatively little similar work, however, appears to have been done on adequate numbers of old people living under natural conditions in their own homes. A medical survey of old persons living alone or with spouse in Sheffield enabled us to carry out such a study.

Methods

1. Selection of Group.—The sample drawn in March, 1948, was a 1:30 random selection from the food office register in Sheffield of men and women who had reached pensionable age (65 in men and 60 in women). Only those living alone or with spouse were included in the medical survey. The haematological investigations were not carried out until at least one year later. Those eligible for inclusion were interviewed by a social worker, who invited their co-operation. Subjects who were willing were then medically examined in their homes and samples of blood were taken. The final group consisted of 177 men between the ages of 66 and 85, and 246 women between the ages of 61 and 87.

2. Dietary Survey.—Information was collected on the food and drink consumption of each subject for a period of one week. A spring balance and standard tablespoons and tea-

Results

Haemoglobin in Relation to Age and Sex.—The mean haemoglobin levels of the 177 males and of the 246 females were calculated, giving values of 14.4 g./100 ml. for the males and 13.8 g./100 ml. for the females. Using the large sample method (Fisher, 1941) for testing the significance of the difference between two means, the standard error of the difference was calculated (0.16), and the difference (0.6) was found to be significant. Thus the females had a signifi-

FIG. 1.—Scatter diagram relating age to haemoglobin levels of the blood in males.

FIG. 2.—Scatter diagram relating age to haemoglobin levels of the blood in females.

cantly lower haemoglobin level than the males. The relationship between haemoglobin content of the blood and age is shown in the scatter diagrams (Figs. 1 and 2). Although from these diagrams there does not appear to be an overall correlation between haemoglobin levels and age, a negative correlation over the age range 65.5–77.5 years for the males and over the age range 60.5–74.5 years for the females is apparent.

The correlation coefficient between haemoglobin level and age for the males within the age range 65.5–75.5 years was calculated and found to be significant ($r = -0.2799$, $n = 154$, $P < 5\%$), whilst the correlation coefficient over the complete age range was not significant ($r = 0.1077$, $n = 177$, $P > 5\%$). Similarly for the females, the correlation coefficient over the age range 60.5–74.5 years was significant ($r = -0.262$, $n = 204$, $P < 5\%$), whilst that over the complete range was not significant ($r = 0.068$, $n = 244$, $P > 5\%$). Thus over a certain age range there was a significant decrease in the haemoglobin content of the blood with increasing age in both sexes, but beyond this age range the haemoglobin levels were narrowly scattered round the mean level for each respective sex group.

Haemoglobin and Social Class.—Based on the classification of occupational status of the Registrar-General, the subjects were divided into three groups: professional and managerial (Class I and II of the R.G.), skilled workers (Class III of the R.G.), and semi-skilled and unskilled workers (Class IV and V of the R.G.). There was no significant difference between the haemoglobin levels in either men or women in the different occupational groups.

Haemoglobin Levels in Those Living Alone compared with Those Living with Spouse.—The mean haemoglobin level of the 46 males living alone was 13.9 g./100 ml. compared with a mean level of 14.5 g./100 ml. in the 131 males who were living with their wives. This difference was significant at the 5% level of probability ($t = 2.06$). There was no significant difference between the mean haemoglobin levels of the females who lived alone (13.9 g./100 ml.) and those who were living with their husbands (13.8 g./100 ml.). Thus living alone seems to be aetiological significant for the males but not for the females.

Haemoglobin Level and Emphysema.—It is often taught that patients with emphysema show a high haemoglobin content of the blood. The mean haemoglobin level of the 45 females showing radiological evidence of emphysema was found to be lower than the mean level in 137 females showing no emphysema. The mean haemoglobin level of the 32 males with radiological evidence of emphysema was slightly higher than that of 106 males showing no emphysema. These differences were not significant. Hence this study does not lend any support to the thesis that in old people with emphysema there is a high haemoglobin content of the blood.

Causes of Anaemia in this Group

Any person with a haemoglobin level of 11.7 g./100 ml. (80% Haldane) or less was arbitrarily considered to have anaemia. Absolute values were estimated in these cases. The incidence of anaemia was as follows: men, 9 cases (5.1%); women, 16 cases (6.5%). It was possible to obtain dietary figures for only the more co-operative cases with anaemia—namely, five men and eight women.

In addition, information on the social and clinical condition of the subjects was available. Eight out of the nine male cases had microcytic anaemia of the iron-deficiency type. The other had macrocytic anaemia associated with Paget's disease. Three out of the 16 female cases suffered from macrocytic anaemia; the rest had microcytic anaemia of iron-deficiency type.

Under the conditions of our survey it was not possible to carry out other investigations—for example, fractional test meals.

In at least 11 out of the 25 cases of anaemia a poor diet seems to have been a contributory factor. Apathy and a low income were the chief reasons for inadequate diets. On the other hand, at least four cases appeared to have had adequate diets.

Another contributory factor was rheumatoid arthritis in seven cases, particularly in women (six cases). Chronic haemorrhage was not detected in any case.

Syphilis in one woman, scurvy in another, and chronic alcoholism in one man were the only other recognizable potential contributory conditions.

Discussion

As different methods have been used for haemoglobin determinations, and as varying standards have been set from time to time for the 100% level, using the same technique, comparison of our results with those of previous workers is feasible only if the results are expressed in grammes per 100 ml. The figures obtained in this survey of old people living in their own homes (14.4 g./100 ml. for males and 13.8 g./100 ml. for females) are in close agreement with those found by Olbrich (1947) for people living in institutions (13.9 g./100 ml. for males and 13.2 g./100 ml. for females).

Howell (1950) obtained very high values (18.3 g./100 ml. for men and 16.6 g./100 ml. for women) in a group of elderly patients in a hospital for the chronic sick. On the basis of these results he was unable to agree with statements made by earlier workers that "old people are anaemic." Exclusion of cases of anaemia and malignant disease, a higher standard of diet than in many cases found in our survey, and use of the Sahli method on the ward may all have played a part in determining his high results.

So far as we are aware, all observers agree that the level is higher in men than in women for all age groups. The present study confirms this observation so far as the elderly are concerned. The Committee on Haemoglobin Surveys (1945) found that in men the mean level tends to fall in later life; the information provided in our study confirms this view. They found, however, that the haemoglobin level in women falls slightly between the ages of 30 and 49, but rises again after that; this fall and rise may be associated with the occurrence and cessation of menstruation respectively. It would appear, however, that in women over 60 the cessation of menstruation no longer plays a part in causing a rise in haemoglobin. The fall in haemoglobin with age in both sexes may be partly due to decreasing ability to absorb haemopoietic substances. Thus Pollard (1933) has shown that the incidence of achlorhydria increases with age. The decrease may also be due to diminished intake of iron, since our survey showed that the intake of iron diminished in both sexes with age. The cessation of these trends in extreme old age is a phenomenon which we have found in other physiological estimations—for example, serum cholesterol, blood pressure. If a relatively low haemoglobin content of the blood gives a diminished risk of survival there may well be a selective removal of those with low haemoglobin levels, particularly in extreme old age, when the death rate is very high. In these circumstances the mean levels in these older age groups would tend to be higher. It would appear that the mean haemoglobin level falls with age in both sexes until extreme old age; this fall is interrupted in women by the cessation of menstruation, but ultimately resumes the downward trend.

The studies of Monroe (1951) on 7,941 patients over the age of 61 in a geriatric hospital revealed a much higher incidence of anaemia than in the present survey. He found that 15.5% of the men and 11.2% of the women had a haemoglobin level of below 70%. We are unable to make a strict comparison with our figures, as the method of haemoglobin estimation was not given. Monroe stated: "Loss of blood was the commonest cause of severe secondary anaemia in old age (522 cases). Malignant disease was the source of the blood loss in over half of them, closely followed by peptic ulcer and cirrhosis of the liver. Infection caused anaemia in 165 cases. Usually it was mild, but those due to the streptococcus occasionally produced so rapid a fall in blood counts as to suggest blood loss." Hence the idea that old people are anaemic may have arisen from hospital experience. These causes are very different from those found in the present study.

One of the most interesting findings of the survey was the lower haemoglobin level of the males living alone compared with those living with their wives.

The cases of anaemia in this group of elderly people living in their own homes were largely due to adverse social factors, such as apathy, a low income, or, in the case of males, living alone. A meals-on-wheels service would have helped considerably.

Anaemia seems to be a condition which is very easily missed in old people, as none of our cases were receiving any form of treatment for it. A simple haemoglobin estimation in all old people would be of great value for detecting a potentially remediable cause of ill-health.

Summary

The haemoglobin levels of 177 men between the ages of 66 and 85 years and of 246 women between the ages of 61 and 87 years were determined. All these old people were living in their own homes either alone or with spouse. In men and women there was a significant downward trend over a certain age range, and the males (mean haemoglobin level 14.4 g./100 ml.) had a significantly higher level than the females (mean haemoglobin level 13.8 g./100 ml.).

There was no significant social class difference in haemoglobin levels in either males or females.

Pulmonary emphysema was not associated with a high haemoglobin content of the blood.

Males living alone had significantly lower haemoglobin levels than those living with their wives. There was no difference in the case of females.

Nine men (5.1%) and 16 women (6.5%) had haemoglobin levels of 11.7 g./100 ml. or less. Eight of the men and 13 of the women had iron-deficiency anaemia, while one man and three women had macrocytic anaemia. None of the patients were having any form of treatment for their anaemia. The main contributory factors appeared to be poor diet (44%) and rheumatoid arthritis (28%). Apathy and a low income were the chief reasons for the poor diet. A simple haemoglobin estimation in all old people would be of considerable value for detecting a potentially remediable cause of ill-health. A meals-on-wheels service would have been of benefit.

We thank Dr. H. Droller for clinical examinations; Dr. J. L. A. Grout for radiological examinations; Miss C. Roseman for help with the statistics; Mr. A. S. Foster, the technical staff of the Haematological Department of the Royal Hospital, and Misses P. M. Ashton and A. A. Hutcheson for technical and clerical assistance; and the field workers and general practitioners, too numerous to mention by name, who helped us in the survey. We are indebted to Dr. E. R. Bransby, of the Ministry of Health, who arranged for a team of dietitians from the social survey to carry out the dietary investigations under the direction of Mrs. Barbara M. Osborne. Our grateful thanks are due to the Nuffield Foundation for its generous grant, which paid for the expenses of this investigation.

CLINICAL TRIAL OF PHENYLINDANEDIONE AS AN ANTICOAGULANT

BY

M. TOOHEY, M.D., M.R.C.P.

Physician, New End Hospital, London

At present dicoumarol and ethyl biscoumacetate (*bis*-3, 3'-(4-oxycoumarinyl)-ethyl acetate; "tromexan") are the two drugs with a prothrombopenic action which are in common use as anticoagulants. Dicoumarol was the first prothrombopenic drug to come into use, but its toxic effect (due, however, in many instances to indiscriminate heavy overdosage and also to lack of proper control, including unreliable estimations of the prothrombin time) has led to severe haemorrhage in many cases. The great drawback with dicoumarol is its cumulative action, which may continue long after the drug has been stopped. This cumulative effect necessitates particularly skilled and detailed control of the drug with frequent estimations of the prothrombin time if severe haemorrhage is to be avoided. Another disadvantage with dicoumarol is the long delay, usually 48 to 72 hours, before a full therapeutic effect is reached.

Ethyl biscoumacetate has a much more rapid action than dicoumarol, a therapeutic effect usually being achieved in 18 to 24 hours. Moreover, the effect of ethyl biscoumacetate, unlike that of dicoumarol, is, owing to the rapid metabolism and elimination of the drug, almost never cumulative. The rapid inactivation of ethyl biscoumacetate, however, often makes it difficult to maintain an even therapeutic prothrombin concentration, especially in the initial stages of treatment. In addition, the wide individual variation in the reaction to ethyl biscoumacetate is another factor requiring detailed and meticulous control in every case.

In recent years a new prothrombopenic drug, phenylindanedione, has aroused interest and been the subject of clinical trial. In 1944 Kabat, Stohman, and Smith showed that certain indanedione derivatives have a specific action in reducing the plasma prothrombin. Soulier and Gueguen (1947) reported satisfactory results from using phenylindanedione, the most active of the indanedione derivatives. Jaques *et al.* (1949) found no toxic effects from phenylindanedione in animals. Blaustein *et al.* (1950) reported their observations on the use of the drug in 53 patients, and concluded that phenylindanedione had an action similar to but more rapid than that of dicoumarol. Bjerkelund (1950) found that phenylindanedione had not only a more rapid effect but also a more uniform action than dicoumarol. In addition, Bjerkelund showed that phenylindanedione had no effect on factor V.

The present paper is a report on the use of phenylindanedione in 68 patients. Most of them were suffering from coronary thrombosis or deep venous thrombosis, and in several there was evidence of cardiac failure. Quick's one-stage method was used for estimation of the prothrombin time, and the thromboplastin was a phenol-saline emulsion prepared from human brain. Therapeutic prothrombin levels of 10-20% (or approximately twice to three times the normal prothrombin time) were aimed at.

Rapidity of Action and Recovery

In practically all cases 200 mg. of phenylindanedione (divided into two equal doses) was given in the first 24 hours, followed by 100 mg. (in two equal doses) in the next 24 hours. On this dosage only 6 cases out of the 68 failed to reach an adequate therapeutic prothrombin level in 48 hours, whilst in only one of these was the prothrombin level above 40% at this time. In many cases in which the prothrombin time was estimated at 36 hours it was found that an adequate therapeutic level had been attained by this time. In most of the 68 cases an appreciable lowering of the prothrombin concentration to 50% or below was reached by 24 hours.

The effective action of phenylindanedione passes off fairly rapidly, and therefore the risk of cumulative effects is slight except where very large doses are given. Twenty-four hours after stopping the drug there was either no change or only a small fall in the prothrombin times in those patients in whom the prothrombin had previously been maintained at a full therapeutic level (10-20%) for at least several days. Up to 36 hours after cessation of phenylindanedione there was still an appreciable effect, but between 36 and 48 hours after the last dose there was a sudden sharp drop in the prothrombin time to near normal levels. By 72 hours the prothrombin times in practically all cases had become normal or almost so.

The return to normal of the prothrombin time in patients on phenylindanedione depends (as with other similar anticoagulants) largely on the level to which the prothrombin had been depressed. The lower the prothrombin concentration, the longer it takes for a normal prothrombin content to be regained. Again, any lowering of renal function will delay the excretion of the drug. In the very few cases in which the prothrombin time failed to return to normal or near normal within 48 to 72 hours after the last dose there were signs of deficient renal function.

The absorption and recovery rates of phenylindanedione are therefore midway between those of dicoumarol and ethyl biscoumacetate. Phenylindanedione has many advantages over dicoumarol in its quicker effect and the very slight danger of cumulative action. On the other hand, although it is not as rapid in action as ethyl biscoumacetate its more prolonged effect makes it much easier to maintain a therapeutic prothrombin level over a prolonged period. Ethyl biscoumacetate is practically all metabolized and excreted within 24 hours, so that omission of the drug for only one day will result in even an excessively prolonged prothrombin time returning to normal or near normal and the drug therefore losing its therapeutic effect. This rapid inactivation, combined with the wide individual variation in the reaction to the drug, necessitates the most detailed and experienced control when ethyl biscoumacetate is used. With phenylindanedione, however, the time-lag of 36 hours before there is any really appreciable change in the prothrombin concentration allows ample time for the clinician to ascertain the prothrombin level and to readjust the dose of phenylindanedione when necessary without wide fluctuations in the prothrombin level occurring.

Dosage

The initial dosage in all 68 cases was 200 mg. (100 mg. morning and evening) the first day, followed by 100 mg. on the second day. By 48 hours the full effect of this dosage was evident, and, according to the prothrombin level then reached, it was possible to estimate with a fair degree of accuracy the further doses needed for maintenance therapy. The greater the rise in the prothrombin time by 36 to 48 hours the more sensitive the patient is to the drug and the smaller the daily maintenance dose that is required. In 44 of the 68 cases this daily maintenance dose lay between 75 and 100 mg. and in only 5 cases did it fall outside the range of 50-150 mg. (see Table). The variation

Maintenance Doses of Phenylindanedione

No. of Cases	Daily Maintenance Doses in mg.	No. of Cases	Daily Maintenance Doses in mg.
2	50	3	125
4	50-75	2	125-150
22	75	4	150
4	75-100	2	150-175
18	100	1	175
4	100-125	2	175-200

in individual susceptibility to phenylindanedione is therefore not very great and seems to be much less than with either dicoumarol or ethyl biscoumacetate.

In all cases the total daily dose of phenylindanedione was given in approximately two equal amounts morning and evening. Dividing up the total daily dose seems to give more uniform results.

Guides to Dosage

There are several factors which help greatly in estimating the required maintenance doses in individual cases. Before, however, these are considered it is necessary to stress one important point. The initial doses for the first two days should (subject to the exceptional cases mentioned below) invariably be kept constant. To give a larger dose than 100 mg. on the second day, solely on the result of one prothrombin estimation taken 24 hours or less after starting treatment, will lead in most cases to too high a dose being given. The full effect of phenylindanedione is not evident for 36 to 48 hours.

To give a smaller dose than 100 mg. on the second day may, however, be justifiable where the prothrombin time at 24 hours (if taken) is already within a therapeutic range. In these few cases the dose of phenylindanedione on the second day may be reduced from 100 to 75 mg.

With phenylindanedione, as with all anticoagulants of the coumarin group, the extent of individual susceptibility is most important, so that the ultimate control of therapy in all cases lies in frequent prothrombin estimations. There are, however, several factors which can help in gauging, with some accuracy, the required maintenance doses of phenylindanedione:

1. Weight is important; the heavier the patient the more likely it is that the daily maintenance doses will be on the large size—that is, 125-175 mg.
2. The more acutely ill the patient (especially cases of coronary thrombosis accompanied by severe shock) the smaller the maintenance doses of phenylindanedione that are needed. It was noticed in several cases, however, that the maintenance doses in the acutely ill patients had to be increased later on when there was an improvement in their clinical condition.
3. Age is not so important in itself, but as older people tend to be more frail they require smaller doses. The apparent age is more important than the real age.
4. Renal function is of particular importance in gauging phenylindanedione (as other anticoagulant) therapy. Deficient renal function will lead to delayed excretion of the drug, so that much smaller maintenance doses are necessary. In this series the few cases in which there was an unexpectedly sharp rise in the prothrombin time were those in which it was not realized that renal function was depressed. As the majority of patients with lowered renal function are in the older age groups, it has been found most useful to perform routine blood-urea estimations in all patients of 60 and over.

Taking all the above factors into account, it will be found that the less acutely ill robust young patients require the largest maintenance doses of phenylindanedione, whilst the seriously ill frail elderly patients need the smallest doses.

Toxic Effects

No toxic effects were noticed in this series of 68 cases and there was no case of haemorrhage. Soulier and Gueguen (1947) reported dryness in the mouth, polydipsia, polyuria, and tachycardia with phenylindanedione, but in their cases very large doses, in the neighbourhood of 700 mg. and over, were given. In a small series of seven cases of mine in which large doses of phenylindanedione were

given in order to produce a severe prothrombin deficiency far in excess of that required for therapeutic purposes, no toxic effects were noticed apart from haematuria in one case only. In most patients on phenylindanedione the urine turns a pinkish-orange colour; this is of no significance.

Antidote.—The great drawback in anticoagulant therapy with drugs of the coumarin group has up till recently been the lack of a really effective antidote. Water-soluble vitamin-K analogues have only a very limited effect in correcting a severe prothrombin deficiency. Vitamin K₁, however, even by mouth, has a most dramatic and rapid effect (within 8 to 20 hours in most cases) in overcoming the prothrombopenic action of dicoumarol, ethyl biscoumacetate, and phenylindanedione (Toohey, 1952).

Frequency of Prothrombin Estimations

After the initial two or three prothrombin estimations necessary in the first four to five days of therapy, it is usually sufficient to carry out prothrombin estimations only twice or, at the most, three times a week. Phenylindanedione is very stable in its action, so that once the individual variation in reaction has been assessed it is not necessary to do daily prothrombin estimations.

It is perhaps advisable to point out here that minor unimportant fluctuations in the prothrombin time, as measured by the one-stage method, are often seen in practice in patients on anticoagulants. Therefore, to avoid unnecessarily frequent alterations in the maintenance doses of phenylindanedione and similar anticoagulants, the method of prothrombin estimation used should allow for a comparatively wide margin in the clotting-time within which the therapeutic control may be regarded as satisfactory. For this reason, phenol-saline thromboplastin is particularly suitable in that the effective therapeutic range of the prothrombin time is two to three times the normal control (or 30 to 45 seconds).

The administration of heparin interferes with the estimation of the prothrombin clotting-times. Therefore, if the patient is having heparin as well as phenylindanedione the sample of blood for prothrombin estimation should be taken at least four hours, and preferably six hours, after the last dose of intravenous heparin.

Summary and Conclusions

Phenylindanedione has been tried as an anticoagulant in 68 patients, mostly cases of coronary thrombosis and deep venous thrombosis. It is a very effective anticoagulant which in its action lies approximately midway between dicoumarol and ethyl biscoumacetate. The dangerous cumulative effect of dicoumarol occurs to a far lesser extent with phenylindanedione, whilst the fact that the metabolism and excretion of phenylindanedione is less rapid than that of ethyl biscoumacetate makes clinical control of anticoagulant therapy with phenylindanedione much easier.

In this series of 68 cases 200 mg. (in two equal divided doses) was given on the first day, followed by 100 mg. on the second day. On this dosage an appreciable fall in the prothrombin level was noticed in 24 hours, and a full therapeutic effect, with a prothrombin concentration in the region of 10-20%, was reached in 36 to 48 hours in nearly all cases.

The further daily maintenance doses of phenylindanedione varied between 50 and 200 mg. In 44 of the 68 cases the maintenance dose lay within the limited range of 75 to 100 mg., and in only five cases did it fall outside the range of 50-150 mg. Phenylindanedione seems to be much more uniform in action, and therefore easier to control, than either dicoumarol or ethyl biscoumacetate.

Important factors in assessing the appropriate daily maintenance dose within the range of 50 to 175 mg. are the weight, age (apparent rather than real), general health, and renal function. The more robust, young, and less acutely ill patients require the largest doses, whilst the frail, elderly, and severely ill cases need the smallest maintenance doses. Any lowering of renal function will materially reduce the amount of phenylindanedione required.

Once the daily maintenance dose has been established, this dose can be continued for a prolonged period without any significant fluctuation in the prothrombin times. (With improvement in a severely ill patient's general condition, a small increase in the daily maintenance dose may sometimes be necessary.) This uniform action of phenylindanedione means that in most cases, once the daily maintenance dose has been established, prothrombin estimations are necessary only twice or, at the most, three times a week. (In patients on prolonged therapy, prothrombin estimations weekly or less often are usually enough.)

No toxic effects from phenylindanedione were encountered in this series. In a small series of seven cases reported previously, the giving of much larger doses than those required to maintain an adequate therapeutic prothrombin level resulted in haemorrhage in one case only and no other toxic reactions. This haemorrhage and the severe prothrombin deficiency seen in the other six cases were quickly controlled within eight to twenty hours by vitamin K₁ given orally.

The total daily dose of phenylindanedione in each case was given in two divided amounts, morning and evening. In most cases it turns the urine a pinkish-orange colour.

I wish to thank Charles E. Frosst and Co. (Canada) for the initial supplies of phenylindanedione ("danilone") and also Evans Medical Supplies Ltd. for additional amounts of the drug ("dindevan"). I also wish to express my gratitude to Dr. E. Lozinski, of Charles E. Frosst and Co., for his help and advice.

Robert James Graves, who died on March 20, 1853, is best remembered to-day for his accurate account of exophthalmic goitre (1835). Although earlier descriptions of the condition were given by Flajani (1802) and Parry (1815), it is best known in Britain as "Graves's disease." He was one of the founders of the Park Street School of Medicine in Dublin. While physician to the Meath Hospital he introduced Continental methods of clinical teaching with good effect. Graves qualified in 1818 and then studied in London and on the Continent. When he was in Austria his fluency in languages led him to be taken for a German spy and he was imprisoned for ten days. During a journey from Genoa to Sicily the ship in which he was travelling ran into a storm and the crew threatened to abandon ship. Graves seized an axe and smashed the ship's boat; he then assumed command and repaired the pumps with leather from his own boots. Graves contributed many papers to medical literature. His *Clinical Lectures on the Practice of Medicine*, 1848, is considered his best work.

TREATMENT OF NAUSEA AND VOMITING OF PREGNANCY WITH ANTIHISTAMINES

BY

SAMUEL LASK, M.D., M.R.C.O.G.

Obstetrician and Gynaecologist, St. Andrew's Hospital,
London, E.3

During the past few years good results have been reported from the use of antihistamine preparations in nausea and vomiting of pregnancy. Dougray (1949) recorded 94 cases thus treated, with 83% cured, and Carliner *et al.* (1949) reported on 43 patients treated with dimenhydrinate ("dramamine"), with 72% cured. At St. Andrew's Hospital during the past three years a large proportion of patients complaining of nausea and vomiting in pregnancy were freed from these symptoms by taking an antihistamine preparation. So successful was this treatment that it was extended to patients who complained mainly of heartburn, with equally gratifying results. After some months it was decided to make a clinical trial, treating one group of patients with an active antihistamine preparation and another group with an inert preparation.

Method

Although all patients were questioned as a routine on vomiting in pregnancy, only those who specifically complained were treated. Cases were divided into three groups: severe vomiting, in which vomiting occurred at frequent intervals during the day or caused the patient a good deal of distress; occasional vomiting, in which vomiting was not frequent and regular and did not unduly distress the patient; and cases in which heartburn and nausea were the predominant symptoms. No attempt at clinical assessment was made, apart from excluding any obvious non-obstetric cause of vomiting, and the patient's own statement was the guide to the group in which she was placed. As the element of suggestion plays a part in the treatment of these patients, and some patients will respond to any form of therapy, it was decided to include only those who had already received some other form of treatment without improving.

Two antihistamine preparations were used, both in tablet form: mepyramine maleate ("anthisan"), 100 mg., and promethazine-8-chlorotheophyllinate ("avomine"), 25 mg. They appeared to be equally effective. The control tablets contained lactose only, and were identical in size and shape, and almost identical in colour with the active tablets. Patients were divided into two groups of 60; one group was treated with antihistamine tablets and the other group with the inert tablets. The tablets were collected from the hospital dispensary and enough for three days' treatment were given. Patients were instructed to take a tablet at night before retiring. This routine was altered occasionally for those whose symptoms were particularly troublesome at a set time—for example, after the evening meal or after getting into bed at night. These patients were instructed to take the tablet about two hours before the expected time of onset of the symptoms.

Patients were seen five days later at the antenatal clinic. Those who were free from symptoms while taking the tablets were classified as cured; others were classified as improved or unchanged. The short period of three days for treatment was chosen because experience had shown that patients who were going to benefit by the treatment did so almost immediately. There was also the additional factor that by giving a short course of treatment and by

seeing the patients soon afterwards there was less risk of their forgetting the facts or becoming confused about details.

Results

Of the 60 patients who were treated with an active antihistamine preparation, 47 reported themselves as cured and six as improved. Thus 88% were either cured or improved by the treatment. In the control group, three patients regarded themselves as cured and four as improved, a total of 10%. Table I shows that no case of severe vomiting

TABLE I.—Results of Treatment

Treatment	No. of Cases	No. Cured	No. Improved	No Change
<i>Severe Vomiting</i>				
Antihistamine	31	25	2	4
Inert tablet	33	—	—	33
<i>Moderate Vomiting</i>				
Antihistamine	17	12	3	2
Inert tablet	16	2	4	10
<i>Nausea and Heartburn</i>				
Antihistamine	12	10	1	1
Inert tablet	11	1	—	10

was affected by an inert preparation, and that it was in the cases of moderate vomiting that the inert tablets had most effect.

Most of the patients in the control series were subsequently treated with antihistamines, when they showed a higher proportion of cured and improved (Table II). Thus

TABLE II.—Control Cases Subsequently Treated with Antihistamines

No. of Cases	No. Cured	No. Improved	No Change
50	43	3	4

out of 50 of these patients treated 86% were cured, 6% were improved, and only 8% showed no change. With this group, however, other factors may have affected the results. These patients were being treated at a somewhat later stage in pregnancy, and it was possible that time was effecting a cure. Also, as the antihistamine tablets they subsequently received were of a brighter colour than the inert tablets, they may well have deduced that they were receiving a more potent preparation, and so the factor of suggestion may have influenced the results.

In most cases three days' treatment was insufficient to effect a permanent cure, and it was necessary to continue treatment for at least a fortnight, and sometimes for four weeks. No other treatment was given and no dietary restrictions were imposed. No adverse effects were noted from even a prolonged course, although occasionally some patients complained of drowsiness.

Comment

The causes of nausea and vomiting in pregnancy are not known, and it is therefore a matter of speculation why the antihistamines give relief. Finch (1938) suggested that the antihistamines are due to an allergic tendency, and that the patient had become sensitized to some secretion of her own corpus luteum. He carried out intradermal tests with corpus luteum extract and found that the reaction produced was in direct proportion to the degree of nausea and vomiting present. Kapeller-Adler and Adler (1943) have shown that there is an increased histamine production by the body in pregnancy. They suggest that, whereas in normal pregnancies the serum is able to inactivate histamine, in cases of hyperemesis gravidarum and mild pre-eclampsia the serum has lost this power and

in consequence there is an excess of histamine in the body and it is this excess which is responsible for the disturbed gastric function.

These theories offer some explanation for the mode of action of the antihistamines. On the other hand, it is well recognized that most of the drugs used for their antihistamine properties have some depressant action on the central nervous system, and it is possible that they exert their influence by lowering the sensitivity of the vomiting centre.

Some of the patients who did not respond to treatment improved after the dosage was increased or when a more powerful form of antihistamine such as promethazine hydrochloride, 25 mg. twice daily, was given. This confirms Dougray's experience, although he found it necessary to give a higher dosage.

A number of patients had a recurrence of symptoms in the latter weeks of pregnancy, and these were all successfully treated with antihistamines. It is occasionally taught that vomiting late in pregnancy is of serious significance, but in the absence of any evidence of pre-eclampsia this is not so.

Summary

A number of patients suffering from gastric disturbances in pregnancy were treated with antihistamine preparations and an equal number were given an inert preparation. The results showed that a high proportion of patients obtained relief with the antihistamines and only a small proportion were relieved with the inert preparation.

My thanks are due to Messrs. May and Baker for a generous supply of avomine tablets and for supplying the inert tablets.

ACUTE NITROBENZENE POISONING WITH TRANSIENT AMINO-ACIDURIA

BY

W. E. PARKES, M.D., M.R.C.P., D.C.H.

AND

D. W. NEILL, M.Sc., A.R.I.C.

(From the Royal Victoria Hospital, Belfast)

Many cases of nitrobenzene poisoning have been recorded. The majority of these have been due to accidental ingestion, contact, or inhalation, especially in industry. The case reported here was the result of a deliberate attempt at suicide and showed the usual characteristic manifestations of methaemoglobinemia. There was also a marked transient amino-aciduria.

Case Report

A married woman aged 24, living apart from her husband and 4-year-old son, became depressed and decided to commit suicide. At 11 a.m. she swallowed "about half a bottle" of a bee mixture, which was clearly labelled as a poison. So far as could be ascertained later, she drank about 1 oz. (28 ml.) of this mixture, which contains nitrobenzene (or oil of mirbane) 2 parts, safrol oil 1 part, and petrol 2 parts. Therefore she may have swallowed almost 200 minims (12 ml.) of nitrobenzene.

She found the taste of the mixture most unpleasant and noted a burning sensation in her mouth. Half an hour

later she vomited twice and felt dizzy and had to be helped to her bed. After a further half-hour she was seen to be deeply cyanosed. Her relatives became alarmed, and with some difficulty persuaded her to go to hospital. She was admitted in the early afternoon of December 13, 1951.

On admission she was hysterical and strongly resented having her stomach washed out with sodium bicarbonate. Her breath and the odour of the gastric residue were suggestive of floor polish. There was an intense blue-grey cyanosis, especially of the lips and face and beneath the finger-nails. She soon became more rational, although apprehensive, and told us that she had swallowed the bee mixture in an attempt to end her life. This preparation is popular with bee-keepers, and we had no difficulty in discovering that nitrobenzene was the active ingredient.

Examination revealed that the pulse was of poor volume but regular at 120 beats a minute. Her blood pressure was 120/70. There was no gross peripheral circulatory failure. She was given 1/30 gr. (2 mg.) of strychnine sulphate by hypodermic injection. An intravenous drip was begun soon after admission. Normal saline was given at first, but when we concluded that the cyanosis was due to methaemoglobinemia, 2 ml. of 10% methylene blue was injected into the drip tubing. Immediately afterwards the intravenous saline was replaced by blood and the patient was placed in an oxygen tent. There was no immediate change in colour, but approximately 20 minutes after the injection of methylene blue her colour reverted to normal. In view of this and as she was not obviously anaemic, the blood transfusion was discontinued after 350 ml. of blood had been given. For the next 24 hours 5% glucose by slow intravenous drip was given. Ascorbic acid, 1 g., was added to each pint (570 ml.). Two hours after admission the pulse rate was 88 and the blood pressure 110/70. The respirations had been rapid on admission, but soon became normal as the patient became more composed. A sample of blood which had been taken as the intravenous drip was started revealed methaemoglobin spectroscopically. A specimen of urine obtained later did not contain albumin or sugar.

The following day the blue-grey cyanosis was again intense and the patient complained of a severe headache, dizziness, and a bad taste in her mouth. The urine contained methaemoglobin and methylene blue in large amounts. Intravenous therapy was abandoned and the following oral regime begun: 16 gr. (1 g.) of methylene blue a day in divided doses and 200 mg. of ascorbic acid thrice daily.

On December 15 the intense cyanosis remained but she felt fairly well. The next day she complained of nausea and low back pain. On December 17 blood examination showed: haemoglobin, 85% (Haldane), or 12.6 g. per 100 ml.; red cells, 4,220,000; white cells, 6,650 (neutrophils 42%, eosinophils 3%, lymphocytes 45%, monocytes 10%). There was no punctate basophilia. The patient remained cyanosed but was free from symptoms.

On December 18 urinary chromatography, using the "rack tank" technique of Datta, Dent, and Harris (1950), revealed alanine, glutamine, serine, glycine, taurine, tyrosine, glutamic acid, and β -aminoisobutyric acid, all present in concentrations markedly in excess of the normal. Two days later the cyanosis finally disappeared and the patient felt well, but on December 24 she became dizzy when she was out of bed. Blood examination revealed: haemoglobin, 66% (Haldane), or 9.7 g. per 100 ml.; red cells, 2,860,000; colour index, 1.12; white cells, 12,750 (metamyelocytes 4%, neutrophils 54%, eosinophils 6%, lymphocytes 34%, monocytes 2%); corrected E.S.R., zero; P.C.V., 28%; M.C.V., 98 μ^3 ; M.C.H.C., 34%. A blood film showed polychromasia and anisocytosis with slight macrocytosis.

On December 27 the patient complained of nausea, but her appetite was good. Haemoglobin was 63% (Haldane), or 9.3 g. per 100 ml.; red cells, 2,890,000; colour index, 1.07; corrected E.S.R., zero; P.C.V., 30%; M.C.V., 103 μ^3 ; M.C.H.C., 31%; white cells, 11,050 (neutrophils 58%,

eosinophils 8%, lymphocytes 32%, monocytes 2%). On January 5, 1952, the haemoglobin was 65% (Haldane), or 9.6 g. per 100 ml.; red cells, 3,260,000; colour index, 0.98; corrected E.S.R., zero; P.C.V., 31%; M.C.V., 94 μ^3 ; M.C.H.C., 32%; white cells, 7,900. Although the blood picture was slowly reverting to normal the patient was given 2 pints (1,140 ml.) of blood by intravenous drip, to expedite recovery.

Blood examination on January 12 showed: haemoglobin, 85% (Haldane), or 12.6 g. per 100 ml.; red cells, 3,950,000; colour index, 1.06; corrected E.S.R., 7 mm. in one hour; P.C.V., 38%; M.C.V., 94 μ^3 ; M.C.H.C., 33%; white cells, 9,200; reticulocytes, 2.5%. On January 12, and again on February 8, the urinary chromatogram was normal.

The patient remained afebrile throughout her stay in hospital and was never jaundiced.

Discussion

This case differs from cases of nitrobenzene poisoning reported by Chapman and Fox (1945) and Nabarro (1948) in that cyanosis was noted one hour after the ingestion of the nitrobenzene, which was much sooner than in their cases. The odour of nitrobenzene is quite distinctive and has been likened to that of essence of bitter almonds by Nabarro.

Hamblin and Mangelsdorff (1938) found methaemoglobin in the blood of all cases of nitrobenzene poisoning, whereas Loeb, Bock, and Fitz (1921) were unable to detect it and suggested the formation of a nitrobenzene haemoglobin compound. In our case the spectrum for methaemoglobin was obtained, although with considerable difficulty, in spite of the intense degree of cyanosis. Nabarro (1948) suggested that if methylene blue was given transfusion might not be necessary, and our case confirmed this, as the blood picture was definitely improving spontaneously before the second blood transfusion. It is unfortunate that the effect of methylene blue seems to be transient. Its mode of action has been discussed fully by Gibson (1948).

In view of the results obtained by Deeny, Murdock, and Rogan (1943) in the treatment of congenital methaemoglobinemia with ascorbic acid we gave the patient large doses of this vitamin, although Shiels and Goldwater (1949) concluded that the beneficial effect of ascorbic acid in experimental and human benzene poisoning was not convincing.

Wirtschafter and Wolpaw (1944) have recorded a case of nitrobenzene poisoning in which there was a low total plasma protein content, a decrease in cholesterol esters, and slight but significant bromsulphthalein retention. It is probable that in their case, as in ours, there was an acute zonal hepatic necrosis. The condition must have been quite transient in our case, as subsequent urinary chromatography and extensive liver and kidney function tests did not reveal any abnormality. Uzman and Denny-Brown (1948) reported persistent amino-aciduria in early cases of hepato-lenticular degeneration (Wilson's disease) before liver-function tests showed any abnormality, and this has been confirmed in a similar case in this hospital. Himsworth (1950) considered that urinary chromatography was the best means of demonstrating amino-acids in the urine in cases of acute liver atrophy, and he suggested that their presence in this condition signified not only that liver cells had been killed but that few survived.

Wirtschafter and Wolpaw recommended glucose to fortify the liver and saline to replace that lost by vomiting. They dismissed replacement blood transfusion as unnecessary, but thought that the inhalation of oxygen in high concentration helped to prevent the formation of methaemoglobin, and they concluded that nitrobenzene affects the circulatory, respiratory, and central nervous systems both directly by toxic action and indirectly by the formation of methaemoglobin, with resultant anoxaemia. They thought that the hepatic and haemopoietic systems were damaged by direct toxic action.

Summary

A case of acute nitrobenzene poisoning is recorded in which there was methaemoglobinemia and amino-aciduria. Urinary chromatography revealed a transient gross excess of all the normal amino-acids. The literature on the symptomatology and treatment of the condition is reviewed briefly. The patient made a rapid recovery.

For permission to publish this case we are indebted to Dr. Robert Marshall and to Dr. J. A. Smyth, physician-in-charge, Biochemistry Department. We wish to thank Dr. M. G. Nelson for the haematological reports, and Mr. J. S. Coulter, F.I.M.L.T., for the spectroscopic demonstration of methaemoglobin.

ACUTE TETRACHLORETHANE POISONING

A REPORT ON TWO FATAL CASES

BY

A. KEITH MANT, M.D.

First Assistant to the Department of Forensic Medicine,
Guy's Hospital

Cases of acute tetrachlorethane poisoning, following its ingestion by mouth, are unusual. Only three such cases are reported in the English literature (Hepple, 1927; Elliott, 1933; Forbes, 1943). Acute tetrachlorethane poisoning is generally suicidal, its distinctive odour rendering its accidental ingestion unlikely. One case of acute accidental poisoning has, however, been recorded (Hauser, 1939). There is no record of tetrachlorethane having been used as a homicidal agent.

Tetrachlorethane is a colourless, non-inflammable, oily liquid, boiling at 146.3° C., and with a specific gravity of 1.600 at 20° C. It is soluble in fats, oils, resins, and waxes, miscible with alcohol, and soluble in water to the extent of 1 part in 5,000. It has a sweetish smell and taste, somewhat resembling trichlorethylene, carbon tetrachloride, and chloroform, but quite distinct to those who are familiar with it. The commercial preparations have a yellow tinge. As a solvent, tetrachlorethane has many applications in industry, but, owing to its intensely poisonous properties, being the most toxic of the halogenated hydrocarbons (Hamilton, 1934; Browning, 1937), it is falling into disuse. At one time it was issued to the Army as "silk cleansing fluid," and two of the three acute cases recorded in the English literature occurred in soldiers. Its widest application outside industry is in horticulture—as an effective insecticide against white fly. In the two cases described below, the tetrachlorethane was originally purchased as an insecticide.

Chronic tetrachlorethane poisoning has been described and reviewed by a number of authors (Willcox, 1915; Minot and Smith, 1921; Legge, 1934; van Oettingen,

1937; Forbes, 1943). Methods for the early detection of chronic tetrachlorethane poisoning by examination of the blood and urine have been described by Minot and Smith (1921), and Gurney (1943). Toxic jaundice due to tetrachlorethane poisoning became compulsorily notifiable in this country after January 1, 1916, as the result of cases occurring amongst aircraft workers, who used it as "dope" for the treatment of fuselage. Twenty-six cases, five of which were fatal, were notified in 1916, but no further cases were notified until a fatal case occurred in 1929. Although chronic tetrachlorethane poisoning is becoming virtually unknown in this country, cases are still occurring abroad. Seven such cases, one of which was fatal, have been recorded by Coyer (1944).

When taken in large quantities by mouth, tetrachlorethane kills by its narcotic action before recognizable changes can take place in the liver and other organs. Consciousness is rapidly lost, and this is followed by a gradual depression of the vital centres, death occurring some 10 to 20 hours after ingestion. In these cases, except for the presence and smell of tetrachlorethane, the necropsy findings are those of narcotic poisoning, with changes in the gastric mucosa depending on the quantity taken and the presence or otherwise of food. In the two cases to be described the tetrachlorethane had been deliberately taken by mouth.

Case 1

A gardener aged 57 had become depressed because the estate on which he had been employed for thirty years was about to change hands. He left home one day as usual at 7 a.m., taking his sandwiches with him. As his mother, with whom he lived, was often in bed before he returned home in the evening, he was not missed until the next morning. At about 10 a.m. on that day he was found dead on the floor of his potting-shed; an uncorked bottle of tetrachlorethane lay by his side and a short farewell note was found scrawled in chalk across his work-bench.

Necropsy was carried out the next morning. A strong smell of tetrachlorethane was apparent on entering the mortuary. The body was that of a well-nourished man. There was an intense cyanosis of the post-mortem livid stains. Anoxic haemorrhages were present in the scalp.

There was no corrosion of the mouth, lips, or tongue. The lower third of the oesophagus was congested, and early superficial necrosis of the mucosa was present. At the cardiac end of the stomach extreme congestion of the entire gastric mucosa was found, with superficial necrosis and frank erosion. At the pyloric end of the stomach the exposed ridges of the rugae were principally affected. From the stomach and the first half of the duodenum 15 oz. (425 ml.) of tetrachlorethane was recovered. The tetrachlorethane had not passed beyond this point. The stomach also contained a further 5 oz. (142 ml.) of fluid consisting mainly of mucus. Food was not present.

Numerous anoxic haemorrhages were scattered throughout the brain, and there was early basal collapse of both lungs. No material natural disease was present in other organs.

Case 2

A carpenter aged 20, recently discharged from the R.A.F., was depressed over an error he had made at work. On the day before his death he returned home as usual for lunch. He had a good meal and left the house at 1.20 p.m. to return to work. At 2.30 p.m. it was noticed that his bicycle was still in the garden, and almost immediately afterwards he was found unconscious in a wheel-barrow which was standing close to a greenhouse. Later a medicine bottle which contained tetrachlorethane was found in the greenhouse, with approximately 1 to 2 oz. (28 to 57 ml.) missing.

POLYPOSIS OF SMALL INTESTINE WITH PIGMENTATION OF ORAL MUCOSA

REPORT OF TWO CASES

BY

A. P. KITCHIN, M.B., B.Chir., F.R.C.S.Ed.

Senior Surgical Registrar, West Herts Hospital Group

The following cases are recorded as further examples of this condition. They both came to hospital with symptoms of intestinal obstruction due to intussusception, one having had two previous operations for a similar condition. The typical pigmentation in the oral region was present in each case.

Case 1

A housewife aged 26 attended hospital complaining of attacks of lower abdominal pain for the previous six months, increasing in frequency and severity. On two occasions she had vomited during an attack. She had no disturbance of bowel function and had noticed nothing abnormal in the stools. Micturition and menstruation were normal, she had not lost weight, and had had no previous gastro-intestinal trouble, nor had anyone else in her family.

She was a well-built woman, dark, with a rather sallow complexion. On the circumoral skin there was a well-marked irregular dark brown mottling which extended over the mucous membrane of the lips and the cheeks, where the patches were more numerous. This had been present as long as she could remember and had not changed in any way during the time. No similar pigmentation was found elsewhere on the skin or the vaginal and rectal mucosa. The only other abnormality found was an elongated tumour in the left iliac fossa which was not tender and which varied in size and position during the course of the examination. A provisional diagnosis of recurrent intussusception was made, and she was admitted to hospital 48 hours later.

There was then a smaller and rounder mass in the right iliac fossa which was very mobile and disappeared completely after palpation. The attacks of pain were now much more frequent.

Laparotomy was carried out through a lower right paramedian incision. There was no free fluid in the peritoneal cavity. In the upper third of the ileum an intussusception was found which reduced easily, and after reduction three polyps about 1 in. (2.5 cm.) in diameter could be felt in the lumen of the bowel, one having been at the apex of the intussusception. In the lower ileum there was a Meckel's diverticulum 2 in. (5 cm.) in length and, just distal to it, a second intussusception with a further polyp rather larger than the others. The rest of the small intestine and the colon appeared normal and no other tumours were palpable. About 7 in. (18 cm.) of ileum, including the diverticulum and the polyp, was resected and a lateral anastomosis made. A similar length, including the tumours in the upper ileum, was removed, and an end-to-end anastomosis made. Her convalescence was uneventful, and she has so far had no further symptoms.

The four polyps removed showed no evidence of malignancy on histological examination.

Case 2

A housewife aged 35 was admitted to hospital complaining of intermittent abdominal pain and the passage of dark tarry stools for the past six days. In 1939 she had been admitted to this hospital with an intussusception, and 20 in. (50 cm.) of small intestine containing five polyps had been resected. In 1943, at another hospital, a second resection for an irreducible ileo-ileal intussusception had been done

but no polyps were found at this operation. Apart from these two incidents her health had been normal.

She had a much lighter complexion than the first case, but the pigmentation was of similar distribution over the inner surfaces of the cheeks and lips, although less marked on the circumoral skin. She was sure the condition had been present since childhood and had never noticed any change in it. There was no other pigmentation of the skin or of the rectal or vaginal mucosa. Apart from the two operation scars nothing abnormal was found on examination. A barium meal and follow-through x-ray examination showed dilatation of some loops of jejunum, suggestive of a subacute obstruction.

Laparotomy was carried out on the following day through a right paramedian incision. No free fluid was found. There was slight distension of the upper jejunum, and about 12 polyps could be felt along the course of the small intestine, one, larger than the rest, causing an intussusception in the upper ileum which was easily reduced. This polyp was excised with a small wedge of intestinal wall. In the lower part of the jejunum a 15-in. (38-cm.) length containing four polyps close together was resected with end-to-end anastomosis. No tumours were felt in the colon, but there was a complete intussusception of the appendix, which was reduced and the appendix removed. It contained three polyps. Histological examination showed no evidence of malignancy in any of the tumours.

She had an uninterrupted convalescence, and has so far remained free from further symptoms.

Comment

Although living in the same district, these two patients are not related. There is no evidence of pigmentation or polyposis in the family of Case 1. The second patient came to this country from Central Europe before the war, and further investigation is not possible, but she knows of no one else being affected in her family.

Four of the 27 cases so far recorded have been in this country—a father and daughter (Foster, 1944), a girl of 16 (Tanner, 1951), and a man of 50, originally operated on for intussusception in 1922 (Wolff, 1952).

Jeghers *et al.* (1949) have described the condition very fully, recording 10 cases of their own, and have shown the familial incidence in several of them and in the original cases of Peutz, in which three generations were involved. The presumptive evidence of polyposis is very strong in a number of cases with the characteristic pigmentation, including one of twins described by Jonathan Hutchinson (1896), Parkes Weber (1919), and two relations of Foster's cases. Wolff describes the typical pigmentation round the mouth and also on the hands in several relatives of his case, including one who died after an intussusception. Renyard (1951) also describes a case of gastro-intestinal polyposis with a number of small brown patches on the lower lip.

The pigmentation is either present at birth or appears in early childhood, and the intestinal symptoms usually appear by the third decade, as in the two cases described here. Polyposis without pigmentation is relatively common, but Jeghers *et al.* state that they have been able to find only one case of typical pigmentation with no evidence of polyposis, a woman of 57 years.

Intussusception of the appendix, as found in Case 2, was described nearly 100 years ago, but only about 90 cases have been recorded since, and Wakeley (1939) considers that the condition is probably much commoner than this would indicate. Various causative factors have been suggested, including foreign bodies, lack of meso-appendix, and enlarged lymphatic nodes, as in the ileo-caecal variety. I can find a record of only five cases due to polyps (McSwain, 1941), although polyposis of the appendix is not very infrequent.

I wish to thank Mr. V. Glendinning, who operated on these cases, for his help and advice, and Dr. White Phillips for the x-ray report.

Medical Memorandum

Recurrent Intussusception Due to Polyposis of the Gastro-intestinal Tract Associated with Pigmentation

The intussusception, gastro-intestinal polyposis, and pigmentation of skin and buccal mucosa sign-complex was first described by Jeghers (1944) and further elaborated by Jeghers *et al.* (1949). Tanner (1951) reviewed the literature and added a further case. Since then, so far as we have been able to ascertain, only two more cases have been reported (Schaffer and Sachs, 1952; Wolff, 1952), bringing the total number of recorded cases to 27. The following case, to the best of our knowledge, is the first to be reported from the Middle East.

The salient features of the syndrome, as borne out by all the reported cases, are: (1) The patients are usually of dark complexion. (2) Pigmented spots are present on the buccal mucosa, lips, and face, and sometimes on the digits. The spots vary in colour from "light brown on the face to dark blue-black on the mucosa" and have been shown to contain melanin. (3) The presence of gastro-intestinal polyposis, predominantly in the small intestine. The polyps are usually benign, but in one case malignant change has been reported. (4) The condition usually presents as recurrent intussusception in the second decade of life. (5) It is often familial, and is believed to be transmitted as a Mendelian dominant.

CASE REPORT

A boy aged 16, who was born in Turkey and had come to Israel in 1950, was admitted to the department of surgery on October 1, 1952, complaining of generalized abdominal pain associated with anorexia and vomiting, following the passage of a hard stool some four to five hours previously. The pain was colicky in nature, maximal in the epigastrium, and radiated to the left flank. Nausea was persistent and he had vomited several times after the onset of the pain. The vomitus contained undigested food. No blood was present in the stools and there was no history of recent diarrhoea. He had had an almost identical attack two weeks previously, when he was admitted to another hospital and discharged 48 hours later, his symptoms having subsided.

He had been well until 18 months earlier (March 8, 1951), when he was admitted to this hospital complaining of abdominal pain, constipation, vomiting, and the passage of dominal pain, constipation, vomiting, and the passage of blood in his stools. On laparotomy an "ileo-ileal intussusception with a polyp about the size of an apricot" was found. The pathological report was that of a "benign polyp of the small gut." On discharge from hospital he continued to have attacks of abdominal pain with occasional bloody stools at approximately weekly intervals.

On August 9, 1952, he was readmitted with abdominal pain, constipation, vomiting, and blood in his stools. A laparotomy was again performed the day after admission, and "ileus due to adhesions related to the ileum and herniation of bowel through a deficiency in the omentum" was reported. After his discharge (nine days later) he was relatively well until the attack two weeks before his present admission to hospital. His mother, father, two brothers, and two sisters are all healthy and have no history of abdominal symptoms or operation.

Examination revealed a dark-complexioned youth, physically underdeveloped for his age—weight 73 lb. 11 oz. (33.4 kg.), height 4 ft. 10 in. (147 cm.). No pubic or axillary hair was present. The genitalia were small and undeveloped and the voice was high-pitched. Small pigmented spots about the size of a pinhead were present over the bridge of his nose and around his mouth. Larger bluish-black macular spots varying in size from 1/16 to 1/4 in. (1.6 to 6.4 mm.) in diameter were present on his lips and buccal mucosa, particularly the lower lip and the inside of the left cheek. No other pigmented spots or papillomata were found on the rest of the body surface. In the abdomen a sausage-shaped mass extending from the left flank to the left of the umbilicus was clearly palpable. Generalized abdominal tenderness was present, but no guarding or rigidity. No free fluid was detected, and the liver and spleen were not palpable. Rectal examination was negative.

A diagnosis of intussusception was made. At laparotomy a jejuno-jejunal triple intussusception was found involving about 1.5 m. of small bowel, with a large polyp (about 1 in. (1.9 cm.) in diameter) at the tip of the intussusception. Resection of 10 cm. of bowel, including the polyp, was performed and the specimen sent for section. The pathological report was of a "benign adenomatous papilloma."

The patient made an uneventful recovery. A barium meal and follow-through, and a barium enema at a later date, showed no radiological evidence of further polyposis. On rectoscopy, however, a cluster of four sessile polypi, each about 1/4 in. (6 mm.) in diameter, was seen on the left lateral rectal wall 9 cm. from the anal verge.

A subsequent examination of the patient's parents and siblings revealed no pigmentation of the buccal mucosa or skin in any of them, nor signs of polyposis of the bowel.

We wish to express our thanks to Dr. N. Rabinowitz, of the department of surgery, Hadassah University Hospital, for permission to report this case, and to Dr. Charlotte Kaplan for drawing our attention to this interesting but rare syndrome.

I. KAPLAN, M.B., Ch.B.

M. FEUCHTWANGER, M.D.

Since its inception in 1947 the National Corporation for the Care of Old People has devoted its resources principally to assisting voluntary organizations by means of grants-in-aid to provide homes, clubs, and welfare centres. Its annual report for 1951-2 records that £116,515 was allocated in this way during the year, making a total of £790,000 during the last five years. The Corporation opened a rest home at Stanmore to admit patients discharged from the geriatric unit of West Middlesex Hospital and from Edgware General Hospital. Another home was opened at Greenisland, near Belfast, and a third is planned for Oxford. An experiment in Bristol was the provision in 1951 of a laundry service for old people. The Corporation, which has power to accept trusteeship of charitable bequests made to benefit old people, pleads that they "should not be regarded as a class apart, as objects either of pity or charity, but as people who with help can retain their independence and make their own contribution to the general welfare." The welfare of old people is also the concern of a special committee of the National Council of Social Service, whose annual report for 1951-2 records its activities. It makes available to Government departments, voluntary societies, students, and others up-to-date information and experience affecting the welfare of old people. At its national conference at Scarborough in 1952, 400 delegates heard Sir Walter Monckton outline the steps taken by the Government to ensure a new and sympathetic approach to the employment of the elderly on the part of employers, trade unions, and the public.

Reviews

CLINICAL NEUROLOGY

Clinical Neurology. By Frank A. Elliott, M.B., Ch.B., F.R.C.P., Professor Brodie Hughes, Ch.M.(Birm.), F.R.C.S., and J. W. Aldren Turner, M.A., D.M.(Oxon.), F.R.C.P. Edited by Frank A. Elliott. (Pp. 751. £2 2s.) London: Cassell and Co. 1952.

This book is "intended for those who are undergoing post-graduate training in medicine rather than for the junior student or the professed neurologist," and to this end it attempts "to present the common problems of neurology within a reasonable compass and to avoid the rare, the recondite, and the contentious."

In general, it follows orthodox lines. The first section is devoted to the principles of neurological diagnosis and includes essential anatomy and physiology, the mechanism of certain major symptoms, and methods of examination, including special diagnostic techniques, to which Dr. A. E. Ritchie contributes a useful section on the electrodiagnosis of neuromuscular disorders. The second section is on individual diseases. The text is throughout clear, concise, and unambiguous and the information sound and up to date. To each major section is appended a brief list of original papers which the reader might consult with profit. Nearly all of these are in English, but a few classical papers in French and German are included.

The growing contribution of neurosurgery is recognized by the admission of a surgeon to full partnership in the trinity of authorship. Professor Brodie Hughes is solely responsible for the sections on abscesses, aneurysms, vascular malformations, and tumours of the brain and cord and their adnexa, and shares responsibility for those on the examination of the patient and injuries to the head and spinal cord. All these are first rate. Other chapters which deserve special notice in an admirably balanced text are those on disorders of speech and language, mental disorders in organic disease, and infections of the central nervous system (though no treatment is given for Weil's disease). To 700 pages of text there are fifty of a most detailed and helpful index.

Useful additions to a future edition would be a section on occupational cramps (writer's cramp is mentioned only incidentally as a symptom of paralysis agitans), and references to the neurological manifestations of systemic lupus erythematosus, posterior interosseous neuritis (another "tunnel" syndrome), and the otolith syndrome, which are certainly not less common in Britain than cerebral schistosomiasis.

There is a notable absence of major typographical errors, but some of the minor defects and inconsistencies of multiple authorship are evident. On p. 186 tower skull is called turriccephaly; on p. 227 it becomes oxycephaly. Snippets of history are dispensed in some instances—for example, with tabes and G.P.I. (p. 357) but not with disseminated sclerosis or Parkinsonism. Sometimes capitals are used for all words in the nomenclature of disease—for example, Chronic Progressive Chorea (p. 252) and Parkinson's Disease (p. 525); in others this is modified—for example, Neuritic muscular atrophy (p. 247) and von Economo's disease (p. 323). Sometimes (Syn.: . . .), at others (Syn. . . .), and yet at others brackets only are used for synonyms; and, for example, in neurofibromatosis (p. 257), rabies (p. 337), and congenital spastic diplegia (p. 221) yet another form is seen. Moreover, "etc." should not occur among the synonyms (for example, p. 412).

The editor's claim that "eponymous terms have been avoided wherever possible" is hardly justified by the retention, even as synonyms, of such names as Fothergill's disease for tic douloureux, Swift's disease for erythroedema, Albl's ring for the calcification seen radiologically in the wall of an aneurysm, and Chastek paralysis for the lesions which

silver foxes develop when fed on a diet of raw fish (what price "the rare, the recondite" here?). On the other hand, though a description is given of "the adrenal type" of fulminating meningococcal septicaemia, the common eponym Friderichsen-Waterhouse syndrome is studiously avoided.

These criticisms might well appear niggardly and trifling, so it must be emphasized that such minor blemishes are commendably few and do not detract from the excellence of a work whose intrinsic merits and handsome production ensure its place in the treasury of neurological textbooks for which English medicine is so justly famed.

HENRY COHEN.

PANCREATIC NEOPLASMS

The Surgery of Pancreatic Neoplasms. By Rodney Smith, M.S., F.R.C.S. (Pp. 157; 111 figures. £1 15s.) Edinburgh and London: E. and S. Livingstone. 1953.

Mr. Rodney Smith won the Jacksonian Prize of the Royal College of Surgeons of England with the essay that forms the substance of this book. In it he has presented an admirable review of this important subject at a time when just such a balanced and impartial assessment is needed. The operation of pancreatoduodenectomy has passed from a hazardous procedure, successful only in the hands of a few pioneers, to an operation safe enough to be given a recognized position in orthodox operative surgery. The time has come for reassessment. And reassessment has shown that the prospects of cure in cases of malignant growth are much less satisfactory than was hoped at first.

In defining the problem, Mr. Smith states that the distinction between the so-called ampullary carcinomas and carcinomas of the head of the pancreas is of little practical value, and he deals with them together. But later, when he discusses symptoms and indications for operation, he admits the practical value of such a distinction, one that the majority of surgeons consider important. An ampullary carcinoma, whether it arises in duodenal mucosa, the lining of the ampulla, or the terminal bile duct, is a carcinoma that obstructs early and ulcerates early and is therefore recognized early. Further, being on the surface, it tends to spread superficially rather than deeply, to give radiological changes that are recognizable at an early stage, and to bleed early, sometimes so profusely as to call attention to its presence by profound anaemia.

The author presents the figures of Cattell, who has a greater experience of pancreatotomy than any other surgeon, and points out that in ampullary carcinoma the operative mortality is one-third that in carcinoma of the head, and the cure rate is 10 times as high. This is the experience of most surgeons, and, as Mr. Smith points out, the position to-day is that pancreatotomy for cancer of the head is attempted only when a careful preliminary mobilization fails to reveal any evidence of local or distant extension. Chapter XI, on the choice of operation, is admirable. Not everyone will agree with the statement that a one-stage resection is essential. Certainly any attempt at dissection, or any preliminary short-circuits, render the subsequent pancreatotomy almost impossible, but preliminary cholecystostomy, which does not interfere in any way with the operative field, has much to recommend it. A fortnight's drainage allows the liver to recover, and after resection the cholecystostomy removes the risk of leakage at the choledochojunal anastomosis.

One reason why the surgical results in cancer of the pancreas are so bad is because the growth is clinically silent in its early stages, and radiological and biochemical investigations give little help. The author quotes two London radiologists as stating that they have obtained positive evidence by a barium meal in over 50% of cases examined; contact with two such optimists must have been a delightful relief from the hard work of preparing this book. The final sentence in Chapter VIII—"It is bad treat-

ment to allow an operation to be unduly delayed in order to carry out a number of tests"—brings back a cool blast of common sense. In Chapter XVII the author brings out well the sharp distinction between cancer of the body of the pancreas and that of the head—in symptoms, in the technical problems associated with the removal, and in prognosis. The leading symptoms are constant and unremitting severe pain referred to the back and loss of weight.

The book is admirably produced and embellished by well-chosen illustrations, many of them in colour. About the only criticism that can be offered is that Figures 4 to 9 illustrating variations in the blood vessels of the pancreas should be further explained; as they stand they are confusing rather than helpful. But this is a small defect in a book which will be of the greatest help to surgeons and essential to every library.

HENEAGE OGILVIE.

RELIEF OF PAIN IN LABOUR

The Practical Management of Pain in Labour. W. D. Wylie, M.B., M.R.C.P., D.A. (Pp. 148; 42 figures. 18s. 6d.) London: Lloyd-Luke (Medical Books) Ltd. 1953.

Dr. Wylie shows an understanding of the practical problems of pain relief in labour that is somewhat unusual in the specialist anaesthetist, who rarely has the time to acquire much practical knowledge of the subject. Now that an increasing amount of midwifery is being done in hospitals this state of affairs is tending to change, and books such as this will undoubtedly be of the greatest value.

Dr. Wylie discusses pain in normal labour from the usual anatomical and pharmacological aspects and gives accounts of all the available methods now in use for mitigating it. In addition he considers in great detail the problems of pain relief during abnormal labour. The influence of an anaesthetist's general experience on problems peculiar to labour is seen when Dr. Wylie properly deprecates the use of thiopentone as an anaesthetic in these circumstances, and also in the prominence he gives to the danger, ever present in obstetric anaesthesia, of vomiting and its sequelae. The illustrations, though not numerous, are adequate, and in the main are reproductions of commercially supplied pictures and diagrams of apparatus. They are mostly gathered together in one group of pages in the centre of the book, an arrangement not always convenient for the reader. Altogether, this is a well-written, helpful, practical account of pain relief in labour as practised in Britain.

W. W. MUSHIN.

THE THYROID GLAND

Joll's Diseases of the Thyroid Gland. By Francis F. Rundle, M.D., F.R.C.S. Second edition. (Pp. 520; 165 figures. £4 4s.) London: William Heinemann Medical Books. 1951.

The Thyroid. By Professor T. H. McGavack, M.D., F.A.C.P. With a section on Surgery by Professor J. M. Winfield, M.D., F.A.C.S., and W. L. Mersheimer, M.D., F.A.C.S., and a section on History by Dorothy B. Spear, Ph.B., and T. H. McGavack. (Pp. 646; illustrated. £4 15s.) London: Henry Kimpton. 1951.

These two excellent books are almost exactly the same size in area and thickness, but they will appeal to different classes of reader. Traditional scholarship is well served by the new edition of "Joll," and, if little of the book was written by its original author, the complaints will be few. It is pleasing that Rundle, who could have written an excellent textbook under his own name, should have preferred to commemorate his old master at the New End Thyroid Clinic, for Joll was greater than the work he left behind him and deserves a memorial. Considering that the preface is dated November, 1950, the book is remarkably up to date. A lot of ¹³¹I has passed through the Geiger-Müller counters since then, but the references to radioactive iodine in diagnosis and treatment are full enough for the general reader. Neither this nor any other scientific consideration is allowed to alter the balance of an essenti-

ally clinical book, which gives an excellent impression of knowledge tested and illumined by the practical experience of its authors.

One can read Rundle for pleasure as well as profit. No one could read McGavack; the facts are too closely packed, the references too detailed and too numerous. It is astonishing how much information is given in so small a space, but because of this McGavack (though it is in fact a few ounces lighter) is heavier going for the reader than Joll. This is a book for the specialist, especially if he wants fundamental physiology, laboratory techniques, and the latest information (which cannot, in a book, be very recent) about radioactive iodine.

I think I would advise buying both books.

RAYMOND GREENE.

OBSTETRICS AND GYNAECOLOGY

Recent Advances in Obstetrics and Gynaecology. By Aleck W. Bourne, M.B., B.Ch.(Camb.), F.R.C.S., F.R.C.O.G., and Leslie H. Williams, M.D., M.S.(Lond.), F.R.C.S., F.R.C.O.G. Eighth edition. (Pp. 339; 92 figures. £1 7s. 6d.) London: J. and A. Churchill. 1953.

This justifiably popular book has reached its eighth edition in twenty-seven years, and the authors' zest and power to sift the wheat from the chaff remain as remarkable as in their first edition. In order to keep the total work the same size and yet to cover individual subjects adequately, the number of chapters is now reduced to eleven. Three of these are on new topics—hypertension and pregnancy, functional uterine haemorrhage, and intravascular thrombosis and embolism. The remaining chapters have been revised and brought up to date, and some of the revision is very extensive. Obstetric radiology is covered by Dr. E. Rohan Williams, and radiotherapy in gynaecology by Dr. W. M. Levitt.

All those specializing, or hoping to specialize, in obstetrics and gynaecology will welcome this book, although views on which chapters are most helpful and interesting will vary with the reader's taste. Some will give pride of place to the articles on lactation and on carcinoma of the cervix—both subjects on which ideas have changed and are changing rapidly. Others may prefer the accounts of weight change and water balance in pregnancy, or thrombosis and embolism. The concise review of the literature and the summing up to give some sort of practical guide are usually masterly, and carry that most important imprint, the authors' personality and experience. When space is limited, how difficult it must be to choose the subjects to be included in a work of this kind, to decide which advances are sufficiently consolidated to merit permanent recognition in this form, and which developments are so uncertain of future acceptance as to warrant discard. The choice made by Mr. Bourne and Mr. Williams will find favour in the eyes of large numbers of readers.

T. N. A. JEFFCOATE.

The well-known *Textbook of Medical Practice* edited by Dunlop, Davidson, and McNee has now reached its sixth edition (E. and S. Livingstone, Ltd., 50s.). All sections have been revised and many of them largely rewritten. New chapters have been included on chemotherapy, rehabilitation, the treatment of poisoning, and the chemotherapy of malignant disease. An unusual change is that the volume has been equipped with that essential feature a completely new index. Also appearing in its sixth edition is *Recent Advances in Pathology*, edited by Professor Geoffrey Hadfield (J. and A. Churchill, Ltd., 30s.). An attempt has been made to discuss in this edition disorders of function and their relation to general physiological principles. The section on endocrine organs has been completely rewritten, and the account of pulmonary diseases covers a wider field than in previous editions. *An Atlas of the Commoner Skin Diseases*, by Dr. C. G. Semon, has been revised for a fourth edition (Bristol: John Wright and Co., Ltd. London: Simpkin Marshall, Ltd. 75s.). All the 147 plates are in colour, and some new ones have been added.

LONDON

SATURDAY MARCH 21 1953

TUBERCULOSIS OF BOVINE ORIGIN

A difficulty with which anyone campaigning for safe milk in recent years has had to contend was the lack of modern information about the amount of tuberculosis attributable to infected milk. The well-known findings of Stanley Griffith are now 20 years old, and only a fresh survey could decide how far the position had changed since the early nineteen-thirties. Such a survey was undertaken by the Medical Research Council as part of an inquiry into the causes of an apparent increase in the death rate from tuberculosis in the early part of the war, and the whole of the findings in the three areas of Great Britain have now been published by the National Association for the Prevention of Tuberculosis.¹ The investigations covered the period 1943-5 in England and Wales, 1943-4 in Scotland, and 1945-50 in Northern Ireland, and consisted in typing tubercle bacilli from cases of non-pulmonary tuberculosis and pursuing detailed inquiries about the patients from whom they were derived. The number of strains examined was 994 in England, of which 261 (26.3%) proved to be bovine, 112 in Wales (19, or 17%, bovine), 1,051 in Scotland (228, or 21.7%, bovine) and 387 in Northern Ireland (16, or 4%, bovine). The fact that the Northern Ireland investigation was carried out later, and the inclusion in it of a very high proportion of cases of meningitis, render direct comparison with the other figures unjustifiable: it would nevertheless seem from these results that the prevalence of infection of bovine origin in Northern Ireland is much lower than elsewhere.

The main result of this survey is to show that tuberculosis of bovine origin has remained a serious problem. It can be calculated from the findings that in 1944 550 deaths in Great Britain from tuberculous meningitis and 1,050 from other varieties of non-pulmonary disease were due to bovine bacilli. This total of 1,600 annual deaths is not far short of the figure calculated from Griffith's results 20 years ago. To this, in any assessment of the effects of milk-borne infection, must be added the consequences of invali-

¹ Wilson, G. S., Blacklock, J. W. S., and Reilly, Lilian V., *Non-pulmonary Tuberculosis of Bovine Origin in Great Britain and Northern Ireland, 1952*, London.

dity or disablement in many thousands of patients with non-fatal infections. Detailed study of the age and sex incidence, history of raw milk consumption, history of contact with another case, and geographical distribution brings out a number of interesting points. The most notable and significant change is in the age incidence. In Griffith's series the highest incidence of bovine infection in every part of the body separately considered was in the 0-4 age group. According to the recent findings the age during which non-pulmonary tuberculosis is most often due to bovine bacilli is now 5-9 years; indeed, there is a general shift towards a later age incidence, a substantial proportion of bovine infections being in patients of 15 and over. The percentages of bovine infection in cases of meningitis and surgical tuberculosis respectively were in England 28.6 and 50.5 at ages 0-4 and 35.4 and 53.7 at ages 5-9. In Scotland the corresponding figures were 17.9% and 51.3% at ages 0-4 and 10.2% and 70.8% at ages 5-9. Why meningitis in Scotland alone should retain the older age distribution is unexplained.

There are several other minor discrepancies or differences of this kind between the findings in the several reports. Changes in feeding habits seem to provide the correct explanation for the more frequent occurrence of bovine infections in older children in recent times. Whereas in earlier days infants were often fed on cow's milk of doubtful quality, the efforts of welfare clinics have led to the introduction of systems of infant feeding with dried or other safe forms of milk, and the risk at this age and for some time after it, when similar foods continue to be used, is thus much diminished. On the other hand, the milk-in-schools scheme has led to a greatly increased consumption of milk from the age of 5 onwards, and some of this is still neither tuberculin-tested nor pasteurized. That the risk is not confined to childhood is illustrated by the fact that 30% of bovine infections in the English series were in patients aged 15 and over. The report also emphasizes that prolonged and regular consumption of raw milk is not always necessary to produce overt infection: inquiries into milk-drinking histories sometimes showed that its consumption can only have been "slight or occasional." Perhaps this evidence should not be accepted too literally: those questioned had to think back for some years, and a surprising number of intelligent people do not know whether the supply to their homes is pasteurized even at the time when they are asked about it. This report nevertheless affords strong support to the case for the general pasteurization of milk from any but T.T. herds.

DISTRIBUTION OF DOCTORS

The fourth report of the Medical Practices Committee, a summary of which is to be found in the *Supplement* of this issue, has just been received by executive councils of England and Wales. It covers a period of 18 months up to the end of 1952. This interesting document contains an analytical survey of the movement of general practitioners since July, 1948, and for the first time an attempt has been made to assess the effectiveness of "negative direction" upon the distribution of doctors. The committee admits that it is rather early for such an assessment. Some of the figures are for various reasons not wholly accurate, and four and a half years is hardly long enough for general practice to have shaken down in the Health Service environment: but the committee thinks that now is the time to look back before entering the new era of the Danckwerts award and the Working Party's scheme, which, in the words of the report, "are bound to have rapid effects on the distribution of medical manpower."

The figures given in the report illustrate clearly the relative changes in the distribution of doctors since 1948. The average size of list throughout the whole country was 2,461 in 1948 and 2,430 in 1952. This reduction is not big, but the wide discrepancies in the average size of list which were evident in different parts of the country have narrowed. In 1948, for instance, the average in Radnorshire was 1,120, while in parts of Glamorganshire it was over 8,000: in 1952 these figures had become 1,320 and 2,832 respectively. In 1948 there were 6,648 principals with average lists of 3,163 in areas where the average lists were high. By January, 1952, the picture had changed to 7,397 principals with average lists of 2,869: this represents an increase of 11% in the number of principals practising in these areas. Conversely, in areas where the average lists were low in 1948 there has been a 10% reduction in the number of principals and an increase in the average list from 1,648 to 2,010. This shift in distribution is clear evidence that the powers given to the Medical Practices Committee under the Act have been used effectively.

A reflection on the effect of the Danckwerts award and Working Party's scheme on partnerships is to be found in the report: "From the numbers of new partnerships of which we have been notified each week since July last we know that the process of assimilating doctors into general practice in this manner (partnership) has again been restored to a satisfactory level. During the next few months the number is likely to exceed those hitherto admitted

during any similar period." Again: "As a result of the Working Party's report, an increasing tendency for assistants in the larger practices to be taken into partnership has been noticed." The number of full-time assistants, other than trainees, dropped from 1,724 in 1951 to 1,566 in 1952. This is encouraging news to all who think that the best way of entry into general practice is by way of assistantship to partnership.

The task of the Medical Practices Committee is not easy. Its decisions must at times be unpopular and open to the criticism that a central body cannot be entirely conversant with local needs. In particular the task of reclassifying areas undertaken by the committee last year might well have led to disagreement with local executive councils and local medical committees. The fact that views were reconciled more easily than expected is a tribute which the central committee gladly pays to the local bodies. All this emphasizes the tact and understanding with which the Medical Practices Committee and its officials did their job.

THROMBOCYTOPENIC PURPURA

A useful introduction to the study of this disease is given in a review of eighty-nine cases by Hirsch and Dameshek,¹ since it provides what is so often lacking in otherwise comprehensive clinical accounts—a clear picture of the natural history of the disease. They define as "idiopathic" those cases of thrombocytopenia in which there is a normal or increased number of megakaryocytes in the bone marrow, and an absence of splenic disease and of conditions affecting the red- or white-cell precursors. Among the cases satisfying these conditions, two sharply differentiated groups were apparent.

The first group, consisting of 18 patients, was characterized by an acute onset of purpura haemorrhagica which subsided spontaneously in a few weeks or months. In 11 of these patients there was a probable aetiological factor such as a virus infection or the taking of a toxic drug before the onset of purpura. The second group consisted of 52 cases of chronic thrombocytopenic purpura in which haemorrhagic symptoms had persisted with fluctuating severity for many months or years, with no complete remission. Aetiological factors were not apparent in the majority of these patients, though in some cases chronic drug intoxication was possible.

It is clear that the recognition of these two varieties of thrombocytopenic purpura is important. In the first (acute) group splenectomy is probably contraindicated, since the condition is self-limiting. Transfusions of fresh blood, preferably taken by means of silicone-coated apparatus, have been found beneficial in tiding

the patient over the worst episodes. It is pointed out that reports of supposedly favourable responses to A.C.T.H. or cortisone may refer to its use in this type of naturally remitting thrombocytopenia.

In the chronic form of the condition only splenectomy seems to be of any real benefit, and the patient is likely to suffer from more or less severe haemorrhagic episodes until it is performed. Of 45 patients whose spleens were removed, 20 were cured, 10 received no benefit, and 3 died, while the remaining 12 survived the operation but were not followed up for a sufficient time to determine its effect.

Much remains to be learned about the aetiology of thrombocytopenic purpura. It is probable that in 11 of the 18 cases of the acute disease reported by Hirsch and Dameshek some toxic or infective process caused the thrombocytopenia, which was relieved when the toxic drug was withheld, or when the infection subsided. It is likely that in the remaining seven patients a similar but unidentified mechanism was operating, particularly as a blood eosinophilia or lymphocytosis was a feature of these acute cases.

Drugs had also been taken by a number of the patients suffering from chronic thrombocytopenia, and one patient was a habitual consumer of "sedormid." Some cases, at least, of chronic thrombocytopenia may be due therefore to chronic exposure to some toxic process. In this connexion the work of Ackroyd² is of the greatest significance. He has shown in thrombocytopenia due to sedormid that there is a factor in the patient's plasma which is capable *in vitro* of destroying platelets, provided that sedormid and complement are both present. It is probable that sedormid forms with the platelets an antigenic complex to which the sensitive patient produces an antibody, and this complex is destroyed by the antibody in the presence of complement. A similarity to the mechanism of haemolysis in acquired haemolytic anaemia is at once apparent. This similarity is emphasized by the observation of Evans and Duane³ that thrombocytopenia occurred in a number of patients suffering from haemolytic anaemia, and by that of Wright and colleagues⁴ that in six cases of "essential" thrombocytopenia there was evidence of an antibody coating the red cells. Evans and his colleagues⁵ have been able to demonstrate agglutination of platelets by the sera of some patients with "essential" thrombocytopenic purpura. The possibility that idiopathic thrombocytopenia is in many cases due to the presence of a lysin, damaging both platelets and megakaryocytes, and sometimes also the red cells, must be seriously considered. The finding by Harrington and co-workers⁶ that thrombocytopenia and purpura occur in normal subjects receiving transfusions of blood from patients with idiopathic thrombocytopenia could be

explained by the presence of such a lysin in the transfused blood. The effect of splenectomy might therefore be the same (though still unexplained) in both haemolytic anaemia and thrombocytopenic purpura.

Lastly, these observations give some information on the mechanism of the haemorrhagic state in the purpura. Ackroyd's finding that the local application of sedormid to the skin of sensitive patients caused purpuric haemorrhage in the area of application proves that a local vascular lesion is produced by the toxic agent. Ackroyd suggests that sedormid may form a complex with the vascular endothelium, which is then susceptible to damage by the platelet lysin, and there is evidence that, antigenically, platelets and vascular endothelium are very similar. Any agent that damages platelets may therefore damage endothelium, and it is probable that the vascular damage, and not the thrombocytopenia, is the principal cause of the haemorrhage. The haemorrhagic manifestations of thrombocytopenic purpura may be temporarily alleviated by the transfusion of platelet-rich blood,⁷ but the clinical improvement lasts up to 48 hours after the platelet count has relapsed to its original level. The platelets therefore exerted some indirect effect on the haemostatic mechanism in this experiment. Perhaps they absorbed from the circulation a lysin which impaired capillary function.

PLANT SEED HAEMAGGLUTININS

The existence of substances in the seeds of certain plants which agglutinate human and animal erythrocytes has been known for over 50 years, and in 1908 Landsteiner and Raubitschek¹ demonstrated that the extracts of seeds of some leguminous plants agglutinated the red cells of certain species of animals, whereas the red cells of other species remained unagglutinated. But not until 40 years later was it discovered that extracts of seeds could be used to distinguish the blood group characters of human erythrocytes.

Renkonen² studied 99 species of the family Leguminosae (pea family) and found that extracts of the seeds of 31 species had a non-specific agglutinating action against human red cells and that extracts of the seeds of six species had a specific action. Among the latter were extracts of *Vicia Cracca* (tufted vetch), which contained a powerful anti-A agglutinin, and extracts of *Lotus Tetragonolobus*, *Laburnum alpinum*, and *Cytisus sessilifolius* (broom) seeds which contained agglutinins reacting strongly with O and A₂ cells. An examination of the seeds of 262 varieties of plants belonging to 63 families by Boyd and Reguera³ and of those of certain Egyptian plants by Boyd⁴ revealed a number of other seed extracts which possessed a moderately specific agglutinating action. Several species of *Phaseolus* had a strong anti-A activity, and in particular *Phaseolus limensis* (Lima bean) var. *limenanus* was found to yield extracts which were completely, or almost completely, specific for erythrocytes of blood group A. No evidence

was obtained that any of the extracts acted specifically on the B, M, or N antigens or on those of the Rh system. Another source of specific and highly active anti-A agglutinins has been demonstrated by Bird,⁵⁻⁸ who has examined the behaviour of extracts of seeds of *Dolichos biflorus*—Belgaum 1-1-8. The agglutinins from these seeds show a much greater affinity for A₁ and A₁B cells than for A₂ and A₂B cells, but Bird considers that the extract can be used as a substitute for human anti-A sera provided special care is taken and freshly prepared extracts are used. As a reagent for the differentiation of the subgroups of A the *Dolichos biflorus* extracts present advantages over absorbed human anti-A serum because of the large difference between the titres against A₁ and against A₂ cells: in tests on 200 Indian blood samples of groups A and AB complete correspondence was found between the results obtained with the seed extract and those obtained with human anti-A serum. Extracts of *Vicia Cracca* seeds also react more strongly with A₁ than with A₂ cells, but this does not seem to be due to the presence of two antibodies, since absorption with A₂ cells was found to remove all antibodies against A₁ cells.⁹

The previous studies on plants of the family Leguminosae were repeated and extended by Cazal and Lalaurie⁹ to cover 420 species. They found agglutinins reacting preferentially with O and A₂ cells in some species in the Genisteae and Loteae and agglutinins for A cells in some species in the Galegeae, Viciaceae, and Phaseoleae, but they failed to find an extract which would react specifically with B cells. Agglutinins re-active to a fairly high titre with B cells have been reported, however, by Krüpe and Braun¹⁰ to be present in extracts of seeds of *Sophora japonica*; the extracts also contain agglutinins reactive with A cells, but the authors have indicated that these can be removed by absorption.

Recently the specificity of certain of the plant seed haemagglutinins has been examined in terms of purified human blood group substances and simple sugars of known structure.¹¹ Aqueous extracts of the seeds of three species reactive with O cells were inhibited by H-substance and the agglutinins in one of these extracts, H-substance and the agglutinins in one of these extracts, were inhibited by α -that of *Lotus Tetragonolobus*, were inhibited by α -that of *Lotus Tetragonolobus*, were inhibited by the methyl-L-fucopyranoside to a higher titre than by the H-substance and also, less strongly, by sugars possessing structures related to that of L-fucose. Human A-structures related to that of N-acetylchondrosamine, substance, and to a slight extent N-acetylchondrosamine, neutralized the anti-A agglutinins extracted from *Vicia Cracca* and Lima bean seeds. The agglutination of A or B cells by extracts of *Sophora japonica* seeds was found to be inhibited by either A or B substances and by N-acetylchondrosamine.

The discovery of agglutinins in plant seeds which exhibit human blood group specificity has suggested the possibility of their future use as reagents for routine blood group determinations in place of human iso-agglutinating sera, but it is too early yet to assess whether this will be practicable or advantageous. The demonstration of these agglutinins in seeds has, however, given further evidence of the wide distribution in nature of materials related serologically to the antigens and antibodies classified within the human ABO system and has provided useful additional reagents for studies on blood group specificity.

ENDEMIC GOITRE

In recent years the treatment of thyrotoxicosis by thiouracil and radioactive iodine has rather stolen the limelight from the immense problem of endemic goitre which has to be solved in countries scattered all over the world. In order to encourage Governments to investigate this common disorder and take steps to remedy it in their respective territories, the World Health Organization at the end of last year brought together a study group at the National Institute for Medical Research, Mill Hill. Fifteen representatives from Britain, Mexico, Australia, the United States, Yugoslavia, Switzerland, Holland, and India were welcomed by Sir Charles Harrington, who has himself made such valuable contributions to the study of the thyroid gland. Sir Charles quoted these words from a memorandum¹ of the Goitre Subcommittee of the Medical Research Council:

"The immediate cause of simple goitre is failure of the thyroid gland to obtain a supply of iodine sufficient to maintain its normal structure and function. This failure is usually brought about by an absolute environmental deficiency of iodine; it may also be caused by factors which interfere with the availability of dietary iodine or which impose an abnormal demand on the thyroid gland."

This simple exposition of the problem was reinforced by Dr. Kimball, who recounted his early experiences with the iodization of salt in Akron, Ohio, and later in the State of Michigan, where school surveys eventually showed the elimination of goitre.

The problem as it presented itself to some of the other members of the group was by no means so simple. In underdeveloped countries salt may be so crude or obtained directly by each individual that it is impossible to add iodide to it. Again, the salt may be so damp or stored in such hot and humid conditions that even when the iodide has been added it rapidly disappears. To add to the complications, some races may consume three times as much salt as others, or so it was claimed. The possibility of adding iodate instead of iodide to the salt was discussed. Iodate is much more stable, as Professor Murray's work showed, and is just as readily available to the thyroid, as Dr. Pochin neatly demonstrated by administering it in radioactive form

Infection

Convulsions may also be due to infection of the brain or meninges. Virus encephalitis, encephalo-myelitis, bacterial meningitis, and, rarely, syphilitic pachymeningitis may begin in this way. Examination of the cerebrospinal fluid will assist the diagnosis and there may be other suggestive physical signs in the central nervous system. Lumbar puncture should not be lightly undertaken in the presence of papilloedema, for a brain tumour is then a possibility, with a pressure cone. Sudden release of cerebrospinal fluid may then prove fatal. If, therefore, in doubtful cases this investigation has to be undertaken, very little fluid should be removed and the operator should be prepared to inject sterile normal saline into the thecal canal immediately any alarming effects are noticed.

Localized Intracranial Lesions

Tumours of the brain situated supratentorially may give rise to convulsions as an early manifestation; in fact a Jacksonian epileptic attack may have some localizing value. Since, however, the cerebellum and pons are much more likely to become involved in children, fits are not often the presenting sign. The commonest site for *abscesses* is either the cerebellum or the temporal lobe, by direct extension from an infected ear or mastoid. Fits are therefore not a common feature, but they may result from pyaemic abscesses, which can develop anywhere in the brain. A more likely cause of fits from a localized lesion is a *subdural haematoma*. Its development from birth trauma has already been mentioned and also the delay before its presence is suspected. This is because it takes time for the haemorrhage to become fibrinized into a cystic tumour which absorbs fluid, gradually increases in size, and encroaches on neighbouring structures. The clinical picture then is that of progressive hydrocephalus with separation of the sutures and, in all probability, fits. Surgical removal of the cyst is followed by complete recovery. A blow on the head, seemingly insignificant at the time, may bring about the same sequence of events. Gross hydrocephalus from other causes may also produce convulsions, and for this reason fits usually occur in a rare protozoal infection—toxoplasmosis.

Epilepsy

This forms the largest group in any paediatric practice, and, although much can be done to control such fits, these cases are always likely to recur. Heredity plays a considerable part, but it is also possible for fits in one generation to be followed by migraine in the next and vice versa. Some indication of the outlook in epilepsy may be gathered from what occurred in a parent or elder brother or sister who suffered from similar trouble in childhood. If the disorder disappeared as they grew older, there is a reasonable prospect of the same happening in the child now brought for advice. Adie singled out a group of patients who suffered from innumerable attacks which were uninfluenced by any form of treatment. They appeared to be familial and tended to clear up at puberty (pyknolepsy).

Petit Mal.—This type of epilepsy is too well known to need detailed description. Difficulty in diagnosis may arise at first, since the lapse of consciousness may be so very brief as to pass unrecognized. The child may merely change colour momentarily or cease what he is doing and not resume where he left off. Two of my patients are particularly good examples of this. One boy was undressing to retire for the night, when he suddenly stopped and proceeded to re-dress himself and walk downstairs, thinking it was time to get up. The other, a young girl, set forth to fetch some milk from the local dairy. On her way she had her first "turn," with a brief gap in her train of thought. She never completed her errand and came home with an empty can. Parents sometimes bring their child because of "day-dreaming," which takes the form of a vacant stare into the distance for a few moments. Occasionally other epileptic equivalents are seen which make children behave

in an odd way. The lapse of consciousness may be just long enough for a child with *petit mal* to lose his balance and drop forward from a sitting posture. Recovery is almost instantaneous, and when the fits are often repeated they resemble the obeisances of an old Indian servant, and hence have been called "salaam convulsions." For the most part, however, *petit mal* is easy to recognize, the short seizures becoming more and more frequent until a bad case may develop as many as 50 a day. The differential diagnosis is not difficult. At times asphyxial attacks as a result of breath-holding have been mistaken for minor epilepsy, but the fact that they occur only when the child is thwarted and in a temper tantrum is enough to give the case away. The remedy, a douche of cold water, is both simple and effective. A Stokes-Adams syndrome is exceptional in childhood, although rare examples have appeared in congenital heart-block. Sudden cerebral anaemia is more likely to occur in the severest forms of Fallot's tetralogy, with an asphyxial "black-out" on the slightest exertion.

Grand Mal.—*Petit mal* can continue for some years, but after a time it generally becomes interspersed by major attacks. The reverse is not seen; if children begin with major epilepsy, this is the type of fit which will be repeated. It has the same characteristics as in adults, sometimes with incontinence of urine at the time, and often with vomiting, headache, and drowsiness afterwards. Auras are not likely to occur or are not recognized as such. Temporary paralysis of a limb, or a unilateral extensor plantar response, persisting for some days after a severe and prolonged fit, is not uncommon (Todd's paralysis). Outside influences, such as an accidental knock or a fever, can also sometimes precipitate an attack. There may then be difficulty in distinguishing true epilepsy from a symptomatic fit, and the diagnosis will depend on whether other attacks have occurred spontaneously. Help will also be gained from an electroencephalogram, which in idiopathic epilepsy will show characteristic waves. Occasionally, epilepsy will begin in a Jacksonian manner, although later it will take on the more usual form.

Status epilepticus, in which one fit succeeds another for one or two days on end, is a most dangerous condition. Every step should be taken to terminate it, otherwise the child may succumb through sheer exhaustion and with a high temperature. In some cases there is irretrievable damage to the brain.

Treatment of Epilepsy

Many drugs have been tried in idiopathic epilepsy. Bromides have largely passed into disuse and their place has been taken by phenobarbitone, which is particularly useful in grand mal, but less effective in *petit mal*. For infants $\frac{1}{4}$ to $\frac{1}{2}$ gr. (8 to 16 mg.) can be given twice a day as a maintenance dose; older children can take up to 1 to 3 gr. (65 to 200 mg.) a day according to age. Toxic signs will appear as ataxia, a rash, depression, and, occasionally, such excitability that the child will become difficult to control. Methylphenobarbitone has been claimed to be less toxic and so can be given in a dosage which is 50% to 100% greater. Phenobarbitone often fails in *petit mal* and then it is worth changing to phenytoin, $\frac{1}{4}$ to 3 gr. (50 to 200 mg.) daily up to 6 years of age; 3 to 4½ gr. (200 to 300 mg.) over 6 years.

Troxidone and "paradione," a less toxic compound, have been recommended as specially useful in *petit mal*, but they can have alarming side-effects, and patients on these drugs should remain under careful medical supervision and have blood counts carried out fortnightly at first, and then at monthly intervals. Leucopenia with agranulocytosis, albuminuria leading occasionally to Type II nephritis, rashes, and digestive upsets are the chief complications. It is advisable to combine troxidone with phenytoin, as otherwise there is danger of the treatment provoking an attack of grand mal. The dose of troxidone is 0.3 g. daily in three divided doses up to 2 years of age; 0.6 g. daily from 2 to 6 years; and 0.9 g. over 6 years. My experience with this drug has not

been very encouraging. "Mysoline" has undergone quite recent trials with reported good results in major epilepsy. A suitable dose would range between 0.25 and 0.75 g. daily, but the treatment is still in the experimental stage, and the optimum dose for children has not yet been established.

It is obvious from this account that of the two types of epilepsy *petit mal* is the most difficult to control, and sometimes the older forms of treatment are still found to be effective. Tincture of belladonna, 10 minims (0.6 ml.), combined with sodium borate, 6 gr. (400 mg.), three times a day for a child of about 6 years, is worth trying, and when everything else fails a ketogenic diet may save the situation. This is made up with an adequate amount of protein and with the proportion of fat to carbohydrate and protein in the ratio of 3 to 1, the total calorie value being 50 to 60 per kg. per day, depending on whether the child is under or over 5 years of age. Obviously with the present rationing in this country it is not easy to maintain this diet out of hospital, but special permits can be obtained at the local food office.

The urgency of treating status epilepticus energetically should again be emphasized. Chloroform and rectal thiopentone (1 g. per 25 kg. of body weight, diluted to a 2½% solution with water) are only temporary measures. Intramuscular injections of paraldehyde, 1 to 6 ml., according to age, is certainly the most effective and may have to be repeated if the fits recur.

Vasovagal Attacks and the Periodic Syndrome

There remain two other disorders which have not so far been considered. Girls, particularly when they are approaching puberty, are sometimes brought to the doctor with a history of fainting. Some strain such as early morning devotions on an empty stomach may be found responsible, and in others it is an inadequately functioning vasomotor system with sudden changes of position which is at fault. In any case the nature of the attacks, the colour of the patient, and the absence of any immediate sequelae are enough to differentiate them from true convulsions. Much more difficult to determine are the short lapses of consciousness which sometimes occur in migraine, cyclical vomiting, and the rest of that syndrome, but these black-outs cease as the child grows up and never develop into true epilepsy. They are nevertheless largely prevented by phenobarbitone.

In conclusion it can be said that fits in children are a common event and have a distinctly varied origin. Many of them are merely an expression of some temporary disorder; others are of a more serious and permanent nature. Among the latter, heredity plays an important part which is not unknown to the laity as well as to the medical profession:

Year by year in pious patience
Vengeful Mrs. Boffin sits
Waiting for the Sleary babies
To develop Sleary's fits.
—RUDYARD KIPLING.

Next Refresher Course Article.—"Recurrent Boils," by Dr. S. T. Anning.

Some details of the scheme to establish medical hostels for industrial workers with rheumatism are given in the fifth annual report of the British Rheumatic Association. The first hostel was established last year at Northwood, in Middlesex, and when funds become available others are planned for Scotland, the industrial North, and the Midlands. Their object is to cut out long delays in waiting for hospital beds. Hostels will be sited near the rheumatic unit of a general hospital so that patients can start treatment at once. The hostels will be managed by the newly formed B.R.A. Homes Ltd., a housing society with charitable status. It is estimated that among miners alone absenteeism caused by rheumatism costs the country £15m. a year.

BEAM THERAPY GIFT TO CANCER CAMPAIGN

Presiding at a special meeting of the British Empire Cancer Campaign at the House of Lords on March 10, H.R.H. the Duke of Gloucester announced a generous gift to the Campaign of a cobalt-60 beam therapy unit. He said that the presence of considerable deposits of cobalt in Canada had led to large-scale experiments there on artificial radioactivity, and a few cobalt units for research into the treatment of cancer had been constructed in the Dominion. A unit had now been built incorporating all the improvements found desirable from experience with the earlier models, and it was this unit which had been presented to the Campaign. Sir Stanford Cade and Professor B. W. Windeyer, who visited Canada recently, had discussed the matter with their Canadian colleagues, and the financial difficulty had been removed by the action of one of Canada's outstanding philanthropists, Mr. McConnell, of Montreal, who had offered to pay for the entire unit himself at a cost of over £25,000.

His Royal Highness added that the unit was due to arrive in this country in August and would be installed at Mount Vernon Hospital, Northwood, after being first exhibited at

A Canadian artist's impression of the cobalt rotational beam therapy unit. (By courtesy of the British Empire Cancer Campaign.)

the seventh International Congress of Radiology at Copenhagen in July. The Campaign had arranged for a prominent physicist, who would be one of those working with the unit when it was installed, to go to Canada next month to gain first-hand knowledge of its operation.

Lord Horder, Chairman of the Campaign, in expressing appreciation of the gift, said that this new apparatus made him feel how far they had travelled in radiophysics in the last 25 years. It also brought home the complexity and difficulty of this subject, the enormously increased cost of the armamentarium, and the demand which its effective operation made upon highly trained personnel.

The Minister of Health, Mr. Iain Macleod, said that this was the most massive weapon ever made in this field. He expressed thanks to all concerned, in particular to Mr. McConnell for his magnificent financial contribution, to Mr. Paul Martin, Minister of National Health and Welfare in Canada, for his co-operation, and to the British Empire Cancer Campaign for undertaking the care and operation of this unit. It was altogether a fine chapter in voluntary effort.

Cobalt in Radiotherapy

Sir Stanford Cade and Professor Windeyer then gave a brief exposition of the place of cobalt in radiotherapy. Cobalt-60, a radioactive isotope, said Sir Stanford Cade, was at present the most suitable substitute for x rays and

radium, and in small quantities it had been used in this country as such. The cobalt unit would be both a tool for research and an instrument for treatment. It was nearly 200 times as powerful as the radium units in use at present. Its depth dose of radiation was about the same as that of 3,000,000 electron volts of x rays, but it was more stable, more reliable, and simpler to control than a supervoltage x-ray machine. The primary object in view was to treat inaccessible tumours which so far had proved beyond the effective range of existing radiotherapy apparatus. A further advantage was that a greater quantity of radiation could be delivered to the tumour with less damage to surrounding normal tissues and less general disturbance of the patient.

Professor Windeyer said that the most obvious way for cobalt-60 to be used was as a replacement for radium in some of the apparatus for telecurie therapy, the so-called radium bomb. Some 10-gramme radium units—the largest yet to be used in Britain—had been replaced by cobalt in amount up to a maximum of 50 curies.

The first massive telecobalt unit had been installed in the Victoria Hospital, London, Ontario, in November, 1951, and at about the same time a similar one, constructed by the staff of the University of Saskatchewan, was installed at Saskatoon. These units contained approximately 1,100 curies of cobalt-60, which was the equivalent of about 1,500 grammes of radium. The unit which was being given to the Campaign would contain the same amount of cobalt-60, but it was a greatly improved model. It could be used for rotational therapy, for example. On both technical and economic grounds the construction of a radium unit of such activity would be quite impracticable. The cost alone would be well over £1m. and the radium would take up too great a space. The cobalt-60 source was in the shape of a disk only 1 in. (2.5 cm.) in diameter and $\frac{1}{4}$ in. (1.3 cm.) thick. The beam of radiation coming from the unit could be compared in penetration power to that produced by an x-ray machine working at 3,000,000 volts, but with a somewhat lower output. It must be realized, however, that cobalt-60 deteriorated to half its original intensity in just over five years, and it was therefore necessary to arrange for reactivation of the source in a nuclear reactor at regular intervals. In addition to the original apparatus in London, Ontario, and in Saskatoon, there was one working in Vancouver, and arrangements were being made for units of this new model to be installed in Toronto, Montreal, and New York.

THE ELDERLY "CHRONIC"

Every student of geriatrics knows that the population of this country has more than doubled during the last 100 years, but that the number of persons of 65 and over has increased between four- and five-fold. Consequently there are continual complaints of the economic burden which the producing community has to carry owing to the rising proportion of ageing persons. There are, however, two qualifications which are often disregarded: one that the ratio of workers to non-workers is more favourable than it was 100 years ago because the child population has diminished to a greater extent than the aged population has increased; and the other that life has not only been prolonged but made more healthy and active, so that in many instances people remain producers to a more advanced age than formerly.

Neither of these considerations has been lost sight of in an admirable report on the treatment and care of the elderly chronic sick in Bristol which has been compiled by the Bristol Local Medical Committee.¹ In 1950 a subcommittee was appointed by the committee to investigate the treatment and care of such persons. It soon found that it had to widen its reference to include the "frail ambulant" (i.e., the aged infirm person), the acute aged sick, and the healthy old person whose principal need is to be properly housed. The

¹ Bristol Local Medical Committee, 7, The Dell, Westbury-on-Trym, Bristol. 2s. 6d., post free.

² *British Medical Journal*, 1952, 1, 1297.

number of people over 65 in Bristol is about 50,000, and reckoning, as is usual, that 3% require to be accommodated in institutions of one kind or another, 1,500 beds would be sufficient to cover the need. By 1975, however, if present trends continue, the number of beds may be 2,400. At present two hospitals with a total of 800 beds are allocated to the aged and chronic sick in Bristol, and there are one or two small institutions outside which accommodate some of Bristol's overflow.

The report states that the hospital-bed situation could be relieved by the provision of non-hospital facilities, mainly through social service agencies, for the elderly infirm as distinct from the chronic sick. The recommendations mention such needs as diversional occupational therapy, help for old people to maintain a healthy diet, an adequate chiropody service, and friendly assistance in various matters. The almoner is considered to be the most appropriate person to act as liaison officer between hospitals, general practitioners, and other authorities, although objection is sometimes raised to almoners undertaking work outside hospitals.

The division of responsibility between three sections of the National Health Service has complicated the problem. Hospitals are often unable to discharge patients because there is nowhere for them to go, and meanwhile other patients languish on hospital waiting-lists. The hard-pressed local authority cannot always find accommodation for the "frail ambulant" and mentally unstable patients whom the hospital authorities consider should be provided with hospital accommodation, while the third authority, represented by general practice, though willing to do its utmost to keep the old people well at home, is frustrated if hospital and local authorities fail to provide the help so necessary in medical and social emergencies. The subcommittee quotes with approval a statement by Dr. Mortimer O'Sullivan² that whatever the future of medicine in this country the chronic sick and aged infirm will in the main be the responsibility of general practice. "It is hard work, often harassing, and occasionally satisfying."

Preparations and Appliances

AN OCCLUDER

Dr. A. ESTCOURT-OSWALD, of Colchester, writes: The occluder illustrated consists of two black disks connected by a small steel clip. The front disk is meniscus in form and

the back disk flat. The occluder can very easily be slipped on over one lens of the patient's spectacles, whether they are glazed with flat, toric, or meniscus lenses. The examiner is thus able to test the sight of each eye while both his and the patient's hands are free. I have used this occluder for many years and have found it most useful. It can be obtained (price 6s., post free) from Messrs. Clement Clarke, of 63, Wigmore Street, London, W.1.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Modern Treatment

SIR,—A Victorian physician, whose name I have forgotten, used to say that "it took a strong constitution to stand a health resort, a convalescent home, a sanatorium, or an autumn holiday." Were he alive now I think he would add to this list "modern therapy."

Our old friend "treatment" seems to be harmless enough; indeed, I notice that the word is hardly ever used by those clever people who send you articles on the scientific aspects of medicine—articles most of which, I confess, mean almost nothing to me, and, I strongly suspect, to the majority of your readers also. (I note that you hint at this in a leading article in your issue of February 28, p. 496.) No, it is "therapy" which is the danger, and especially modern therapy, to be spoken of in reverential tones and written only in capital letters. I propose to refer to it as M.T. in accordance with the prevailing fashion of obscuring things by calling them by initial letters. M.T. lurks in every doctor's bag usually in the form of tablets or ampoules, but occasionally as a more innocent-seeming lozenge or ointment, and very rarely as a mixture. It accompanies him on his rounds and is ready to jump out at the slightest provocation and grapple with the disease—or should I say the "pathology"?—and it is when there is a tug of war between M.T. and the "pathology," with the patient as the rope, that a really strong constitution is required. M.M. (modern medicine) aids and abets M.T., for, being unable to diagnose the simplest case of "pathology" without numerous investigations, punctures, x-ray reports, and specialist opinions, the patient is usually pretty well exhausted before M.T. comes on the scene at all.

I am glad to see from your correspondence columns that the abuse of modern remedies (and their cost) is beginning to be recognized; but I think there should be a new petition in the litany to be read in hospital chapels or wherever doctors and nurses do, or ought to, congregate. It might be as follows: "From inability to let well alone; from too much zeal for the new and contempt for what is old; from putting knowledge before wisdom, science before art, and cleverness before common sense, from treating patients as cases, and from making the cure of the disease more grievous than the endurance of the same, Good Lord, deliver us." I could suggest several more petitions to meet our present needs, but the above may do to go on with.—I am, etc.,

ROBERT HUTCHISON.

Streatley, Berks.

Sensitization to Local Application of Antihistamine

SIR,—I was interested to read Dr. W. A. Heaton-Ward's account of a case of sensitization to the local application of an antihistamine (February 21, p. 455). A similar though more dramatic case happened only a few days ago in the routine of our practice.

A healthy young man who, apart from a period of observation for suspected pulmonary tuberculosis earlier in his life, gave no history of previous chest illness developed coryzal symptoms with marked acute rhinitis. He was given "antistin-privine" inhalant to relieve this latter symptom. About five hours after his first inhalation he developed a tightness in the chest. I saw him about 12 hours after the onset of this and found him in a typical, though slight, attack of bronchial asthma. The symptoms rapidly subsided after taking ephedrine $\frac{1}{2}$ gr. (32 mg.) three times daily. Twenty-four hours later the chest was almost clear.

In this case it would appear that the inhalation of an antihistamine spray produced a sharp allergic response in the form of bronchospasm.—I am, etc.,

Hereford.

A. DERRICK ROSE.

SIR,—I was interested in Dr. Heaton-Ward's report of a case of dermatitis following the use of phenindamine hydrogen tartrate ("thephorin") ointment (February 21, p. 455). Antihistamine creams and ointments are now widely used in the treatment of various itching dermatoses. For most of these conditions they are contraindicated, and in the remainder they are of doubtful value. In a controlled trial Baldridge¹ found that the addition of a histamine antagonist did not increase the antipruritic action of a vanishing-cream base.

The fact that a substance is capable of neutralizing histamine does not, unfortunately, prevent its being a potential cutaneous sensitizer, and it has been estimated² that 2-6% of patients so treated develop eczematous reactions. Sidi *et al.*³ report that a third of their recent cases of dermatitis medicamentosa resulted from sensitivity to antihistamine creams. Several of these patients became photosensitive, and those sensitized to promethazine hydrochloride ("phenergan") tended to give cross-reactions to the sulphonamides, paraphenylene diamine, and other substances of similar chemical structure.—I am, etc.,

HAROLD WILSON.

London, W.1.

Early Diagnosis and Cancer Education

SIR,—The headquarters of the British Empire Cancer Campaign in London have issued to every general practitioner a most useful booklet on *The Early Diagnosis of Cancer*. At the same time each is asked: "Do you consider that the launching of a scheme of lay educational propaganda (by pamphlets, lectures, films, etc.) would be of assistance in securing the earlier diagnosis of cancer and thereby improving the chances of a cure? Please answer Yes or No."

Surely, Sir, such a question is premature, since the practitioner can have no evidence whatever on which to base an opinion. In this country cancer education has only just been started in a very few centres. It would be useless to judge by the methods used in other countries, which may suit the psychology of their own people but would not be suitable in this country. It is to be noted that no one is allowed to have an open mind on the subject—the answer must be "Yes" or "No." So far no such question has been sent to consultants, many of whom see in a week as many cases of cancer as a general practitioner sees in a year. I am glad to be able to report that in this area, where all practitioners and consultants are kept fully informed about the efforts to carry out "Cancer Education," the medical profession seem open-minded, most co-operative, and prepared to try out a scheme for educating the public concerning cancer.—I am, etc.,

MALCOLM DONALDSON.

Correct Names for Drugs

SIR,—As one recently qualified, I have followed the correspondence on the cost of prescribing and the use of registered trade names with considerable interest, in view of my own experiences. As a student I was taught by a pharmacologist to avoid the use of proprietary names, especially in examinations. Yet, in a finals examination, I was asked, "What about 'physeptone'?" immediately after I had been talking about amidone (now methadone). When working in the wards as clerk and dresser, I knew that the housemen's prescribing was restricted to drugs and preparations found in the *B.P.*, the *B.P.C.*, the *N.F.*, and the hospital pharmacopoeia (now obsolete). On taking up an appointment as house-surgeon at a non-teaching hospital, I attempted to use only "approved names" where such existed. I found that many of these were quite unknown, and that the nurses did not know these names, but only some proprietary names. I was requested to put the ordinary name in brackets after those "fancy names."

Some of the "fancy names" were sulphadimidine, phthalylsulphathiazole, theophylline, amylobarbitone, and pentobarbitone. The hospital in question is a recognized training school for nurses, and I would have thought it a matter of some importance that "approved names" were known, as there are so many proprietary names for the same substance. Some of those in use—for example, one for phthalylsulphathiazole—were previously unknown to me.—I am, etc.,

Oswestry.

F. B. SINGLETON.

Classification of Diseases

SIR,—As co-author of the *Textbook and Guide to the Standard Nomenclature of Diseases and Operations*, I wish to say that your review (November 15, 1952, p. 1082) is an excellent one and we appreciate your comments. However, I would like to clarify two points which your reviewer does not know or understand. I am also associate editor of the *Standard Nomenclature of Diseases and Operations*, and I note that the reviewer made the following statement: "It is regrettable that in their enthusiasm for correlating the two codes the editors of the *Standard Nomenclature* invented numerical subdivisions for some international categories, thereby violating an important recommendation of W.H.O." The editors of the *Standard Nomenclature* worked very closely with the Bureau of Vital Statistics in Washington, D.C., and absolutely no international code numbers were assigned other than those by Dr. Selwyn D. Collins, of the Bureau, and his assistant, Mrs. Louise Bollo. When Dr. Collins and Mrs. Bollo started combining the two nomenclatures they realized there were deficiencies in the *International Statistical Classification* and made provisions accordingly. They considered it important that all *Standard Nomenclature* diseases should have a cross reference to the *International* rather than state that the item was not part of the *International*.

Perhaps, too, the reviewer does not understand the value of the disease service classification in the *Textbook and Guide to the Standard Nomenclature of Diseases and Operations*. The *Standard Nomenclature* is being used by 71.5% of the hospitals in the U.S. and there had not been a disease service classification written since 1927, when the alphabetic nomenclature was in use. Hospitals had been clamouring for a disease service assignment for diagnoses as they were listed in the *Nomenclature*, but the editorial advisory board of *Standard Nomenclature* did not consider it advisable to include the classification, therefore its inclusion in the *Textbook and Guide*.—I am, etc.,

Chicago.

ADALINE C. HAYDEN.

Information to Patients in Hospital

SIR,—All of us will agree with Dr. E. B. Grogono (February 14, p. 402) that the end we seek is a sympathy and understanding with our patients. Few of us, however, seem to be sufficiently gifted to attain this end without help, and I feel that any means which will lead towards it should be justified. My method of the printed sheet happens to be one I have found satisfactory. I cannot think that there can be such an objection to the printed word, nor do I believe that there is such a lack of originality in the profession that my "wretched" sheet will be copied to any great extent; it can, at most, be a guide to those who would like to try a similar method themselves. I would like to thank the many who have shown an interest in my sheet and could wish that Dr. Grogono had been amongst the numerous general practitioners who wrote to me asking for a copy.—I am, etc.,

Swindon.

GUY ROWORTH.

Against Umbrellas

SIR,—In your columns the haphazard use of "umbrellas" of assorted antibiotics has been properly condemned by Mr. Norman C. Lake (December 13, 1952, p. 1307) and

others, and you have stressed the desirability of making exact bacteriological diagnoses when prescribing these substances (December 13, p. 1301). To-day I have received a new invitation to expensive inaccuracy: a manufacturer's brochure about a pill which contains an assortment of anti-anæmic substances—for example, iron, liver, vitamin B₁₂ folic acid, etc. Surely it should be obvious that it is an economy and a refinement to have every clinical diagnosis of anaemia substantiated, and progress controlled, by simple haematological examinations so that unnecessary substances should not be prescribed. It is, unfortunately, not rare to come across a patient with a low colour index who has been receiving liver or B₁₂ for years without benefit to himself and at great expense to the National Health Service. Such cases of inadequate diagnosis may become commoner if "multiple" pills, which confuse by giving rise to a partial improvement, become popular. Whatever the type of anaemia, two-thirds of the ingredients are likely to be wasted, since an iron deficiency will not need liver, and a B₁₂ deficiency will recover without iron.

The National Health Service cannot afford to pay for these wasted ingredients.—I am, etc.,

London, N.W.11.

MAIR E. M. THOMAS.

Aetiology of Bronchiectasis

SIR,—While commenting on the papers of Dr. K. D. Forgan Morle and Squadron Leader Philip W. Robertson on "Segmental Aspiration Pneumonia and Bronchiectasis,"^{1,2} Dr. W. S. Davis (February 14, p. 400) asks for information regarding the frequency of a history of an abdominal operation as an aetiological factor in bronchiectasis. In a series of 166 cases (137 adults and 29 children) at the Bedford Chest Clinic,³ four adults traced the start of their symptoms to a general anaesthetic. In two this was for appendicectomy, in one for cholecystectomy, and in one for the treatment of a war wound.—I am, etc.,

Bedford.

N. WYNN-WILLIAMS.

The General Practitioner and Mass Radiography

SIR,—Dr. F. A. Nash, Mr. B. Benjamin, and Dr. T. J. Lee, in their recent article (February 7, p. 304) describing the facilities for chest radiography offered to general practitioners by the South-west London Mass X-ray Service, state that, to be adequate, such a service could only be possible were the available mass x-ray units to confine themselves to investigations of this nature. As pointed out in your annotation (February 7, p. 322), this is obviously most undesirable, but it is equally obvious that the chest clinics, under existing conditions of staff and equipment, are incapable of dealing with the number of examinations necessary if the estimated requirement of five examinations per 1,000 patients per month is accepted.

In an attempt to overcome these difficulties in the Blyth (Northumberland) area use has been made of an "odelca" 70-mm. camera unit recently provided at the chest clinic. Although primarily installed to assist in the routine work of the clinic, the unit gave such excellent results that it was decided to make an "open" chest radiological service freely available to general practitioners in the area, Friday evenings and Saturday mornings being reserved for this purpose. As the scheme has only been in operation for about two months no figures can be given, but the response has been most encouraging and averages between 50 and 60 examinations each week. This figure, if maintained, comfortably exceeds the estimated requirement quoted above for the area served. Already a number of cases of active pulmonary tuberculosis in need of treatment have been brought to light in which there might otherwise have been delay in diagnosis.

Practitioners are naturally reluctant to burden the chest physicians with extra examinations unless they have reason to suspect that disease may be present, and many in the area served have intimated that they find the "open" radiological sessions of the greatest possible assistance.—I am, etc.,

Blyth, Northumberland.

JAMES M. GILMORE.

A Journal and its Readers

SIR,—Those who criticize the *British Medical Journal* because it fails to please all its readers all the time can have little idea of the duties of an editor of a medical weekly journal. Not only must he hold the right balance between news and views, but he must also decide where general interest justifies his giving any particular scientific paper the benefit of a 78,000 circulation. At the same time, by its sponsorship of a fine series of specialist journals, the *British Medical Journal* admits that there is a field for both types of paper. The question which your leading article (February 28, p. 496) poses is whether general practice is a specialty in its own right, and therefore entitled to specialist journals of its own.

Setting aside the main question, it must at least be admitted that the conditions of work of the G.P. differ substantially from those of other doctors. Alone in the profession, he works regularly by both day and night; it is commonplace for him to be seeing his last patient not at 6 p.m. but at 9 p.m. or even later. The inevitable result is that his reading time is strictly limited. I cannot help wondering whether most G.P.s find time to read the articles with which they are presented each week.

Length in itself is less putting off than a turgid style of writing, which afflicts so many of us when we put pen to paper. Here the best remedy is the ruthless sub-editor; the author who objects to this type of surgery can have little regard for his message, for his readership will vary inversely with his verbosity. So I am ready to welcome any journal devoted to general practice, provided it says what it has to say in as few words as possible. And if it stimulates you, Sir, to further efforts in blue-pencil work, it will have done all in general practice a good turn.—I am, etc.,

London, N.7.

STEPHEN TAYLOR.

SIR,—A weakness of many journals intended for general medical reading (cf. leading article, February 28, p. 496) is that the accumulated knowledge of a general practitioner rarely finds expression therein for the benefit of other practitioners, general or otherwise. This does not necessarily reflect on editorial policy, for what an editor does not receive he most clearly cannot publish; and I suspect that he receives few articles from general practice. This would not be surprising. While clinical material and problems abound in general practice, there are many difficulties in taking advantage of them. Time is scarce, and especially time free from interruption. The general practitioner usually has no secretarial assistance, and is often unable to obtain laboratory and other investigations. He may be physically separated from reference libraries, he usually works alone in his surgery, and his work lacks the natural checks provided by registrars, house-men, nursing staff, and laboratory assistants. When a publication is the joint production of a team of workers, it gains in "printability." Even when two heads are no better than one, two witnesses certainly are. In these circumstances an article from a G.P. is likely to lack polish, and this renders publication unpredictable. Whether the *British Medical Journal* would be justified in printing this rather "rough" type of contribution is not for me to say.

I was dismayed to learn that the "Refresher Course" articles and "Any Questions?" cater specially for the general practitioner—as if to say that no other section of the profession needs any refreshing or feels impelled to send in

a question. In any case, an article in the "Refresher Course" should be able to hold its place in the *British Medical Journal* on its own merits and should not need to explain itself as being "for the general practitioner."—I am, etc.,

Lowestoft.

N. B. EASTWOOD.

SIR,—In a leading article (February 28, p. 496) you remind your readers that the *British Medical Journal* is not for general practitioners, or consultants, or public health officials, or laboratory workers, but that it is a journal which aims at representing the best of British medicine in order to "promote the medical and allied sciences." Such an *apologia pro vita tua* must be accorded universal approbation without lack of agreement that the programme is fully implemented; but I do not think you are comfortably convincing in your further reference to the general-practitioner reader.

I am not, of course, prepared with authoritative figures, but of the 78,000 copies distributed weekly a very large proportion must go to general practitioners or (pace your disapproval of the term) average readers. You rightly point out that they are catered for by the inclusion of the "Refresher Course"—a series of articles of practical importance and value. It would appear that, if to this feature are added the answers to "Any Questions?" and occasional synopses in short leaders or annotations, the pabulum for the average practitioner has been fully comprehended.

Yet, in order to forestall any charge of inadequate provision that may be supplied elsewhere, you question if the multiplication of journals which aim at the general practitioner's special requirements is a healthy tendency. It is a tendency, you say, that has behind it the assumption that the general practitioner is intellectually inferior, and he must be reassured to the contrary and be encouraged to keep up to date by reading a journal which tries to put before its readers the whole of medicine, not just part of it. I wonder if the large number of average doctors among the 78,000 will feel flattered or offended by the somewhat condescending and surely gratuitous reassurance that they are not intellectually inferior. If I may venture to express an opinion from their point of view, I apprehend that they read a medical journal primarily to maintain and increase efficiency in practice, although there are, of course, many other details in which they will be interested. But, although one may approve the enterprise of those who like to acquire knowledge for its own sake, it is practical application, not Utopian idealism, that must appeal to the majority. Is the average doctor expected to read the fifteen pages of research comprehended in the article on "Isoniazid in Treatment of Pulmonary Tuberculosis" (March 7, p. 521)? All medical men, you point out, have the same basic training, so he ought, I suppose, to be fully equipped to wrestle with "Capacity of a Cationic Exchange Resin ('Zeo-Karb 225') in Vivo" (March 7, p. 544). I think he would turn more willingly to the "Assessment of Chlorophyll as a Deodorant" (March 7, p. 541), which is admirably epitomized in a short annotation (p. 554), or to the "Effect of Nikethamide by Mouth in Man" (March 7, p. 547), which occupies only one page. Indeed, he could restrict himself to the last six lines of the article, which state that it has no effect whatever.

It is only right that all the details of such communications as the first to which I have referred should be recorded, so that other workers on the subject may critically examine all the evidence which they may wish to confirm or refute. It is only right that rare pathological conditions should be reported, and that the results of investigations of new drugs should be published. The academic approach towards "keeping up to date" demands an intimate study by those on the staffs of teaching hospitals, by examiners for higher degrees and diplomas, and by the candidates for these distinctions, however much or little they relate to their practice. But the average doctor must and can keep up to date without the impracticable effort demanded by such scientific study. It seems to me that you are in error in deprecating the consideration of his special requirements and particularly in introducing the question of intellectual inferiority.—I am, etc.,

London, W.1.

ADOLPHE ABRAHAM.

Chlorophyll as a Deodorant

SIR.—We have been using as a deodorant in radical mastoid cavities a solution containing nine parts by volume of a 10% solution of chloramphenicol in propylene glycol with one part of a preparation of chlorophyll which is perfumed similarly to the "solution C" of Dr. J. C. Brocklehurst (March 7, p. 541). The presence of "solution C" does not interfere with the destruction of cultures of sensitive organisms by the chloramphenicol, and the two solutions make a homogeneous fluid. The presence of "solution C" does not appear to be an irritant to the surface of the cavity nor to increase the occurrence of otitis externa.

Narrow ribbon gauze, soaked in the chloramphenicol and "solution C" fluid, is used in the cavity and external auditory meatus. The perfume does help to make the smell less unpleasant for the patient and those dressing the cavity, and disturbance of the gauze, by withdrawing the latter slightly, increases its effect. This disturbance (mentioned by Dr. Brocklehurst) and its effect upon odours have long been common knowledge.

We are obliged to Dr. Crawford and Mr. Thompson, Hope Hospital, Salford, for their help.—We are, etc.,

Manchester, 3.

W. B. MCKELVIE.
EDITH V. WOODCOCK.

SIR.—With reference to the paper by Dr. J. C. Brocklehurst on chlorophyll (March 7, p. 541), there are certain points with regard to the chemistry of the subject to which I should like to draw your attention.

(1) The formula for chlorophyll, as shown, is incorrect. The two hydrogen atoms attached to the nitrogen atoms of the pyrrole rings should be deleted. (2) Methyl mercaptan cannot be obtained from thiourea sulphate by the action of sodium hydroxide. The standard method of obtaining it is by the action of sodium hydroxide on S-methyl isothiuronium sulphate, which is a derivative of thiourea, and obtained by the action of dimethyl sulphate on thiourea:

(3) Methyl mercaptan, in common with other mercaptans, is oxidized by iodine to give dimethyl disulphide and hydriodic acid, which reaction may be represented as follows:

—I am, etc.,

Stockport.

H. H. ARMSTRONG.

SIR.—I should like to answer criticisms raised by Dr. W. Mitchell and Mr. L. Deadman (March 14, p. 621) concerning my article on "An Assessment of Chlorophyll as a Deodorant."

The substance referred to as thiourea sulphate is, of course, S-methyl-iso-thiourea sulphate. The method of producing methyl mercaptan gas is that described by Arndt.¹ Chlorophyll (solution "A") was not assayed spectrophotometrically: it was supplied especially for experimental use by a chlorophyll manufacturer, who described the sample as consisting chiefly of sodium copper chlorophyllin. Solution "C," however much chlorophyll it contains, was a true sample of this substance as it is sold to the public. The mercaptan solution used in experiment 4 was a saturated solution of methyl mercaptan in water. Syrup of garlic used in the experiments was the B.P.C. compound: this contains approximately 20% juice of garlic, the composition of which is fully described in the B.P.C. monograph. The short time of exposure of methyl mercaptan to chlorophyll in the first two experiments is admitted. The third and fourth experiments were devised to allow a long-continued exposure.

I was interested to read of Dr. Mitchell's experiment with benzyl mercaptan, and look forward to hearing of the outcome of his trials with methyl mercaptan.—I am, etc.,

London, W.12.

JOHN C. BROCKLEHURST.

Spinach

SIR.—We feel that your expert has not given the whole picture when answering the question on spinach ("Any Questions?" November 29, 1952, p. 1217). Spinach contains 500–800 mg. of oxalic acid per 100 g., more than enough to form insoluble salts with all the calcium and magnesium present in it. Experiments on animals and man have demonstrated the poor availability of calcium in spinach as compared with other greens, milk, whole wheat, etc. Many workers, experimenting with rats, have shown that the oxalic acid in spinach interferes with calcium metabolism, producing increased calcium excretion, considerable calcium deficiency, and consequent poor calcification of bone, deposition of large amounts of oxalates in the kidneys, and formation of urinary calculi and kidney damage. This is particularly so if adequate calcium, magnesium, phosphorus, and vitamins are not included in the diet. Spinach, raw or cooked, when added to the diet of dogs which includes meat, cracker meal, and skimmed milk powder, produces not only a greater negative calcium balance but also poor absorption of nitrogen.

Comparable experiments on children with calcium-deficient diets could not be justified, but it has been calculated that 100 g. of spinach fed to an infant contains sufficient excess oxalic acid to precipitate the calcium in 200 g. of milk, or one-fifth of the total calcium given to the infant. McLaughlin,¹ using spinach as the only food high in calcium in a diet consisting of some of the most commonly used foods, produced positive calcium balances in six out of seven healthy women, but the duration of the experiments was only six days. McClendon and Sedgwick² found that the average gain per week was markedly increased when spinach was added to the diets of infants. They used dried and powdered spinach, mixing it with 6% of sea salts. It is possible that excess of salts and consequent water retention had something to do with the weight increase. Sherman and Hawley,³ on the other hand, were able to show that calcium and phosphorus retention after addition of spinach to the diets of children was in no case as good as with milk feeding alone, while Schlutz *et al.*⁴ found, in a six-day experiment, that the use of raw or puréed spinach as a supplement to milk feeding in very young infants did not affect the mineral balance in either direction, but when dried spinach was used the retention was slightly lower than that which prevailed when the minerals were derived solely from milk. Bonner *et al.*⁵ fed 10 children aged 5–8 years with 100 g. of spinach for 25 consecutive days, and found that the storage rates for nitrogen, calcium, and phosphorus were not significantly altered. However, they used healthy children, who were fed sumptuously on basal diets which had more than sufficient calcium to obviate any deleterious effect that the oxalic acid of spinach might have produced. It is to be expected that if excess of calcium is present in the diet, particularly in the form of milk, the oxalic acid of the spinach will be neutralized, but what if, as we have sometimes found, children refuse to take their daily quota of milk, and if, as may happen in poorer families, the children are not fed well enough to counteract the effect of spinach in the diet—particularly as it appears that utilization of dietary calcium may be impaired if there is a deficiency of protein in the diet?

Even if there is no upset in calcium balance, calcium oxalate crystals from the ingested oxalates of such substances as rhubarb, spinach, and asparagus are known to cause bladder irritability with frequency of micturition and

occasionally albuminuria and haematuria in man. Spinach also makes the lips of some children red and chapped and the buttocks round the anus red. Is it not possible that the intense dislike of spinach shown by most children is Nature's way of protecting them from its harmful effects? And yet we know of conscientious mothers who have forced large quantities of spinach on their unwilling children day after day.

Are the useful constituents of spinach irreplaceable? We think not. Many workers have pointed out that the cooking or canning of spinach entails a loss of vitamin C—12% by steaming for eight minutes, 60–65% by canning, and over 95% by cooking in a saucepan at 100°C. for 10 minutes. In our experience boiled or canned spinach is generally used in this country. Besides, even slightly wilted leaves will have lost much of their vitamin C before they reach the saucepan. Is it not better to rely on foods which need no cooking?

The use of spinach became widespread when it was shown that it contained large amounts of iron, but it was soon established that for most foods there was no correlation between the total amount of iron and its availability, and that only by feeding experiments could the availability of iron in individual food materials be accurately ascertained. Such experiments on animals have shown that the iron of whole wheat and wheat bran is equal in availability to ferric chloride, followed by beef and pork liver, soya beans, and peas (60% availability). There is little to choose between spinach, beef muscle, and egg yolk (20–40% availability). Spinach feeding is known to have only a moderately favourable effect on Hb formation in anaemic dogs, for the addition of iron salts to the spinach gives a summation effect, indicating that the spinach effect is not due to the iron in this vegetable.

It is of interest that Davidson *et al.*⁶ have established clinically the necessity of having calcium-rich diets if a normal blood picture is to be maintained on a diet with a moderate amount of iron. This finding, if applied to spinach, might result in the following train of events in the body: the excess oxalic acid will combine with calcium at the expense of the phosphorus, and the phosphorus thus released will combine with iron, forming insoluble iron phosphate, thus reducing the availability of iron. It is unlikely that vitamin A (or carotene) will be deficient in children's diets if the recommended dose of cod-liver oil or substitute is given, and if foods such as carrots, tomatoes, bananas, beans, brussels sprouts, eggs, and liver are included in the diet.

May we then suggest that, until further light is thrown on the subject, spinach should be considered a doubtful article of diet for children?—We are, etc.,

Feeling the Cold

SIR.—Your annotation on "Feeling the Cold" (February 21, p. 445) tells us that "cold and warmth are separately appreciated. Different points on the skin respond either to cold or to warmth."

A homely experiment leads one to believe that the perception of a temperature gradient on the surface of the body is one thing, while the realization of whether we are dealing with a hot or cold agent is quite another. The dealing with a hot or cold agent is quite another. The experiment is the pleasurable one of lying extended in a warm bath. If the toes are extruded and the cold tap is turned gently on, the sensation is instantaneous, yet one has to tell oneself that the extraneous agent is a cold one; the actual sensation, for me at any rate, does not differ from that produced by a stream of hot water on a cold foot.

Temperature gradients, like ionization gradients, find a quick response by the body, but the mind does not immediately register the agent.—I am, etc.,

Bognor Regis.

SIDNEY RUSS.

Impetigo Contagiosa

SIR.—The bacteriology of this common condition is worthy of further study. It is an example of the unusual, but not unique, state of affairs in which a reasonably uniform syndrome appears to be associated with either or both of two very different organisms, both of which may also be present as harmless commensals in the body. Here are a few more figures to put alongside those of Dr. R. E. Church and his colleagues (February 7, p. 334):

During 1948 swabs were examined from the lesions of 39 patients with impetigo. None of these patients had received treatment with antibiotics or sulphonamides. The results were as follows:

	Occasions Grown
<i>Staphylococcus pyogenes</i> (coagulase positive) alone	18
<i>β-haemolytic streptococcus</i> alone	6
<i>Staphylococcus pyogenes</i> + <i>β-haemolytic streptococcus</i>	12
<i>Staphylococcus pyogenes</i> + diphtheroid	1
<i>Staphylococcus pyogenes</i> total	31
<i>β-haemolytic streptococcus</i> total	18
Other organisms (<i>Corynebacterium</i>)	1

The haemolytic streptococci were not all of the same group. The question immediately arises: When A infects B with impetigo and a staphylococcus or streptococcus or both is recovered from the lesions of both patients, are the organisms identical in the two cases? In other words, is the streptococcus the infectious component, preparing the ground for secondary invasion by an indigenous staphylococcus, or is the staphylococcus the continuous factor and the streptococcus the indigenous secondary invader? Or do both organisms when present take part in the serial transmission? There is, of course, another possibility—namely, that some third factor is responsible for the case-to-case transmission, both streptococci and staphylococci being secondary invaders.

On the few occasions on which it has been possible for us to examine the streptococci when impetigo has been transmitted inside a family these have been of the same group and type in all the cases. We have not yet examined the phage type of staphylococci in similar epidemiologically related cases. Though some people claim to be able to forecast from the appearance of the lesions what organism will be found on culture, I have been unable to do so. Despite the advent of chemotherapy and antibiotics the ebb and flow of impetigo in general practice do not seem to have altered very much during the past 20 years.—I am, etc.,

Cirencester.

R. E. HOPE SIMPSON.

The Teaching of Preventive Medicine at Oxford

SIR.—The progress report of the Social and Preventive Medicine Committee of the Royal College of Physicians was published in January, 1953, and was recently a subject for annotation in the *Journal* (February 7, p. 323). In this report there is implied criticism that Oxford is the only provincial school without a separate department of social and preventive medicine. The purpose of this letter is to point out that there is a small department of social medicine and that in any case Oxford medical students do get a and that in any case Oxford medical students do get a sound education in preventive medicine. The report gives details of the main topics dealt with by teaching departments of social and preventive medicine, and, with one possible exception, all appear to me to be covered in one way or another in the Oxford curriculum.

In the report, progress is measured by the number of hours allocated throughout the course to direct instruction in social medicine, but is this necessarily a reliable estimate of the total volume of preventive medicine teaching? Surely, we must all

agree that, ideally, each clinician should include preventive medicine as an essential part of his teaching, and that the nearer we can get to this ideal the less is there a need for a special department to cover the subject. From my knowledge of the consultant staff of the teaching hospital in Oxford and the close collaboration which exists between the health department and the special hospital departments dealing with obstetrics, paediatrics, otolaryngology, ophthalmology, orthopaedics, mental diseases, chest diseases, venereal diseases, dermatology, etc., I have no hesitation in stating categorically that the volume of preventive medicine teaching carried out in Oxford by the consultant staff, both by practice and precept, is very material, and Oxford medical students are most fortunate in this respect. In addition, the medical officer of health is also consultant in infectious diseases to the United Oxford Hospitals, so that in my infectious diseases course I am able to combine epidemiological and clinical instruction. Any gaps in this preventive medicine teaching by the consultant staff were filled, until recently, by the staff of the Institute of Social Medicine and will, I am sure, continue to be very adequately filled by the new reader in social medicine.

In addition to the preventive medicine teaching given within the hospital, it is of the utmost importance that medical students should have a sound knowledge of the functions of local-authority health departments, so that after qualification, whether as general practitioners or as doctors in hospital, industry, or laboratory, they will be able to co-operate fully with the many health services provided by the health departments in their area. I have therefore tried to give Oxford medical students a sound knowledge of the work of my department, partly by means of a course of lectures (admittedly short, but compensated to some extent by detailed lecture notes), but mainly by a good deal of practical instruction. For some time now, students in small numbers have regularly attended child welfare clinics, where, in addition to the routine work of the clinic, they have received instruction in various immunological procedures, including vaccination. They have also seen something of the work of the school health service, and more recently a series of public health visits has been arranged in which students, in groups of four, have gone out on successive afternoons with health visitors, mental health officers, sanitary inspectors, midwives, and district nurses (Warin, J. F., *Supplement*, September 20, 1952, p. 133). In connexion with this public health instruction, the report states that "in almost every school the former public health courses have been replaced by modernized courses in social and preventive medicine"; in Oxford it could be claimed that the reverse has also occurred in that a former course in social medicine has been replaced by a modernized course in public health. Perhaps Oxford is leading the way rather than lagging behind, as is inferred in the report.

The advantages of the development of statistical departments in close association with departments of social medicine is rightly stressed in the report, and certainly medical students should have a knowledge of statistical method, but care must be taken that the statistical tail does not wag the social medicine dog. Recent experience in Oxford demonstrated that you can have too much of a good thing, and the students showed signs of acute statistical indigestion by rebelling against the whole course in social medicine.

In the report, and in this letter, the terms "preventive medicine," "social medicine," and "public health" have all been used freely, but neither I nor, I think, anyone else knows precisely what is supposed to be the difference underlying these three terms. Is it not time that there was general recognition that, in actual fact, there is no fundamental difference and that it would simplify matters considerably if we could all agree to use one term, which I think might well be "preventive medicine"?—I am, etc.,

Oxford.

J. F. WARIN.

Dosage of Stilboestrol

SIR.—MR. J. Beattie in his Refresher Course article (February 21, p. 447) recommends a dosage of stilboestrol up to 25 mg. daily and increasing again thereafter. As the standard dose of stilboestrol is 0.5 mg. (not 5.0 mg.), the recommended dose seems extraordinarily high—beyond, in my opinion, the dose of toleration. Patients with malignant disease on treatment with stilboestrol seem unable to tolerate a dose greater than 15 mg. daily for very long.

Perhaps Mr. Beattie might think it worth while to make further comment.—I am, etc.,

Derby.

E. C. DAWSON.

Cleansing of Anaesthetic Machines

SIR.—One of the manufacturers of anaesthetic ether recently received a complaint from a hospital that the ether supplied to them was below standard and that the patients would not take it. On investigation it was discovered that the fault lay in the bottle of the anaesthetic machine itself, which had not been properly cleaned.

This letter is written on behalf of the makers of anaesthetic ether in the hope that you will publish it and the attention of interested parties will be drawn to the danger of using such machines without old ether having first been removed.—I am, etc.,

Ilford.

Sales Manager,
Howards & Sons, Ltd.

"Therapeutic Thorns"

SIR.—Professor D. M. Dunlop's review (February 21, p. 441) of the English translation of the Dutch book *Side Effects of Drugs*, of which we were co-translators, is as ingenious as the qualities—or lack of them—which he attributes to the work in question, and shows a very narrow appreciation of the labour involved in trying to make an English silk purse out of a foreign sow's ear. As regards his view that the "translators have a somewhat sketchy knowledge of English," he will probably be devastated by the riposte that one of us (W. M. C.) is a brother Sassenach born (Irish, not Scottish) and the other (Ph. V.) is a Dutchman who, although highly appreciative of Mr. Jingle, does not let himself be guided by that worthy in his efforts in the English language.

We feel that Professor Dunlop has not been quite fair in his summary disposal of this book. The author accumulated a vast amount of data which had to be condensed into a volume of handy size. This accounts for the "Jingle" style of writing. Professor Dunlop quite forgot to mention that there is a list of getting on for 2,000 references to the literature, from which the author drew his facts, and references to *Excerpta Medica* were only made when he had not access to the original article. Professor Dunlop's rather insular outlook is regrettable when foreign workers are endeavouring to make their observations available to their English-speaking colleagues. Whatever the shortcomings of Dr. Meyler's book, our job was to translate it, not to rewrite it. The end-result, if not redolent of an Osler or a Lane, is at least intelligible, and the condensed information given, if indeed "odd and alarming," represents a considerable amount of serious research on the author's part into the findings of observers all over the world.—We are, etc.,

Amsterdam.

W. MULHALL CORBET.
PH. VUJSJE.

Grease on the Skin

SIR.—Will you allow me a slight squeal of protest at your article "Grease on the Skin" (February 28, p. 499)? You say there that Squire and his co-workers¹ showed that the self-sterilizing effects of the skin depend on the action of fatty acids, mainly the unsaturated ones. I showed this many years ago,² and Professor Squire has himself acknowledged my work not only in the paper above referred to but in a letter accompanying reprints of his paper. In this letter he too generously describes his own work as very largely a confirmation of my own. It is, of course, far more than that. He and his colleagues demonstrated that the long-chain fatty acids, especially oleic, extracted from the skin itself are the responsible sterilizing agents, whereas I only deduced this fact from experiments done for the most part on hair fat, which at the time seemed far easier to obtain in reasonable quantity.

I think that the real pioneers of this work on autogenous disinfection of the skin are Brann,³ who discovered that human hair rarely contains pathogenic organisms and suggested that the fats of the scalp and hair might be lethal to

them; Marchionini and his school (in a whole series of papers in the Swiss and German medical press between 1928 and 1939), who showed the cardinal importance of the "acid mantle" of the skin; and Colebrook,⁴ who pointed out how rapidly the haemolytic streptococcus and other micro-organisms disappear from various areas of the skin. None of these workers is mentioned in your article, but I dare say you would argue that it was no part of your intention to give a comprehensive review of the subject.—

I am, etc.,

J. M. L. BURTENSHAW.

"Thorough Overhaul"

SIR.—I was interested in the letter of Dr. Ronald Coldrey and others (February 28, p. 507) concerning the "thorough overhaul." In what follows, I take it the request has been made when nothing is complained of. Otherwise, of course, the doctor does whatever is in his opinion necessary in the way of examination.

I always discourage such requests, as in general tending to increase the unnecessary and time-wasting interest the public is taking in disease, and as being outside the scope of the N.H.S. When it is pointed out to patients making this request that the number of doctors who themselves have such regular examinations must be practically nil, they sometimes see the matter in a different light.

Incidentally, I have discovered that the expression "check-up" is not necessarily synonymous with "overhaul," and is often used when the patient has signs or symptoms and is desirous to be treated for or reassured about them—which is the correct time for him to consult a doctor.—I am, etc.,

T. J. KIRKPATRICK.

Stockport.

Smoking and Lung Cancer

SIR.—Dr. R. Doll and Professor A. Bradford Hill (February 28, p. 505) have given an admirable reply to Professor R. D. Passey (February 14, p. 399) but not, I think, entirely disposed of the point he was making. He expressed concern, shared by others, about the effect which some of the wilder statements being made about the results of this work may have on the public. The extent of the real increase of this disease in the last 40–50 years is unknown. Over 80,000 people are now recorded as dying each year in this country from respiratory diseases; about 17% of these deaths are registered as due to pulmonary tuberculosis and about 17% to lung cancer. Smoking would seem to be one of the most important predisposing factors in the development of these tumours, but it is certainly not the only one. It is important that we keep our sense of proportion and remember our responsibility to the public, in whom fear of cancer is already a serious problem.

Doll and Hill have done a fine piece of work and submitted a reasoned and balanced view; others who have not done the work should consider whether the remarks they make about it are helpful and what impact their statements may have on an anxious and ill-informed public. The letters from Dr. H. Binysh and Dr. Lennox Johnston (February 28, p. 505), for instance, do not seem to me to add anything of value. It is, contrary to Dr. Binysh, quite legitimate to suggest that the diagnosis of lung cancer has changed in the last 10 years. Antibiotics have made a clear difference, and this controversy alone is changing it still. It is, of course, and this controversy alone is changing it still, unjust to infer that Professor Passey dismissed the relationship between smoking and lung cancer as of no account. It is difficult to see how Dr. Johnston can "call on the nation to stop smoking now" without doing more harm than his drama than could be compensated for by any gain over the more prosaic, gradual, and realistic methods of enlightenment which are being adopted.

There are, amongst others, two pieces of information which might be welcomed by the present generation of doctors as they wait for their deaths to round off Doll and Hill's experiment. First, whether the proportion of metastases found in the brain which are due to lung cancer changed with the years from the 30–50% found in the 1920s and 1930s (Elkington¹). This proportion was thought to be remarkable despite the propensity of bronchial carcinomas to dissemination because of the view then held of the relative infrequency of primary tumours at this site. Secondly, whether the smoking habits of patients developing carcinoma of the larynx, with its falling recorded death rate, are really similar to those of patients with lung cancer (Jacobsson²), and, if so, what this may mean.—I am, etc.,

London, S.W.3.

D. W. SMITHERS.

Intercourse after Syphilis

SIR.—Much has been written already on the topic of marriage after syphilis, but, as a most startling statement has been made in a section of the *Journal* ("Any Questions?" January 10, p. 115) which aims at answering questions and avoiding controversial matter, it is felt that it should be ventilated more fully so as to minimize any damage which may have been done. The criteria of cure for early syphilis have remained quite unaltered since the newer and simpler treatments have been evolved. It always has been impossible to be sure of the cure of early syphilis until adequate follow-up procedures have been conducted for at least two years following proper treatment. To my knowledge no one writer, American or otherwise, accustomed to dealing with large numbers of these infections has shifted from this viewpoint, or is likely to.

However, the question of matrimony after syphilis is rather different from the mere granting of permission to have sexual intercourse, for this conjures up the rather novelette situation of a Dorian Gray contemplating marriage to the vicar's daughter. In practice quite another state of affairs usually exists, and the decision regarding marriage is often made on social grounds rather than on those which are entirely medical. Thus, the syphilis may have been acquired from the girl in the first place, in which case both partners will already be under treatment, and, if marriage is still contemplated, sexual intercourse will continue whether the doctor "allows" it or not. Or the fiancée, although apparently uninfected, may be pregnant. In which case she probably has to be examined as a contact and given prophylactic treatment, but certainly not necessarily discouraged from immediate marriage, even if the man has not yet completed his injections.

The basis for any decision depends on whether or not premarital intercourse has recently taken place, and, at the risk of commencing a further controversy, the cynic might say that in this present day and age it is the rule rather than the exception—it certainly is in the bulk of patients for which such decisions have to be taken. If such intercourse has taken place, then the situation is similar to that when a married man has acquired syphilis. Thus it is essential that the fiancée is examined as a contact, and this means that the man has to own up to his misdeeds and to his misfortune. By this time the damage, if any, has been done, and the woman must either be observed to see whether she develops the infection (fifty-fifty chance), or given prophylactic treatment and observed subsequently for two years as if she had actually had the disease.

These events at once entail that the female re-examines the question of marriage. If she still wishes to proceed, provided that both parties are aware of the risks which may result from relapse in either, and both attend regularly for observation to safeguard them, and avoid pregnancy, then to advise that they wait even six months is unrealistic, as the patients will not heed the advice. On the other hand, when no intercourse has occurred, and when the

girl is unaware of the situation, to recommend that a man who has had early syphilis may get married after only six months from the initiation of treatment is out of step with all our knowledge of the condition.—I am, etc.,

London, W.1.

R. R. WILLCOX.

POINTS FROM LETTERS

Dr. Hugh Welch Diamond

Dr. J. B. WRATHALL ROWE (Harrow) writes: The above-named doctor, who died at Twickenham in 1886, was a pioneer in the field of medical photography and photomicrography. He contributed to the Royal Society in 1856 a paper entitled "The Application of Photography to the Physiognomic and Mental Phenomena of Insanity," and made several photographs of mental patients to illustrate his paper. Although the original paper is still preserved in the Archives of the Royal Society, the photographs have disappeared. I have already obtained from the Royal College of Surgeons, the Medical Society of London, and the Royal Photographic Society information and material regarding Dr. Diamond, but am anxious to trace his original medical photographs if they are still in existence. I should therefore be most grateful if anyone having knowledge of, or early examples of, Dr. Diamond's work would write to me c/o The Medical Department, Kodak Ltd., Harrow, Middlesex. In the library of the Royal College of Surgeons there is a photograph of a mental patient taken by Dr. Warren Hastings Diamond, who may have been the son of Hugh Welch Diamond. Hugh W. Diamond is believed to have had a grandson named R. Hugh Clarke. Any information regarding these persons or their descendants would also be gratefully received.

Alternative to Postgraduate Courses for General Practitioners

Dr. J. B. BAMFORD (Ely) writes: As an alternative to the usual postgraduate course at a teaching hospital, I suggest that the general practitioner could apply to his old teaching hospital, or other central body, for a senior registrar to come and spend a week in his own house. The advantages to both, in my opinion, would be great. I feel that more medicine and more tips are learnt over a cup of coffee or glass of port in the evening than by attending any number of postgraduate lectures. The registrar would also have the advantage of seeing how a general practitioner works and possibly make useful contacts, and would undoubtedly see a number of interesting and rare cases. The general practitioner would be able to obtain another opinion on many of his undiagnosed cases. A registrar could surely be spared by his chief at hospital for one week, or possibly two, in a year. A general practitioner could apply for this visit once in every three or five years. . . . I will be interested to hear what other general practitioners and registrars think of this suggestion and how to put it into operation.

Cancer in General Practice

Dr. W. A. MACKAY (Southport) writes: Your reviewer of this book (February 14, p. 381) passes without adverse comment the statement that in spite of all forms of treatment 50% of cases with stage 1 carcinoma of the breast die in five years. This conclusion is at variance with the report of Sir Gordon Gordon-Taylor to the B.M.A. meeting at Plymouth 15 years ago of 84% survival at ten years. Is the practitioner to conclude that Gordon-Taylor's figures were "optimistic," that cancer is becoming more malignant, or that treatment of cancer of the breast is deteriorating?

Medical Evidence in Court

Mr. J. H. C. PHILLIPS (Northampton) writes: In giving medical evidence it is all too easy to be unintentionally misleading by inference, but I feel that one cannot stress too strongly the grave responsibility of a medical witness in giving the court the benefit of his specialized knowledge, not only to be factually correct, but to be most careful not to imply more than was intended by failure to qualify his statements when necessary. In particular, it is important that witnesses, however eminent, who practise in one particular specialty should neither by direct statement nor by implication give evidence that goes beyond their competence.

Ferrous Sulphate Tablets

Dr. L. F. BECCLE (South Woodford, Essex) writes: I wonder why ferrous sulphate tablets are so freely prescribed for so-called anaemia. In three recent fatal cases of poisoning in infants with which, as a coroner, I have dealt in the last few months, no laboratory investigations whatsoever appear to have been made as to the existence or otherwise of anaemia. What makes the situation worse in my opinion is the utter uselessness of ferrous

sulphate in any other conditions. These bright green sugar-coated pills form an irresistible attraction to young infants, who devour them with great relish, with the most unfortunate consequences. What the answer to this menace is I do not profess to know at the moment. I am merely stating facts in the hope that this letter will direct the attention of doctors to this important matter and perhaps influence some to the extent of a little more circumspection in their prescribing of this drug.

Smoking and Lung Cancer

Dr. W. A. BELLAMY (Aylesbury) writes: Dr. Lennox Johnston's outpourings (February 28, p. 507) require an answer. He says, "The performance of our duty . . . is clearly to call on the nation to stop smoking now, voluntarily in the first instance." The magnitude of such a task, even if we as a profession agreed to participate, is so great as to be quite impracticable. And I do not like the implication in "voluntarily in the first instance." I hope, for his sake only, that Dr. Johnston is not suggesting that other means be used. He has, of course, alternate methods of raising £613,000,000 obtained last year from tax on tobacco. He should contact Mr. R. A. Butler immediately. "The upsurge in national health and morale" can take care of itself without Dr. Johnston's help. The nation's health has never been better, and its morale was proved in its "finest hour" not so very long ago—and it would be again should the need arise.

Damages Against Casualty Officer

Mr. J. H. ARMSTRONG (Accrington) writes: Having read the information on the case of *Payne v. St. Helier Group Hospital Management Committee* (January 17, p. 166), it seems that an important aspect of the matter has been passed over. No mention seems to have been made by the advocates for early operation as to exactly what should have been done having exposed a bruised caecum. Applying general surgical principles, one would leave a bruised but still viable portion of gut alone, apart, perhaps, from applying hot wet towels as in reduced strangulated enterocoele, which, however, would scarcely be useful in the case under consideration. If a clearly non-viable area of caecum could have been found at the time suggested for operation it seems impossible that the patient could have remained for so long without operative treatment in the comparatively fit condition described. If, on the other hand, a bruised but viable caecum had been found it seems that the operation would then have been concluded and to have been of an exploratory nature only and to have played no part in the effective treatment.

Catheterization in Retention of Urine

Dr. D. D. MACDONALD (London, N.1) writes: This problem does concern the general practitioner first and the urological surgeon second. Not infrequently, however, a casualty officer is the first, by reason of equipment ready to hand, to relieve this patient of his distress. One does not like to use the catheter immediately the condition of acute retention is ascertained. Provided the patient's general condition and age will allow of such treatment, $\frac{1}{4}$ - $\frac{1}{2}$ gr. (11-16 mg.) morphine given intramuscularly and followed by $\frac{1}{4}$ - $\frac{1}{2}$ hour's rest on a couch under an electrically heated blanket (or in a hot bath) will bring great benefits. The least of these is that passage of the catheter is infinitely easier for the medical attendant and much less uncomfortable for the patient. The warmth tends to relieve the prostatic vascular congestion, the morphine indirectly to relax spasm of the internal urethral sphincter. The combined effect is often sufficient to dispense with use of the catheter, with its risks and discomfort.

The Metric System

Dr. FRANZISKA FISCHER (Rotherham) writes: Dr. C. Langton Hewer (February 21, p. 450) is somewhat horrified at the idea that instead of "1 drachm per stone body weight" one would have to order "3.55 ml. per 6.35 kg." of a certain drug. That sounds terribly complicated, but nobody dreams of putting it like that under the metric system. One would give "0.6 ml. per kg." or perhaps 0.5 or 0.7 if that was more appropriate. After all, a drachm per stone is an approximate dosage only, though in general it is sufficiently accurate. I often thought that to put the literal equivalents of the English weights and measures in brackets, as is done in the *Journal*, discourages the use of the metric system. These figures look very complicated and may be a deterrent. The appropriate procedure in my opinion would be to put after the English weights not the exactly corresponding amount in the metric system but the amount one would actually order. If a weight is accurately given in stones, pounds, and ounces, then an accurate equivalent is, of course, required; but it would be much more helpful to put 0.015 g. or 0.01 g., or, if you like it better, 15 or 10 mg., for $\frac{1}{4}$ or $\frac{1}{2}$ gr. than 16 or 11 mg.

Obituary

W. JOBSON HORNE, M.D., M.R.C.P.

Dr. W. Jobson Horne, who died at Mereworth, near Maidstone, Kent, on March 7, at the age of 87, made important contributions to the advance of laryngology, mainly with reference to tuberculosis of the larynx. He was one of the last links with the older generation of laryngologists, for he missed the expected appointment in the 'nineties to the throat department of St. Bartholomew's Hospital because he had taken the M.R.C.P., as was usual in days gone by, instead of the more modern F.R.C.S., which had just become essential.

Walter Jobson Horne was born on August 2, 1865, and educated at Tonbridge School and Clare College, Cambridge, where he took a first class in the Natural Sciences Tripos in 1887, and went on to St. Bartholomew's Hospital, graduating M.B., B.Ch. in 1892, and proceeding M.D. nine years later. He took the M.R.C.P. in 1896, and was awarded the Weber-Parkes medal of the College in 1903. After holding a number of house appointments at Bart's he became chief assistant in the throat department there, and then continued his study of laryngology as a postgraduate at the University of Berlin. In 1896, when the Metropolitan Ear, Nose, and Throat Hospital was reorganized by Hemington Pegler, Jobson Horne joined the staff and began a long connexion with the hospital, which he served not only as honorary surgeon and later consulting surgeon but as honorary treasurer for many years to the board of management. He made his reputation rather as a laryngological pathologist than as a clinical laryngologist, and was the first to point out, by means of serial microscopic sections, that in tuberculous laryngitis the infection could begin in the laryngeal ventricle as well as in more obvious areas. Nevertheless, he was the inventor of two of the most useful and practical adjuncts to otolaryngology—the Jobson Horne ring-probe and the Jobson Horne head-mirror, both favourably known all over the world.

Jobson Horne was honorary secretary and editor of the catalogue of the museum of the British Congress for the Prevention of Tuberculosis in 1901. Having been honorary secretary and vice-president of the Section of Laryngology of the Royal Society of Medicine, he became president of the Section in 1920-1. He was the third laryngologist, following McBride and Killian, to be invited, in 1921, by the University of London to give the Semon Lecture, instituted in 1913 (no lecture was given during the years 1915-20). His lecture was entitled "The Relationship of the Larynx to Pulmonary Tuberculosis," and emphasized the fact, not then universally recognized, that tuberculous laryngitis was always secondary to pulmonary tuberculosis. During the war of 1914-18, when his hospital became the ear, nose, and throat subsection of Millbank (Queen Alexandra's) Hospital, Jobson Horne took a prominent part in the care of aural casualties, and wrote on gun deafness and its prevention. After the war he became aural specialist to the Ministry of Pensions for a number of years.

A B.M.A. scholar in the years 1902 and 1903, Jobson Horne continued to take an interest in the affairs of the Association; he was chairman of the Marylebone Division in 1927, and he held various offices in the Section of Laryngology and Otology at a number of Annual

Meetings, being president of the Section in 1924, when the Association met at Bradford. He also served for two years on the Science Committee. His colleagues in London had seen little of him since he retired from practice on the outbreak of the last war. A man of wide culture and recondite knowledge, he was interested in the history of medicine, had been vice-president of the Section of History of Medicine of the Royal Society of Medicine, wrote in its *Proceedings* on St. Blaise—the patron saint of laryngology—and had a notable collection of old lancets. He was unmarried, and in his retirement he enjoyed the rustic life in his country home in Kent. His brother had been a famous collector of Italian works of art, and he himself collected old silver and mediaeval antiquities. The stout, lumbering frame of Jobson Horne concealed a worldly wisdom and quick intelligence that have left their mark in laryngology.—R. S. S.

G. A. RYRIE, M.B., Ch.B.

The news of the death of Dr. G. A. Ryrie at Kirkcaldy on March 9 at the age of 53 will be received with regret by all those who admired his efforts to make easier the life of those afflicted with leprosy.

Gordon Alexander Ryrie was born in 1899, and was educated at Montrose Academy and at the University of Edinburgh, where he graduated M.B., Ch.B. in 1926. He entered the Colonial Medical Service in 1928, and was sent to Sungei Buloh, in Malaya, to act as medical officer to the leper settlement for three months; he stayed for 17 years. Having overcome the feeling of revulsion which the first sight of the settlement inspired, he accepted the appointment of medical superintendent and held the post until 1945, except for a period of about a year, during which he was a prisoner in a Japanese internment camp at Singapore. As medical superintendent he was responsible for great changes at the settlement. He emptied the leper prison of its inmates and dismissed the armed guards; he was successful in stamping out opium-smoking in the colony; and he improved the general health of his patients by installing modern sanitary arrangements. By the time the Japanese invaded Malaya in 1942 he had had the great satisfaction of seeing the colony transformed from a miserable collection of huts into a model community. The hospital was equipped with modern apparatus, and there were new houses and shops in the village. It was hardly surprising, therefore, that his patients, for whom he worked so hard, should reward him with their love and veneration. It was a bitter blow to him when the Japanese destroyed in a few months all he had built up over a period of 13 years.

After the defeat of the Japanese in 1945 Ryrie returned to Sungei Buloh for a short time, but the hardships he endured during the war and recurrent attacks of malaria greatly weakened his health, and he returned to England. In 1947 he was appointed medical secretary to the British Empire Leprosy Relief Association in succession to Dr. Ernest Muir, and he held the post until the end of 1950, when ill-health compelled him to resign the appointment.

We are indebted to Dr. ERNEST MUIR for the following appreciation:

The death of Dr. Gordon Ryrie ends a life of rare usefulness and devotion, with much suffering bravely borne during his last 10 years. A strong individualist and somewhat of a rebel by nature, he found it hard to fit into the usual routine of the Colonial Medical Service, but when appointed

medical superintendent of the new Sungei Buloh Leprosy Colony, near Kuala Lumpur, a job which few would have chosen, he found there a congenial task. For the next 14 years he devoted himself to the service of the victims of that disease, and built up one of the largest and best-equipped leprosy institutions. Ryrie took a deep interest not only in the social but also in the scientific aspects of leprosy. He contributed particularly to the study of the racial differences of the disease as found among Indians and Chinese.

When the Japanese advanced into Malaya in 1942, and most of the European civilians withdrew, Ryrie refused to leave his post or to abandon his patients. He continued to serve them for some two years. Short of food and medical appliances, he had to watch them day by day dying of starvation and slowly rotting away, in spite of all he could do for them. His life was repeatedly threatened, but he was saved by the devotion of the indigenous inhabitants, whose good will the Japanese were anxious to preserve. In the end he was removed to a concentration camp.

Ryrie had a rare facility in writing, and had his sympathy with suffering not led him to become a physician he might have been a successful literary man. During the years at Sungei Buloh his wife took a large share in the welfare work of the colony. When increasing ill-health made it impossible for him to continue in active work, he retired to Mrs. Ryrie's home in Fifeshire. We extend to her our deep sympathy in her loss.

Dr. A. G. BADENOCH writes: Sungei Buloh Leper Settlement in the Federated Malay States, beautifully sited in a closed valley, contains a central hospital and offices, playing fields, recreation rooms, a small theatre, and a school. Those who care may grow vegetables or keep poultry or pigs. The separate cottages have each its own flower garden. Unfortunately these amenities counted for little until Ryrie was appointed medical superintendent. Leprosy work had been dominated by the tradition that it was a loathsome and incurable disease: segregation and palliation were the rule. The atmosphere was charged with hopelessness and resentment. Gordon Ryrie changed all that within a few months. Trained in tuberculosis work, his new system gave a sense of security to all his staff, and he showed an example by his personal care of the worst cases, many of whom he dressed with his own hands. He appointed the lepers themselves to nursing, administrative, sanitary, and other duties. He was the friend of every one of his 1,500 patients, and after winning their confidence he set the burdensome routine of treatment on a firm and humane basis, with diagnostic and record centres, operation theatre, and isolation wards. Educational and sports clubs were formed, plays were produced, a magazine, *The Dawn*, was printed. Mrs. Ann Ryrie taught in the school. There was an annual sports day, a weekly cinema show, and the usual seasonal festivities. The whole atmosphere of the place soon changed to one of ordered activity and happiness. A survey showed that many patients had become cured or, as the phrase goes, "burnt out" and non-infectious. When Ryrie offered these their freedom, many pleaded to remain, and jobs were found for them on the outside staff.

When the Japanese invaded Malaya, Ryrie refused to leave his leper patients and stayed, sharing their poor rations and scant supplies. He was suspected of underground activities, and a local Chinese threatened to report him unless a large bribe was paid. Ryrie arranged to hand over the money at dead of night. A sick man already, he kept the appointment, limping on his wife's (international) hockey stick. He also carried dummy money and a syringe of HCN. The Chinese got the latter—and the hockey stick to make sure. This led to Ryrie's removal to a concentration camp. When he was released, though suffering severely from malaria, dysentery, and sores, he skipped the home convoy and trekked in disguise back to his lepers. His death—a result of his voluntary martyrdom in Malaya—marks the passing of a good and faithful servant of humanity.

JOHAN M. HOLST, M.D., Hon. LL.D., Hon. F.R.C.S.
Hon. F.R.C.S.Ed.

The death of the Norwegian surgeon Professor J. M. Holst on February 17 at the age of 60 came as a great shock to his many friends, who were accustomed to regard his lithe, athletic figure as an expression of vitality and an index to longevity. The son of the physician Professor Peter F. Holst, of Oslo, Johan Martin Holst was born on June 23, 1892, and began his surgical career as a volunteer in Finland during its war of 1918. Just over 20 years later he was again in Finland, this time in charge of a Norwegian ambulance service in 1939. When Norway was invaded by the Germans in 1940, Holst was appointed chief officer to the Royal Norwegian Army, Navy, and Air Force Medical Corps, a post he held for the rest of the war. He escaped from Norway in dramatic circumstances, and continued to take an active part in the war as an organizer and administrator abroad. In 1930, when only 38 years of age, he was appointed professor of surgery in the University of Oslo and was in charge of a surgical department at the Rikshospitalet. He specialized in surgery of the stomach, thyroid, and lungs, and it was his work on the operative treatment of pulmonary tuberculosis in particular which earned him the international reputation he so richly deserved. Holst was a member of the Scientific Academy of Oslo; the Académie de Chirurgie, Paris; and the Finnish and Swedish Medical Societies. His eminence as a surgeon was recognized by his election to the Honorary Fellowship of the Royal College of Surgeons of England in 1943, the Royal Society of Medicine in 1944, and the Royal College of Surgeons of Edinburgh in 1946; the honorary degree of LL.D. was conferred on him by the University of Glasgow in 1951.

Medical Notes in Parliament

Streptomycin Exports

Mr. PETER THORNECROFT, President of the Board of Trade, told Dr. Barnet STROSS on March 10 that, so far as he knew, no streptomycin was exported to China and Hong Kong in the first six months of 1950. Dr. STROSS recalled a statement that future exports to China for civilian purposes would be based on the amount exported during that period, and asked for an assurance that the fact that none was exported in that time because we had none to export did not mean that there would be no exports to China. Mr. THORNECROFT declined to go further in this direction than pointing out that the export of streptomycin was governed not by the export of that particular drug during the period but by the export of the group of drugs in which it was included.

Vivisection Experiments

The HOME SECRETARY, in a reply to Mr. Peter Freeman on March 12, stated that records were not kept of the number of animals used in vivisection, but the total number of experiments for the years 1885 to 1951 inclusive was 26,511,783, including 7,570 experiments on horses, asses, and mules, and 113,422 experiments on cats and dogs. The figures for horses, asses, mules, cats, and dogs did not include experiments where the animal was killed while still under anaesthesia, since separate records were not kept before 1949; nor did they include certain experiments on cats and dogs in 1940 and 1941, since the records were destroyed by enemy action.

Paying for Health Services

Sir GUY LLOYD asked the Minister of Health on March 12 whether, on all forms issued by his department and handled by the public in relation to the health services, he would cause to be printed a statement to the effect that the health services were not free but that the cost was borne principally by the taxpayer.

Miss PAT HORNSBY-SMITH, the Parliamentary Secretary, replied that, while agreeing that this fact could not be too widely known, she did not think that the form of publicity suggested would be practicable.

Spasticity in Children

Mr. W. T. WILLIAMS asked the Minister of Education on March 12 how many special schools were provided for spastic children by her department and by voluntary organization, what sums were provided for the training and education of such children by her department and how such sums were allocated, and how many children of under 16 years of age were registered as spastics. Miss FLORENCE HORSBROUGH replied that there was no general register of spastic children, and she did not collect separate figures for spastic as distinct from other physically handicapped children. Educable spastic children might be sent by local education authorities to ordinary schools or to special schools for the physically handicapped. There were four special schools in England, of which three were maintained by voluntary organizations, and one by a local education authority, specifically for children suffering from cerebral palsy, and a number of others made special arrangements for them.

Tuberculosis Among Immigrants

Mr. KENNETH ROBINSON asked the Minister of Health on March 12 how long the Standing Tuberculosis Advisory Committee had been considering the problem of tuberculosis among persons taking up residence here from abroad, and what recommendations the committee had made on the subject.

Mr. IAIN MACLEOD said the actual reference to the Tuberculosis Advisory Committee was made in December. He understood it was to be discussed in a few days.

Mr. ROBINSON said there were indications that tuberculosis was being "imported" to a disturbing extent. It was not confined to aliens, as had been suggested recently, but included British subjects from parts of the Commonwealth and from Ireland.

Mr. MACLEOD said he did not quarrel with what Mr. Robinson had said. The wider questions he had raised were under discussion with the Ministry of Labour and the Aliens Department of the Home Office.

Aureomycin Supplies

Dr. SANTO JEGER on March 12 asked the Minister of Health whether, now that aureomycin was manufactured in this country and the limitations on its efficacy were so well known among general practitioners, he would make it more freely available to doctors so that delay is avoided when its use is indicated.

Miss PAT HORNSBY-SMITH, the Parliamentary Secretary, replied that the manufacture of aureomycin in this country still involved bulk importation of the crude drug at considerable dollar cost, and the Minister thought that its issue ought to be subject to the present safeguards. He was not still to be subject to the present arrangements, there was any undue delay in supplying this drug to general practitioners in cases where its use was indicated. Since October 1, 1952, 896 applications by general practitioners for the use of aureomycin had been granted. About 5% were refused.

The Births and Deaths Registration Bill, a consolidation measure which has passed the House of Lords, was read a second time in the House of Commons on March 11.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending February 28 (No. 8) and corresponding week 1952.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenzal pneumonia.
‡ Includes puerperal pyrexia.

Vital Statistics

Smallpox in the North Country

Up to March 17 four cases of smallpox had been diagnosed in three men working in a cotton mill at Todmorden, Yorkshire, and in the wife of one of them. One man had died. The cases are as follows:

Todmorden M.B., Yorkshire West Riding.—On March 12 a man aged 45 who had sickened on March 3 and developed a rash on March 7 was admitted to Halifax General Hospital. Here smallpox was suspected, and he was transferred three hours later to the Oakwell Smallpox Hospital. On March 16 there was laboratory confirmation. He had been vaccinated only at the age of 2. On March 15 a man aged 60 and his wife aged 57 were admitted to Oakwell Hospital. The man had sickened on February 28, and a rash, then thought to be chickenpox but now diagnosed smallpox, appeared on March 4. The wife's rash appeared on March 16. He had been vaccinated in infancy and again in the 1914-18 war. She had never been vaccinated.

Bacup M.B., Lancashire.—On March 12 a man aged 51 residing at Bacup but working in Todmorden was admitted to a cubicle at the Florence Nightingale Hospital, Bury, with the diagnosis of scarlet fever. On March 13 petechiae appeared, and the man died. Subsequently smallpox was suspected, and on March 16 there was laboratory confirmation. This man had been unwell with a quinsy since February 28, but was forced to take to his bed with what was probably the onset of smallpox on March 9. He had been vaccinated only in infancy.

In view of the delay in the recognition of the causes of the illness in several of these cases, amounting in one instance to a fortnight, it is very probable that the outbreak will continue.

Infant Mortality by Social Class

The latest *Annual Report* of the Registrar-General for Scotland (1950) contains an analysis of stillbirths and infant deaths according to social class of father. The following figures extracted from a table in the report (p. 47) illustrate how the stillbirth and infant mortality rates increase in relation to social class.

Social Class	Rates	
	Stillbirths per 1,000 Total Births (Live and Still)	Total Infant Mortality per 1,000 Live Births
I	16.3	25.9
II	22.6	24.2
III	26.4	37.0
IV	29.1	43.9
V	32.3	53.6
Total	26.9	38.6

The infant mortality in classes IV and V combined is 93% higher than in classes I and II. The difference between the social class becomes greatest for death rates later in the first year of life, neonatal causes (i.e., in the first four weeks) being only 54% higher in classes IV and V than in I and II.

Infectious Diseases

Falls were recorded in the number of notifications of infectious diseases in England and Wales during the week ending February 28—2,006 for measles, from 32,890 to 30,884; 245 for acute pneumonia, from 2,142 to 1,897; 95 for scarlet fever, from 1,550 to 1,455. The only large rise was 549 for whooping-cough, from 2,197 to 2,746.

The incidence of measles, which in the preceding week had reached the highest level since this disease was made notifiable, declined sharply. The largest falls were 367 in Southampton County, from 1,631 to 1,264; 321 in Lancashire, from 2,150 to 1,829; 268 in Durham, from 897 to 629; 335 in Middlesex, from 2,190 to 1,855; 208 in London,

from 1,832 to 1,624; 202 in Warwickshire, from 1,630 to 1,428. The largest exceptions to the decline in the incidence of measles were rises of 196 in Devonshire, from 841 to 1,037, and 126 in Kent, from 1,543 to 1,669. Only small variations occurred in the local trends of scarlet fever, with the exception of a decrease of 50 in Lancashire, where the notifications fell from 260 to 210. The largest increases in whooping-cough were 142 in Lancashire, from 540 to 682, and 69 in Kent, from 49 to 118. 27 cases of diphtheria were notified, 11 more than in the preceding week. The chief features of the returns of diphtheria were rises in Lancashire from 2 to 7 and in Warwickshire from 0 to 4. The largest centres of infection were Liverpool C.B. 5, Plymouth C.B. 4, and Birmingham C.B. 4.

13 cases of acute poliomyelitis were notified, and these were 13 fewer for paralytic and 1 fewer for non-paralytic cases than in the preceding week. Huntingdon, with 2 cases, was the only area with more than one case.

The notifications of dysentery rose from 241 to 252. The largest returns were Lancashire 58 (Liverpool C.B. 20, Manchester C.B. 20), London 50 (scattered through 16 boroughs), Yorkshire West Riding 39 (Leeds C.B. 29), and Warwickshire 14 (Rugby R.D. 12).

9 of the 10 cases of paratyphoid fever notified in Scotland were reported from Banff County.

314 deaths were attributed to influenza during the week in the great towns, 207 fewer than in the preceding week.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1944-52 are shown thus ----, the figures for 1953 thus ———. Except for the curves showing notifications in 1953, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Week Ending March 7

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,534, whooping-cough 2,758, diphtheria 22, measles 27,638, acute poliomyelitis 17, dysentery 289, paratyphoid fever 6, and typhoid fever 6.

Medical News

Institute of Almoners.—The Jubilee Dinner of the Institute of Almoners was held at the Holborn Restaurant on March 14, with Professor Alan Moncrieff in the chair. In proposing the health of the Institute, Sir Russell Brain said that the Institute had 50 years of great achievement behind it. The almoner had been created by the growing complexity of society. "We doctors," he remarked, "cannot do without you." The almoner was a new form of social consciousness. He looked forward to the time when all non-medical workers in health would join with doctors in a voluntary council to meet the challenge of the welfare State. Miss E. C. Warner, A.M.I.A., in reply, said that 50 years ago the first almoners' committee was formed, and in the course of time this grew into the Institute. In 1903 there were in existence seven working almoners. Now the Institute had over a thousand members, and they were pleased to have been given university recognition by the recent decision of Edinburgh to provide a third-year course for almoners. Thanks, among others, to their chairman, the Ministry of Health had agreed to provide grants to the students. A third point she would like to mention was the successful result of the negotiations on scales of remuneration, and in this connexion they owed much to their general secretary, Miss M. Steel. In 1951 a committee was set up to survey the work of almoners, and the report now

drawn up had been almost unanimously accepted. "We have," Miss Warren concluded, "a place within the structure of our society. We must increase our recruits and improve standards of training." The toast of the guests was proposed in a most gracious and witty speech by Miss M. B. Streatfield, A.M.I.A., and Miss E. L. Younghusband maintained the high standard of speeches in her response.

Queen Elizabeth College of Household and Social Science.—The granting of a royal charter to the King's College of Household and Social Science, University of London, which is to be known henceforth as Queen Elizabeth College, after Queen Elizabeth the Queen Mother, was celebrated by a luncheon at the College on Campden Hill on March 11. The principal speaker was Lord Horder, who said that the College dated from a modest beginning in 1908, followed four years later by the foundation of the Household and Science Department of King's College for Women, with Sir Cooper Perry as first chairman. In 1916 a diploma and in 1920 a degree were granted in household and social science. Sir John Atkins, the present chairman, was elected to that office in 1922. Now a royal charter had been granted, and the university degree of B.Sc. had been replaced by two new degrees—B.Sc. in Household Science and B.Sc. in Nutrition. No more significant step could have been taken at Queen Elizabeth College, Lord Horder added, than the addition of the subject of nutrition to its curriculum. There were excellent opportunities in this field of research. Dame Caroline Haslett, who also spoke, mentioned the suitability of nutrition as a career for girls. They would find the theoretical and practical training given at the College invaluable.

Pictures, Books, and Music in Hospitals.—Last week Miss Pat Hornsby-Smith, Parliamentary Secretary to the Ministry of Health, opened a one-day conference on "Pictures, Books, and Music in Hospitals" at the Wellcome Research Institution, London. The conference was sponsored jointly by the British Red Cross Society Picture Library, the St. John and Red Cross Hospital Library, and the Council for Music in Hospitals. Lady Falmouth was in the chair. After an introductory talk on the work of the B.R.C.S. Picture Library by Lady Falmouth, the keeper of the Birmingham City Museum and Art Gallery, Dr. Mary Woodall, spoke on "Pictures and Patients." She was followed by Mrs. Harold Raymond, who described the great expansion of the St. John and Red Cross Hospital Library Department, which now caters for 1,500 hospital libraries in Britain as well as for all Service hospitals at home and overseas. Later there was a demonstration on the art of hospital librarianship. The last part of the conference, devoted to music, was introduced by the Earl of Harewood, president of the Council for Music in Hospitals. Dr. S. F. Mitchell described the curative value of music, particularly for those in mental hospitals. The conference concluded with a talk by Mr. Adrian Hill.

Ciba Foundation.—Since the opening of the Ciba Foundation for the Promotion of International Co-operation in Medical and Chemical Research less than four years ago, the Foundation has done much to live up to its title. Perhaps the most useful of its activities are the informal symposia which it holds in London. To these are invited 40 to 50 experts in the subject under discussion from all over the world. Last year there were six of these symposia, three being devoted to endocrinology ("Bio-assay of Anterior Pituitary and Adrenocortical Hormones," "Hormonal Factors in Carbohydrate Metabolism," and "Synthesis and Metabolism of Adrenocortical Steroids"), and three to general subjects ("The Spinal Cord," "Mammalian Germ Cells," and "Chemical Structure of Protein"). The proceedings of these conferences are later published (see our review pages, February 21, p. 440). Last year the Foundation inaugurated a series of exchange bursaries with the Institut National d'Hygiène in France. The bursaries are to allow doctors to pay short visits to France (or England) in order to obtain clinical experience or undertake research. Last year bursaries were awarded to five British doctors and six French. A constant stream of medical and scientific visitors have been accommodated at the Foundation's house

in Portland Place, London, W.1. On an average there were seven guests each night throughout the year, and they came from 29 different countries.

Cambridge University Health Service.—During the year 1951-2 all except 7 of the 2,296 freshmen arriving at Cambridge (99.7%) submitted to mass miniature radiography. Among them were found 15 cases of "possibly active" tuberculosis, five of which were previously unknown. Another five cases were found among the senior undergraduates, though here only about a quarter of those in residence were examined. This failure to take full advantage of the x-ray service is disappointing and the College authorities are blamed for not exerting more persuasion. Four seniors who failed to report for x-ray examination developed pulmonary tuberculosis during the year. Over three-quarters of the freshmen were also examined clinically (half an hour each), and, although the commonest causes of reference were eye symptoms or bad teeth, the University's major medical problems are said to centre round pulmonary tuberculosis and mental upset—as at Oxford. The health service is analysing its height and weight records of 7,000 undergraduates with a view to preparing standard tables.

Honorary Degrees at Edinburgh.—Among those who will receive the honorary degree of LL.D. at the summer graduation ceremonial at Edinburgh University in July are Professor Charles McNeil and Dr. S. L. A. Manuwa. Professor McNeil is professor emeritus of child life and health in the University of Edinburgh, and Dr. Manuwa is inspector-general of Medical Services, Nigeria. During the bicentenary celebrations of the publication of Dr. James Lind's "Treatise of the Scurvy," which are due to be held at Edinburgh on May 22, Surgeon Vice-Admiral Sir Sheldon Dudley will be made an honorary M.A. Lind recommended the juice of citrus fruits for the prevention of scurvy, and it was largely owing to him that scurvy was eventually eradicated from the British Navy.

New Geriatrics Journal.—The American Geriatrics Society has begun publication of a new journal on its specialty, the *Journal of the American Geriatrics Society*. It will appear six times a year at an annual subscription of £4 2s. The agents in this country are Messrs. Baillière, Tindall & Cox, 7-8, Henrietta Street, London, W.C.2. Interest in this subject in the U.S.A. is already sufficient to sustain two other journals, the quarterly *Journal of Gerontology*, and the bi-monthly *Geriatrics*. There is at present no British journal specializing in this subject.

Register of Orthoptists.—The 1953 *Register of Orthoptists* has now been published, and is available free to medical practitioners on application to the secretary and registrar, Board of Registration of Medical Auxiliaries, B.M.A. House, Tavistock Square, W.C.1. Orthoptists are classified on a geographical basis, and the *Register* gives addresses and telephone numbers and denotes where private practice is undertaken.

Public Health (Infectious Diseases) Regulations, 1953.—New regulations on the notification and prevention of infectious diseases come into force on April 1. In general substance and form the new regulations are similar to the old. The main changes relate to the control of food-poisoning: wider powers are provided for its prevention.

Emergency Bed Service: Applications and Admissions.—During the seven days ending March 16 the number of applications made by doctors to the London Emergency Bed Service for admission of patients was 1,336, of whom 87.2% were admitted.

Dr. George Oliver, of Harrogate, in 1904 gave to the Royal College of Physicians £2,000 to endow a lectureship or prize in memory of William Sharpey. The College has not yet been able to obtain a portrait or photograph of Dr. Oliver, and if anyone knows of the existence of one would he kindly communicate with Professor E. C. Dodds, Harveian Librarian, Royal College of Physicians, Pall Mall East, London, S.W.1.

Dr. A. Q. Wells, a member of the Medical Research Council's staff at the Sir William Dunn School of Pathology, Oxford, and an authority on murine tuberculosis, has been appointed a Sheriff of Oxfordshire.

COMING EVENTS

Association of Clinical Biochemists.—The inaugural general meeting of the Association of Clinical Biochemists will be held at 2.30 p.m. on March 28 at the Postgraduate Medical School of London.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, March 23

MEDICAL SOCIETY OF LONDON.—8.30 p.m., discussion to be introduced by Dr. T. H. Mills and Mr. M. A. Falconer: Value of Arteriography.
ROYAL EYE HOSPITAL.—5.15 p.m., Dr. T. H. Whittington: Physiology of Accommodation Clinically Considered. Treatment of the Hypermetrope.

Tuesday, March 24

●INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. W. N. Goldsmith: Vegetating Dermatoses.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor H. H. G. Eastcott: Arterial Grafting for the Ischaemic Lower Limb.
WEST END HOSPITAL FOR NERVOUS DISEASES.—5.30 p.m., Dr. N. G. Hulbert: Neurological demonstration.

Wednesday, March 25

BIRMINGHAM MEDICAL INSTITUTE: SECTION OF PSYCHIATRY.—At Monyhall Hall, King's Heath, 8 p.m., clinical meeting.
EUGENICS SOCIETY.—At Burlington House, Piccadilly, W., 5.30 p.m., Dr. Gertrude Willoughby: Population Problems and Family Policy in France.
●INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Lichenoid Eruptions.
INSTITUTE OF UROLOGY.—At St. Paul's Hospital, W.C., 4.30 for 5 p.m., Mr. H. G. Hanley: Disorders of Micturition in Females.
ROYAL EYE HOSPITAL CLINICAL SOCIETY.—8 p.m., Mr. M. A. Falconer: Visual Field Changes in Compressions of the Optic Nerve.
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Dr. J. B. Alexander: Recent Advances in the Treatment of Pulmonary Tuberculosis in the Adult.

ROYAL SANITARY INSTITUTE.—At Town Hall, Walspool, 10.15 a.m., Dr. J. J. Jones: Trend of Population and its Effect on Public Health; Mr. F. A. Lodge: Slum Clearance Problems of To-day.
WELSH NATIONAL SCHOOL OF MEDICINE.—At Reardon Smith Lecture Theatre, Park Place, Cardiff, 8 p.m., 4th William Sheen Memorial Lecture by Sir Cecil Wakeley, P.R.C.S.: Modern Trends in the Treatment of Cancer.

Thursday, March 26

●INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Mycology—Epidemiology of Fungous Infections.
LIVERPOOL MEDICAL INSTITUTION.—8 p.m., Dr. Lennox Johnston: Cure of Tobacco Smoking.
LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—At 11, Chandos Street, W., 8.30 p.m., Dr. M. H. Pappworth: Science of Diagnosis.
MIDDLESEX COUNTY MEDICAL SOCIETY.—At Central Middlesex Hospital, 3 p.m., clinical meeting; 4.45 p.m., Dr. F. Avery Jones: Australian Journey (with colour slides).
NORTH-WESTERN TUBERCULOSIS SOCIETY.—At Manchester Royal Infirmary, 4.30 p.m., Mr. J. F. Dark and Mr. P. Jewsbury: Lung Resection in Pulmonary Tuberculosis.
ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Dr. E. R. Cullinan: East African Interlude.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor S. S. Rose: A Clinical and Radiological Survey of 150 Cases of Recurrent Swellings of the Salivary Glands.

Friday, March 27

BIOCHEMICAL SOCIETY.—At Department of Biochemistry, University College, W.C., 11 a.m., annual general meeting.
●INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. L. Forman: Lichen Planus.
MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.—7.30 p.m., general meeting. Dr. A. H. Harkness: Therapeutics of Non-gonococcal Urethritis.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Feilden.—On March 5, 1953, at the Roan Antelope Copper Mines Hospital, Luanshya, Northern Rhodesia, to Elspeth (formerly Brown), M.B., B.S., wife of Francis Antony Feilden, a son—Humphrey John.
Howell.—On March 3, 1953, at St. David's Hospital, Cardiff, to Jean, wife of Dr. David Gordon Howell, a son—David Vaughan.
Masters.—On March 8, 1953, at Mason's Hill Maternity Hospital, Bromley, Kent, to Jean (formerly Newland), wife of Edgar James Masters, M.B., B.S., a son—Nigel James.
Sers.—On January 22, 1953, to Dr. Phyllis (formerly Neil), wife of Dr. Rolf Sers, Goldboro, Nova Scotia, a son.
Turner.—On March 3, 1953, at University College Hospital, London, W.C., to Joan, wife of Robert G. Turner, F.R.C.S., a son—Peter.

DEATHS

Buckle.—On February 27, 1953, at 56, Woodlands Lane, Great Shelford, Cambridge, William Frederick Buckle, M.D.
Cartwright.—On February 22, 1953, at the Lonsdale Nursing Home, Tunbridge Wells, Kent, Ernest Henry Cartwright, M.D., D.P.H., formerly of Myskyns, Ticehurst, Sussex, aged 87.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

The Origins of Clinical Thermometry

Q.—When was the measurement of the temperature of the body first used systematically for medical purposes, and when and where was the first clinical thermometer made?

A.—Hippocrates regarded heat as the chief diagnostic sign of acute diseases. Galileo is generally credited with the invention of the spirit thermometer. Sanctorius introduced it to the medical profession; in his commentary on Avicenna (Venice, 1626) he demonstrated its usefulness in the study of disease. His book includes an illustration of a thermometer. Fahrenheit introduced his scale in 1714, and Réaumur in 1730 introduced a mercury thermometer with a scale of 80° between freezing and boiling points. The centigrade scale was invented by Celsius, of Upsala, in 1742, with 100° as the melting point of ice and 0° as the boiling point of water. In the following year Christin, of Lyons, reversed this scale.

The first accurate observations on the temperature of healthy men and animals seem to have been recorded by G. Martine in his *Essays, Medical and Philosophical*, 1740. Boerhaave used the thermometer extensively in clinical work, probably employing the ordinary weather instrument. In 1835 Becquerel and Breschet established the mean body temperature in health as 37° C. (98.6° F.). The self-registering maximum thermometer for medical use was invented by Aitken about 1865. It was a cumbersome instrument some 10 in. (25 cm.) long, and in 1867 Clifford Allbutt instructed a Leeds firm to make him a series of experimental thermometers, and succeeded in reducing the length of the tube to 3 in. (7.6 cm.). The pocket clinical thermometer thus devised by him came rapidly into general use. The word *thermomètre* first appears in J. Leurechon's *Recréation mathématique*, 1624.

Intermittent Claudication Unrelieved by Sympathectomy

Q.—What further treatment is available for sufferers from intermittent claudication after the failure of lumbar sympathectomy?

A.—Conservative measures such as Buerger's exercises and the use of vasodilator drugs such as tolazoline ("prisco") should be persisted with. If there is no improvement a year after sympathectomy section of the tendo Achillis must be considered. This aims at relieving pain in the gastrocnemius and soleus muscles by inactivating them. It may also relieve pain arising in other muscles of the leg by reducing the bulk of muscle demanding blood during exercise. The most suitable cases are those in which pain starts in the back of the calf and radiates upwards or downwards without encircling the leg. A forecast of the possible effect of tenotomy may be made by applying a below-knee plaster cast to fix the ankle, and then observing the effect on walking distance of this method of reducing the activity on the affected side is sometimes helpful. The most suitable cases for tenotomy are those in which the opposite limb is relatively unaffected and in which the walking distance is less than 50 yards (45 m.). The operation should not be done unless the nutrition of the skin of the limb is good. There is some loss of power in certain actions such as pressing the brake pedal of a car, and this must be considered before operation is decided upon.

Reconstructive operations such as grafting are now possible in highly selected cases in suitably equipped centres.

Arteriography is a necessary first step. Localized thrombosis in an otherwise relatively healthy arterial tree may allow the insertion of a graft. The operation is best reserved for patients with more serious symptoms than claudication alone.

Sudden Death after Penicillin

Q.—Sudden death has been recorded following the injection of penicillin and ascribed to undue sensitivity to it. (1) Should sensitivity-testing be adopted routinely before giving penicillin? (2) What is the medico-legal position if there is a fatality and sensitivity-testing has not been done?

A.—Sudden death after a penicillin injection is almost unheard of and not explicable as the result of sensitization, when the principal effects are fever and urticaria, although occasionally a shock-like condition may result. Death has been caused by the injection of excessive doses intrathecally and by the accidental penetration of a vein during an intramuscular injection of certain preparations of penicillin other than those ordinarily used, but presumably the question does not refer to such cases. In view of the enormous number of doses of penicillin given daily with no ill effects by practitioners who could not possibly afford the time for precautions to guard against a highly improbable contingency, the answers must obviously be: (1) No; (2) There appears to be no cause of action.

Exact Identification of Bacteria

Q.—(1) What methods of typing bacteria are now available to assist the study of the spread of disease? (2) To which diseases of man may these methods now be usefully applied?

A.—(1) Bacteria can be typed by serological methods or by means of bacteriophage. The former are applicable to pneumococci, streptococci, meningococci, staphylococci, diphtheria bacilli, and in a modified sense of the term to certain of the *Enterobacteriaceae*, such as salmonella and dysentery bacilli. The latter is used chiefly for typing *Salmonella typhi*, *S. paratyphi* B, *S. typhi-murium*, and staphylococci. Methods for typing other organisms by bacteriophage have been described, but are not in routine use.

(2) These methods can be applied to the investigation of any of the diseases caused by the organisms which have been mentioned. In general, serological typing involves a good deal of work, and is reserved for special investigations. Bacteriophage typing of *S. typhi*, *S. paratyphi* B, and the staphylococci is relatively simple, and is employed as a routine where there is any reason to expect that the information obtained would be of epidemiological interest.

Kieselguhr Powder

Q.—What is kieselguhr powder? Has it any harmful effect if inhaled or in contact with the skin? A patient is exposed to the powder in his work, and complains that it causes a sore throat and cough.

A.—Kieselguhr powder is one of the diatomaceous earths, consisting of the skeletons of extinct diatoms. Its composition is almost pure silica in an amorphous form. Because of its amorphous form it is generally regarded as being a harmless dust to inhale. When inhaled in sufficient quantity over a long period of time it can cause silicosis; but whether or not silicosis develops probably depends on the treatment—for example, grinding or crushing—which the kieselguhr undergoes. The powder also has a drying effect on the throat and trachea, causing soreness and cough.

Some authorities state that calcined diatomaceous earths cause silicosis much more rapidly than those not so treated. For this reason it is very difficult to give any specific safe maximum concentration of dust. This type of silica may be mixed with alkalis and soap powders in the manufacture of abrasive cleaners, in which case the action of the silica

on the lungs seems to be increased by the presence of alkali. Apart from its abrasive qualities, which may rarely give rise to a friction dermatitis, the powder should not be harmful to the skin.

Kieselguhr powder should be handled with care. If the method of use is such as to cause continuous clouds of dust, it should be handled under exhaust ventilation. Special care is required in the case of calcined and ground kieselguhr.

Non-operative Treatment of Dupuytren's Contracture

Q.—Is there any non-operative treatment likely to improve an early case of Dupuytren's contracture? Would splinting during sleep be helpful? The patient's main relaxation is playing the piano.

A.—There seems to be no doubt that the progress of some cases of Dupuytren's contracture can be delayed, if not arrested, by the wearing of an appropriate splint at night combined with frequent manipulation of the finger by the patient himself during the day.

For many years a search has been made for some internal or local medicament which would soften contracting fibrous tissue. The use of "fibrolysin" and "iodolysin" (thiosinamine derivatives) in this way will be remembered by older practitioners. Recently two further materials have been suggested, the one vitamin E, and the other phenyl-cinchoninic acid. The writer has not noted much improvement from the employment of any of these methods, but some maintain that in the case of vitamin E the doses frequently used are inadequate and that if massive doses are given for a prolonged period results are obtained.

NOTES AND COMMENTS

Asthmatic Attacks in Infancy.—Dr. E. R. WINTON (London, S.E.9) writes: In the *Journal* of January 31 (p. 285) under the heading "Any Questions?" an inquiry was made about the alternative to injecting adrenaline in treating an asthmatic attack in a child. The questioner and his respondent (and perhaps others) might be interested to know that for about a year I have tried an unorthodox method with a modest amount of success. The treatment is to administer sublingually two or three minims (0.12 to 0.18 ml.) of ol. myristicae B.P. It had occurred to me that the essential oils used as carminatives, which somehow relaxed the cardiac sphincter sufficiently to permit eructation, might also act on other plain muscles; and an old wives' tale to the effect that nutmegs hung round the neck protected against asthma led me to use the particular oil mentioned as a pilot experiment. The administration of this oil is simple, requires no technical skill as does the syringe, conveys no discomfort in use, and in the dosage employed appears to produce no bad side-effects. If only one could say this of adrenaline, isoprenaline, and like preparations!

As it chanced, my first two cases, a girl of 6 and a woman of 35, were both completely relieved in an attack within a few minutes. In the case of the child I had my stethoscope applied to the chest and a stopwatch in my other hand; all spasm disappeared in two minutes exactly. In a later attack in this same child I had the pleasure of being able to demonstrate to my wife complete relief exactly two minutes after instilling the oil. Subsequently I obtained identical results in a little boy; the rest of a dozen cases either required a further dose after five minutes to obtain fair relief, or were very little helped. One lad of 16 acquired resistance to the treatment over weeks, and had never had relief comparable to isoprenaline or adrenaline; he is now considerably resistant to adrenaline also. In no case was there report of undesirable side-effects; I have myself taken sublingually five times the maximum B.P. dose without untoward effect.

My impression from this small, by no means statistically significant group of cases is that the better result may be looked for in young children, and that where irreversible bronchial changes have taken place the drug is likely to be useless. Certainly, of the six adults treated with this oil, only one obtained good relief. The only lesson I draw from this small experiment is that at least one essential oil containing many complex substances happens to contain some ingredient or combination of ingredients which relaxes smooth muscle. There are many essential oils, and a properly conducted clinical investigation combined with a laboratory study of the individual substances contained in them may reveal some useful non-toxic preparations to be added to our armamentarium. And in asthma, at least, this would be very welcome.

OUR EXPERT writes: There are very many unorthodox treatments of asthma, none of which were included in my brief answer. Some of the unorthodox treatments help individual cases by virtue of their ingredients, others work by faith. Most of these unorthodox treatments have been tried by orthodox doctors interested in asthma and have not been found to be helpful in a sufficiently high proportion of patients to be advised generally. Dr. Winton's results are not really surprising, for carminatives are known to help some attacks of asthma in some cases, perhaps rather more frequently than is appreciated in these modern days. The older clinicians some 20 to 30 years ago who emphasized "reflex causes" of asthma appreciated the relief that might be obtained when treatment was directed to relieving or avoiding gastric or colonic distension, but the older physicians were also all agreed on the value of ephedrine and adrenaline when they first came. We must also not forget that an injection of sterile water will sometimes stop an attack of asthma quite dramatically and within a few minutes. Asthma is a psychosomatic disease, and confidence and enthusiasm are assets in its treatment, as they are in many other illnesses.

It is of interest to learn of Dr. Winton's experience, but one would hesitate to conclude that "at least one essential oil containing many complex substances happens to contain some ingredient or combination of ingredients which relaxes smooth muscle." It does not necessarily follow, for an attack of asthma can be relieved by sterile water injection and also by an enema (I have known quite a few children relieved by enema), but in neither case is there any substance with relaxes smooth muscle. One would hesitate to recommend these methods of treatment as a routine. Carminatives have a very slight antispasmodic action, but it is indeed very slight, even though Dr. Winton tends to push up the dose a little high, and large doses can be dangerous.

A PHARMACOLOGIST writes: According to the published statements the treatment of asthma in children with 2 to 3 minims of ol. myristicae is not without risk. The oil constitutes about 10% of the material present in the nutmeg, and the toxic dose of nutmeg is 5–10 g. Hence the toxic dose of the oil may be as low as 0.5 g., and the doctor is giving nearly that dose. He states that he himself has taken about five times this dose by putting it under his tongue. There is great variation in the toxicity of a substance like ol. myristicae for different individuals, and he may be unusually resistant. There was a discussion of nutmeg poisoning in the *Proc. roy. Soc. Med.*, 1908 (Sect. of Therapeutics and Pharmacology), p. 39, and again in 1909, p. 69, in which Cushny and Dale took part. Numerous cases of poisoning by one or two grated nutmegs were described. There is no mention of an action on smooth muscle. There is a reference to nutmeg as a mild and safe hypnotic for children, and Dale thought that this therapeutic use was at least worth considering.

Foot-drop after Delivery.—Dr. W. S. ANDERSON (Brechin) writes: As a comment to the query on this subject ("Any Questions?" March 7, p. 575) may I state that my one experience of this condition was with a patient who developed foot-drop soon after delivery, and who gradually exhibited the signs and symptoms of disseminated sclerosis, from which she ultimately died some 12 years later? The foot-drop was treated, in the first place, orthopaedically.

Allergic Rhinitis.—Drs. MORRIS CUTNER and B. S. SWEETMAN (Chelsea, S.W.3) write: Your expert writes ("Notes and Comments," March 7, p. 576), "I have no personal experience of histamine ionization, but zinc ionization will help about half those with allergic rhinitis." May we just point out that zinc ionization is a localized treatment applied to the nasal mucosa for a localized result, whereas in the former treatment the histamine is ionized into the skin of the forearm and aims at a cure by effecting a general reaction.

"Any Questions?" Book: Second Series.—This is now available, price 7s. 6d. (postage 6d. extra), from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

ACTION OF THE OVARIAN HORMONES ON UTERINE MUSCLE*

BY

GEORGE W. CORNER, M.D.

Director, Department of Embryology, Carnegie Institution of Washington, Baltimore, Maryland, U.S.A.; George Eastman Visiting Professor, Oxford University, 1952–3

AND

ARPAD CSAPO, M.D.

Staff Member, Department of Embryology, Carnegie Institution of Washington, Lecturer in Obstetrics, Johns Hopkins University School of Medicine, Baltimore

In 1907 Sir Henry Dale reported from his laboratory at Herne Hill the curious discovery that the uterus of the cat does not always react in the same way when its muscular tissue is stimulated through the hypogastric nerves or by intravenous injection of adrenaline. If the cat is not pregnant these stimuli cause relaxation of the uterus, but if she is pregnant they cause contraction. Before Dale's paper was printed Professor A. R. Cushny (1907) made identically the same observation at University College and reported it to the Physiological Society. Although it probably did not occur to either of these eminent pharmacologists that the reversal of muscular response which they had noticed was caused by action of the ovary, and although in fact "pregnancy reversal" still awaits detailed explanation, it was this observation that opened the way to study of the relation between the ovary and the behaviour of the uterine muscle.

In that same year the Heidelberg gynaecologist Erwin Kehrer (1907) was making his pioneer studies of uterine muscle *in vitro*, in which he applied the then very recent discovery of Rudolf Magnus that strips of involuntary muscle cut from the intestine will long remain active if immersed in warm oxygenated physiological salt solution. By attaching such a strip to a lever, the spontaneous isotonic contractions of the muscle and its response to stimulation can be registered. This beautifully simple method began at once to be used in every pharmacological laboratory where oxytocic drugs were studied, Kehrer himself leading the way. In 1908, reporting his first studies on the action of ergot derivatives, he recommended the use of young virgin cats, for he had found that uterine tissue from adult animals taken during the breeding season was often less active and less predictable in its responses. This precautionary specification of the virgin uterus for tests of oxytocic drugs was written into all the pharmacopoeias of the world long before it could be understood in the light of endocrinology.

In 1913 Max Stickel noticed that the movements of the rabbit's uterus *in situ* are greatly reduced by ablation of the ovaries, and a few years later (1919) Athias, of Lisbon, confirmed this fundamental observation by *in vitro* experiments on guinea-pigs' uteri by

*Fourth Annual Ciba Foundation Lecture, delivered in London on December 4, 1952.

the Magnus-Kehrer method. Castration, he wrote, causes a gradual weakening of the automatic contractions to the point of disappearance. If, however, ovarian tissue is regrafted into the animal at the time of castration the uterus retains full power to contract spontaneously *in vitro*. Evidently uterine contractility depends upon an internal secretion of the ovaries. We shall be able, later in this lecture, to explain this remarkable fact, in part at least, on biochemical grounds. Thus, before the two ovarian hormones were isolated or even clearly foreshadowed, characteristic differences in the behaviour of uterine muscle were observed which we can now see were related to the action of progesterone and oestrogen respectively.

Shrewd Conjecture

One of us (G. W. C.) was fortunate in having in his laboratory, about the years 1921–2, a group of medical students doing research on various aspects of the ovarian cycle. Two of these young men, the twin brothers Guttmacher, happened to read Dale's paper of 1907, and made the suggestion that the changes in uterine response to adrenaline observed during pregnancy may be due to the action of the corpus luteum, and hence might be expected to occur also in non-pregnant animals during the corpus luteum phase of the reproductive cycle. This was an extraordinarily shrewd conjecture to be made by medical students. Going on to other studies, the Gutmachers were unable to test their conjecture, and with their consent it was turned over to another student, John D. Keye.

Keye was taught to utilize for this purpose the uteri of swine, which were readily available at an abattoir near the Johns Hopkins Medical School. The sow has a clearly defined reproductive cycle consisting of a follicular phase lasting one week, which culminates in oestrus and ovulation, during which oestrogen is the dominant hormone, and a corpus luteum phase about two weeks in length, during which progesterone is dominant. Such a sequence of events occurs, with various modifications, in all mammals that have been studied. In the rabbit, which is the chief subject of our contribution, oestrus is not periodic and ovulation does not occur spontaneously. Mature does will accept mating at almost any time, and then only do the follicles mature and rupture. The

follicular phase of the cycle (if we may speak of a cycle in this case) is therefore of indefinite length. The corpus luteum phase is ordinarily associated only with pregnancy, but an infertile mating (which may be arranged by the experimenter) gives rise to a corpus luteum phase or "pseudo-pregnancy" comparable in all respects to the corpus luteum phase of the sow's or the human cycle.

Uterine Contraction Pattern

For the purpose of Keye's investigation, strips from sows' uteri at various stages of the cycle were suspended in warm oxygenated salt solution by the Magnus-Kehr technique, and were to be treated with adrenaline and other oxytocics. But Keye (1923) never arrived at that stage of the experiment, for we were amazed to find that the pattern of spontaneous contraction of the muscle, before treatment with oxytocic drugs, varies in a dramatic way throughout the cycle. At oestrus, when ripe follicles are present in the ovaries, the contractions are large and infrequent, occurring once every one or two minutes; during the corpus luteum phase they are small but very frequent, at the rate of five to eight a minute. By observing these changes and the transitions between them it was possible to characterize the contraction pattern almost from day to day of the cycle. Simultaneously with Keye's study, a student of H. M. Evans—Blair (1923)—found something of the same sort in rats. But the shortness of the cycle in that species obscures the pattern of uterine contraction and no further work was done on the rat.

When the ovarian hormones became available they were promptly put to use in following up the earlier observations on uterine contractility. In 1929 Van Dyke and Gustavson reproduced the Dale-Cushny "pregnancy reversal" in kittens treated with crude lipoidal corpus luteum extracts. In the same year S. R. M. Reynolds introduced his ingenious method of recording uterine contractility *in situ* by a small balloon inserted into the rabbit's uterus through a vaginal fistula. He showed (Reynolds, 1931) that spontaneous contractility is almost abolished by castration but is quickly restored by subcutaneous injections of oestrogenic hormone.

Interest in the relation between the hormones and uterine motility was now greatly stimulated by a series of contributions from Herman Knaus (1930). This investigator noticed that uteri of pregnant and pseudo-pregnant rabbits studied *in vitro* do not respond to "pituirrin" by vigorous contraction as do the uteri of virgin rabbits. Learning, as had Van Dyke and Gustavson, of the corpus luteum hormone recently isolated by Corner and W. M. Allen, Knaus made the first crude progesterone produced in Europe, and with it induced in the virgin uterus an altered response to pituitrin resembling that seen in his earlier experiments on pregnant and pseudo-pregnant rabbits. As soon as crystalline progesterone was available, Makepeace, Corner, and Allen (1936) obtained the same result with the pure hormone. Reynolds and Allen (1932) found also that the large, regular, relatively infrequent contractions observed by the Reynolds fistula technique in oestrous rabbits or after oestrogen treatment are almost totally suppressed for hours by a single subcutaneous injection of progesterone. J. M. Robson (1936) added much to our detailed knowledge of the action of oxytocic hormones under varying hormonal conditions.

Beyond this point there has been no significant progress. Summarizing what has been learned, we see that (1) oestrogen is necessary for spontaneous motility; (2) the pattern of spontaneous contraction differs greatly according to the dominant hormone—namely, oestrogen in the unmated and oestrous rabbit, progesterone in pregnancy and in the corpus luteum phase of the cycle (pseudo-pregnancy); (3) the response to stimulation by certain oxytocic drugs may also differ under different hormone domination.

The observed facts cannot all be fitted together, nor do they permit, as yet, effective theorizing about their functional

significance for the behaviour of the uterus as a whole organ. They do, however, provide the basis for a new effort to discover, at the level of the muscle cell, and in biochemical terms, the mechanisms by which the ovarian hormones actually control uterine motility.

Molecular Physiology

For a clearer insight into the myometrial cell we must turn to molecular physiology. One single contraction-relaxation cycle of the uterus, observed in the obstetrical ward as a labour pain, or registered *in vivo* or *in vitro* by the techniques of classical physiology, is clearly a complex phenomenon involving a whole series of elementary events. In 1946 one of us (A. C.), a clinical obstetrician at the time, became convinced, after reading the articles of Szent-Györgyi and his associates, that the function of the myometrium, like that of the voluntary muscle which they were studying, could be understood only if the complexity of the contractile system were broken into simpler component elements and analysed step by step with biochemical and physico-chemical techniques. It was to be hoped that the system thus taken apart can gradually be put together again.

Muscle contraction involves basically a contractile substance, a supply of energy, a stimulus to initiate the contraction, and a means of conducting the stimulus to the contractile elements. Study of the process must be directed toward these four basic systems. The research which we here summarize began with the final contractile substance because, thanks to the efforts of the biochemists, it was far better characterized than any of the other systems.

Szent-Györgyi (1945) greatly simplified the problem by showing that "contraction" can be produced *in vitro* by merely bringing together the isolated constituents of the process—namely, the fibrous protein complex actomyosin (A.M.), the energy-rich nucleotide adenosine triphosphate (A.T.P.), and ions. Thus he claimed that muscle contraction in a final sense is an interreaction between A.M., A.T.P., and ions. His observation was the climax of a long extensive study conducted in several laboratories of different countries and led by outstanding biochemists and physical chemists (see for literature Szent-Györgyi, 1951).

Actomyosin

It is now a textbook statement that the final contractile substance of skeletal muscle is A.M. This complex, first recognized by Banga and Szent-Györgyi (see Szent-Györgyi, 1945), was decomposed in the latter's laboratory into its two component proteins, myosin (M.) and actin (A.). Actin-free myosin was prepared in pure ("crystalline") form by Szent-Györgyi himself, and actin was purified by his pupil Straub. A.T.P., the compound containing high-energy phosphate bonds ($\sim$ ph) was first demonstrated in muscle by Lohmann (1938). Myosin, as Engelhardt and Ljubimowa (1939) have shown, has the property of acting as an enzyme (more specifically, as an adenosine triphosphatase) which can break the high-energy linkage of the terminal phosphate of A.T.P. and release its free energy, calculated by Meyerhof to be 11,000 calories.

Weber (1935), who extracted from muscle a "myosin gel" (now known to consist of actomyosin), was able to form it into fibres similar in appearance to fine cotton threads. Szent-Györgyi (1945) showed that such threads of A.M. will shorten when A.T.P. is added, if they are suspended in a salt solution similar in ionic strength to serum. Objections were raised in various laboratories against the idea of analogy between this thread-contraction phenomenon and muscle contraction. This criticism led to the effort to make the molecular structure of the A.M. thread more like the structure of muscle. This was done by stretching the A.M. fibres, so that the A.M. micelles become parallel as they are in muscle. Such threads shorten and become thicker without changing volume. This effort culminated in Szent-Györgyi's preparation of glycerin-treated psoas muscle from the rabbit (Szent-Györgyi, 1947,

1951) in which the muscle-cell membrane is destroyed (in a functional sense as indicated by the loss of electrical excitability) and the water-soluble components are removed, but the contractile proteins preserve their architecture. When A.T.P. is added, such fibres develop tension similar to that of intact muscle. Taking all the opinions into account, Mommaerts (1950) wrote in his recent survey: "It seems justified to conclude that Szent-Györgyi actually succeeded in a dissolution, separation, and resynthesis of the contractile system."

With the information thus briefly outlined in hand, let us turn to the uterus and ask whether the final contractile system in the myometrium is fundamentally the same as that of skeletal muscle. With modifications required by the smaller amount of material available and the difference in structure, Csapo (1948, 1950a) succeeded in isolating A.M. from human, rabbit, rat, and cow uteri.

All tests performed so far on the A.M. of the uterus support the conclusion that it is fundamentally the same as that of skeletal muscle. It is true that slight differences have been observed between the two substances, which may be partly responsible for the differences between the two kinds of muscle long known to physiologists. First, however, let us consider the similarities.

Characteristics of Actomyosin

What are the characteristics of actomyosin? (see literature, Szent-Györgyi, 1951). A.M. can be extracted from fresh muscle by 0.5 mol KCl, and can be purified simply by precipitation by dilution. If redissolved in 0.5 mol KCl it has a high anomalous viscosity, which indicates that it is made up of highly asymmetric particles. If the purified extract is studied in the Svedberg ultracentrifuge or the Tiselius electrophoretic apparatus it tends to be distributed into two portions, yielding curves with a larger peak which represent A.M. and a smaller peak representing free M. uncombined with A. (Snellman and Erdős, 1944a, 1948b).

If A.T.P. is added to A.M. in the viscosimeter an immediate drop in viscosity will be observed. The viscosity of the component proteins, A. and M., being less than that of the complex, A.M., this drop in viscosity indicates the dissociation of the complex into its component parts. M. being an A.T.P.-ase, A.T.P. will be split and its dissociating effect on A.M. will be terminated; the A. and M. will then reassociate, combining to form A.M., as indicated by the gradual rise in viscosity. Actomyosin threads can be prepared from uterine muscle and will contract energetically when A.T.P. is added.

All the properties just mentioned are characteristic of uterine A.M. as well as that from skeletal muscle. As for the differences, observations by viscosimetry show that the amount of A.M. is much less in the uterus than in skeletal muscle (about one-seventh) and, moreover, A.M. forms only about one-third of the total amount of the contractile proteins, whereas in skeletal muscle extracts two-thirds is A.M. (Csapo, 1948, 1949, 1950a, 1950b).

By following the change of viscosity when A.T.P. is added to identical amounts of the two kinds of contractile proteins it is found (Csapo, 1949) that the recombination of uterine A.M. indicated by increase in viscosity does not begin as soon and does not proceed as fast as does that of skeletal muscle. This can be explained either by a lower A.T.P.-ase activity of the uterine extract or else by the lower activity of the myokinase system resulting in the accumulation of A.T.P. which keeps A.M. dissociated.

When the "contraction" of threads of the two kinds of actomyosin is compared (Csapo, 1950a), it is found that uterine A.M. contracts much more slowly than that from skeletal muscle, and with a longer "latent period" after the addition of A.T.P. Moreover, uterine A.M. threads contract only below the A.T.P. concentration of 4×10^{-3} mol. At this critical concentration the threads first lengthen before they contract, whereas above this concentration they

completely dissolve. In contrast threads of similar A.M. concentration (obtained by dilution) from skeletal muscle readily contract even in a twenty-times higher concentration of A.T.P. solution (Csapo, unpublished).

Uterine A.M., unlike that of skeletal muscle, practically loses its ability to contract (Csapo, 1949) if precipitated only once (by dilution). This process is reversible, however, and the precipitated A.M. can be reactivated if fresh watery extract is added to the precipitate or to the salt solution in which the thread is suspended. The speed of thread contraction thus depends on a factor (or factors) present in the watery extract of the uterus, and the speed of contraction is directly related to the concentration of this factor, which we will call "X." Skeletal muscle also contains X-factor in a much higher concentration or else in a more active form (Csapo, 1949). This matter of the X-factor is mentioned to emphasize the possibility that the differences between skeletal and uterine muscle extracts are not all necessarily due to differences of the A.M. itself, but may well be due to differences in their prosthetic groups or other active substances attached to the A.M. framework. When highly purified actin and myosin from the uterus become available this question can be further studied.

In summary, the final contractile substance in uterine muscle is actomyosin, generally resembling the characteristics of the contractile protein-complex of skeletal muscle, but present in much lower concentration and forming a smaller fraction of the total proteins.

Effect of Ovarian Hormones on Contractile Proteins of Myometrium

Next let us examine the effect of the ovarian hormones upon the contractile proteins of the myometrium. In skeletal muscle the concentration of A.M. and the ratio of A.M. to free M. are found to be constant. In uterine muscle, however, the concentration of A.M. is significantly different under varying hormonal conditions of the ovaries. When a rabbit is castrated the concentration of A.M. drops to about one-fifth that found in the oestrous animal. In late pregnancy, on the other hand, the concentration is about twice as much as in oestrus. In oestrus, moreover, two-thirds of the contractile protein is free M. and only one-third is A.M., whereas in late pregnancy the ratio is reversed, as viscosimetry has shown. The same holds for the human as demonstrated by ultracentrifugation and electrophoresis. These observations already suggest that the concentration of uterine A.M. is under the control of the ovaries (Csapo, 1948, 1950a, 1950b; Csapo, Erdős, Naeslund, and Snellman, 1950).

Studying the course of the change in A.M. concentration during pregnancy in rabbits, we observed a slight drop in the first third, followed by a sharp increase in the second third. A high plateau is maintained in the last third of pregnancy with a climax at labour, after which the concentration of A.M. drops rapidly to the non-pregnant (oestrous) level. This curve gives a further indication that oestrogen is responsible for the changes in A.M. concentration of the uterus (Csapo, unpublished). Final evidence for this conclusion was given by the following experiments.

Rabbits were bilaterally ovariectomized and a few weeks later the previously mentioned great decrease in A.M. concentration of the uterus was observed as a result of the castration. Oestrogen was then administered, and a gradual increase in the A.M. concentration caused by the removal of both ovaries can be experimentally reversed by supplying oestrogen to the animal (Csapo, 1950b).

In another set of experiments it was found that progesterone does not have any such effect as oestrogen upon concentration of A.M. in the uterus (Csapo and Corner, 1951). We believe that the slight drop of A.M. concentration during the first week of rabbit pregnancy mentioned above is due to the decrease or disappearance of tissue oestrogen and not to the increasing action of progesterone.

How oestrogen controls A.M. concentration in the uterus we do not know as yet. As pointed out by D. Needham (1952), it is possible that oestrogen affects the formation of A.M. by providing a means by which the "building stones" or precursors (of smaller molecular weight) are bound together to form longer fibrous units. This mechanism cannot, however, be the only one involved in A.M. formation, since in an oestrogen-treated castrate rabbit the uterine weight increases ten to twenty times while the protein concentration per unit of weight is also increasing. Thus large amounts of proteins must be synthesized as a result of the action of oestrogen upon the uterus. It is worth emphasizing that in the uterus we possess a tissue in which the effect of oestrogen on protein synthesis has been experimentally established. In skeletal muscle similar changes have been observed only during embryonic and post-natal development (Csapo and Herrmann, 1951); once sexual maturation is complete the contractile proteins of skeletal muscle are not subject to hormonal control.

The concentration of A.M. in uterine muscle is, however, not alone affected by oestrogen; the properties of extracted A.M. are also changed. With the viscosimeter we find that the "splitting-time" of A.T.P. is reduced by oestrogen treatment and the recombination of dissociated A.M. after A.T.P. has been split becomes faster (Csapo, 1949). The speed of A.M. thread contraction is also increased, as shown in specimens from late pregnancy (Csapo, 1948, 1950a). We assume tentatively that the concentration or activity of the X-factor is also affected by oestrogen.

Relation of Ovarian Hormones to the Energy-yielding System of the Uterus

With this we conclude our brief summary of the facts known at present about uterine A.M. and its dependence upon oestrogen. The next inquiry concerns the relation of the ovarian hormones to the energy-yielding system of the uterus. Before proceeding any further we must recall Szent-Györgyi's thread-contraction experiments, from which it is evident that not A.M. but A.M.-A.T.P. is the final contractile substance. Experiments in our laboratory have shown (Csapo and Gergely, 1950) that the total high-energy phosphate content of the uterus is only about one-seventh that of skeletal muscle, and recent measurements by means of Kalckar's differential spectrophotometric technique show that the same ratio holds for A.T.P. in particular (Menkes and Csapo, unpublished). Others have observed similar or lower values for the $\sim$ ph content of the uterus (see for literature Walaas and Walaas, 1950a). Since the concentration of actomyosin in uterine muscle was also found to be one-seventh that of the skeletal muscle a stoichiometric relationship may be assumed to exist between A.M. and A.T.P. The amount of A.T.P. present is much greater than is used in one concentration cycle, and since resynthesis of A.T.P. goes on with great speed the surplus may serve other purposes, such as to make the system complete and reactive. We calculated the amount of A.T.P. used in one contraction cycle and arrived at the figure of 0.25 micromols $\sim$ ph bond energy per gramme uterus per contraction (Csapo and Gergely, 1950). This value is identical with that calculated by A. V. Hill for skeletal muscle.

When the uterus is not under the influence of oestrogen its high-energy phosphate store is at a low ebb. In immature rabbits and also in adults after castration we found (Menkes and Csapo, 1952) a low concentration of A.T.P. and absence of creatine phosphate (C.P., another energy-rich phosphate ester in muscle from which the depleted A.T.P. is immediately resynthesized through the Lohmann reaction). Since the A.M. concentration is also very low in these conditions and there is no significant muscle function, A.T.P. is split only slightly and can be resynthesized slowly by other means than through C.P. The presence of a supply of A.T.P., thus maintained, without appreciable contractile activity indicates that this substance is essential not only for the contractile function but also for the

"private life," so to speak, of the myometrium. A certain amount of it is obviously required merely to keep the tissue alive.

When during sexual maturation the ovaries become functional and oestrogen production is increased, A.T.P. begins to increase and C.P. appears in significant quantities (Menkes and Csapo, 1952). The same occurs when oestrogen is administered experimentally to ovariectomized animals (Menkes and Csapo, unpublished). The increase of high-energy phosphates in response to oestrogen treatment is much quicker than that of A.M., and their concentration in the muscle reaches a climax while A.M. concentration is still not maximal and function is not yet fully restored. One possible explanation of the early rise of A.T.P. is that it may be involved in the resynthesis of the contractile proteins.

If oestrogen administration is continued, the $\sim$ ph will not increase further. These observations seem to be in contradiction to what one would expect when function is maximal. There is, however, another mechanism which takes care of the energy supply of increased function without increase of the concentration of A.T.P., by controlling the turnover of $\sim$ ph. As shown by Walaas and Walaas (1950b) and by Borell (1951), using P^{32} , oestrogen increases the turnover of the easily hydrolysable phosphate esters of the uterus. Thus we assume that in the castrated or in the immature animal—that is, in the non-functional uterus—both the final contractile system and the energy-yielding system are quite incomplete. If oestrogen is administered, A.T.P. and the turnover of the high $\sim$ ph increase with the simultaneous appearance of C.P. The increase in A.T.P. concentration soon becomes constant while function is still increasing, the extra amount of energy used being compensated for by the increased turnover of $\sim$ ph. A similar phenomenon has been observed in our laboratory to occur in the uterus during pregnancy (Menkes and Csapo, 1952). Until the twentieth day of pregnancy in rabbits the easily hydrolysable phosphate fraction of the uterus gradually increases. No further increase, but rather a decrease, can be observed after this period, which coincides with the beginning of a gradual increase in muscle activity and pharmacological reactivity. Thus we must assume that the low concentration of $\sim$ ph found after the twentieth day of pregnancy or in oestrus is optimal for maximal function, and the increased use of energy is taken care of by increased turnover of $\sim$ ph.

Progesterone, unlike oestrogen, has no activating effect on the uterus of castrates nor a regenerating effect on the final contractile system (Csapo and Corner, 1951). It increases the concentration of the easily hydrolysable phosphate fraction without influencing the A.T.P. concentration. It results, as observed so far, in the accumulation of an unknown compound in this fraction which is neither A.T.P. nor A.D.P. (Menkes and Csapo, unpublished). This effect can be evoked by injected progesterone or by mating (which results in natural progesterone domination through ovulation and corpus luteum formation). It has been shown recently by Walaas (1952) that oestrogens selectively increase the glycogen (and thus the potential $\sim$ ph) content of the myometrium of rats and rabbits. The effect is absent in the endometrium and in skeletal muscle and is independent from the blood-sugar level. He concludes that an increased rate of the hexokinase reaction is responsible for increased glycogen formation resulting from oestrogen effect. He found progesterone to be ineffective on the glycogen concentration of the uterus. All these observations indicate that the ovarian hormones affect the energy-yielding system of the uterus, but much more needs to be done before a more complete understanding can be achieved.

Considering the varying concentrations of actomyosin and of high-energy phosphates in various hormonal conditions of the reproductive tract, we ask how these changes alter myometrial function. For the answer we must turn to living muscle and the

data obtained at the molecular level. A first step in this direction is to observe the relation between actomyosin concentration in the myometrium and the working capacity of the muscle. The most adequate measure of this function is the isometric tension; that is to say, the force developed by contraction of an electrically stimulated strip of muscle that is not allowed to shorten. Thermodynamic studies of Szent-Györgyi (1951) and his associates on frog skeletal muscle have shown that for adequate information on working capacity isometric tension must be studied rather than isotonic amplitude.

One would expect that under well-standardized and optimal conditions the maximum isometric tension which the muscle is able to develop will depend on its actomyosin concentration. Experiments confirm this. After castration the actomyosin concentration and the maximum isometric tension both fall practically to zero and both are restored in similar fashion by administration of oestrogen. The ratio of actomyosin concentration in the oestrous uterus to that of the castrate is 4.6:1; the ratio of maximum isometric tension in the two conditions is 4.2:1. Progesterone, on the other hand, does not affect either actomyosin concentration or maximum tension (Csapo and Corner, 1953).

An Unexpected Observation

During the course of our work on isometric tension we made an unexpected observation which we think will help in understanding just how the ovarian hormones act upon the tissue which they affect. The answer to this question being of extreme importance in the physiology of reproduction, we summarize here what we have discovered, although the final proofs are still not available.

It is well established that the function, not only of the myometrium but of all other parts of the reproductive tract, is determined in a final sense by the two ovarian hormones, oestrogen and progesterone (see for literature Reynolds, 1949). Removal of both ovaries results in partial atrophy of the whole reproductive tract, including the myometrium. Castrate atrophy can be avoided, or, if it occurs, the original condition can be restored by the administration of oestrogen to the castrated animal. Special histological and physiological changes functionally adapted to pregnancy are brought about by progesterone.

How the ovarian hormones act upon the tissues to produce these conditions is unknown, and, indeed, the hope of understanding their basic action has been slight because of the great variety of their effects upon various elements of the reproductive tract. It has, however, proved helpful to assume that each ovarian hormone has but one type of effect, which shows itself in different ways in various parts of the reproductive tract because the structure and function of the component cellular elements are different. Moreover, the action of oestrogen and progesterone on a specific tissue, often seemingly opposite or antagonistic, may be fundamentally similar, differing only in the direction of the effect produced. This conjecture rests on a more general assumption about hormone action developed by Dr. Albert Szent-Györgyi (personal communication) from studies of the isolated frog heart, which postulates that hormonal effects are exerted upon the ionic balance of the living cell, and thus the same hormone may similarly affect tissues which are quite different in their organized structure and functions.

Maximum Isometric Tension in Relation to Stimuli

Although in our experiments with the final contractile system we followed the effect of the ovarian hormones down to the molecular level, we do not suppose that their effect

actually occurs at this low level of organization and that the hormone directly participates in the individual reactions of which myometrial function is composed. No one, indeed, has ever demonstrated an effect of the sex-gland hormones on any isolated enzyme system, a negative fact which makes it probable that these hormones act at the cellular level, and that their action is to produce favourable or unfavourable conditions for a set of reactions taking place in the cell. Our experiments so far indicate, though they do not

Fig. 1.—Dependence of maximum isometric tension on frequency of stimulation. Electrical stimulation at intervals of $\frac{1}{4}$, 1, 2, and 4 minutes. A, oestrogen-treated castrate; B, castrate treated with oestrogen plus progesterone; C, untreated castrate; D, natural oestrus; E, seven-days pregnancy.

as yet completely prove, that the effect of the ovarian hormones on the myometrium is accomplished by alteration of the potassium balance of the myometrial cells. The new observation from which this conclusion stems is that the maximum isometric tension which a strip of uterine muscle can develop depends on the rate at which successive stimuli are applied. If the rate of stimulation is varied from once every half-minute to once in four minutes, the oestrogen-dominated uterus exhibits a decrease in tension with decreasing rate of stimulation (Fig. 1), whereas the progesterone-dominated uterus increases its tension as the intervals become longer. This difference occurs not only in castrates treated with the respective hormones but also in intact animals under natural conditions—that is, in oestrus and pregnancy. Whether the hormone is supplied by the animal's own ovaries or by infection, the effect is the same. It should be added that the castrate uterus is insensitive to changes in rate, its weak isometric contractions developing the same tension regardless of the intervals.

It is surprising to see that the progesterone-dominated uterus, which completes a single isometric contraction cycle in shorter time than the oestrogen-dominated muscle, requires more rest between two stimuli in order to develop maximum tension. Return to zero tension, therefore, does not indicate complete recovery of the contractile system as a whole in the progesterone uterus. We first believed that the incomplete resynthesis of $\sim$ ph was responsible for the unique behaviour in this hormonal condition. This possibility can still not be completely disregarded in view of the active sodium transport, which may overlast the contraction cycle and which uses a considerable amount of energy (Steinbach, 1952). The suggestion of Ling (1952) also has to be considered, that high-energy phosphates influence muscle function not only because of their stored energy but also because of their high-valency negative charges, which participate in linking cations to the contractile proteins. Their concentration, therefore, will partly determine the cation gradient between the outside and the inside of the cell on which the resting potential depends. A more direct explanation results from the realization that the effect we have been discussing is quite similar to the well-known staircase phenomenon of heart muscle.

Hajdu and Szent-Györgyi (1952) have recently studied the Bowditch phenomenon of the frog heart under isometric conditions, varying the frequency of stimulation in a "steady state." They find that the steep slope of the staircase that develops in regular Ringer-Conway solution can be completely abolished if the potassium concentration of the perfusion fluid is decreased to one-eighth of the usual level.

Referring to the data of Fenn (1937) and Fenn and Cobb (1936), who found that contraction entails a loss of potassium, they assumed that the resting frog heart contains more intracellular potassium than is optimal for the development of maximum tension, and therefore the heart must be stimulated very frequently to exclude the supra-optimal amount of potassium and keep it out. If stimulation is discontinued, intracellular potassium accumulates, the staircase reoccurs, and the tension drops. This effect can be abolished by decreasing the potassium outside, the increasing gradient being unfavourable to the return of potassium. They have also demonstrated that the staircase disappears at 0° C., whereas its slope becomes steeper with increasing temperature. Serum, desoxycorticosterone, and digitalis glucosides have the same effect as the decrease of potassium in the perfusion Ringer. They believe that these substances inhibit the return of potassium to the cell.

The Uterine Staircase

We have shown that the uterus of a castrate rabbit exhibits no staircase if stimulated with constant frequency after a period of rest (Fig. 2). This suggests that the phenomenon

FIG. 2.—Uterine staircase. Maximum isometric tension developed upon stimulation at intervals of 1 minute, beginning after 10 minutes' rest. Castrated mature virgin rabbits; A, treated with oestrogen; B, oestrogen plus progesterone; C, untreated.

is not a fixed characteristic of the myometrium, but rather an expression of the dominant hormonal effect. The oestrogen-dominated uterus has a similar staircase to that of the frog heart, as first observed by Bowditch, whereas the progesterone-dominated uterus behaves in an opposite manner—that is, it has a staircase sloping

in the reverse direction, which will be designated as "negative staircase" in contrast to the regular or "positive staircase" (Csapo and Corner, 1952).

One would expect to see slopes intermediate between the extreme positive and negative staircase if the two hormones are simultaneously administered in various proportions. Experiments have shown this to be the case. For this and similar studies in which quantitative precision is important the frequency of stimulation has to be varied in an otherwise steady state.

The staircase was found to be most negative in early pregnancy. This condition can be imitated in the castrate only if after three days' oestrogen treatment progesterone is administered without oestrogen, a fact which suggests that the latter is not present during the first few days of pregnancy. By the administration of oestrogen during early pregnancy we expected, therefore, to produce a levelling effect on the negative slope of the staircase and also a disturbance of pregnancy. We found that a single dose of 5 µg. of oestrogen per 4 kg. body weight, administered between the second and fifth days of pregnancy, significantly reduces the slope of the negative staircase and completely abolishes pregnancy (Csapo, 1953).

Effect of Temperature and the Potassium-sodium Ratio

Inasmuch as the staircase so accurately reveals the delicate balance of the ovarian hormones, it is important to learn its nature. In agreement with Hajdu and Szent-Györgyi's observation (1952), we found that the positive staircase of the oestrogen uterus disappears at low temperature (Fig. 3), whereas its slope increases with increasing temperature. On the other hand, the negative slope of the

FIG. 3.—Temperature dependence of slope of staircase and negative staircase.

staircase of the progesterone uterus decreases with increasing temperature. Like the frog heart, the oestrogen uterus exhibits an increase in tension within about two minutes if the potassium-sodium ratio is decreased in the bath. The staircase does not disappear, however; its slope is only slightly reduced. If the tissue is subjected to repeated washing for half-hour periods in potassium-free Krebs solution, a gradual decrease in the slope of the staircase can be observed, with a complete disappearance of the staircase after about two hours' treatment, but at the same time the tension also decreases gradually (Csapo, 1953).

If the oestrogen uterus is kept in potassium-free Krebs solution as before and the perfusion fluid is then changed to normal Krebs solution, the potassium-sodium ratio thus being suddenly increased, and if the muscle is stimulated once every half-minute, the tension drops and remains at the low level for about 20 minutes, increasing slowly thereafter. If during this short period of time the staircase is observed a negative slope appears. Thus this rather drastic treatment results in behaviour of the oestrogen uterus similar to that of the progesterone uterus. It is a transitory effect, however, and after the 20 minutes the staircase is positive again (Csapo, 1953).

The effect of alterations in temperature and potassium-sodium ratio can be more easily observed with the progesterone-dominated uterus (Fig. 4). Increase of either

FIG. 4.—Dependence of slope of negative staircase upon potassium concentration and temperature.

temperature or the external potassium-sodium ratio results in gradual disappearance of the negative staircase. At sufficiently high potassium-sodium ratio outside (about fourfold increase in potassium concentration of the original Krebs solution), the negative slope of the staircase with the progesterone uterus not only disappears but there is a slight positive slope, such as is characteristic of the oestrogen uterus. Thus by alterations in the potassium concentration of the perfusion fluid the characteristic behaviour of oestrogen and progesterone uteri with respect to the slopes of their respective staircases can be more or less completely reversed (Csapo, 1953).

A striking difference in the behaviour of oestrogen and progesterone uteri with respect to maximum tension also appears if the potassium-sodium ratio outside is gradually increased (Fig. 5). The oestrogen uterus exhibits

FIG. 5.—Dependence of maximum isometric tension upon potassium concentration. Each bar represents a group of four contractions in response to stimulation at 1-minute intervals. The K concentration is raised in each group from left to right, from standard or half-standard K concentration of Krebs solution, to standard or half-standard K concentration of Krebs solution; B, 2×, 3×, . . . 10×K. A, castrate treated with progesterone; C, as A; D, castrate treated with oestrogen plus progesterone; C, after 24 hours' storage at 0° C. strip from same uterus as C, but after 24 hours' storage at 0° C. Note resemblance in Krebs solution of standard K concentration. to B.

decrease in maximum tension with increasing potassium-sodium ratio, whereas the progesterone uterus shows the opposite behaviour up to a threefold increase in the potassium concentration over the original Krebs solution. If the oestrogen uterus is subjected to storage it loses its characteristic behaviour and exhibits a pattern similar to that of the progesterone uterus (Csapo, 1953).

The duration of a single isometric contraction cycle is also greatly dependent on temperature and on the external potassium-sodium ratio. In general, a decrease in temperature increases the duration of both oestrogen and progesterone uteri, but the former has a much greater temperature dependence. Decrease in the potassium-sodium ratio outside increases the duration of the contraction of the oestrogen uterus and steepens the ascending phase of the isometric contraction cycle. The progesterone uterus has no change in duration under similar experimental conditions (Csapo, 1953).

Conclusions

From these experiments one can conclude that oestrogen and progesterone alter myometrial function in 'opposite directions, as revealed by measurements of maximum isometric tension. Their effect can be counteracted or even reversed *in vitro* by changing the temperature or the potassium concentration of the perfusion Krebs solution. Whether a different intracellular potassium concentration exists in the uterus *in vivo* in the two contrasting hormonal conditions or as a result of the alteration of the potassium concentration in the perfusion fluid, we cannot say as yet, because we do not know the extent of the extracellular space in the uterus. It is possible that not the absolute quantities of the respective ions, but rather the dynamics of their movements, are changed. If the intracellular potassium concentration is changed as a result of hormonal action, the question ought to be considered whether a change in the distribution of other ions occurs simultaneously as a consequence of this alteration or as an independent effect.

The demonstrated *in vitro* effect of the potassium ion on the myometrial cell cannot be discussed in any detail at present, because the system in which the experiments have been performed is too complex. Hajdu and Szent-Györgyi (1952) proposed that alterations in the potassium balance of the muscle cell directly affect the contractile protein, actomyosin. The effect of potassium is, however, probably more complex. Its extreme importance in activating enzyme reactions, especially those involved in the glycolytic sequence of rabbit skeletal, cardiac, and uterine muscle, has been recently emphasized by Boyer (1953). We know from Walaas's work (1952) that oestrogen controls glycogen formation in the myometrium, perhaps through the hexokinase system.

Thus we have to consider, as one possibility, that the ovarian hormones, through their alteration of the potassium balance of the myometrium, will modify the activity of specific enzyme systems, especially those involved in cellular energetics. Ling (1952) has shown that A.T.P., C.P., and hexosephosphates occupy key positions in muscle function not only because of their stored energy but also because of their high-valency negative charges which link cations (especially potassium) to the contractile and other proteins of the muscle cell. Their concentration therefore determines not only the amount of energy which can be spent immediately during activity but also the gradient of cations between the outside and the inside of the cell, which in turn determines the resting potential of the cell. Thus we see that a change in the potassium balance of the myometrium evoked by the action of the ovarian hormones might easily modify a whole series of intracellular reactions, thus producing great variations in function of the organ as a whole.

This concept may ultimately not only explain the "pregnancy reversal" described 45 years ago by Sir Henry Dale but also provide a key to many other problems of uterine physiology and hormone action.

The *Journal de Génétique Humaine*, a new quarterly publication, is intended for doctors, biologists, anthropologists, and others interested in problems related to heredity. Its editorial board comprises Professor A. Franceschetti (Geneva), Professor L. van Bogaert (Antwerp), and Professor M. Lamy (Paris). The journal is published by Editions Médecine et Hygiène, 15, Boulevard des Philosophes, Geneva, and the subscription is 30 Swiss francs (£2 10s.) per annum.

A SURVEY OF PRESCRIBING IN SCOTLAND IN 1951

BY

D. M. DUNLOP, M.D., F.R.C.P., F.R.C.P.Ed.

R. S. INCH, M.B., Ch.B., M.R.C.P.Ed.

AND

J. PAUL, Ph.D., M.B., Ch.B., M.R.C.P.Ed.

(From the Department of Therapeutics, University of Edinburgh)

A survey of 17,301 prescriptions issued on Form E.C.10 in England in 1949 (Dunlop *et al.*, 1952) provided an incentive to a further and more extended investigation of prescribing, and in addition indicated how a subsequent study could be planned in order to give more varied and statistically valid information, and to avoid some of the errors to which our attention was drawn in the previous paper. Scotland was chosen as the area to be surveyed, as it formed a manageable unit and represented all types of medical practice.

Material and Method

The material consisted of an approximately 1% sample of all E.C.10 forms issued in each of the 25 executive council areas in Scotland during the month of October, 1951. There were 13,340 of such forms, which included a total of 18,848 prescriptions. Except for a few minor changes the method of tabulation and sorting was similar to that adopted in our previous survey of English prescriptions. Nevertheless, since the method of selection was different and since the present survey follows the previous one after an interval of two

years, no very close comparison can be made between the results of the two surveys. It will be seen, however, that on the whole the frequency with which different drugs are ordered and the form in which they are prescribed are not dissimilar in England and Scotland.

In addition to the E.C.10 forms all the E.C.10A forms (stock order forms) for the same month of October were scrutinized. Their total number was 1,569. In Scotland such forms are used by practitioners to order drugs and appliances which they personally administer.

Results

That the orders on E.C.10A forms comprised only an insignificant part of the cost of the total prescriptions is indicated by the following figures:

Total cost of orders on Form E.C.10A in Scotland in October, 1951	£ 8,500
Total cost of prescriptions on Form E.C.10 in Scotland in October, 1951	412,500

Thus the cost of orders on Form E.C.10A comprised only about 2% of the total prescribing costs, and involved an average yearly expenditure per practitioner of £42 10s. About 45% of the orders on these forms were for dressings and appliances.

A study of the E.C.10A forms revealed only a small number of lavish and extravagant orders, though a total of 200 ml. of a proprietary liver extract on one form seemed hard to justify. Over 7 tons (7,112 kg.) of cotton-wool are ordered yearly on E.C.10A forms alone. Though the figure seems formidable, it represents a yearly consumption of rather less than 6½ lb. (2.9 kg.) per doctor.

The figures in Tables I and II have been grouped under the five Scottish regions. In addition those pertaining to the four main cities have been extracted separately. Even with this grouping a considerable variation in the average number of patients per practitioner (list size) and in the number of E.C.10 forms issued per unit (1,000 persons) of population is apparent, and the proportion of E.C.10 forms

Amphetamine	2.0	1.8	2.1	1.7	1.3	1.5	1.9	1.8	0.5

issued per unit of population seems to vary according to the population density of the area. The significance of this finding is discussed later.

Vitamins, tonics, and symptomatic remedies (sedatives, hypnotics, analgesics, cough mixtures, stomachics, and laxatives) constituted 51.6% of all prescriptions written. A large proportion of these drugs must be prescribed as placebos. They are often relatively cheap in themselves, yet the total cost of compounding and packing them is relatively enormous. Thus, if the cost of prescriptions to the State is to be diminished it must be directed to a reduction of these symptomatic remedies as well as to extravagant prescriptions of expensive drugs to which so much attention has been directed in the past.

The general pattern of prescribing was similar to that found in the earlier English survey, but the following points seem worthy of emphasis because of their dissimilarity or of reiteration because of their importance.

As was to be expected after a lapse of two years, there was some increase in the prescription of newer drugs such as the antibiotics and the antihistamines. In Scotland, however, the prescription of the amphetamines was not significantly more frequent than it had been in England two years previously—a somewhat surprising finding in view of the Pricing Bureau's figures for 1952.

The variation in the proportion of proprietary preparations prescribed in the different areas was not great, but the overall proportion (30%) is considerably higher than the corresponding figure (21%) in the previous survey. An accurate comparable English figure for 1951 was not available to us, but this suggests that the tendency to prescribe proprietary medicines is either increasing generally or is greater in Scotland than in England.

It is satisfactory to note that bromides were prescribed alone very rarely (1%) compared with the previous English figure of 5.8%. Bromides seldom prove more effective than phenobarbitone either as sedatives or as anticonvulsants. Their frequent side-effects and the undesirable cumulative toxic effects which result from their prolonged administration relegate bromides to the group of drugs which should largely be discarded in modern therapeutics. Bromides, however, were prescribed with chloral hydrate on 40 occasions, representing some 4,000 of such prescriptions in Scotland in

October, 1951. It seems unfortunate that this mixture should appear in the *National Formulary* for 1952, for bromides are sedatives which have to be administered frequently before there is a sufficient replacement of chloride by bromide ion to exert a depressant effect on the central nervous system, and their occasional administration with a hypnotic such as chloral has no more effect than a dose of salt water.

Compound cough mixtures containing sedatives and expectorants were ordered as often as sedative preparations, but purely expectorant cough mixtures were not ordered as often as either. This is satisfactory, as there is considerable doubt about the value of expectorants, which were found to be very commonly prescribed in the English survey.

The proportion of prescriptions for cough mixtures was higher in the urban than in the rural areas. This was particularly noticeable in the case of Aberdeen City (12.4%) in comparison with the remainder of the North-eastern Region (7.7%). Such figures seem to indicate that coughs are one of the hazards of city as opposed to country life, and support is given to this hypothesis by the mortality figures for respiratory disease in the Registrar-General's report. On the other hand, there was no constant similar trend in the proportion of prescriptions for stomachics in town and country, which does not support the general impression that dyspepsia is also one of the penalties of urban life.

As in the previous survey, vitamins were prescribed more often than iron, and constituted about 5% of all prescriptions. The actual number of prescriptions for vitamins in the 1% sample of prescriptions analysed was 976—that is, approximately 97,600 for the month of October in Scotland, or over one million for the year. When it is remembered that the average prescription on Form E.C.10 costs the country over 4s., and that vitamins are often relatively expensive drugs, a very conservative estimate of the cost of vitamin prescriptions in Scotland for the year is £230,000. As the population of Scotland is about one-ninth that of the United Kingdom it might be argued that the bill for vitamin prescriptions alone in Britain is at least £2,000,000. This estimate is intentionally a very conservative one, since, as will be seen later, the number of prescriptions issued in October happened to be above average. That the figure

is not an overestimate can be deduced from the fact that vitamins account for at least 5% of the total annual expenditure on drugs, which was well over £40,000,000 in 1951, giving a figure in excess of £2,000,000. It is probable that only a very small proportion of the vitamin prescriptions representing this vast sum serve any very useful purpose, especially as cod-liver oil and orange juice for babies and expectant mothers are issued at antenatal and child welfare centres and do not appear on Form E.C.10. When it is recalled that, owing to the present financial position of the country, health centres cannot be built and that all hospital boards are being faced with serious difficulties as regards the staffing and general administration of their hospitals, these figures applied to vitamins alone, quite apart from other placebo prescriptions, deserve serious consideration.

In the English survey it was noted that liver extracts were ordered 50 times, in comparison with only 68 prescriptions for insulin. As the megaloblastic anaemias are relatively uncommon in comparison with diabetes mellitus it was concluded that liver extract was often used for its questionable general tonic rather than for its haemopoietic properties or for anaemias other than megaloblastic, for which it could be of no service. The present survey gave even more striking figures in this respect, for it showed that liver extract was ordered 125 times, in comparison with only 97 prescriptions for insulin and 134 for digitalis. Further, folic acid was ordered 32 times. When it is recalled that this drug should be used only in tropical sprue and in some rare cases of megaloblastic anaemia, such as the megaloblastic anaemias of the malabsorption syndrome and pregnancy, and that it is absolutely contraindicated in pernicious anaemia, some 3,000 prescriptions for it a month in Scotland would seem to be excessive.

It has been suggested from time to time by lay members of executive councils that quantities of expensive toilet requisites are commonly prescribed on Form E.C.10. This survey did not suggest that there was any justification for such strictures.

Factors Influencing Prescription Rates

The interest of these various findings should not divert attention from the more fundamental fact, demonstrated in Table I, that there is a remarkable variation between the different areas in the number of scripts (E.C.10 forms) issued per unit of population, although there is generally not much variation in the type of drug prescribed (Table II). It was realized that the figures for October alone might not give a truly representative picture of prescribing practice. Consequently the information shown in Table III for the months of July to December, 1951, inclusive was obtained. It will be noted that the number of scripts issued in October, which was chosen fortuitously for the detailed survey, was actually considerably higher than in the other months. The data collected in Table III are analysed in Table IV and in Figs. 1, 2, and 3.

Table IV suggests that there is a relationship between the script rate and the population density, though the position of Banff at the head of the list is inexplicable. The figures for population density do not take into account the uneven distribution of the population over the areas concerned. Thus in Lanarkshire there is a highly industrialized portion in the north, where the population is of almost urban density, while the remainder of the county is agricultural and sparsely populated. The same considerations apply to Fife, Dunbarton, Dumfries, and Stirling, and account for their apparently incongruous position in the Table. That there is nevertheless a definite statistical relationship between script rate and population density is obvious from Fig. 1.

Fig. 2 shows that the script rate varies with list size, and it can also be demonstrated that there is a statistical correlation between list size and population density. There is thus an intimate interrelationship between these three factors—script rate, population density, and list size.

FIG. 1.—Correlation between script rate and population density. ($Y = 225.1 + 26.9X$; $r = 0.617$; $P < 1\%$, d.f. 23.)

FIG. 2.—Correlation between script rate and list size. ($Y = 83.3 - 0.0667X$; $r = 0.7$; $P < 1\%$, d.f. 23.)

FIG. 3.—Correlation between coefficient of variation of monthly script rates with population density. ($Y = 10.44 + 2.75X$; $r = 0.83$; $P < 1\%$, d.f. 23.)

* See text.

The correlation between script rate and population density is an overall relationship, since associated with population density, though not necessarily dependent upon it, are such factors as the availability of the doctor, differential morbidity, the psychological attitude of the patient to disease, and the list size. Thus in urban areas the practitioner is usually conveniently available for a consultation and a prescription, often for very trivial maladies, in contrast to the Highlands and Islands of Scotland, where moor and fen, crag and torrent, and even stormy seas may intervene between the patient and doctor. Secondly, there may be an increased morbidity in the urban as opposed to the country population. Respiratory disease, as has been noted, is an obvious example. Thirdly, as Ferguson (1945) has suggested, the industrial population, perhaps because of family tradition, trade union example, habit, and economic pressure, are possibly more likely to declare themselves unfit for work than the rural population. To a bored, disinterested workman, with an unpleasant job in squalid surroundings and in the company of uncongenial associates, a very minor disability may perhaps be a welcome pretext to absent himself from work, and prescriptions follow.

Lastly, list size has been implicated as a cause for a high script rate, and this is suggested by Fig. 2. The overworked practitioner with an excessive number of visits to make and an inflated attendance at his surgeries may well find that it takes a long time to get a full history and to make a complete clinical examination, but only a short time to write a prescription. Nevertheless it will be readily understood that script rate may be related to list size simply because the latter depends upon population density. To assess accurately the significance of list size on script rate it would be necessary to obtain the figures for script rate in large as opposed to small practices among populations of similar density, but this information is not available. By an indirect approach, however, some evidence can be obtained to suggest that list size is not at any rate the sole factor involved, and probably not the most important one.

Table III shows a considerable monthly variation in the number of scripts issued in each area, and it is apparent that the degree of variation tends to be greater where the population is dense. There can be no doubt about the co-significance of the correlation shown by plotting the coefficient of variation against the population density (Fig. 3). This implies that the seasonal variation is relatively greater in densely populated areas. It is improbable that this can be entirely attributable to list size, and it is more likely to be due to other factors. If among these other factors the availability of the doctor and the psychological attitude of

the industrial worker towards disease are, as has been suggested, important, then the 1s. charge on prescriptions, which has been instituted since 1951, may be justifiable as a mild mass deterrent, though it is unfortunate that it penalizes the chronic sick without greatly discouraging the hypochondriac with a passion for medicine.

Summary

A survey has been made of 18,848 prescriptions on Form E.C.10 and of 1,569 E.C.10A forms issued in Scotland during the month of October, 1951, and the general pattern of prescribing has been analysed and reviewed.

In an attempt to elucidate the factors determining prescribing rates the number of scripts issued in the 25 executive council areas in Scotland in the months of July to December inclusive was contrasted with the population density and the average list size. A considerable degree of correlation was established, and the factors concerned are discussed.

URINARY EXCRETION OF THE PRESSOR AMINES IN RELATION TO PHAEOCHROMOCYTOMA

BY

GEORGE P. BURN, B.M.

(From the Department of Biochemistry (Radcliffe Infirmary), University of Oxford)

The presence of adrenaline-like substances in human urine has acquired importance from the increase in the number of adrenal medullary tumours diagnosed during the past three years. Of cases of hypertension it appears that a certain percentage owe their symptoms to the release of adrenaline or, more usually, to the non-methylated substance noradrenaline, from an abnormal adrenal gland in which the medullary tissue is greatly hypertrophied. These patients suffer from intermittent attacks of high blood pressure, but there appear to be a few in whom the pressure is also raised above the normal between the attacks (Green, 1946). The diagnosis of the presence of such a tumour is a matter of importance, since its removal is followed by a disappearance of the symptoms.

Tumours examined (Holton, 1949; Swan, 1951) usually contain excessive amounts of active material. The normal suprarenal gland in man, obtained *post mortem*, was found by West, Shepherd, and Hunter (1951) in 36 cases to contain an average of 0.2 mg. of total pressor amine per gramme. This figure may be low, as in laboratory animals it is about 1 mg./g. Tumours have been found to contain from 2 to 20 mg. of total pressor amine per gramme, and this mostly of noradrenaline. It is not surprising that the release of some active material causes a rise of blood pressure, and theoretically it should be possible to demonstrate active material in the blood. This is, however, not easy, and Engel and Euler (1950) showed that a large amount of noradrenaline can be found in urine.

Holtz, Credner, and Kroneberg (1947) were the first workers to show that human urine contained adrenaline, noradrenaline, and hydroxytyramine. This last substance

is relatively of low pressor activity. They found from 100 to 150 $\mu\text{g.}$ of adrenaline or *noradrenaline*, and 2 to 3 mg. of hydroxytyramine per 24 hours. They also stated, without giving figures, that urine from a subject with essential hypertension contained a larger amount of pressor substances than urine from a normal subject.

Euler and Hellner (1951) studied 24-hour urine specimens from 20 young normal subjects. They obtained mean values of 11 $\mu\text{g.}$ of adrenaline and 29 $\mu\text{g.}$ of *noradrenaline* per subject. They did not find sufficient hydroxytyramine in the extracts to interfere with the estimations.

In the present work the urinary output of pressor substances as obtained by Euler's method of extraction has been investigated. No attempt has been made to divide the pressor activity into adrenaline and *noradrenaline*; it has been estimated as though it were all *noradrenaline*.

Method

Extraction of Urine.—The urine was collected into a Winchester bottle containing 5 ml. of concentrated hydrochloric acid. It was stored in the refrigerator at about pH 3 whenever more than two days elapsed before it could be extracted. The volume was measured.

An aliquot of 300 ml. was adjusted to pH 1–2, and boiled under a reflux for 20 minutes. The acidity was checked during the boiling, as the solution tended to become alkaline. The hot urine was cooled in running water and 4 ml. of 20% (w/v) aluminium sulphate per 100 ml. was added. A smaller amount of aluminium sulphate solution very often failed to produce much precipitate, especially in concentrated urine. The cold urine was first neutralized with 20% (w/v) caustic soda, till the first appearance of aluminium hydroxide; and then the neutralization was completed with 2% caustic soda to pH 7.5, using phenol red as an external indicator. The solution was allowed to stand for 10 minutes, when the reaction was readjusted to pH 7.5.

The precipitate of aluminium hydroxide was separated by centrifuging at 800 g. for 5 to 10 minutes. The supernatant fluid was decanted off and the precipitate dissolved in 5N sulphuric acid. This solution was carefully neutralized with 20% caustic soda with vigorous mixing, till aluminium hydroxide just failed to be precipitated again; bromphenol blue, as an external indicator, became a greenish colour. This neutralization was important, because an acid solution depressed the blood pressure of the cat used for the final test.

A mixture of one volume of acetone and one volume of alcohol was then added and the solution allowed to stand in the refrigerator for one hour or more, usually overnight. The precipitate and crystals were filtered off and the filtrate was evaporated *in vacuo* to a small volume. This volume, together with the washings from the flask in which evaporation occurred, was 2–4 ml.

Biological Assay.—The extract was compared with a known solution of *noradrenaline* by intravenous injection into a cat anaesthetized with chloralose and given atropine to exclude vagal reflexes. The amount of the extract which caused the same rise of blood pressure as a given dose of *noradrenaline* was determined.

Results

Recovery of Added Noradrenaline.—To test the efficiency of the extraction process a specimen of urine was divided into two parts. To one part was added a quantity—for example, 100 $\mu\text{g.}$ —of *noradrenaline*. Both parts were then extracted, and the difference between the two assays gave the amount of *noradrenaline* recovered. In 20 observations the mean amount recovered was 100%, the values lying between 75 and 125%. As a further indication of the accuracy of the method, from one specimen of urine

two aliquots of 300 ml. were extracted, and both extracts were assayed three times. The figures obtained for the first extract were 29, 34, and 33 $\mu\text{g.}$, and those for the second extract 27, 29, and 29 $\mu\text{g.}$ Other pressor substances may be present in urine. These are piperidine (Euler, 1944), *isoamylamine* (Bain, 1914), tyramine (Bain, 1910), nicotine (Corcoran *et al.*, 1939), and the posterior pituitary hormone (Burn and Singh Grewal, 1951). A series of experiments was carried out in which each of these substances was added in large amount to a sample of urine. The urine was then extracted and tested. It was found that none of them appeared in the extract in sufficient quantity to be mistaken for *noradrenaline*.

Variation in Daily Excretion.—The excretion of *noradrenaline* was followed in one subject aged 31 for 14 successive days. The excretion per 24 hours varied from 16 to 86 $\mu\text{g.}$ on different days, which is about fivefold. The mean figure was 41 $\mu\text{g.}$

Influence of Age.—Urine from older people was found to contain a larger amount of *noradrenaline*. Table I contains the results on 38 subjects, divided into four age

TABLE I.—Influence of Age on the Urinary Excretion of Pressor Amines Estimated as *Noradrenaline*. The Figures Were Obtained After Hydrolysis of the Urine

Age Limits	Mean Age	No. of Subjects	Mean <i>Noradrenaline</i> ($\mu\text{g.}$)
3 months–10 years	6	9	18
23–30 years	27	12	59
31–40	32	10	64
41–63	50	7	71

groups. The mean excretion of children, aged from 3 months to 10 years, was 18 $\mu\text{g.}$ of *noradrenaline*. The mean excretion in the second group, young adults aged from 23 to 30, was 59 $\mu\text{g.}$ of *noradrenaline*. The difference between these two age groups is significant ($P=0.05$). The mean excretion in the two older groups aged 31–40 and 41–63 was 64 $\mu\text{g.}$ and 71 $\mu\text{g.}$ respectively. These figures are only slightly larger than the figure for the second group, but they conceal the wide variation observed. In adults of any age, the 24-hour excretion of *noradrenaline* may be at any value from 15 to 150 $\mu\text{g.}$

Free and Conjugated Noradrenaline.—Boiling the urine for 20 minutes at pH 1–2 hydrolysed any conjugated *noradrenaline* and rendered it free for adsorption on the aluminium hydroxide. If this preliminary hydrolysis was omitted some so-called “free” *noradrenaline* was extracted. The results in 12 adults and 9 children are shown in Table II.

TABLE II.—Mean Excretion of Free and Conjugated *Noradrenaline* in $\mu\text{g.}$ by Night and by Day, for 12 Adults and for 9 Children. Night for adults was from bedtime to the time of rising. Day for adults was all the rest of the 24 hours. For the children, night was 6 p.m. to 6 a.m., the day 6 a.m. to 6 p.m.

	Night			Day			Total		
	Free	Conj.	Total	Free	Conj.	Total	Free	Conj.	Total
12 adults	6	17	23	36	28	64	42	43	85
9 children	4	4	8	6	4	10	10	8	18

Conjugated *noradrenaline* was obtained by subtracting the figure for “free” from that for “total” *noradrenaline*, which was the result obtained after boiling the urine.

Essential Hypertension.—It is well known that older people commonly have a higher blood pressure than younger people, and one cause of this may be diminished destruction of pressor amines in the blood. Such a diminished destruction might result in increased excretion in the urine. The output of pressor amines was therefore determined in a series of subjects with a blood pressure less than 130 mm., and was compared with the output in a second series having

TABLE III.—Relation of Excretion of Pressor Amines to Blood Pressure in the Middle-aged

Normal Blood Pressures				Raised Blood Pressures			
Sex	Age	B.P. (mm. Hg)	<i>Noradrenaline</i> ($\mu\text{g.}$)	Sex	Age	B.P. (mm. Hg)	<i>Noradrenaline</i> ($\mu\text{g.}$)

M	50	115	85	F	50	140	70
F	45	120	60	M	59	155	120
M	48	120	150	F	35	170	67
M	45	120	83	F	57	180	94
M	46	122	69	F	63	190	61
F	63	130	22	F	57	200	36
				F	55	220	46
Mean	50	116	71		54	170	80

a blood pressure greater than 130 mm. The results are shown in Table III. The systolic blood pressures in the first group ranged from 95 to 130 mm., the mean being 116 mm.; those in the second group ranged from 135 to 220 mm., the mean being 170 mm. The ages in the two groups were similar, the means being 50 and 54 respectively. The mean output of pressor amines in the first group was 71 $\mu\text{g.}$ per day and in the second group 80 $\mu\text{g.}$ per day. Thus the subjects with the higher blood pressures did not excrete more pressor amine in the urine than the others.

Toxaemia of Pregnancy.—The excretion of *noradrenaline* was studied in cases of toxaemia of pregnancy associated with hypertension. The results are given in Table IV. A 24-hour collection of urine was made as soon as possible after the diagnosis, as rest in bed often caused the blood pressure to fall. The normal pregnancy group shown in the table were also resting in bed. Table IV shows that

TABLE IV.—Relation of Excretion of Pressor Amines to Blood Pressure in Toxaemia of Pregnancy

Normal Pregnancy			Toxaemia of Pregnancy		
Age	B.P. (mm. Hg)	<i>Noradrenaline</i> ($\mu\text{g.}$)	Age	B.P. (mm. Hg)	<i>Noradrenaline</i> ($\mu\text{g.}$)
28	100	26	31	130	38
34	100	57	32	130	46
31	100	63			
23	100	80	31	130	55
36	105	42	24	140	67

29	125	71	29	170	50
Mean: 30	106	56	29	142	58

there was no difference between the two groups, but the blood pressures of those with toxaemias were not very high.

Phaeochromocytoma.—In this series there were three cases of phaeochromocytoma, all suffering from paroxysmal hypertension. At operation an adrenal tumour was removed from each. Table V contains the figures for free and total *noradrenaline*. It is seen that the figures for *noradrenaline* are all greater than the highest normal figure, which is about 100 $\mu\text{g.}$ for free *noradrenaline* and 150 $\mu\text{g.}$ for total *noradrenaline*. In Case 2 of Table V the tumour itself was examined and found to contain 15 mg. of pressor amines per gramme, of which *noradrenaline* was about 50%, and adrenaline 50%. In addition there were 10 cases of suspected phaeochromocytoma, some of whom were suffering from sustained hypertension and some from paroxysmal hypertension, and whose general symptoms and signs were consistent with the diagnosis. The output of *noradrenaline*

TABLE V.—The 24-hour Output of Pressor Amines in Three Cases of Phaeochromocytoma

Case	Sex	Age	<i>Noradrenaline</i> Output in 24 Hours ($\mu\text{g.}$)	
			Free	Total
1	F	32	180	180
2	F	33		300
3	F	23	2,700	3,800

in these 10 cases ranged from 20 to 100 $\mu\text{g.}$, all being less than the highest normal figure of 150 $\mu\text{g.}$. No case has been operated on, but one patient died, and at the post-mortem examination the adrenal glands were found to be normal.

Discussion

The value of a determination of pressor amines in the urine seems to be confined to the diagnosis of phaeochromocytoma. Euler (1952) has stated that *noradrenaline* is excreted in increased amounts in a certain proportion of cases of hypertensive disease. Out of a total of 500 cases of hypertension he found that the excretion of pressor amines was normal in about 60% of the cases, but that it was increased in the remaining 40%. He has not yet published details to show the extent of the increase. It is difficult to compare this result with the present work, because the excretion of *noradrenaline* has been found to increase with advancing years.

The figures for the excretion in the three cases of phaeochromocytoma show a wide variation, and the lowest figure is not very much greater than the highest figure obtained for normal adults. It is reasonably certain that the excretion in patients who have these tumours will depend on the number of paroxysms which they suffer. On a quiet day with no paroxysms the excretion may be low. For certainty of diagnosis it is therefore important that the urine be examined for a period in which paroxysms have occurred.

Urine should not be collected on a day when a benzodioxane test has been carried out. In one case when this was done the benzodioxane test was negative, the systolic pressure rising from 200 to 260 mm. Hg, and the output of pressor amines in the 24-hour period was 490 $\mu\text{g.}$. An abnormally high output of pressor amines was not obtained in this case on three later days.

Green (1946) introduced a source of ambiguity when he showed that 37 out of 53 cases of phaeochromocytoma suffered from sustained hypertension. He defined sustained hypertension by the statement that the blood pressure did not fall between attacks to below 140 mm. systolic and 90 mm. diastolic, or that it did not fall below 95 mm. diastolic. He did not mean that the blood pressure was always at a constant high level.

On present evidence, however, the sustained hypertension of phaeochromocytoma should be marked by a high urinary excretion of pressor amines, while essential hypertension which is accompanied by paroxysms should not.

My thanks are due to Mr. J. R. P. O'Brien for his constant help and encouragement; to the Nuffield Foundation for a personal grant; and to Bayer Products Ltd. for a supply of *noradrenaline*. The biological estimations were carried out in the Department of Pharmacology, University of Oxford.

The Turkish National Bibliographical Institute has started publication of a monthly selective bibliography of articles appearing in Turkish periodicals. Information is given in Turkish and French, classification is by the International Decimal Code, and there is an index of authors and journals which will be cumulated annually. Medicine is well represented in the bibliography, which may be obtained from Milli Kütüphane, Ankara.

CROHN'S DISEASE INVOLVING THE
STOMACH

A REPORT ON TWO CASES

BY

F. R. R. MARTIN, M.B., F.R.C.S.

Surgeon, Bradford Royal Infirmary

AND

R. J. CARR, M.D., D.M.R.

Consulting Radiologist, Bradford "A" Group Hospitals

Crohn's disease is now a well-recognized pathological and clinical entity. It is generally agreed that the characteristic lesions occur predominantly in the terminal ileum, but that "skip" lesions are found anywhere in the jejunum, ileum, or colon. Crohn (1949) describes three main varieties: regional ileitis, ileo-jejunitis, and ileo-colitis. He also mentions cases in which the second and third parts of the duodenum were involved, and states that in two of these there were radiological appearances suggesting spread of the disease to the stomach. So far as we are aware, no cases have been published in which there has been proof of the disease occurring in the stomach, nor have the clinical or radiological features been described. In the following two cases Crohn's disease was shown to be present in the stomach.

Case 1

A single woman aged 23 was first seen on May 6, 1949, when she complained of peri-umbilical pain, accompanied by vomiting. Her vomit was alleged to have contained streaks of blood. Her appetite was good, she had no indigestion, and her bowels were said to act normally. Examination revealed the presence of a small, tender, irreducible umbilical hernia, which was dealt with by operation. She returned to the out-patient clinic one year later complaining of repeated attacks of epigastric pain, lasting for one to two hours at a time, associated with nausea. She had not lost any weight and had had no diarrhoea. Nothing abnormal was found on examination except some generalized abdominal tenderness. The operation scar was soundly healed.

During the next three months she was kept under observation, and a series of barium meals at six-weekly intervals revealed changes which may be summarized as follows. (a) There was absence of normal peristalsis in the pyloric antrum and cap. (b) There was deficient mucosal pattern in the pyloric antrum, the duodenal cap, and the upper half of the second part of the duodenum. The transition from normal to pathological mucosa was sharp and well defined in the stomach (Fig. 1) and in the second part of the duodenum (Fig. 2). Above and below the involved area the mucosal relief pattern was normal. Throughout the affected region the margins of the barium-filled lumen were slightly irregular, suggesting the possibility of superficial ulceration, but no definite ulcer crater was identified. The duodenal cap showed some contraction of the fornices, and its mucosa was devoid of folds. In the second part of the duodenum the usual feathery pattern was replaced by an unbroken column of barium until the normal mucosa was reached. The whole of the involved area remained motionless, showing complete absence of peristalsis, and even the cap was persistently full of barium. (c) There was no gastric or small-bowel stasis, and the colon showed no gross abnormality. At the x-ray examination on August 8, 1950, early changes in the mucosal pattern of the last 2 in. (5 cm.) of the terminal ileum were detected for the first time. (d) Her lung fields were normal, except for a calcified focus.

The changes in the stomach and duodenum were interpreted as a gastroduodenitis, and, in view of the appear-

ances of the terminal ileum, a provisional diagnosis of Crohn's disease associated with a gastroduodenitis was made.

During the three months she was under observation as an out-patient her general condition steadily deteriorated. On August 20 she was admitted to hospital. By this time her vomiting had become more insistent and she could retain only water. Attacks of severe abdominal pain occurred, but she had no diarrhoea during the week she was in bed before operation. Her pulse rate varied considerably, rising at times to 120-130, and she had some pyrexia. Though on palpation generalized abdominal tenderness persisted, at no time was there any distension or rigidity of the abdomen. Her haemoglobin was 82% and her E. S. R. (Westergren) was 38 mm. in one hour.

On August 29 it was decided to explore her abdomen. Typical changes of Crohn's disease were found in the terminal ileum and irregular inflamed patches were present throughout the colon. The stomach wall appeared to be only a little thickened, but in view of the previous barium-meal reports a biopsy of the gastric mucosa was taken from the region of the pyloric antrum. The disease was clearly too widespread for any benefit to be expected from short-circuiting or excision of affected portions of the bowel. The abdomen was therefore closed.

The histological report on the gastric biopsy was: "The stroma is heavily infiltrated by lymphocytes, plasma cells, and endothelial cells. Giant cells are present. No caseation or tubercle bacilli were found. A chronic granulomatous process like Crohn's disease appears to be present."

After operation the patient appeared to convalesce satisfactorily. In view of her pyrexia it was decided to try the effect of a course of streptomycin, which was given with apparent benefit. Her vomiting became much less frequent, and she was sent home on the sixteenth day.

FIG. 1.—Case 1. Showing the absence of mucosal folds in the antrum, cap, and upper half of the descending part of the duodenum. The arrows indicate the junction of the normal and pathological mucosa.

FIG. 2.—Case 1. Showing the irregular margins of the duodenal cap and absence of folds in the mucosa of the cap and upper descending duodenum.

Her subsequent history is of interest. Some weeks after going home persistent vomiting and anorexia returned. She became seriously ill. Though she remained at home, in retrospect it is clear that she should have been readmitted to hospital at this time, since the difficulties of giving her enough nourishment might then have been decreased. As it was, she started to make a slow improvement in the spring of 1951, and was well enough to come to the follow-up clinic in August. She then stated that there had been much less vomiting and abdominal pain in recent months, and that she was feeling much better. A barium meal was given on September 10. It showed that active peristalsis had now returned to the pyloric region and to the whole of the duodenum. Though there was still some residual narrowing of the lumen of the antrum, the outline was smooth and the mucosal relief pattern was normal. There was, however, delay in the emptying of the ileum, where after seven hours a considerable residue of barium remained. The last 3 in. (7.6 cm.) of the terminal ileum showed narrowing, and there was a typical Steirlin sign in the caecum. The ileum proximal to the narrowed portion was slightly dilated (Fig. 3). The x-ray appearances had therefore, after 12 months, become those typically found in regional ileitis.

FIG. 3.—Case 1. Showing the typical appearances of Crohn's disease in the terminal ileum and caecum at the end of the first year.

FIG. 4.—Case 2. One year later, when peristalsis and mucosal pattern were absent from antrum, cap, and upper descending duodenum.

seen in June, 1950. She complained that during the past three years she had suffered from lack of energy, lassitude, and attacks of abdominal pain and diarrhoea. Her stools were watery, but did not contain blood or mucus; her pain was relieved by evacuation of the bowels. Her appetite was good. On examination the only abnormal finding was tenderness in the right iliac fossa, where there seemed to be a palpable swelling. She was admitted to hospital for

observation. The results of investigations were as follows: F.T.M. was normal, haemoglobin 73%, and no pathogenic bacteria were found in her stools. On October 30 a barium meal showed normal functioning of the stomach and duodenum. No gross changes were seen in the small bowel.

She returned home, and on a subsequent visit complained of a vaginal discharge, for the treatment of which she was referred to a gynaecologist. He detected the presence of an ovarian cyst, and on February 7, 1951, he performed a laparotomy. The cyst was removed. On examination of the small bowel it was obvious that the terminal ileum was affected by changes indicating the presence of Crohn's disease. She was then referred to one of us (F. R. R. M.), and on April 6, when the abdomen was reopened, the diagnosis was confirmed. As the disease appeared to be confined to the terminal ileum, a right hemicolectomy was carried out, the caecum, ascending colon, and the last 3 feet (0.9 metre) of the ileum being resected. Histological report on the excised bowel confirmed the diagnosis.

She made a good recovery from the operation. When seen as an out-patient two months later she still complained of frequent motions, but the abdominal pain had disappeared. On August 21 she complained of anorexia and repeated vomiting. She had lost 14 lb. (6.4 kg.) in weight since her previous visit, and looseness of the bowels still continued to trouble her. She looked ill, but examination of her abdomen failed to reveal any significant abnormality. Further investigation showed that her E.S.R. had risen from 12 to 23 mm. in one hour. Her haemoglobin was 80%. The clinical picture thus seemed similar to that found in Case 1, and this opinion was confirmed when the supporting evidence of a barium meal was obtained (R. J. C.). The report may be summarized as follows: (1) There was pronounced gastric dilatation, with an excess of fasting juice. (2) Gastric peristalsis was almost completely absent. (3) The normal mucosal pattern in the pyloric antrum and in the duodenal cap was absent (Fig. 4). (4) The emptying rate of the stomach was normal. In six hours all the barium was in the colon, and in 24 hours most of it had reached the sigmoid.

Comparison of films taken at this time with those taken on October 30, 1950, showed that a great change had occurred in the interval. It was now clear that the change in symptoms had a pathological basis—that is, that of a gastroduodenitis, the nature of which might well be presumed to be similar to that described in Case 1.

Her subsequent history has amply confirmed this opinion. She has been in hospital since October, 1951. Her general condition has deteriorated on account of persistent anorexia and vomiting, and consequent inability to take adequate nourishment. She has become anaemic (Hb 63%) and suffers from frequent pyrexia. Oedema from alteration in serum proteins has occurred, and at times since admission to hospital it has often seemed as if she were going to die.

Discussion

These two cases appear to shed fresh light on the significance of anorexia and vomiting in cases of Crohn's disease. It would seem that such symptoms may herald the onset of this disease, and that when Crohn stated that "nausea and vomiting are rare manifestations and only occur in the later stenotic phases of the disease. Appetite is usually well preserved," he had not this possibility in mind. In neither of the above two cases was stenosis a primary feature. In fact, it was found only in the later stages of Case 1 when vomiting had ceased to feature in her complaints and when her gastric symptoms had largely subsided. No stenotic lesion was demonstrated in Case 2. It therefore seems justifiable to assert that when persistent anorexia and vomiting occur in Crohn's disease, and if other clinical evidence of intestinal obstruction is absent, the possibility of the stomach and duodenum being involved in the pathological process should always be considered. Having seen two cases of gastroduodenitis due to Crohn's disease in the limited practice of one surgeon in the last 18 months, we

Case 2

A married woman aged 24 with two children was first

Summary

The 55 toxoplasmin-positive patients found in a population of 698 mental defectives have been scrutinized for evidence of toxoplasmosis. Most of the patients were children. The incidence of positive cases increased with advancing age. In two cases eye lesions suggestive of toxoplasmosis were found. Radiology and lumbar puncture showed no findings suggestive of toxoplasmosis. In no cases could the mental defect be definitely attributed to toxoplasmosis. In some cases other definite causal factors were present—for example, epiloia, phenylketonuria, mongolism. It was concluded that in mental institutions or elsewhere a positive toxoplasmin reaction is acquired like a positive Schick reaction with increasing age, and is very infrequently associated with clinical toxoplasmosis; and that toxoplasmosis is not a common cause of mental defect.

Our thanks are due to Dr. I. A. B. Cathie and Dr. J. A. Dudgeon for provision of toxoplasmin and laboratory data, to Dr. O. D. Fisher for the results of skin testing, to Miss M. Ross and Mrs. L. Mundy for psychological data, to Dr. M. I. Robinson for radiological reports, to Dr. W. W. Kay for examination of the cerebrospinal fluid, and to Dr. L. Crome, the neuropathologist, and Dr. L. T. Hilliard, the physician-superintendent of the Fountain Hospital, for help and advice.

MYXOEDEMA AS A CAUSE OF DEATH

REPORT OF TWO CASES

BY

H. S. LE MARQUAND, M.D., F.R.C.P.

W. HAUSMANN, M.R.C.P.

AND

E. H. HEMSTED, M.B., B.Chir., D.C.P.

(From Reading Combined Hospitals)

Since the introduction of treatment with thyroid extract by Murray in 1891, it has been presumed that myxoedema as a cause of death is rare. We have been able to find only three recent references, and therefore report the following two cases.

Case 1

A woman aged 61 was admitted to hospital on January 7, 1951, with the following history. Thirty-five years ago she developed a left-sided hemiplegia, from which she made a good recovery. Two years ago she had another stroke, also involving the left side. Again recovery was fairly complete. The patient had had four children without trouble and the menopause had occurred at the age of 48. She had been in fairly good health until a fortnight before admission, when a cold and a severe cough developed. Her condition gradually deteriorated until January 6, when she first called in her doctor. He found her semi-conscious, and the following morning noticed considerable puffiness of the face.

On admission her pulse rate was 62 and temperature 97° F. (36.1° C.). She was moderately obese, and had pronounced supraclavicular fat pads. She was extremely lethargic but obeyed simple commands. Her voice was low-pitched and croaking. The scalp hair was dry and scanty, the pubic hair was extremely sparse, and the axillary hair was missing. Her skin felt dry and cold; her face, especially the eyelids, was puffy. Nothing abnormal was found in the heart, lungs, or abdomen. The blood pressure was 140/100 mm. Hg. There was pitting oedema of the legs up to the knees, and the hands were swollen but did not pit on pressure. Some evidence of previous hemiplegia was found in slight spasticity of the left side with an extensor plantar response, but there was no other abnormality in the central nervous system.

Investigations.—Urine: albumin was present; film showed scanty red cells, leucocytes, and mixed bacterial flora. The haemoglobin was 90%; blood urea, 50 mg. per 100 ml.; blood sugar, 57 mg. per 100 ml.; blood cholesterol, 390 mg. per 100 ml.; serum potassium, 18.4 mg. per 100 ml.; serum sodium, 345 mg. per 100 ml.; plasma chlorides, 595 mg. per 100 ml.; serum protein, total 7.2% (albumin 3.7%, globulin 3.5%, A/G ratio 1.1). An electrocardiogram showed flat and inverted T-waves in all leads, suggestive of myxoedema.

The diagnosis was difficult. Renal failure was suspected, but there was no confirmatory evidence on investigation. It was thought that an adrenal failure might be the cause, so treatment was started with penicillin and adrenal cortical extract, 10 ml. four-hourly. Although the patient became brighter mentally, her general condition deteriorated, respiration became laboured, and she died four days later. Her temperature remained at a low level all the time, and varied between 95 and 97° F. (35 and 36.1° C.). Her pulse rate varied between 60 and 70.

Necropsy

The following were the outstanding features: a widespread consolidation of the lungs; ante-mortem haemorrhages involving the suprarenals; remnants of thyroid gland; a heart of normal size and coronary vessels normal for her age.

Histological Examination.—Sections taken from both lobes of the thyroid gland showed marked fibrosis. A few small islets of lymphoid tissue were present in each lobe, and within these the remains of thyroid acini could be identified. The latter were composed of large pale irregular cells showing variable eosinophilic staining properties. Colloid was absent except in one small area. These remaining acini were surrounded by plasma cells and an outer zone of small lymphocytes. The lungs showed the picture of grey hepatization, with the alveoli distended by polymorphonuclear exudate. No heart-failure cells were present. **Kidneys:** the cortex was thinner than normal and patchy interstitial fibrosis was present. A considerable number of normal-looking glomeruli were to be seen. The vessels showed some thickening of the walls, but no elastosis.

Evidence of antemortem haemorrhage was found in the suprarenal gland. The pituitary gland was larger than normal. Acidophilic staining cells were noted to be extremely scanty, otherwise the histological appearance was within normal limits.

Case 2

An unmarried woman aged 50 was admitted to hospital on January 7, 1952. The previous history was that she had been well enough to do her own housework until five months before admission. Since then she had complained of weakness and of feeling cold, and these symptoms had gradually become worse. On the day of admission she suddenly complained of loss of vision, and the doctor found her lying across the bed unconscious.

On admission her temperature was 95° F. (35° C.) and pulse 42. She was semi-conscious and repeated such sentences to herself as, "What have I done?" but she would obey simple commands. Anasarca was present and the face and eyelids were swollen. The skin was coarse and dry. The scalp, pubic, and axillary hair was scanty; the superciliary hair was absent. Coarse rales were heard at the bases of both lungs, and there was tracheal rattle; the heart sounds were normal; the blood pressure was 250/140 mm. Hg. Nothing abnormal was found in the abdomen or in the central nervous system.

Investigations.—Urine: albumin was present; film showed many Gram-negative bacilli. The blood urea was 25 mg. per 100 ml.; blood cholesterol, 495 mg. per 100 ml.; serum sodium, 295 mg. per 100 ml.; plasma chloride, 420 mg. per 100 ml.; alkali reserve, 44 c.cm. CO₂; serum protein, total 6% (albumin 3.4%, globulin 2.6%, A/G ratio 1.3). The cerebrospinal fluid contained 1 white cell per c.mm. and 56 mg. of protein per 100 ml. An electrocardiogram showed flat T-waves in all leads; the tracings were compatible with the diagnosis of myxoedema.

Ten hours after admission the patient had a tonic fit. She was given a small amount of thiopentone intravenously; when the respiration stopped and the pulse became impalpable. Artificial respiration was started and she recovered. She was treated with continuous oxygen and penicillin, 1,000,000 units six-hourly. She improved considerably, but remained confused and slightly maniacal. Her blood pressure was about 160/100 mm. Hg. On January 10 she was given 10 mg. of thyroxine, with great improvement in the general condition. The puffiness and the subcutaneous oedema disappeared and the blood cholesterol fell to 388 mg. per 100 ml. Nine days later her temperature went up to 101° F. (38.3° C.), her breathing became laboured, and her general condition deteriorated. On the 21st day she became unconscious and her pulse impalpable, and she died.

Necropsy

A full post-mortem examination revealed very little positive information. Macroscopically the heart and coronary arteries appeared normal.

Histological Examination.—The thyroid gland was slightly enlarged and the cut surface firm and pale. The histological appearance was that of a Hashimoto or lymphadenoid goitre. **Kidneys:** Both were of normal size and appearance. Histological examination showed slight thickening and elastosis of the vessels. An occasional glomerulus was undergoing hyalinization. Adequate numbers of normal-looking glomeruli were present, however, and there was no evidence of tubular degeneration or interstitial fibrosis. The appearance was thought to fit in with an early hypertensive kidney.

The pituitary gland seemed to be quite normal. The ovaries were fibrotic.

Discussion

In our opinion myxoedema was the main cause of death in both cases. In Case 1 it can be presumed that a patient with severe untreated myxoedema was exposed to the stress of pneumonia and that this produced suprarenal failure. McGavack (1951) says that there is atrophy of the zona fasciculata in myxoedema and the excretion of 17-keto-steroids and glucocorticoids is greatly diminished. It seems feasible that when such a gland is exposed to additional stress acute adrenal cortical failure may ensue. The fact that there was widespread haemorrhagic destruction of the adrenal glands is in agreement with this assumption.

Case 2 is not quite so conclusive. Hypertensive encephalopathy had to be considered in the differential diagnosis. The reasons, however, against hypertension playing a major part in the fatal outcome of this case are: (1) the normal appearance of the eye background; (2) the normal size of the heart; and (3) the electrocardiogram, which was

suggestive of myxoedema rather than of hypertension. The fact that the blood pressure, except on admission, was within normal limits is also against this diagnosis.

Recent reports of death due to myxoedema are scanty. The largest series is that by McGavack and Schwimmer (1944), who described nine deaths, all due to cardiac complications of myxoedema. One case was described by Foster and Barr (1944) in which there was myxoedema of long duration with slow deterioration. A case was reported by Chioloro and Meerwein (1939), but it was doubtful whether myxoedema was responsible for death, as the case was complicated by the presence of schizophrenia and chronic ulcerative colitis. The largest series described was in a Report on Myxoedema (1888) in which 22 cases were mentioned. There it was stated that the majority of the patients died from intercurrent diseases, mainly pulmonary or renal, but in some cases death was the direct result of myxoedema. These cases showed intense anaemia and a variety of nervous symptoms, such as maniacal excitement, coma, etc.

A very interesting report has recently been published by Sheehan and Summers (1952) which stressed the important part that hypothermia played as a cause of coma in similar cases. In their patients the rectal temperature was recorded as 77 and 83° F. (25 and 28.3° C.). They point out that the clinical thermometer does not register below 95° F. (35° C.) and therefore this condition goes unrecognized. In retrospect, it is probable that our two cases fall into the same class. The temperature recorded in Case 1 was between 95 and 97° F. (35 and 36.1° C.), which most likely meant that the thermometer did not register, and the difference in the temperature depended only on how far the mercury column was pushed down by the nurse. In Case 2 the temperature was recorded on admission as 95° F. (35° C.). Only after the administration of thyroxine were temperatures above 98° F. (36.7° C.) recorded. The pulse rate in both cases was very low, which is in agreement with the observations recorded by Sheehan and Summers. Perhaps a significant fact is that both cases were admitted in the middle of winter, when the danger of hypothermia is obviously greatest.

The lesson to be learned from our cases is that under certain circumstances myxoedema may be a fatal disease. Therefore it is essential to diagnose these cases early and to treat them promptly. Unfortunately, the possibility of myxoedema may not even be considered. In our cases the diagnosis on admission was chronic nephritis, and that is probably the most common mistake. The patients may also be treated with iron and liver in the belief that the condition is due to anaemia, or cardiac disease may be suspected. It is important to stress the fact that the diagnosis may not only be missed in life but that, even when a necropsy is done, it may remain uncertain because the thyroid gland may not be examined.

In Case 2 the thyroid gland was of normal size, and only on histological section could destruction be confirmed. For these reasons we think that this condition may often remain undiagnosed.

Unfortunately, treatment of these two cases was not successful. In Case 1 adrenal cortical extract was used but did not prevent the fatal outcome. In Case 2 we had the experience of the first to suggest the possible diagnosis. The patient was given an adequate dose of thyroxine without success. Probably, irreversible change had taken place before treatment was begun. The answer is, of course, early diagnosis.

Summary

Two cases in which death was due to myxoedema are reported. It is suggested that this diagnosis is often missed, and that it is necessary to examine the thyroid gland after death as a routine procedure, particularly in elderly people.

rare, and in this instance there is no indication of how the organisms gained a "bridgehead" in the muscle. It is, however, possible that in some cases of clostridial myositis following a wound or an injection the infecting organism has been derived from the bowel rather than by inoculation from the exterior of the body. There was a rather suggestive latent period of at least eight days in the case reported by Shaw and Evans (1953), though admittedly delays of longer than five days may occur even in grossly contaminated wounds.

Direct evidence that phenylbutazone contributed to death is lacking. However, in view of the rarity of the condition, and the known effects of phenylbutazone on the continuity of the gut mucosa and on the circulating white corpuscles, it is difficult to dissociate the drug from some part in the initiation or spread of the gangrene or terminal septicaemia.

Since these two cases, both treated in general practice, two other fatalities have come to my notice. Both were instances of death due to perforation of peptic ulcer during phenylbutazone treatment. It should be noted that in Case 1 the perforation was unsuspected, nor was the cause of death clinically apparent in Case 2. The possibility of analgesic properties masking signs and symptoms is therefore of some importance.

It seems pertinent to iterate that, apart from the known contraindications, phenylbutazone should never be given without regular and frequent clinical assessment of the patient and appropriate white-cell counts.

Assessment of the precise risks attached to new drugs is never easy, and risks are not necessarily as great in hospital as they are in general practice. It is perhaps desirable that statutory post-mortem examinations should be held on all patients dying while treated by any new drug within a specified time of its inception even if there is no *prima facie* reason for supposing death to be attributable to treatment.

A Case of Subserous Duodenal Haematoma

A case of this condition due to non-penetrating and apparently trivial injury is reported because a search of the literature has not brought to light any record of a similar case.

CASE REPORT

A thin boy aged 9 was admitted to hospital on April 9, 1952, for abdominal pain and vomiting. Five days before admission he had "gone over" the handlebars of his bicycle; he thought he had fallen mainly on his left side, and had had a small abrasion of the left temple and left leg. From his own and his parents' account of the injury, it seems to have been regarded as trivial, and he was riding his cycle again a short time after the accident. He complained of some abdominal pain, but this was not severe and passed off in a few hours. Two days later he was seized with a sudden abdominal pain of such severity that he had to be put to bed; a hot-water bottle was applied to the abdomen, which apparently relieved him and he slept, but he woke at midnight and vomited food. Pain was felt in the central abdomen and remained in this area. The next day his general condition became worse; the abdominal pain was more severe, and vomiting and retching continued all day. His bowels were not open. His doctor decided that the condition was probably appendicular colic. He was kept in bed and given fluids and "sulphatrad."

On the day before admission he seemed to be slightly better: the pain was less severe, but vomiting and retching

continued. There was a slight rise of temperature and pulse rate. His bowels had still not been open. On the day of admission the pain had again increased and vomiting and retching were very frequent. The doctor noted a slightly raised temperature, but the pulse rate had risen further.

Apart from the usual childhood diseases he had always been well.

On admission the patient was slightly flushed and seemed to be in some distress. His temperature was 98.6° F. (37° C.), pulse 74, respirations 22. The tongue was coated and dry, and there was some fetor oris. The abdomen was slightly distended but moved freely with respiration. There was no evidence of bruising or abrasion of the abdominal wall. The boy pointed to the site of pain as immediately below the umbilicus, and there was some guarding and tenderness in this region. Hard faeces could be felt in the descending colon. No other abnormality could be detected on abdominal examination. On rectal examination hard faeces were felt; there was no tenderness or induration. Routine urine examination showed no abnormality. The haemoglobin was 15 g.%; total leucocyte count, 16,200 (polymorphonuclears 84%, lymphocytes 16%); bleeding-time, 5½ minutes; clotting-time, 9 minutes. A straight x-ray film of the abdomen showed that the stomach contained a considerable quantity of gas.

The child was placed under observation and given fluids only by mouth. He vomited twice soon after admission; each vomit was of a few ounces and contained mucus and flecks of altered blood. An intravenous drip of glucose-saline was set up, a Ryle's tube passed, and gastric suction started; about 1 pint (570 ml.) of a "coffee ground" type of gastric fluid was aspirated. Further examination of the abdomen about eight hours later revealed a fixed ill-defined mass in the midline above the umbilicus.

On the morning of April 10 the boy's general condition had improved, and it was decided to perform a laparotomy to find the cause of what was obviously a high small-intestine obstruction. The abdomen was opened through an upper midline incision. The mass was found to be a gross enlargement of the second, third, and fourth parts of the duodenum and the first 4 in. (10 cm.) of the jejunum. At first sight the mass appeared to be gangrenous, being blue-black. Further examination showed that there was a very large subserous haematoma: 4 oz. (114 ml.) of fluid blood was aspirated from beneath the serous coat, and after incision of the serosa a great quantity of clot was evacuated with the finger. The underlying muscle coat appeared to be intact, but the presence of such a large clot had completely closed the lumen of the duodenum. The serosa was left unsutured and the abdomen closed without drainage.

Convalescence was slow but uneventful, and the patient was discharged from hospital six weeks after operation. When seen one month and three months after discharge he was very well. He had gained weight and was taking normal diet. No mass could be felt on abdominal examination.

COMMENT

Although there is no clear history of injury in this case, it is reasonable to assume that the lesion was caused by abdominal injury at the time of the accident. That the force of the blow was slight is evident from the fact that neither the child nor the parents were definitely aware of it, and from the absence of bruising of the anterior abdominal wall. The injury seems to be related to the blast injuries of the abdomen seen in the late war, and the effects of the injury were maximal in that area because of the immobility of the second, third, and fourth parts of the duodenum and the relative immobility of the duodeno-jejunal flexure.

I wish to thank Dr. C. D. Agassiz, physician-superintendent of Queen Mary's Hospital for Children, and Mr. A. M. Desmond, who performed the operation, for permission to publish this case.

D. I. STIRK, F.R.C.S.,
Resident Surgical Officer, Putney Hospital;
Late Surgical Registrar, Queen Mary's Hospital for Children.

Reviews

MEDICAL BIBLIOGRAPHERS

The Great Medical Bibliographers: A Study in Humanism. By John F. Fulton. (Pp. 83, with 5 appendices, index, and 37 figures. 32s.) Philadelphia: University of Pennsylvania Press. 1951.

The wine of Dr. Fulton's providing needs no bush. To one who loves books, without any vestige of knowledge of bibliography, his account of *The Great Medical Bibliographers* has brought vividly back to memory his delightful pen-picture of the three wise men—Welch, Arnold Klebs, and Cushing—toiling up an Apennine pass "bursting with the erudite gossip of the ages." As a young graduate John Fulton had come to England to work under Cushing's old teachers, Sir Charles Sherrington and Sir William Osler, *quibus ille studiis ab ineunte anno imbutus* he became enamoured of the humanistic traditions of Europe's scholar-physicians, started then to collect old books, and, in his own words, "has been at it ever since." To-day, his term of office as Sterling Professor of Physiology at Yale having expired, he is the fortunate director of that university's medical historical library, founded on the joint bequest of Cushing's, Klebs's, and his own collections. "Thrice happy men are they whose Nature sorts with their vocations."

How can one with no pretensions to the bibliographer's expertise proceed to review this book? Simply by trying to convey some small share of the pleasure its reading has given him. For Dr. Fulton wears his learning as lightly as ever cavalier wore cloak, conveying with enviable ease through text and footnote the pleasure that may be found in the collection and collation of ancient texts. To him, as collector and connoisseur, bibliography is "the noble art of describing useful and beautiful books"—a happier description than any to be found within the covers of the *Encyclopaedia Britannica*. His enthusiasm is infectious.

In a memorable passage Harvey Cushing has described the febrile state induced by handling a calf-bound volume (1542) published by Etienne Dolet,

"the unfortunate young Renaissance scholar, contemporary and friend of such as Erasmus and Rabelais, who lived in Lyons when Lyons was a place to live in, who published eighty books, and for three words which left his meaning dubious went to the stake and was burned with his books."

Inscribing his book to the memory of three great medical bibliographers—Conrad Gesner, whom Osler named as the father of bibliography, Albrecht von Haller, in whose soul burned the fire of incessant industry, and John Shaw Billings, whose legacy to medical scholars has been the *Index-Catalogue* of the Surgeon-General's Library at Washington—Dr. Fulton takes his readers straight to sixteenth-century Lyons. Texts then were few, and books both new and rare, but the printers Gryphus and Dolet, for whom Champier, Canappe, and Rabelais—humanist physicians all three—translated and corrected the ancient texts, made their city the first intellectual centre of France. On then from Lyons to Zurich, where Gesner spent his youth poring over the literature of learning as he compiled his *Bibliotheca universalis*. Dr. Fulton's brief account of the scholar rising from his table to tend his ailing wife, as poor and young as he, explains Osler's affection for him.

Through the sixteenth and seventeenth centuries collections of books were private, made by wealthy practitioners only. On their death the collections were either bequeathed to institutions or sold by auction. Printed sales catalogues of "vendible books" first appeared towards the end of the seventeenth century, and copies are still extant of Jean Riolan's collection (1654), of Sir Kenelm Digby's (1665), and of the 20,000 books belonging to Dr. Bernard, at whose sale sixteen Caxtons were sold for five shillings apiece. Such catalogues are of value to-day as evidence of the medical interests of the time or in tracing the provenance

of rare books. With the growth of hospitals and medical societies in the eighteenth century came the growing demand for libraries, biographies, and dictionaries.

If, as Butterfield will have it, the seventeenth was the century of the *philosophes*, the eighteenth was as definitely that of the *encyclopédistes*. Greatest of these was the amazing Haller, who as a precocious child of 8 had written 2,000 potted biographies of men of history, and at 10 had completed a Greek lexicon. These were the forerunners of the encyclopaedic work of his maturity: the monumental bibliography of physiology in nine volumes, and his four great *Bibliothecae* of botany (1771), of surgery and anatomy (both in 1774), and of medicine (1776).

And so, not failing in tribute to many lesser luminaries, we are brought down to our own days, in which the expansion of medical literature has surpassed the energy of the individual bibliographer. Even the *Index Medicus* is in arrears, and the *Index Catalogue* of Billings's creation has had to suspend publication, to the consternation of librarians the world over. Choulant and Osler have been known in person to many who will read this fascinating book, and Geoffrey Keynes is happily with us still to carry on the humanist tradition, working *manu sua* as did his forerunners to the delight of all literate men.

"A collection of books is a university, and the custodian of books is necessarily a teacher." They are the words of Osler, who made old books, and the men who wrote them, live. His *Bibliotheca* is to-day a Canadian shrine, tended with loving care by his nephew. And through these Transatlantic collections, from Montreal and Baltimore, through Boston, New Haven, and Washington, runs J. C. Bay's "golden thread" which connects all members of a noble lineage back to the little house in Zurich in which Gesner worked and died. The weaving of the thread has been the task of the bibliographer. How fascinating the task, whether of weaving or following, Dr. Fulton's pages most eloquently tell.

WM. DOOLIN.

POLIOMYELITIS

Poliomyelitis. By W. Ritchie Russell, C.B.E., M.D.(Edin.), M.A.(Oxon.), F.R.C.P.Ed., F.R.C.P.Lond. (Pp. 84; 20 figures. 14s.) London: Edward Arnold. 1952.

It is refreshing to read a book on anterior poliomyelitis written by an author conversant with modern trends in neurophysiology and versed in the clinical vagaries of diseases affecting the central nervous system. The book is short, and certain aspects of the disease are scarcely mentioned. There is very little, for instance, about the method of spread of infection. Possibly this was omitted as being outside the author's personal experience, but it is a pity that he does not say more about the morbid anatomy, in which interesting work has been done in the past few years. The account of the clinical features of the acute illness is admirable, and Ritchie Russell makes clear the nature of the "muscle spasm," a term which has been used in such the varying senses in the literature of poliomyelitis. He notes that muscle fasciculation may be an important sign in the pre-paralytic phase, occurring in muscles which are likely to become weak during the succeeding 24 hours.

Two-thirds of the book are devoted to the treatment of the disease, about which Ritchie Russell has obviously thought deeply. His account of the importance of postural drainage in bulbar poliomyelitis, and of the use of the respirator in respiratory failure, is of great value, and explains several points which were previously by no means clear to the reviewer. The most controversial feature of the book concerns the methods advised for the treatment of weak or paralysed muscles. By now Ritchie Russell's of weak or paralysed muscles. By now Ritchie Russell's work on the importance of strict rest in the pre-paralytic stage is generally accepted, but there is likely to be some disagreement with his opinion about treatment when the acute phase is over. He advocates passive movements from the first appearance of paralysis to prevent contractures in

the opposing muscles, avoidance of splints so far as possible, and, within two weeks of the onset of paralysis, progressive active movement to the point of physiological fatigue. He has not been able to confirm that deliberately induced fatigue does any harm to weak muscles in the recovering stages of poliomyelitis, but he emphasizes that research is needed to find out the best method of exercising weak muscles under different conditions.

This is the most stimulating work on poliomyelitis which has appeared for years. Possibly some of the author's ideas on the treatment of weak muscles will not be proved to be correct, but the book should encourage all who treat patients suffering from the disease to think again about treatment. The whole theme of the book, and the unsolved questions which it poses, emphasize the need for special centres for the treatment and study of patients with poliomyelitis so that the best results can be obtained—a pressing problem with the increasing incidence of the disease.

ADVANCES IN MEDICINE

Advances in Internal Medicine. Volume V. Edited by William Dock, M.D., and I. Snapper, M.D. (Pp. 464. £4.) Chicago: Yearbook Publishers. London: Interscience Publishers. 1952.

The average clinical scientist or academically minded consultant tries to skim through at least 30 to 40 weekly, monthly, and quarterly journals to keep *au fait* with what is going on in his subject. It is more difficult to establish a routine for dealing with the annual publications, of which the present is an example, and there are therefore good grounds why they should be reviewed in the same way as books are. Some of these volumes are reprints of courses of lectures and owe their publication merely to local piety or the need to expend an earmarked bequest. Others, however, are of more serious interest, and this one has shown itself to be a useful annual review on whose table of contents the aspiring physician should keep a watchful eye. The present volume of approximately 450 pages contains seven articles, five by American and two by European authors. The lists of references in most of them run up to 150–200 titles. The subjects treated are diseases of the pregnant woman affecting the offspring, catheterization of the heart, portal hypertension, the anaemia of infection, gout, ganglionic and adrenergic blocking agents, influenza, A.C.T.H. and cortisone, and the abnormal proteins in myeloma. The last is an article by Waldenström in which he discusses the whole subject of hyperglobulinaemia. It is an admirable review of a recondite subject which is nevertheless of great interest to haematologists. Most of the other articles are of more general interest. This is indeed an excellent publication, and the only drawback to it is the high price.

PSYCHOLOGY OF TWINS

Twins: A Study of Three Pairs of Identical Twins. By Dorothy Burlingham. (Pp. 94 and 28 appendices. £1 15s.) London: Imago Publishing Co. 1952.

Mrs. Burlingham's publications with Miss Freud on the work of the Hampstead war nurseries have achieved worldwide recognition. We now have a beautifully produced volume which is a study of three sets of identical twins, and this too will redound to the credit of those who organized the remarkable work done in the war nurseries in London under air attack. The high price of the book must be due to the development charts which are an essential part of it. Mrs. Burlingham has found a method, using three-colour printing, whereby the reader may easily follow the details of the development of each child as a person, and of each child in relation to the development of the twin.

The text is short; it contains well-balanced views on twins and their special problems of emotional development, with the attendant problems of management. Mrs. Burlingham is also able to show that close observation of twins can pro-

vide material for work on the theory of the early stages of personality growth.

Children have brothers and sisters, they have animals, real or stuffed or imaginary, they have dolls, they have dream-siblings, fantasies of belonging to a home other than their own, and so on. The problem is, How does a real twin fit in with all these and other similar enrichments and complications that belong to all infants and children? According to Mrs. Burlingham the relationship to the twin is used to soften the crude anxieties that belong to the relation of the child to the parents—that is to say, that belong to the Oedipus complex. But there is also the meaning of twinning to infants who have not yet reached the Oedipus complex level, to those children who have not developed well enough at the earliest stages and who cannot achieve the status of whole persons engaged in inter-personal relationships. There is much work to be done just here, and twins do give a special type of evidence that is useful, and which can, moreover, be collected outside psycho-analysis, by direct observation. For those who are interested in this type of problem the book is probably the most comprehensive work of its kind in existence.

D. W. WINNICOTT.

GYNAECOLOGICAL DIAGNOSIS

Handbook of Gynaecological Diagnosis for Practitioners and Students. By Professor Walter Neuweiler, M.D. Translated from the German by Dr. Paul Ederer. (Pp. 448; 406 figures. £4.) London: William Heinemann Medical Books. 1952.

Dr. Walter Neuweiler is professor of midwifery and gynaecology at the University of Berne, and this is a translation of his *Lehrbuch der gynäkologischen Diagnostik für Ärzte und Studierende*. And an excellent translation it is. The English is impeccable, and the illustrations are not only numerous but are mostly of a high quality. The reproduction of radiographs could hardly be bettered.

The author's thesis is that satisfactory treatment depends on accurate diagnosis, and that the diagnosis demands study of the patient as a whole rather than of her pelvic organs. He concentrates on clinical methods rather than adventitious aids, and the first 100 pages are devoted to a masterly account of history-taking and physical examination. The accounts of colposcopy, hysterosalpingography, endometrial biopsy, and other methods of investigation are short but satisfying.

The major part of the book, however, is rather surprisingly planned on the basis of pathology and follows the usual scheme of setting out in logical order the various morbid processes which may affect each pelvic organ. The clinical features and aetiology of each are discussed separately, but many useful clinical hints and observations can be found. There are also small sections devoted to symptoms such as backache, sterility, discharge, amenorrhoea, and excessive uterine haemorrhage. These, although showing a more clinical approach, do not attain the high standard set elsewhere. One pleasing result of the particular arrangement is that the pathological basis and mechanism of production of clinical features are often explained.

Although all manner of quite rare conditions receive some mention, the work is not intended to be exhaustive or to be an all-purpose textbook. It is designed to supplement rather than to replace standard gynaecological books, and, judged in this light, it is unquestionably attractive.

T. N. A. JEFFCOATE.

During the war Dr. George Spanopoulos, now a general practitioner in Cyprus, served as an R.M.O. with the British Army, and in a little book, *Rabaguena* (Nicosia: Zavallis Press), he describes his experiences from arriving in the middle of the Kalahari Desert to being made a Bechuana chief with the title "Father of Crocodiles." He tells some good stories of the natives of Bechuanaland, their evident enjoyment of castor oil, and the schemes he had to resort to in order to impress them with the powers of his remedies. Indeed, his story has many illustrations of how primitive people prefer the doctor to bring his magic rather than his science to their aid.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MARCH 28 1953

POST-PARTUM HAEMORRHAGE

Post-partum haemorrhage, including third-stage bleeding, is still a leading cause of maternal death. That this should be so despite the advent of the blood bank and of the obstetric flying squad, and at a time when an increasing proportion of deliveries are conducted in hospital, has led in recent years to expressions of dissatisfaction with the traditional methods of management of the third stage of labour. Despite the rear-guard action of the old school, championed most recently by Hammond,¹ the trend in institutional midwifery is to discard controlling the fundus, to deprecate Credé's method of placental expression, and to favour the prophylactic intravenous injection of ergometrine towards the close of the second stage. In last week's *British Medical Journal* (p. 643), Drs. J. D. Martin and J. G. Dumoulin added to the literature another report on the efficacy of intravenous ergometrine in shortening the third stage and in preventing post-partum haemorrhage. Secondary relaxation of the uterus may still occur after the delivery of the placenta, but this can be prevented by a further intramuscular injection at this time.² In some hospitals prophylactic intravenous ergometrine is given in all labours, but in others it is used only when shortening of the third stage is particularly desired because the risk of bleeding is thought to be greater than average—for instance, when the birth is a multiple one, when there has been a previous history of an abnormal third stage, and when delivery has been performed under general anaesthesia. Prolonged labour is also generally quoted as predisposing to post-partum haemorrhage, but it is surprising how often such bleeding follows a short and efficient labour. One further advantage of delivering the placenta as soon as possible is that it reduces the blood loss from lacerations or episiotomy wounds because these can then be sutured earlier.

Martin and Dumoulin confirm that the timing of the injection of ergometrine with the crowning of the foetal head or the delivery of the anterior shoulder is a most important point of technique. They differ from some, but not all, previous investigators in having found that the procedure caused a significant increase in the rate of manual removal of the placenta. But, even if this point is conceded to them, it is not a serious drawback in hospital practice, where the operation of manual removal is a safe procedure in skilled hands.³ But this operation does not carry the same freedom from risk in domiciliary practice, in which, therefore, the routine use of prophylactic intravenous ergometrine is not advised. This may seem a serious disadvantage to the general practitioner, but it must be viewed in proper perspective, for factors other than the length of the third stage are concerned in the prevention and treatment of post-partum haemorrhage. Thus, for example, it is of the first importance to keep the haemoglobin of the expectant mother at as high a figure as possible. Skilled conduct of the first stages of labour is reflected in a low rate of traumatic as well as atonic post-partum haemorrhage. In particular the slow delivery of the foetal body encourages normal uterine action in the third stage. Further, Hammond¹ has shown that the proper and efficient management of the third stage along traditional lines has excellent results. Some would modify the classical instructions by substituting a "hands off the uterus" policy for the time-honoured controlling or guarding of the fundus, but with well-trained attendants little if anything is gained thereby. In an obese patient a relaxed uterus distended with blood may be overlooked unless the fundus is controlled.⁴ Finally, should the third stage be marked by atony and bleeding, the prompt administration of intravenous ergometrine will cause the uterus to contract, and the placenta can then be delivered or, at worst, the bleeding will be controlled until either the obstetric flying squad answers the summons or preparations are made for manual removal of the placenta.

Once the placenta is delivered the mother should be watched for a further hour. It is in this time that true post-partum haemorrhage is most likely to occur: indeed, there is much to commend the suggestion that this first post-partum hour be designated the fourth stage of labour.⁵ If bleeding occurs after the completion of the third stage oxytocic drugs are the first line of treatment, but if the haemorrhage persists or recurs exploration of the uterus should not be deferred. Most commonly clots or retained placental fragments will be found, but it is also necessary to exclude rupture of the uterus and even incomplete

uterine inversion. From the point of view of the mother, perhaps the least fortunate patient is the one who loses a moderate amount of blood—more than normally attends labour but less than warrants transfusion. An unremarked and untreated post-natal anaemia is a serious handicap, lessening the resistance to infection, slowing the rate of recovery from labour, and denying the mother the fullness of energy and well-being necessary for the discharge of her duties and the enjoyment of her baby.

THE HEALTH SERVICE ESTIMATES

A year ago, in commenting on the Health Service estimates, we pointed out that they appeared to have achieved an uneasy stability—which, as it happened, was temporarily upset by the Danckwerts award to general practitioners. Now the budget season has come round again, and the Health Service estimates are being scrutinized to see whether stability has been maintained.

Last year, if the Danckwerts award is ignored, stability was achieved by the imposition of new charges on the patient. Apart from their deterrent effect, the charges for spectacles, dental treatment and dentures, and for drugs were between them estimated to bring in over £23m. in the year now ending. In addition, small sums were to be saved in the hospital service by charges for appliances and drugs for out-patients, and by a higher charge for amenity beds. The effect was to allow the Health Service roughly the same amount of resources at the new prices—which had risen sharply in the preceding twelve months—but to make the patient rather than the taxpayer meet the heavier bill. This year policy seems to have somewhat changed. As a special correspondent shows on page 723, the net cost to the taxpayer has risen to £410m. largely because of the higher payments to general practitioners. There are also increases of varying amounts in the other main items of expenditure. But the charges in the coming year—in the ophthalmic, dental, and pharmaceutical services—are estimated to yield less than £18m. In other words, whereas last year the patient was intended to relieve the taxpayer, this year the taxpayer appears to be shouldering more of the burden.

On Budget Day the Chancellor of the Exchequer may give some information on how effective the charges have been. What is chiefly significant at this stage is that in spite of maintaining the yield from the charges roughly at last year's figure the taxpayer's

drugs bill is increased by over £4m. The fall in the total estimated yield from the charges is mainly accounted for by a reduction of £4m. in patients' payments for dental treatment and dentures. In this case, however, the charge seems to have been more effective as a deterrent than the prescriptions charge, for the gross receipts of dentists are estimated to show a further fall—but not enough to save the taxpayer from having to pay a little more for this service as well.

An important feature of this year's estimates is the virtual stability of the grants to hospital boards. Hitherto hospital budgets have been allowed to jump by something like £20m. from year to year, and even then hospital authorities have not been able to undertake much desirable expansion and re-equipment. This year they have not even been able to increase their expenditure to take into account the rise in prices—which has continued in 1952–3, though to a much smaller extent than in the previous twelve months. On the face of it this would imply that the hospitals' budgets have been reduced in real terms, which would in its turn imply a contraction in services. Or it may be that expansion planned a year ago is not being carried out. What does seem to be clear from the estimates is that Health Service expenditure is now marked by a duel between the hospitals and prescriptions. Last year the hospitals were allowed an increase of about £21m. in their budgets, while an attempt was made to keep prescribing in check by means of the shilling charge. This year prescribing has been allowed more latitude, whereas hospital budgets have been rigidly kept down. In fact there are signs that the drugs bill is getting out of control. In the first full year of the Health Service £35m. was spent on drugs prescribed by general practitioners, and this figure was high enough to impel the Labour Government to take power to impose a charge. In the coming year the comparable cost is estimated at nearly £52m., and, even when allowance has been made for the charge, the net cost to the taxpayer is £10m. more than in 1949–50.

The drugs bill is difficult to control because, apart from increasing costs of material year by year, its size depends ultimately on the action of individual general practitioners. It cannot be reduced to any extent by cuts in chemists' fees, for, as the analysis shows, three-fifths of the total is accounted for by the cost of ingredients. Again, many important new drugs are very expensive. Our correspondent points out that in Scotland the pharmaceutical service is estimated to cost less in the coming year than in 1952–3. Yet the price of drugs is the same on each

side of the Border. Perhaps Scottish patients are not so attached to bottles of medicine as the English and Welsh. Or are Scottish doctors more careful in their prescribing?

POISONS IN AGRICULTURE

Since the Threshing Machine Act of 1878 and the Chaff Cutting Machine Act of 1897 no further legislation had been introduced to safeguard the health of agricultural and horticultural workers until the enactment of the Bill known as the Agriculture (Poisonous Substances) Act, 1952. Regulations under the Act have now been made by the Ministry of Agriculture and Fisheries in England and Wales and the Secretary of State for Scotland. They are for the purpose of protecting employees against risks of poisoning from the dinitro and organo-phosphorus compounds, which are now extensively used in agriculture and horticulture for the control of weeds and pests.

Because of the food shortage since the war, the search for chemical substances to be used as selective weed-killers and insecticides became intense. Many of these chemical substances are extremely toxic to both man and animals. They were brought into general use before methods of safe handling had been studied, and deaths and cases of acute poisoning occurred in Britain, on the continent of Europe, and in the U.S.A.¹⁻⁵

The dinitro compounds named in the regulations are D.N.C. (dinitro-*ortho*-cresol, or D.N.O.C.) and "dinoseb" (dinitro-*sec*-butyl phenol, or D.N.B.P.). D.N.C. is a selective weed-killer and is widely used in the spring as a spray on cereal crops; dinoseb is mainly used as a spray on leguminous crops. They behave like cumulative drugs in man.⁶ The symptoms of acute poisoning are insidious in onset, but, once initiated, progress with extreme rapidity. Death has occurred within one hour of the first signs of illness.¹ The basal metabolism may be raised to above 300% of normal, and death from asphyxia or heat stroke occurs. There is no specific treatment for poisoning by the dinitro compounds.

The organo-phosphorus insecticides named in the regulations are "parathion," "schradan," "dimefox," "mipafox," and T.E.P.P. (H.E.T.P.). These compounds are powerful insecticides and are extremely toxic to both man and animals. Their pharmacological action is that of irreversible inhibition of the cholinesterase enzymes. Reports of cases of poisoning and methods of treatment have been fully described.²⁻⁴

The regulations prohibit the use of the dinitro and the organo-phosphorus compounds unless the men working with them are wearing protective clothing. The protective clothing varies according to the particular operation carried out, and includes rubber gloves, rubber boots, face-shield, hood, and either overalls or mackintosh. The number of hours during which workers can

be employed are restricted to ten hours in any one day and sixty hours during seven days. The employment of any worker under the age of 18 is prohibited. The regulations also contain requirements about the provision and maintenance of protective clothing, the provision of washing facilities for workers, the notification of sickness and absence, the training and supervision of workers, and the keeping of registers.

The regulations serve to emphasize to both worker and employer that these chemicals are highly toxic. They are open to criticism for the reliance they place on the wearing of face-shields rather than full face respirators. The main route of absorption is through the lungs, and face-shields do not prevent absorption by this route during spraying operations. They are likely to be particularly ineffectual when organo-phosphorus compounds are used in an enclosed space such as a greenhouse. The regulations do not make adequate provision for the medical supervision of workers. Since the early symptoms and signs of poisoning are vague and indefinite and do not occur until potentially dangerous quantities of the poisons have been absorbed, routine blood tests on the workers would serve to detect absorption of significant amounts before the onset of symptoms, which are often irreversible. Methods for the measurement of dinitro compounds in small quantities of blood have been developed,⁷ as also have methods for estimating the cholinesterase activity on 0.1 ml. of blood.⁸

MORTALITY IN AMPUTEES

Some surprising effects of amputation and sepsis are revealed by a searching investigation, recently completed, into the medical fate of several thousands of Service amputees of the 1914–18 war. In 1950 the Ministry of Pensions appointed a committee of eminent medical men under the chairmanship of Sir Ernest Rock Carling to consider whether amputees are living as long as other people and whether they are more liable to cardiovascular disease. An interim report appeared in 1951, and now a final report has been issued.

The interim findings were as follows. First, living amputees did not seem to be unduly prone to suffer from heart disease or hypertension. Secondly, the mortality rates during 1930–50 of all pensioners who had suffered limb wounds during 1914–18 did not differ much from what was expected, but those who had suffered the more severe wounds and amputations had appreciably higher rates. Thirdly, among the pensioners who died during 1945–9 the average age at death of leg amputees was a little lower, and more of the deaths were due to cardiovascular disease (though not to a statistically significant extent) than among a control group of pensioners who had suffered minor leg wounds only, without amputation. The investigation was subsequently continued in order to explore these divergencies further, to extend the terms of reference to cover certain types of wound, particularly fracture of femur, that did not lead to amputation, and to consider the influence of serious sepsis, overweight, and sedentary life. Little information about the last two factors was forthcoming, but a detailed analysis of the effects of sepsis was carried out.

The full medical records of one-third of the pensioners who had received leg wounds in the 1914-18 war and who had died during 1945-9 were classified into several categories. It was found that men who had had one leg amputated as the result of their 1914-18 service died on the average at a younger age during 1945-9 than those who had sustained a fracture of femur merely, and these in turn died sooner than those who had only a minor wound. But within each of these three classes the pensioners with a history at some time of serious sepsis died younger than those with no such history. Thus the nature and severity of the wound, and, independently, the degree of sepsis associated, both had their effect upon the average longevity of the individuals concerned. It was also found that men who had had both legs amputated, or had had single above-knee amputations, died somewhat younger than those with below-knee amputations or minor wounds only; and that cases classed as serious sepsis on account of osteomyelitis or suppurating joint fared worse than those with necrosis, sequestra, or sinuses allocated to the "serious" sepsis category because of their chronicity. The percentage of deaths at ages under 60 in the main groups analysed can be summarized as follows:

	Double Leg Amputees	Single Leg Amputees	Fractured Femur	Minor Wounds
With serious sepsis	78.8	60.8	60.1	52.2
Without serious sepsis	63.5	55.5	45.3	44.0

The causes of death of single leg amputees, fractured femur cases, and those with minor wounds were studied, and this revealed only a small excess of cardiovascular disease among the amputees. But when the various groups were subdivided in accordance with history of serious sepsis it was found that men whose records showed evidence of serious sepsis at some time in the past had a higher proportion of deaths from cardiovascular causes, particularly coronary or myocardial disease. For example, among single leg amputees with serious sepsis almost 32% of the deaths were attributed to coronary or myocardial disease, compared with only 22% among amputees with no record of serious sepsis. And over all the cases studied there were 5.5% more deaths from these cardiac causes among the serious sepsis cases than among the others.

As the analysis of causes of death was based on proportionate death rates, an excess of 5.5% from cardiac causes had to be balanced by a corresponding reduction in deaths from other causes, and we should expect the reduction to be distributed evenly among all of the other causes. But surprisingly it was found that in the serious sepsis group, where the 5.5% excess of coronary and myocardial deaths occurred, the excess was almost completely balanced by a deficit of 5.3% for one other main cause—namely, cancer. These figures prompt the suggestion that in some way serious sepsis had two long-term effects on those who suffered from it—some susceptibility to die from certain forms of cardiac disease and some resistance to the attack of cancer. The committee did not regard the deficit of cancer deaths as bearing on its terms of reference but thought it worthy of separate study. However startling to common sense

the demonstration of any causative connexion here would be, the decision that it is worth investigating is a sound one. The figures are not easily argued away. They may be a highly improbable coincidence, for the long-odds bet occasionally comes off. But they seem to be free from obvious fallacies, and the committee had the benefit of an analysis of them by Dr. Logan, chief medical statistician at the General Register Office. All the same, two members of the committee sign a minority report in which they doubt the possibility of serious sepsis having these dual long-term effects. They suggest that the basic classification of the cases according to the degree of sepsis suffered was unreliable and led to unwarrantable conclusions, but they do not explain exactly how the suspected fallacy has come about.

Neither the size nor the content of this report makes for easy reading, consisting as it does mainly of statistical tables with brief factual commentaries, but it records a vast amount of tedious though useful research in what is yet a practically unexplored field. The Ministry of Pensions is to be congratulated on its initiative in sponsoring the investigation. There must be plenty of interesting clinical information in the voluminous case records of this Ministry, and it is to be hoped that further research will follow based upon this exceptional store of carefully compiled material.

BETTER CONTROL OF FOOD INFECTION

Some of the infectious diseases have been made notifiable by Act of Parliament. From time to time others have been added to the list by regulations. In the Public Health (Infectious Diseases) Regulations, 1927, which added malaria, dysentery, acute primary pneumonia, and acute influenzal pneumonia to the list of notifiable diseases, provisions were included for reducing the danger of food-borne enteric fever and dysentery by enabling a local authority to prevent persons with these infections from engaging in the handling of food. It is these latter provisions which are affected by the new Public Health (Infectious Diseases) Regulations, 1953, which supplant the 1927 regulations, the provisions with regard to notification remaining unaffected.

As time passed it became apparent that the valuable precautionary measures provided by the 1927 regulations had two drawbacks which seriously limited their effectiveness. The first of these was the fact that the medical officer of health had to report to his local authority before action could be taken in suspending an infected person from an occupation connected with the handling of food. As speed in such matters is essential, it is a wise provision of the new regulations that a local authority may now authorize the medical officer of health to issue notices requiring persons to stop handling food without making a prior report to the local authority, though he is still required to report the circumstances at the earliest opportunity.

The power to deal with food-handlers who were carriers of enteric fever or dysentery naturally led to the desire for similar powers for use on the far more numerous occasions when food-handlers were found to be harbouring the causative organisms of food-poisoning.

The report of the Catering Trade Working Party of the Ministry of Food in 1951 suggested that consideration should be given to the desirability of amending the Public Health (Infectious Diseases) Regulations, 1927, by extending their scope, so far as was practicable, so that the provisions relating to typhoid and paratyphoid fevers and dysentery should become applicable to salmonella infections, staphylococcal food-poisoning, and other infections which may be spread by food. This advice has been taken into account in the framing of the new regulations. A local authority, or the medical officer of health, may now take action when any food-handler is found to be suffering from, or to be a carrier of, typhoid fever, paratyphoid fever or other salmonella infection, dysentery, or staphylococcal infection likely to cause food-poisoning. Moreover, if a medical officer of health has reason to believe that a food-handler may be a carrier of any of these infections, the local authority may give notice to the manager that a medical examination is necessary, and the manager shall give all reasonable assistance in the matter.

The period between 1927 and the present time has seen the establishment of the Public Health Laboratory Service, and nowadays far more food-poisoning outbreaks are fully investigated bacteriologically than formerly. This fact has led to an increasing demand from medical officers of health for the powers given to them in the new regulations. Their proper use will call for close co-operation with the laboratory, particularly in regard to "staphylococcal infection likely to cause food-poisoning."

TERRAMYCIN

Terramycin is now available in hospitals without restriction as to indications for use, and general practitioners will be able to obtain it from regional distribution centres for the treatment of brucellosis, ornithosis, atypical (virus) pneumonia, lymphogranuloma inguinale, and penicillin-resistant staphylococcal infections. Hospital doctors prescribing it for conditions other than these will need to consider how it may best be used. The ranges of activity of all three newer antibiotics, aureomycin, chloramphenicol, and terramycin, coincide closely. Typhoid fever is exceptional in that only chloramphenicol is useful in treating it. This superiority extends to other intestinal infections by Gram-negative bacilli generally, although in most of these the need for antibiotic treatment is not usually imperative. Other diseases for which these three antibiotics alone are valuable, other forms of chemotherapy being without effect, are comparatively rare or unheard of in Britain or difficult to diagnose. They are the virus infections mentioned above, brucellosis, and the typhus group of fevers. But the newer antibiotics have been extensively used for a variety of bacterial infections when these are, or are assumed to be, resistant to penicillin. Here the clearest indication is a serious and demonstrably penicillin-resistant staphylococcal infection: aureomycin and terramycin are both more active against this organism than chloramphenicol. These antibiotics

have also been used, where freely available as in the United States, for treating diseases, such as pneumonia, rather than infections by any particular and identified micro-organism, because their "broad spectrum" covers almost every aetiological possibility. Another indication is a mixed infection, such as peritonitis due to bowel perforation, where they are preferable for the same reason. It needs to be emphasized that, when time and facilities permit, treatment should be based on laboratory tests of bacterial sensitivity. Such tests ought to be made, for instance, in order to direct intelligently the treatment of an infection of the urinary tract.

When there are good reasons for believing that any of these three antibiotics will serve, and choice has to be made among them on other grounds, it will doubtless be borne in mind that chloramphenicol is alone among them in being capable of causing aplasia of the bone marrow. However rare a complication this may be—and, as we pointed out recently,¹ its true incidence remains to be determined—its possible occurrence cannot be ignored when other things are equal. Neither aureomycin nor terramycin has been known to produce this effect, but, of the two, aureomycin is rather more liable to cause the minor toxic manifestations of nausea, vomiting, and diarrhoea.

LEFT HEMICOLECTOMY

In the resection of rectal cancer increasing attention is now being paid to the advantage of dividing the main vascular pedicle as high up as possible. Miles,¹ in his classical description of the combined abdomino-perineal operation, advocated ligation of the inferior mesenteric artery below the point where it gives off its first sigmoid branch. According to the work of Goligher,² this level is on the average 1½ in. (3.75 cm.) distal to its point of origin from the aorta, and Grinnell and Hiatt³ have now suggested that attempts to remove this additional short length of artery (and, more important, its accompanying lymph vessels) may be worth while. These authors found no fewer than 10 lymph nodes in this small area. It is only by increasing, in this way, the upward limit of the lymph-node resection that surgeons will be able to save more patients with disease in the C2 category—that is, with metastases present in the glands up to the level of the ligation of the blood vessels.⁴ When the arterial ligature is placed on the inferior mesenteric artery at its origin the nutrition of the left side of the colon from above is dependent on the left branch of the middle colic. An adequate blood supply from this source can reasonably be expected to a point well down in the sigmoid, always provided care is taken to preserve the marginal vessels. Blood reaches the rectum and anus, however, only along the middle and inferior rectal arteries.

that it may occur with boils on any part of the body as a result of a septic embolism. If cooks or others who touch food have boils, outbreaks of food-poisoning may occur. The precipitation of coma in a diabetic with boils or carbuncles has already been mentioned.

Diagnosis

In the diagnosis of recurrent boils there is little difficulty except to determine the cause, and this requires a full assessment of the underlying factors. Unless a careful history is taken and the patient is examined fully a blunder will occasionally be made. A bromide eruption with small papulo-pustules developing into sterile boils, pustular ringworm (kerion) with discrete lesions, papulo-pustular syphilide, and papulo-pustular tuberculide may all be mistaken for boils if care is not taken. Cutaneous anthrax, which is seen occasionally in this country in leather workers or others who handle hides, might be mistaken for a single boil but not for recurrent ones. A papule, rapidly becoming a pustule, appears usually on an exposed area of skin. There is intense local inflammation, necrosis of the pustule follows with the formation of a black slough, and secondary vesicles soon form around it.

General Treatment

The treatment of widespread boils clearly demands general measures, but even in grouped or localized boils these must not be neglected. The treatment of any patient with recurrent boils must be considered as a general medical problem and the underlying factors dealt with. We must think in terms of focal sepsis and the resistance of the patient to infection. Chemotherapy and the antibiotic drugs provide specific therapy and are most impressive in the treatment of boils. Those occurring on the face should always be treated in this way. Unfortunately, in suppressing the staphylococcus so effectively they do not allow the process of active immunity to be developed, and a relapse often follows cessation of treatment. Care must be taken that concentration on local treatment combined with injections of penicillin does not lead to neglect of the cause of the problem.

Whether the boils are localized in groups or whether they are widespread, the possibility of focal sepsis should be considered. Infection of the teeth, nose, nasal sinuses, or throat must receive appropriate treatment. Tinea pedis must not be neglected.

Whenever emotional or mental strain plays a part rest will be required, possibly a holiday from work or away from home. Mild sedation is helpful in such patients, and phenobarbitone, $\frac{1}{2}$ gr. (16 mg.) twice daily by mouth, may usefully be given.

The question of employment must be considered. The seborrhoeic type of individual tolerates heat and moisture badly, and skin sepsis is common in miners of this type who work under such conditions. After greasy work the skin should be washed thoroughly with soap and water. Sponging with cetrimide as a 1% solution in water removes grease and dirt from the skin and is actively bactericidal. It is inactive in the presence of soap and occasionally irritates the skin, but otherwise is helpful if the patient can be persuaded to go to the trouble of using it.

A balanced diet is important. Sweet cakes, suet puddings, fried potatoes, and other carbohydrates should be eaten in moderation. Chocolate is best avoided. Sugar in tea and coffee may be replaced by saccharin. Citrus fruits and fresh vegetables may be eaten in abundance. Additional vitamin-B complex is helpful. Yeast is not of much value unless it is fresh and taken in large quantities. Patients with boils are sometimes anaemic, and iron may be given—for example, one or two ferrous sulphate tablets three times a day after meals.

Active immunization by an autogenous staphylococcal vaccine or staphylococcus toxoid is found to be effective by some physicians, toxoid appearing to be the better. It is as well to start a course when there are no active boils. A combination of toxoid and a stock vaccine such as "vac-coid" may be used, 0.1 ml. of the weak preparation being enough for the first dose. The material is injected intradermally and the dose increased by 0.1 ml. each week until 0.5 ml. is reached, when the stronger preparation, containing five times the quantity of toxoid, may be used in a similar manner, beginning once more with a dose of 0.1 ml. Reactions, general or local, are to be avoided, and if such occur the dose for the following injection should not be increased.

If boils do not stimulate the production of active immunity it seems unlikely that vaccines will do so unless they provide a stronger stimulus, whether specific or non-specific. Some authorities believe the action of vaccines and toxoid to be one of desensitization to the staphylococcus and its toxins. However, treatment with vaccines or toxoid, or with manganese or tin, does not provide a cure, and, like antibiotic therapy, will prove disappointing unless the essential cause is found and treated.

Local Treatment

The principles of local treatment are rest, dry heat, and the minimum of interference. Because it is important to prevent, if possible, the infection of other follicles, the surrounding skin should be kept healthy and as sterile as practicable. The skin around a boil should be swabbed with spirit or brilliant green paint (perchloride of mercury 0.5%, brilliant green 0.5%, industrial spirit 99%). The topical application of antibiotics is only of temporary value, and may lead to sensitization of the skin. Hot fomentations and bread or kaolin poultices should be avoided, as these may burn the skin and certainly make it sodden and more liable to infection. Adhesive plaster dressings also make the skin unhealthy. Dry heat is useful; an infra-red lamp or an old-fashioned electric radiator or even a hot-water bottle over dry dressings may be employed. Short-wave diathermy, if available, is helpful. Local fractional doses of superficial x rays seem to abort the condition in the early stage and to prevent crops of boils appearing in the area treated.

The squeezing of boils is best avoided. Surgery has little place in the treatment, but when a boil becomes fluctuant, and not before, it may be incised. Large cruciate incisions and packing are quite unnecessary and do more harm than good. A dry dressing to absorb the pus may be applied and changed frequently, though if preferred magnesium sulphate paste may be used.

Widespread Boils

Once a boil has burst there is a great increase in the bacterial population of the skin near by and over the body as a whole. With lowered resistance this may result in recurrent widespread boils, and the condition must be treated as a contagious disease in which there is superficial external infection and reinfection. Every precaution possible to prevent the continuation of autogenous reinoculation must be taken. The bacterial increase can be controlled to some extent by bathing in or sponging with 1% solution of cetrimide or with 1 in 4,000 potassium permanganate. The permanganate must be dissolved in a little water before addition to the bath, as contact of a crystal with the skin may cause burning. Potassium permanganate discolours the bath, which is cleaned with difficulty, though the brownish stain can be removed with vinegar, oxalic acid, or some of the abrasive cleansers. Antiseptic soaps may be preferred, but they do not have the toughening and tanning effect of permanganate, and they may neutralize the acid mantle. After such antiseptic baths a dusting powder

containing 10% of calomel in zinc oxide is especially useful with widespread furunculosis, provided the patient is not sensitive to mercury. Cotton underclothes, changed daily, should be worn, as they can be boiled. Soiled dressings must not be allowed to touch skin areas which have not been protected by disinfectant solutions, and the hands of the patient and those attending him should be kept scrupulously clean.

The bacterial population of the skin remains high for weeks after a boil has healed, and these efforts to reduce the staphylococcal flora must be continued for some time. The nose of the patient is likely to be harbouring numerous virulent staphylococci, although physical signs are absent. Careful cleansing of the nasal vestibule with soap and water several times a day or a thin smear of ammoniated mercury 10 gr. (0.65 g.) in hydrous ointment 1 oz. (30 g.) reduces the danger from this source. In the presence of sinus infection this measure is, of course, purely palliative, and, as mentioned before, treatment of the nose and sinuses may be required.

Grouped Recurrent Boils

Hidradenitis suppurativa is an example of recurrent boils appearing as a local condition. The apocrine sweat glands develop at the time of puberty in the axillae, on the nipples, and in the region of the anus and genitals. They are subcutaneous and their ducts usually open into hair follicles.

A troublesome inflammation of these glands occurs occasionally and is more common in women. One or both axillae may be affected, and sometimes the perineum and groins. In these areas recurrent abscesses may result. A tender subcutaneous swelling appears, with redness of the overlying skin. Although it may settle down without suppurating, it often becomes fluctuant and discharges pus after bursting. Other glands become infected, and the condition may continue for weeks with great discomfort. Irregular scarring with cheloid formation may result.

It is probable that there is sweat retention followed by secondary infection. Although psychological and endocrine factors play an important part, mechanical causes may be present, such as maceration of the skin from sweat, especially when rubber dress protectors are worn. Damage to the duct openings by deodorant applications or depilatories may be a cause.

As with skin infection elsewhere, the cause of the breakdown of the patient's resistance must be determined. Antibiotics are only helpful temporarily, because a relapse often occurs when their use is stopped. The application of brilliant green paint (see above) to the whole of the axilla or other affected area, together with irradiation by x rays in a few fractional doses at intervals, will usually clear the disease rapidly, provided general causes are not neglected. As with other boils, fomentations are best avoided and dry heat should be applied. Short-wave diathermy is helpful. Incision may have to be considered, but it is wise to be conservative in order to avoid scarring and cheloid formation. Many of the swellings settle with treatment, and incision is justified only if there is marked fluctuation over an abscess. Full consideration of the treatment, which may involve endocrine therapy or even excision and grafting, is outside the scope of this article.

Conclusion

The objectives in the treatment of recurrent boils should be to keep the skin dry, clean, and free from irritation, to eradicate foci of infection, and to raise the general resistance of the patient.

Next Refresher Course Article.—"Prolapse," by Mr. A. J. Wrigley.

HEALTH SERVICE COSTS

[FROM A SPECIAL CORRESPONDENT]

A year ago, Mr. Crookshank, then Minister of Health, was being hard put to it to maintain the £400m. limit on the Budget's share of Health Service expenditure set by Labour Chancellors of the Exchequer. He could do it, in fact, only by imposing the charges on drugs, appliances, and dental treatment authorized by last year's National Health Service Act. But no sooner had his Health Service estimates been published in full than the Danckwerts award to general practitioners knocked the limit for six, mainly because of the back payments involved. This year's estimates are freed from this complication of back payments, but the effect of the award on the limit is clearly seen in the following table:

Health Service Estimates*

Total Net Cost to Taxpayer	£m.			
	1951-2 398	1952-3		1953-4 410
		Original 392	Revised 429	
Grants to local health authorities	18.6	20.6	21.2	21.6
General-practitioner service	48.4	48.5	86.9	58.2
Pharmaceutical service†	43.6	39.9	40.9	45.0
Dental service†	36.2	20.1	20.4	22.0
Supplementary ophthalmic service†	14.6	6.3	6.3	6.4
Grants to hospital boards	274.3	295.6	296.0	297.1
Of which maintenance	260.8	285.7	286.1	287.0

* Excluding civil defence. † Allowing for charges to patients.

Thus, compared with the pre-Danckwerts estimate, the total net cost of the Health Service to the taxpayer has risen by £18m. Of this, more than half is accounted for by the higher payments to general practitioners resulting from the award; but there are also small and, in one case at least, ominous increases in the other main items of expenditure.

Expenditure of Local Health Authorities*

	£m.		
	1951-2	1952-3	1953-4
Health centres	†	†	†
Care of mothers and young children	9.4	9.6	9.5
Midwifery	5.0	5.4	5.1
Health visiting	2.7	3.1	3.2
Home nursing	4.3	5.4	5.5
Vaccination and immunization	0.5	0.6	0.6
Ambulance service†	7.9	9.3	9.7
Prevention of illness and aftercare	1.7	2.1	2.2
Home helps	3.5	4.3	4.7
Mental health	1.8	2.1	2.2
Miscellaneous	0.2	0.3	0.3
	37.0	42.2	43.0

* Including estimated expenditure from rates.
† Less than £100,000 in England and Wales.
‡ England and Wales only.

Expenditure on the services of the local health authorities has virtually been stabilized. Indeed, it is impossible to see how it could be otherwise. The initiative in this branch of expenditure comes from the local authorities, and about half the total cost falls on the ratepayer. Already local authorities have had to raise their rates for the coming year—increases of as much as 2s. in the pound are common. They may well hesitate before expanding further any of their health services. And the argument that by so doing they might relieve the hospitals, and therefore the taxpayer, will, not unnaturally, carry no weight. Estimated expenditure on health centres in England and Wales is falling from £94,000 to £50,000, which must mean a virtual cessation of new centres. In Scotland, on the other hand, where the cost of health centres is borne on the executive councils' vote, although the original

estimate for 1952-3 was scaled down from just over £100,000 to £70,000, in 1953-4 an increase to £85,000 is budgeted for.

The effect of the Danckwerts award on the cost of the general-practitioner service has already been referred to. In terms of allocation of financial resources it means that family doctors now receive 12% of central Health Service funds, compared with 10% two years ago. There can be few people who would regard this proportion as too high.

The Pharmaceutical Service

There can be few people, too, who are undisturbed by the continued rise in the cost of the pharmaceutical service. A year ago the Minister of Health stated that it was running at more than £50m. a year. Through the shilling charge he hoped to bring the gross cost down to £47½m.—as a result of the deterrent effect of the charge—and to save another £7½m. by the payments made by those who were not deterred. This would bring the net cost down to £40m. As it turned out, the gross and net cost were put a little higher. But it is now known that the charge has not yielded so much as was expected. Recently Mr. Macleod, the Minister of Health, said that because of the fog and influenza the number of prescriptions issued in 1952-3 would not be less than in the previous year. It is therefore surprising that the yield from the charges has not risen *pro tanto*. According to Mr. Macleod, it was originally estimated that in England and Wales alone in a full year £6.8m. would be saved by patients' payments and £3.9m. by a reduction in the number of prescriptions. This would make a total saving of about £9m. in the ten months for which the charge was in force. But the total saving is in fact now estimated at only £5m. paid by patients. In the circumstances it is a little surprising that the reduction in the estimated yield from the charges in the coming year is not greater than it is.

Cost of Pharmaceutical Service

	£m.		
	1951-2	1952-3	1953-4
(a) Payments to pharmacists:			
Dispensing fees and rota payments	13.6	13.1	12.7
Cost of ingredients and allowance for containers	24.5	27.2	29.9
Allowance for overheads and profits	3.6	6.5	7.2
(b) Payments to doctors and dentists for drugs supplied:	1.9	1.5	1.9
Total gross cost	43.6	48.2	51.7
Patients' payments	—	7.3	6.7
Net cost	43.6	40.9	45.0

An interesting feature of the estimates is that the whole of the increase in costs is accounted for by the service in England and Wales. In Scotland, the total gross cost and the cost of ingredients are put at a lower figure than a year ago, and patients' payments are estimated to be slightly higher, so that there is a saving of about £500,000 in the net cost.

The Dental Service

The effect of the charge for treatment on the cost of the dental service is also interesting. The significance of these

Dental Service

	£m.		
	1951-2	1952-3	1953-4
Gross receipts of dentists	41.0	31.2	28.8
Payments by patients	4.8*	10.8	6.8
Net cost of service	36.2	20.4	22.0

* For dentures only.

figures is that the charge for dental treatment is evidently still acting as a deterrent, as was expected, and because of this the estimated gross receipts of dentists show a further fall for the coming financial year. But the estimated receipts from the charges were evidently wide of the mark a year ago, and have accordingly been greatly reduced for 1953-4. The net effect is a rise of £1.6m. in the cost of the dental service—with Scotland again managing to show a small reduction. But the proportion of the total cost of the Health Service taken by the dental service is down from nearly 10% in 1950-1, the year before the charge for dentures was introduced, to less than 5% in 1953-4.

The Hospital Service

By contrast the hospital service now accounts for a much larger share of Health Service costs (61%) than was originally contemplated. What is significant about the new estimates is that for the first time there has been virtually no rise in the estimated grants to hospital boards. Such rise as is shown is, in fact, mainly accounted for by Scottish hospitals. The teaching hospitals in England are actually to have a cut of over £1m. in their grants for maintenance.

The following Table compares the estimated expenditure on the main items of the running costs of hospitals in England and Wales:

Gross Hospital Maintenance Expenditure

	£m.		
	1951-2	1952-3	1953-4
Medical salaries (including specialists)	26.9	31.5	28.8
Nursing salaries	55.5	60.7	59.1
Other salaries and wages	62.7	71.7	76.0
Provisions	25.9	29.1	30.4
Drugs and dressings	9.4	10.4	11.3
Medical and surgical appliances	7.0	8.1	6.7
Fuel, light, and power	11.2	13.9	14.6
Maintenance of buildings	10.3	10.1	8.8
All other	31.9	33.5	33.4
Total	240.8	269.0	269.1

The interesting feature of this Table is the estimated fall in medical and nursing salaries in the coming financial year—the more interesting in view of the higher salaries recently granted to nurses, which were expected to cost £5m. in a full year. The fall may be connected with the freezing of hospital establishments, which has prevented hospital authorities from carrying out expansions planned a year ago. Whatever the reason, it evidently does not apply to Scottish hospitals, whose estimates show no such cut in medical and nursing establishments.

For the first time the Health Service estimates include a forecast of the numbers of staff to be employed by hospital authorities at the beginning of the financial year. They are given in the following Table:

Estimated Hospital Staff* on April 1, 1953

	England and Wales	Scotland†
Consultants	5,300	1,250
Other doctors and dentists	12,000	1,250
Nurses and midwives	148,000	21,400
Administrative and clerical staff	28,000	3,200
Other professional and technical staff; maintenance staff and tradesmen and craftsmen, including transport staff; all other staff	188,000	22,250
	381,300	49,350

* Including the approximate whole-time equivalent of part-time staff.
† Estimated averages for 1953-4.

This Table shows another difference between England and Wales and Scotland. South of the Border, only 30% of total medical and dental staffs are consultants. In Scotland consultants account for half the total.

COLLEGE OF GENERAL PRACTITIONERS

REGIONAL FACULTIES

It is proposed that the peripheral activities of the College shall be organized by a number of Regional Faculties.

Headquarters

Ideally the headquarters of these Regional Faculties should be situated near the offices of the undergraduate and postgraduate deans or directors of the medical schools and the university research departments, for educational purposes and to facilitate arrangements for postgraduate study and research. But in some places this may not be possible; or headquarters may be offered to the College elsewhere, as has already occurred in Birmingham and in Edinburgh. It is felt that a close link like this with the universities will underline the academic nature of the College's work.

In London the Director of the Postgraduate Medical Federation of the University of London has generously offered the College accommodation at his headquarters—2, Gordon Square, W.C.1. This arrangement will lead to close co-operation between the two bodies, and should be of considerable benefit both to general practitioners and to those organizing their postgraduate courses. It is hoped that similar co-operation may be arranged between the College's regional faculties and the postgraduate deans or directors of other university cities.

There are 19 universities with medical schools in the British Isles and Republic of Eire—Aberdeen, Belfast, Birmingham, Bristol, Cambridge, Cardiff, Cork, Dublin, Durham, Edinburgh, Galway, Glasgow, Leeds, Liverpool, London, Manchester, Oxford, Sheffield, and St. Andrews. Pilot faculties will be formed at once in London, Birmingham, Bristol, Cardiff, Edinburgh, Belfast, and Dublin. After the first annual general meeting, to be held in the autumn, a further 12 or more regional faculties may be set up in the British Isles: plans for these will be made soon. In areas far away from these university cities faculties may be needed in a few cities or towns that have no medical school (e.g., Plymouth and Inverness). Other regional faculties may be developed in parts of the Commonwealth. Further details will be published next month.

The Foundation Council has approved the establishment of a "Council of the College in Scotland" to co-ordinate the regional faculties and other local organizations in Scotland, and to maintain liaison with the council of the College. It is proposed to open an office in Edinburgh at once.

A meeting of general practitioners in Eire, held in Dublin on March 15, 1953, decided to form a Faculty of the College in Dublin; and an interim committee was set up to study this. Dr. John Fleetwood, of Dublin (chairman of this interim committee), has been elected to the Foundation Council of the College in London.

A meeting of the full Foundation Council, held in London on March 18, 1953, agreed that the College provisional by-law 1 (B) should be altered to read: "A 'registered medical practitioner' means a person holding a medical qualification which has been registered with the General Medical Council or with the equivalent organization of a country or State within the British Commonwealth of Nations and the Republic of Eire."

Status

The status of all Regional Faculties will be equal. For those in Scotland, Wales, Northern Ireland, and Eire it must be clearly understood that they will be free to form colleges of their own in the future if they wish to do so.

Duties

In general the duties of these Regional Faculties will be to relieve the central College council of local responsibilities connected with the activities of the College in the regions

concerned. For the first few years the main concern of the faculties will be to help (1) in the teaching of certain aspects of general practice to final-year students and those newly qualified, (2) in the postgraduate education of general practitioners in the region, and (3) in research in general practice. Later, many other functions of the College may devolve upon the Regional Faculties. Members of the board of each faculty will work in close liaison with the local medical school, the postgraduate departments of the university, and the university research departments, the local medical committees of the Ministry of Health, the local Divisions of the B.M.A., and the local medical societies.

Boards of the Regional Faculties

Each board will have up to 21 members—chairman (who may be a member of the College council or co-opted to the council), deputy chairman, member for undergraduate instruction, member for postgraduate study, research member, and honorary secretary. The secretary will keep in touch with members and associates of the College who work in the region, receiving information from them and providing them with information, so that the College and its regional faculty can give them all possible help in the academic field. There will be up to 15 other members, including two associates; and the boards will have power to co-opt further members from the university and elsewhere.

Members of the boards of the Faculties will be elected annually by the members of the College who live in each region. The officers will be elected by the boards themselves.

Meetings of the boards will take place about once a month. Five will be a quorum.

Copies of the minutes of the meetings of the boards will be sent to the College headquarters in London for filing and reference. Each year an annual report from each board will be sent to the College headquarters and incorporated in the College's annual report.

Subcommittees on undergraduate education, postgraduate education, research, etc., will be elected by the boards at any time for special purposes. These subcommittees will have power to co-opt members from the university departments concerned.

The secretarial expenses of the boards will be met by the College.

Will members or associates who care to make further suggestions or comments on the development of these regional faculties please write to the Secretary, The College of General Practitioners, 14, Black Friars Lane, Queen Victoria Street, London, E.C.4.

MATERNITY GRANTS

Over a year ago the National Insurance Advisory Committee (chairman, Sir Will Spens) recommended changes in maternity insurance benefits (*Supplement*, January 26, 1952, p. 28). A Government Bill—National Insurance Bill, 1953—has now been published giving effect to nearly all the recommendations of the advisory committee. A woman confined at home is to get a lump-sum grant of £12, and a woman confined in hospital a grant of £9 (both grants including an attendance allowance of £1 a week for four weeks). The arrangements for paying maternity allowances to women in employment are to be changed. At present a grant of 36s. a week is paid for 13 weeks beginning with the sixth week before the expected date of confinement, making £27 8s. in all when the maternity grant of £4 is added. The Bill increases the grant from £4 to the standard amount of £9 (or, when the confinement takes place at home, £12), and the maternity allowance, reduced from 36s. to 32s. 6d. a week, is to be paid for eighteen weeks, starting eleven weeks before the expected date of confinement. These

changes have the effect of increasing the total amount paid from £27 8s. to £38 5s., or in the case of home confinement to £41 5s. It is estimated that these proposals will cost an additional £2,500,000 a year.

Nova et Vetera

THE FIRST GREAT AMERICAN PHYSICIAN

Letters of Benjamin Rush. Edited by L. H. Butterfield. Published for the American Philosophical Society by Princeton University Press, 1951. Vol. I: 1761-1792, pp. lxxxvii+624. Vol. II: 1793-1813, pp. 625-1,295. Price for 2 vols. 97s. 6d. London: Geoffrey Cumberlege. 1951.

Benjamin Rush (1745-1813), of Pennsylvania, a signer of the American Declaration of Independence, was a figure highly characteristic of his time and circumstances. He was a graduate of Princeton and Edinburgh. At the latter university he had as teachers Cullen, Black, and Alexander Monro Secundus. In his own country he came to occupy a very important position both in politics and in the medical profession. He introduced clinical instruction in the Pennsylvania Hospital, to which he was physician for 30 years (1783-1813), and he was for long also Treasurer of the United States Mint (1799-1813). Despite these avocations he found time for some excellent first-hand research describing cholera infantum in 1773 and dengue in 1780, writing a first-class account of the Philadelphia yellow-fever epidemic in 1793, giving the first account of the diseases of American Indians in 1774 and 1798, and issuing a work on the hygiene of troops in 1777. He was a strong advocate of temperance, and emphasized the importance of diet and the necessity to health of the extraction of decayed teeth. He wrote and spoke freely on non-medical subjects, was a vigorous and magnetic personality, and had a full, balanced, and active mind. He left an autobiography which was edited in 1948 for the American Philosophical Society by Professor G. W. Corner.

Rush's vivid personality is much involved in his immediate environment. He was essentially a townsman and a Philadelphian, for he never took a holiday, and after his return to America he seldom left Philadelphia, and almost never by choice. In his *Autobiography* he says that he "by no means depended exclusively on books. I made, as far as was in my power, every person I conversed with contribute to my improvement." His correspondence was immense, and no American, and few English, writers furnish so many and such excellent pictures of city life in his era. As a writer he was studiously clear, and this induced many to elicit his views on a multitude of topics. His correspondence deals with subjects as diverse as psychiatry and forestry, veterinary science and ventilation of ships, the study of punishments and of chemistry, the training of children, the liberation of the Spanish colonies, university curricula, and how a stepmother should comport herself. Despite the positiveness of his opinions he remained on terms of intimate friendship with men of the most diverse views. The collection of letters in these two large volumes is thus a record of the many amiable traits in Rush's character which his deadly earnestness and his contentiousness have hitherto often obscured. Rush was essentially a communicative man, and his abundant personality can best be conveyed in his own words. For this reason the great length of these volumes fully justifies itself. Each letter and each reference in it is fully documented by Dr. Butterfield, their editor. The result is an admirable commemoration alike of Rush, of his *alma mater*, Princeton University, and of the American Philosophical Society.

It is, however, impossible within the limits of this column to give more than a couple of extracts from the hundreds of letters in these volumes, many of which are quite thrilling. Two of medical interest must suffice.

A Slave Freed

"To the Pennsylvania Abolition Society.

"Philadelphia, November 14, 1788.

"There is now in this city a black man of the name of James Derham, a practitioner of physic, belonging to the Spanish settlement of New Orleans on the Mississippi. This man was born in a family in this city in which he was taught to read and write and instructed in the principles of Christianity. When a boy, he was transferred by his master to the late Dr. John Kearsly, Jr., of this city, who employed him occasionally to compound medicines and to perform some of the more humble acts of attention to his patients.

"Upon the death of Dr. Kearsly, he became (after passing through several hands) the property of Dr. George West, surgeon to the Sixteenth British regiment, under whom, during the late war in America, he performed many of the menial duties of our profession. At the close of the war he was sold by Dr. West to Dr. Robert Dove, of New Orleans, who employed him as an assistant in his business, in which capacity he gained so much of his confidence and friendship that he consented to liberate him, after two or three years, upon easy terms. From Dr. Derham's numerous opportunities of improving in medicine, he became so well acquainted with the healing art as to commence practitioner at New Orleans under the patronage of his late master. He is now about twenty-six years of age, has a wife but no children, and does business to the amount of three thousand dollars a year.

"I have conversed with him upon most of the acute and epidemic diseases of the country where he lives, and was pleased to find him perfectly acquainted with the modern simple mode of practice in those diseases. I expected to have suggested some new medicines to him, but he suggested many more to me. He is very modest and engaging in his manners. He speaks French fluently and has some knowledge of the Spanish language."

Strong Armchair

"To John Redman Coxe.

"Dear Sir,

"September 5, 1810.

"In attending the maniacal patients in the Pennsylvania Hospital, I have long seen with pain the evils of confining them, when ungovernable, by means of what is called the mad shirt or straight waistcoat. It generally reduces them to a recumbent posture, which never fails to increase their disease. In this state they often lie whole days and nights, and sometimes in a situation which delicacy forbids me to mention. The straight waistcoat moreover renders it impracticable to feel their pulses or to bleed them without taking off the greatest part of it. To obviate these evils and at the same time to retain all the benefits of coercion, I requested, by permission of the sitting managers of the Hospital, Mr. Benjamin Lindall, an ingenious cabinetmaker in this city, to make for the benefit of the maniacal patients a strong armchair, with several appropriate peculiarities as noticed in the drawing which I have herewith sent you for your *Museum*. From its design and effects I have called it a TRANQUILLIZER."

And lastly, as a timely warning to all medical men, a letter to his son:

"To James Rush.

"My dear Son,

"Philadelphia, November 18, 1803.

"Herewith you will receive your boots. They will serve I hope two purposes: 1st, to keep your feet and legs warm during the winter, and 2ly, to remind you that you have a father and mother in Philadelphia who have never forgotten you for a *whole week* since you came into the world. O fie—O fie, James!

"I never knew an instance of a man becoming eminent, respectable, or even wealthy in the profession of medicine who was deficient in punctuality in letter writing.

"Adieu! From your affectionate though neglected parents,

"Benjn. and Julia Rush."

Let those who object to writing certificates take this to heart.

The reviewer feels that he must not end without assuring the reader, what he will have already gathered, that Dr. Butterfield has produced a work of first-class importance for the general history of the late eighteenth century. It is perhaps the most important contribution to American history that has been made for a good many years. It is impossible, however, to do justice to that aspect here.

CHARLES SINGER.

Correspondence

Modern Anaesthesia in Prostatic Surgery

SIR,—In the recent discussion on prostatic surgery in your columns, little has been said of the contribution to success made by modern anaesthesia. Indeed, it may well be that safe anaesthesia is every bit as important as the anatomical route of operation or the degree of operative precipitancy shown in these cases. In our department we have lately been using a combination of low spinal analgesia with regional analgesia of the abdominal wall for prostatectomy. This method was advocated by Gordon-Taylor.¹ Rowbotham,² who attributed the method to Jennings Marshall, emphasized its value in minimizing bleeding. It seems, however, that such a technique is not widely used at present.

Our procedure has been as follows: After a pre-operative injection of morphine $\frac{1}{4}$ gr., spinal anaesthesia is administered in the sitting position. The fourth/fifth lumbar space is used; 0.5 to 0.75 ml. of "nupercaine" (cinchocaine 1:200) is injected without barbotage. The patient is kept sitting for five minutes and is then placed in the supine position. The solution used for the infiltration of the lower abdomen is conveniently made by mixing 20 ml. of a 2% solution of "xylocaine" (lignocaine) with 140 ml. of normal saline, and then adding the contents of a $\frac{1}{2}$ -ml. ampoule of adrenaline 1:1,000. The injection is usually made by the anaesthetist, but, if not practicable on account of obesity, the solution is injected layer by layer by the surgeon.

In our short series of cases the operations have been either retropubic (6) or transvesical (14). One transvesical operation included a segmental bladder resection. Ten operations have been emergencies for acute retention of urine (transvesical, 6; retropubic, 4). The patients have ranged in age from 57 to 84 years, six being octogenarians. All have tolerated the procedure well, though one patient complained of some discomfort during enucleation of the gland by the retropubic method, where it was recognized that there had been an error in technique. In all the circulation has remained good and bleeding has been slight. All the patients have been able to drink copiously from the moment of their return to the ward.

Many authorities condemn spinal anaesthesia for prostatectomy on two grounds: (1) that the fall in blood pressure carries a risk of reactionary haemorrhage; and (2) that the bladder, for some hours after operation, loses its power to expel its contents through the drainage tube, so that the risk of clot retention is increased (Magill³). Rowbotham² stressed that with low spinal anaesthesia vasoconstriction in the prostatic bed and contraction of the prostatic cavity resulted from unopposed sympathetic action following paralysis of the sacral autonomic nerves. Forrester⁴ maintained that extension of the "low spinal" to include the third lumbar segment, planned to leave unaffected the sympathetic fibres arising in the first and second lumbar segments, still allowed incisions to be made in the lower abdomen. As the skin of the lower abdomen is innervated from the tenth thoracic to the first lumbar segments, it seems that spinal anaesthesia allowing such incisions to be made would of necessity inactivate some of the sympathetic outflow. The advantages of a sustained systemic blood pressure and of unopposed vasoconstrictor action in the prostatic bed would then be lost.

We favour the use of spinal analgesia confined to the sacral segments in order to diminish bleeding without depressing systemic blood pressure. The regional analgesia of the lower abdominal wall produces less disturbance than even the best general anaesthetic. The combination of both is well tolerated by the elderly, bad-risk prostatic patient and seems worth an extended trial.—We are, etc.,

H. W. LOFTUS DALE.

R. B. CLAYTON.

W. R. PROBERT.

Sterility after Lumbar Ganglionectomy

SIR,—In his article (January 31, p. 247) Mr. S. S. Rose rightly draws attention to the fact that male patients are certainly by no means invariably sterile after a resection of the lumbar paravertebral sympathetic chain which includes the first lumbar ganglion. Indeed, he describes one of his cases of extensive sympathectomy who was later able to produce a seminal emission, and he mentions three cases in the literature. We should like to report a similar patient who not only has been able to produce semen but has achieved paternity.

This patient has been followed up for three and a half years after the operation of bilateral paravertebral sympathectomy and splanchnicectomy for hypertension. The resection included T₁-L₂ ganglion on the right side, but at the second operation two months later technical difficulties prevented the resection from being carried with certainty above the T₁₀ level, but the lower end included the L₂ ganglion. Three months after the operation on the right side and three weeks after that on the left, the patient was tested for residual sweating by the electrical skin resistance method after first heating until he was sweating freely. The patterns showed complete denervation in the L₁-S₂ dermatomes on both sides and in T₁ to approximately T₁₀ dermatomes on the right thorax, but only about T₁₀ and T₁₁ dermatome on the left thorax (Boyd, J. D., and Monro, P. A. G.).

Subsequent testing 19 months after the first operation showed an essentially similar pattern, except that the edges of the anhidrotic areas were less irregular and the area of anhidrosis on the left side after injection of carbachol consisted of a single belt on the flank extending to within about two inches of the midline front and back. At this time the patient stated that he thought he was producing semen on intercourse, but, though he experienced orgasm, this was not accompanied by *rhythmic* ejaculation. His child was born 16 months later. ABO grouping is not incompatible.

More recent testing 42 months after the first operation shows that the sweating pattern on the right side is unaltered, but on the left thermoregulatory sweating is now present in the axillary line in about a 2 in. (5 cm.) wide strip across the belt of previous anhidrosis in the T₁₀-T₁₁ dermatomes—thus indicating a partial recovery of sympathetic function at this level. The anhidrosis in the L₁-S₂ dermatomes remains unchanged on each side.

In an article (Boyd and Monro¹) it has been shown that the "escape area" in the L₁ and L₂ dermatomes—with probable overlap into the T₁₂ and L₃ dermatomes—is supplied by ganglion cells situated in the lumbar intermediate sympathetic ganglia which, because of their inaccessible position in close proximity to the nerve roots, have survived the paravertebral sympathetic resection. A sweating test will therefore not indicate whether or not any part, or whole, of the paravertebral sympathetic chain from the level of T₁₂ to L₃ has been left behind. In this particular case it seems to us more probable, in view of the partial return of sympathetic function to the left T₁₀-T₁₁ dermatomes after three years, that the recovery of sympathetic control of the pelvic viscera has been by regeneration of preganglionic pathways from T₁₁ nerve root (at the lowest) on the left side. A possible alternative pathway could be from intermediate ganglia related to either L₁ or L₂ nerve roots. Serial section of post-mortem material has shown that such a pathway from intermediate ganglia may be traced along the course of the lumbar arteries towards the aorta, and that these fibres had escaped section. Though it is possible that this pathway might contain preganglionic fibres to the mesenteric ganglia it appeared more probable that the fibres in this bundle, which was very small, were mostly distributed to the blood vessels (Monro²). Seminal anorrhoea is the usual finding after extensive sympathectomy, but the presence of lumbar intermediate sympathetic ganglia is invariable. It therefore does not appear that after paravertebral sympathectomy these intermediate ganglia easily establish functional communication with the pelvic viscera.

The upper level of sympathetic denervation to be found after bilateral resection of the paravertebral ganglia L₁, L₂, and L₃, as shown in Mr. Rose's paper, appears to lie at the lower edge of the L₁ dermatome. We cannot agree that

end of his course of chemotherapy the P.Z. insulin (as well as the isoniazid therapy) was discontinued. After two weeks without insulin or isoniazid the glucose tolerance test was repeated and showed:

	Blood Glucose (mg./100 ml.)
Before glucose	200
1 hr. after	304
2 hrs. "	366
2½ "	328
3 "	305

Urine specimens examined during the glucose tolerance test showed:

	Amount	Containing Total Glucose
Fasting	132 ml.	338 mg.
After 1 hr.	20 "	190 "
" 2 hrs.	45 "	2.1 g.
" 2½ "	56 "	3.1 "
" 3 "	46 "	2.9 "

Following this investigation, the patient was restabilized on insulin P.Z. 32 plus soluble 12 each morning and treated as an ordinary diabetic. He was allowed home for further bed rest only, but readmitted on January 19, 1953, for further reassessment over a period of a week as laid down for the M.R.C. isoniazid trial. This was six months after commencing his three months' course of chemotherapy.

On admission his clinical condition was very satisfactory and the sputum was negative on direct smear examination. The radiograph showed no further change in the tuberculous lesion. The insulin requirements had fallen and the patient was restabilized on P.Z. 24 units and soluble 6 units daily.—We are, etc.,

CYRIL EVANS.
PETER STRADLING.

London, W.12.

The Young Delinquent

SIR,—In the review of my book *Juvenile Delinquency*, Sir Cyril Burt (February 7, p. 317) very properly points out my slip with regard to Dr. H. H. Goddard. The corrected sentence should of course read: "Some of the more outstanding contributions to this development have been made by Sir Cyril Burt in this country; by H. H. Goddard, W. Healy, and . . . in the United States of America. . ."

I have not, however, fallen into the error, as he suggests, of saying that intelligence quotients and similar devices were not used in clinics for diagnostic purposes before World War II. What I have said is that since World War II intelligence quotients and personality profiles have for the first time been assessed in many hospitals and clinics as an essential part of any psychiatric diagnostic procedure. During the past few years there has been a great development in the use of these and similar techniques in clinical practice, as most medical practitioners know full well.—I am, etc.,

London, W.1.

J. D. W. PEARCE.

Sympathectomy for Recurrent Albuminuria of Pregnancy

SIR,—The problem of recurrent albuminuria of pregnancy with repeated stillbirth in the seventh or eighth month of successive pregnancies has long exercised the minds of obstetricians. Mr. G. W. Theobald is greatly to be congratulated upon his imagination and enterprise in devising a perivascular sympathectomy operation (February 21, p. 422) to increase the uterine blood supply and thus provide an answer. His pilot survey of three cases is at least suggestive that the operation deserves a more extensive trial. However, it is my experience that a young primigravida with toxæmia of pregnancy, as opposed to hypertensive disease, will almost invariably remain free from recurrence in her next pregnancy however early the albuminuria developed in her first. As hypertensive disease and

toxæmia are often difficult to distinguish, I believe that Mr. Theobald should have laid even more emphasis upon the need for two albuminuric stillbirths before his operation was indicated.

I have recently had under my care two young primigravidas with alarming toxæmia at the twenty-fourth week of pregnancy. In one case hysterotomy was undertaken, while the other delivered herself after the insertion of laminaria tents. Both were encouraged to become pregnant again without delay despite a residual hypertension of 140/90 in one case. Both had uneventful pregnancies without albuminuria one or two years later. Unless the strictest criteria are laid down for the indications for this operative procedure it will be impossible to assess its true value.—I am, etc.,

Birmingham.

W. G. MILLS.

Prophylaxis of Tetanus

SIR,—As a comment upon Dr. Leslie Cole's Refresher Course article on tetanus (January 17, p. 150), may I suggest that the real solution of the whole problem of prophylaxis lies in a combined diphtheria-tetanus toxoid given in the first year of life with a "boosting" dose later? I believe the public would readily accept this, and the cost would not, I think, be prohibitive even if it became universally accepted, for it would be spread out over the years. It should, if adopted, gradually wipe out the death rate from tetanus, which, after all, is about twice that from diphtheria at the present time, and there would at least be a great saving in respect of serum.

It is no reflection upon medical officers of health to suggest that pressure to secure this valuable extension of preventive medicine must come from the general practitioner, who is always in a potentially vulnerable position in regard to tetanus. If he sees the wound soon after it is inflicted and does not give serum, and the patient later develops tetanus, he is very likely to be blamed, whereas if anaphylaxis comes like a bolt out of the blue, as it can after a dose of serum, he is not likely to be popular.—I am, etc.,

London, N.W.7.

A. H. MORLEY.

A Journal and its Readers

SIR,—Surely your leading article on this subject (February 28, p. 496) must give rise to deep thought amongst many of your readers. To me, at any rate, it seems to be more an apology for the general layout and contents of the *Journal* than anything else. Certainly the original work is refreshing for those who have the time to read it; but how many of us have? The correspondence columns sometimes contain interesting letters when these are not crowded out by the uninteresting, and the *Supplement* when it was separated from the *Journal* was a ready guide to current medical politics.

Considering what an overwhelming number of your members are general practitioners, it is amazing how little of real interest to them appears therein. You may say there are the "Refresher Courses," but if you come to read them how many of them avoid the technical and keep to the simple and produce something easy to read and remember? Let me compare the article on "Tachycardia" in the *Journal* (February 28, p. 500) with that on "Recent Advances in Geriatrics" (*Medical World*, December 5, 1952), which was an object lesson in clarity and usefulness. I could give many more.—I am, etc.,

Worthing.

HAROLD LEESON.

SIR,—Dr. J. M. B. Morwood (March 14, p. 620) laments that the *Journal*, in his opinion, fails to produce very much for anybody.

Until qualified, the student's tastes in medicine must remain catholic. This being so, he is amongst the *Journal's* most important readers. Popular demand dressed the

"Refresher Course" series of articles in book form. The implied insult in this title is very hard to see. Whatever one's chosen path in the healing art and success on it, the most and best one can claim is to remain a student of it.—I am, etc.,

London, N.1.

DUNCAN D. MACDONALD.

Cross-resistance between "Daraprim" and Proguanil

SIR,—A letter from Drs. G. I. Robertson, D. G. Davey, and Sir Hamilton Fairley (December 6, 1952, p. 1255) reported that a proguanil-resistant strain of *Plasmodium falciparum* from Malaya had proved to be resistant also to pyrimethamine ("daraprim"). Proguanil-resistance in Malayan strains of *P. falciparum* has been recognized since 1949¹; and if a true cross-resistance exists, this might—as implied by Dr. J. S. K. Boyd (February 7, p. 337)—go far to explain the pyrimethamine failures described in our paper (January 31, p. 253).

Proguanil has been so widely used throughout Malaya for the past six years that there can be few strains of parasite which have not yet come into contact with it; thus there is little chance of deciding now how the "parent" strains (without previous contact with proguanil) might have responded to pyrimethamine. We have not, however, been able to confirm that there is any consistent cross-resistance between these two drugs in naturally acquired falciparum malaria since pyrimethamine was first used in Malaya in 1951. Pyrimethamine failures have been successfully treated with normal doses of proguanil, and proguanil-resistant infections have responded readily to pyrimethamine. In some of these cases an interval of several days was allowed to elapse between treatments, so the possibility of a combined action of the two drugs should have been small.

We consider that these apparently conflicting results can best be explained by assuming that some present-day strains of *P. falciparum* in Malaya possess a "natural" resistance to pyrimethamine, whether or not any particular strain is also demonstrably resistant to proguanil. With this species of parasite, a true cross-resistance has still to be proved.—We are, etc.,

Kuala Lumpur, Malaya.

T. WILSON.
J. F. B. EDESON.

REFERENCE

"Butazolidin"

SIR,—The first clinical report on butazolidin was made, not in the U.S.A., as you state in your leading article (December 27, 1952, p. 1401), but by Dr. John Currie at the European Rheumatology Congress, Barcelona, in September, 1951.¹

You ask whether butazolidin is merely a potent analgesic or whether it has specific anti-rheumatic action. The following considerations after 200 cases have left me in no doubt that it has a specific effect on rheumatic inflammation. Pains from sources other than joints and muscles, such as sciatic pain from carcinoma of pancreas, cellulitis, and psychogenic rheumatism, carcinoma of pancreas, cellulitis, and psychogenic rheumatism, have not been relieved. In five rheumatic patients acute gastric pain has been brought on by butazolidin, while joint pains have been relieved. In 20 cases acute swelling of a single joint has subsided dramatically at the same time that the pain has been relieved. The joints were not rested; several acutely swollen knees and ankles subsided while the patient continued to walk about.

I do not believe that we have any means—other than low dosage and careful clinical observation—of preventing or forestalling toxic side-effects. I have not found any abnormalities in the blood in 35 patients with nausea, rashes, or oedema. Therefore the patient's own symptoms are the safest guide to toxicity. Granulocyte counts have remained consistently normal in a total of more than 1,000 cases reported by various authors; Steinbrocker and others² detected five cases of neutropenia, but in three the count returned to normal with continued butazolidin treatment. Lowering of platelet counts—reported by Currie³ and Stephens and others⁴—was not associated with purpura or any

other untoward symptoms; in the single case of purpura reported by Rhys Davies and others⁵ the platelet count was normal.

Routine and repeated counts of platelets and granulocytes are laborious, and they may lead us astray because we do not know the hour-to-hour and day-to-day fluctuations of platelets and granulocytes in the normal subject. Laboratory observation of the blood should not be mandatory, and failure to observe this precaution should not be regarded as neglect.—I am, etc.,

Melbourne, Australia.

"Unfit for Military Service"

SIR,—May I endorse the letter of Dr. A. Barham Carter (February 7, p. 334) and take the point he raised one step further? As a regimental medical officer I am frequently called upon to interpret certificates given to Service personnel who are sick on leave which are either unreadable or couched in technicalities which give no indication as to the seriousness (or otherwise) of the soldier's illness.

It also does not appear to be widely known that Service personnel sick on leave must produce, on return to their unit, a certificate stating that they were *unfit to travel* at the termination of their leave. Failure to do so, or to provide other suitable evidence, may result in disciplinary action being taken against the man concerned. Minor ailments which do not prevent the man from travelling are not accepted as an excuse for absence.

May I therefore put in a plea to practitioners treating these patients to write their certificates in plain language, and state that the patient was fit, or unfit, to travel on the dates concerned, so that his commanding officer can assess the case in its proper light?—I am, etc.,

Walton-on-Thames.

C. D. ELTON.

Nicotinic-acid Deficiency in Psychiatric Practice

SIR,—Increasing attention is now being paid to the large numbers of psychiatric patients who exhibit signs and symptoms suggestive of deficiency of the vitamin-B group, and articles by Jolliffe *et al.*,¹ Wadsworth *et al.*,² Sydenstricker and Cleckley,³ Washburne,⁴ and Gregory,⁵ among others, are worthy of study. The following account of a recent psychiatric case admitted to hospital may be of interest as being illustrative of such deficiency states.

A man aged 43 was admitted to hospital in a stuporose condition on October 9, 1952. He was restless, agitated, and confused, and resisted all attempts to feed him, examine him, or converse with him. He was also depressed, emotional, and actively suicidal. Physically he was in an extremely weak and emaciated condition, quite unable to stand, and with a coarse tremor of his tongue and limbs. His skin was dry, scaly and atonic, and there were large patches of dermatitis on his abdomen and back, and smaller ones on the backs of his knees and elbows, and also on his wrists, hands, and feet. His lips were dry, sore, and cracked. His tongue was dry, red, raw, and fissured, and his teeth and gums were unhealthy and neglected. His stools were loose, he was doubly incontinent, and there was a huge bedsore as large as a tea plate over his sacrum.

His wife gave a history of gastric carcinoma first suspected in 1943 and successfully treated by partial gastrectomy. Early in 1952 he complained of dyspepsia, began to lose weight, and developed a terrible fear of recurrence of cancer. Despite negative findings with x-ray examination and reassurance he became increasingly depressed and introspective, refused all food, and finally was admitted to hospital because he was suicidal. He did not use his voice for some months prior to admission to hospital, but his speech was confined to incoherent whisperings about "cancer." He was diagnosed as suffering from a confusional state with marked depressive and phobic features, and on purely clinical grounds he was thought to have a nicotinic-acid deficiency of such a degree as to present almost a classical picture of pellagra. He was immediately given nicotinic acid 1,500 mg. intrapellagra. He was immediately given nicotinic acid 1,500 mg. intrapellagra. He was immediately given nicotinic acid 1,500 mg. intrapellagra. The solution was injected slowly into a vein at the bend of the elbow,

and after an interval of two and a half minutes there was an intense reaction with marked flushing, first of the face and then of the trunk and limbs. The patient appeared to awaken from his lethargic state, conversed normally for about 15 minutes, and then slipped back into a state of torpor again. This treatment was continued daily, and after 24 hours he was co-operative and willing to take food and drugs orally. As his condition improved his diet was supplemented, and by the tenth day of treatment he had full volition and was co-operating well and conversing normally. Nicotinic-acid therapy was continued for 28 days, supplemented by oral vitamin "B-complex," and afterwards combined oral therapy was continued.

The results have been most gratifying. The patient is now up all day, is usefully employed in the hospital, and is bright and optimistic about the future. He has a good appetite, and his weight has increased by 2 stone (12.6 kg.) since admission. Within a month all his skin and mouth lesions had cleared up completely, and the huge ulcer crater over his sacrum is almost completely healed. He is now fit enough to return to his former employment.

Such a case is probably met with very infrequently in clinical practice, but minor degrees of nicotinic-acid deficiency are comparatively common in pre-senile and senile depressive and confusional states, and the signs and symptoms should be looked for and treated early, as the response is usually very gratifying.

I am indebted to Dr. L. Barber for permission to publish this case, and to Dr. D. C. Dewar for his help and advice.—I am, etc.,

Walton-on-Thames.

Attitude Surveys with Patients in Hospitals

SIR,—Since a contented patient is likely to regain physical health more quickly than one who is unhappy or frightened, it is important for responsible staff in hospitals—medical, nursing, and administrative alike—to know in detail the views of their patients. But hospitals are complex organizations, and it is difficult for the staff to obtain an accurate picture of the patients' attitudes towards all the various aspects of their stay in hospitals. The vocal patient is not necessarily the typical one. Whether the patients' views are favourable or unfavourable, whether they are based on fact or on misapprehension, they are equally important in their effect.

One method of gaining this information is by conducting attitude surveys by the "confidential individual interview method" with a representative sample of patients shortly before they are discharged. Such surveys are best conducted by an impartial outsider who can inspire confidence in the promise of anonymity, who has time to devote to the inquiry, and who has the special training and skill to get a flow of information without prompting or question. The procedure of conducting attitude surveys in hospitals would at first have to be experimental, but might follow some such lines as those indicated below.

The co-operation of the staff, medical, nursing, and administrative, would first be obtained so that they realized that the purpose of the survey was to give constructive help. Then a representative sample of patients would be interviewed, each as near to the time of discharge as possible. Before each patient was interviewed he would receive a letter from a senior member of the hospital staff urging him to co-operate. He would be asked to comment on all aspects of his stay in hospital, and told that what he said would be reported, but with no name mentioned. An account of the survey would give the hospital information on the views of its patients, analysed by ward, age, length of stay, etc. When a number of surveys had been made in different hospitals a general report could be prepared which, while preserving the anonymity of the hospitals concerned, would indicate matters found common to many hospitals that could be altered for the benefit of the patients.

Considerable interest has been expressed in this scheme by the doctors, nurses, and administrators with whom it has been discussed, and a pilot survey has been undertaken. It is hoped that more hospitals will be ready to collaborate in it.—I am, etc.,

London, W.1.

Assistant Director,
National Institute of Industrial Psychology.

Bilateral Cough Fractures

SIR,—Articles by Dr. J. B. Mitchell¹ and Dr. N. Wynn-Williams² and subsequent correspondence drew attention once again to cough fractures as a cause of pain in the chest. There has been no mention of the fact that these fractures can, on occasion, be bilateral: a search of the literature shows that no cases of this type have been described in this country and only four articles in the American literature record such fractures. Howson³ quotes one case with three fractures on the right side and one on the left. Richardson,⁴ reviewing 1,903 patients, found 30 cases with cough fractures, in which four were bilateral. Swineford and McKinnon⁵ quote a patient who fractured eight ribs in six months, three on the left side and five on the right. Bodenheimer,⁶ reviewing the literature up to that date, gives a figure of 4% as the incidence of bilateral fractures. Details of two further cases are given below.

The first patient, a woman schoolteacher aged 25, became ill early in December and was sent to the school sanatorium: she was told she had "congestion of the lungs." About December 8 she coughed while bending over to pick up her bedroom slippers from under the bed, and felt an acute pain in her left side. This was treated with poultices. On December 15 she was allowed up to help pack her luggage for the Christmas holidays, and while bending over her case she coughed and had quite severe pain in her right side. She came home on holiday and was sent to hospital for an x-ray examination of her chest on January 2. This showed recent fractures of the 8th and 10th right ribs and the 10th left rib. The patient was quite unaware of these fractures and had felt no pain since Christmas.

The second patient was a woman aged 39 who had "bronchitis" for several weeks and developed pain in the left side of her chest. X-ray examination in January showed fractures of the 5th, 6th, 7th, and 8th left ribs and fractures of the 6th and 7th right ribs. Those on the right side were healed and had probably occurred several months or more before the fractures on the left side, all of which were recent fractures. She had suffered from a persistent cough for several years and could remember an attack with some pain in the right side much earlier in the year. The pain in the left side had started after a bout of coughing which had occurred when she was lifting some heavy washing. In both patients the fractures were antero-lateral.

Both these cases have one factor in common: the ribs were fractured when coughing occurred as the patient was bending—i.e., when the diaphragm was pushed up by the abdominal contents; they are in this respect similar to the cough fractures occurring in late pregnancy. In neither case did the patients show any radiological signs of either pulmonary tuberculosis or of any other abnormality of the ribs.

It is difficult to assess the incidence of bilateral cough fractures. The figure of 4% quoted by Bodenheimer is probably high, but it is certain that the condition is much commoner than the literature would suggest. It adds one further possibility to the list when the differential diagnosis of pain in the chest is being considered—and casts doubt on the diagnosis of "intercostal myalgia" or "fibrositis" when the pain is bilateral; in all respects the clinical features are similar to those found with unilateral fractures.

My thanks are due to the Librarian of the B.M.A. for his help with the references, and to Miss Marjorie Collins for secretarial assistance. Dr. C. B. Lanyon and Dr. J. Deighton kindly referred the patients to me.—I am, etc.,

Falmouth.

POINTS FROM LETTERS

Tetanus

Dr. K. M. HAY (Birmingham) writes: I have seen a case of tetanus recently in a young man which might be of interest. The patient pricked his finger on his wife's sewing about ten days before the onset of tetanus, but no blood was drawn. There was no other history of injury, nor had the patient ever suffered a severe laceration. Minor injuries of this sort are so common that it would be impossible to give antitoxin whenever they occur. . . . As things stand, it would seem that a doctor who fails to give serum in every case of injury, however trivial and whether blood is drawn or not, is likely to face considerable medico-legal trouble if tetanus should supervene, in spite of its rarity. The best solution would be for all the active members of the population to be immunized, as in the Services.

Dummies for "Air Babies"

Dr. MARY E. BUDDING (Tavistock) writes: Sir Harold E. Whittingham in Part I of his Refresher Course article (March 7, p. 556) on air travel makes a suggestion that mothers with babies should perhaps be instructed to give them a dummy to suck during ascent and descent. Perhaps unwittingly this might have the effect of once more increasing the sales of the undesirable dummy, which has at long last fallen into disrepute, even among mothers. . . . I myself have always appreciated the excellent brands of chewing-gum and peppermint ("extra strong") provided by the airlines, and wonder if Sir Harold Whittingham can use his influence to persuade them to provide our babies, when travelling, not with dummies, but perhaps with glycerin-based rapidly dissolved once-used-only large sweets?

Litigation Against Doctors

Dr. LESLIE HARTLEY (Camberley) writes: Under the new regulations a newly qualified doctor must take an appointment in a hospital. If he feels that the stigma of an action for damages against him may be attached to him at the very beginning of his career, the medical student may become as rare a bird as the infallible doctor. Actions such as these are bound to react ultimately on the public themselves, as medical men will refuse to take responsibility and will pass more and more work to the specialist if they feel that they are liable to be involved in litigation. A doctor friend of mine told me that when he got a foreign body underneath his upper eyelid in New York he had to put up with it for three hours before he could contact an ophthalmic surgeon to evert his lid and remove it, as no nurse or doctor would touch his eye. When he told the ophthalmic surgeon that any trained nurse or doctor in England would have done it for him, he said, "Ah, yes, but they do not litigate in your country." A High Court judge recently called attention to the increasing amount of litigation in this country since the introduction of free legal aid, which means that people can bring actions at the taxpayer's expense.

Misuse of Words

Dr. R. T. D. FITZGERALD (Eastbourne) writes: May I add to your collection of misused words two favourites from my own collection? In the days when doctors wrote English and confectionery was rife it was not uncommon for patients to suffer from Hutchinson's triad, but now that doctors follow the artists in their search for novelty for novelty's sake, and write indifferent journalese and ambiguous jargon, congenital syphilis has given way to congenital heart disease and patients suffer from Fallot's tetralogy. Let us remember that, however interested we may be in Fallot's tetralogy, our patients can only suffer from Fallot's tetrad. The anthropoid pelvis has recently been so called from its resemblance to that of the ape, but it so happens that our learned fathers called the apes anthropoids from their resemblance to the human species.

A Coroner's Remarks

Dr. M. G. L. LUCAS (H.M. Coroner for the North District of the County of Bedford) writes: My attention has been called to the literature which accompanies a current advertisement of the "Bedford" Corporation. It quotes remarks made by the "Bedford" Corporation on September 23, 1952, and the suggestion is made in an accompanying letter from the medical director of Clinical Products, Ltd., that he is entitled to use the remarks of the "Bedford Coroner" as testimony of the advantages and safety of the tablets in question. I wish to make it clear that I did not take up office here until October 1, 1952. The verdict was not mine and I cannot associate myself with the opinions expressed.

Obituary

LEO DOYLE, M.B., M.S., F.R.A.C.S.

The sudden and unexpected death of Mr. Leo Doyle at the close of an operation which he had been performing at the Mercy Hospital, Melbourne, has robbed the Australian continent of one of its foremost surgeons. We are indebted to Sir Gordon Gordon-Taylor for the following appreciation:

Born in 1891, Leo Doyle graduated in medicine at the University of Melbourne in 1913, and served in the Royal Australian Navy in the 1914-18 war. He had belonged to the first batch of undergraduates who joined St. Vincent's Hospital when it became recognized by the University of Melbourne as a clinical school; he subsequently became its first registrar, and lived to be senior surgeon for a number of years to the hospital of his choice. Doyle was never afflicted with any *furor scribendi*, and his name is therefore less well known than some of his compatriot colleagues', save to those of this country to whom has been vouchsafed the privilege of visiting the great surgical centre of Melbourne and to the many young surgical aspirants in London and Britain to-day—a goodly proportion from "Vincent's"—by whom the name of Leo Doyle is respected and esteemed and to whom the man himself was a veritable surgical father.

Leo Doyle's reputation will not rest upon his teaching, nor was he one "to be sought for in the council of the people": he was a man of few words, a flair for diagnosis, and a sharp knife—not that he contemned the diathermy, for there were some who regarded his diathermy gastrectomy for peptic ulcer, without the employment of clamps, as one of the very best examples of his superb surgical technique. He was never satisfied with himself, always wanting to do something better:

Who, not content that former worth stand fast,
Looks forward, persevering to the last,
From well to better, daily self-surpass.

Like the artificer of Ecclesiasticus, he "set his heart upon perfecting his works, and he will be wakeful to adorn them perfectly," so that of Leo Doyle it may be truly said that he was *simplex munditiis*, a worker simple in his elegance.

I believe that most Australian surgeons would share the writer's view and acknowledge Doyle's supremacy in the operative treatment of malignant disease, and I have memories, on my many visits to Melbourne, of cases in his wards convalescing from operations as diverse as pharyngectomy, laryngectomy, pharyngolaryngectomy, oesophagectomy, total gastrectomy, and the "hindquarter" amputation, of which he had done several. He was proud of having been house-surgeon to that great pioneer of thyroid surgery, Sir Thomas Dunhill, and never tired of expressing his indebtedness to his old chief. A true exemplar of Cromwell's hope—"To be a Seeker is to be of the best sect next to a Finder"—he remained a humble student to the end.

His home life was a happy one, and loyal assistants like Lorna Sisely and Ellery Ryan, who each remained with him for many years, virtually belonged to the family. Leo Doyle worthily maintained the prestige and lustre of a hospital which could boast of Dunhill and of Devine as having served on its staff, but by his intense humanity he also proved himself a true disciple of that

Father Vincent, dead nearly 300 years ago, whose name attaches to hospitals on either side of the Equator, but whose spirit and example pervade a far larger number who lack the title of "Vincent's." From the manner of his passing he was not destined to repine the dwindling activities of advancing years, when in the words of Adam Lindsay Gordon, whose statue finds a place only a few yards from Leo Doyle's hospitable home in Spring Street:

The songs are ended, the deeds are done,
There shall none of them gladden me now, not one,
There is nothing good for me under the sun,
But to perish, as these things perished.

Leo Doyle lived and died "the happy Warrior . . . that every man in arms should wish to be."

Mr. J. W. WALKER, who was well known in the West Riding as a surgeon and as an archaeologist, died at his home near Bristol on February 17 at the age of 93. John William Walker was born at Wakefield on October 15, 1859, the son of Thomas Walker, J.P., and was educated at Rossall School and at University College, London. After qualifying in 1882 he worked in London for a time and held appointments at University College Hospital. Later he settled in practice at Wakefield, where he became surgeon to the Clayton Hospital. During the war of 1914-18 he served in the R.A.M.C. at the 2nd Northern General Hospital at Leeds. For his war services he was appointed O.B.E. in 1920. Mr. Walker was admitted to the Fellowship of the Royal College of Surgeons of England in 1941, at the age of 81, as a Member of 20 years' standing, and thus joined his two sons, R. Milnes Walker, now professor of surgery in the University of Bristol, and J. H. Milnes Walker, of Crewe. He took a leading part in local affairs, being a J.P., a governor of Wakefield High School, and an honorary life member of the St. John Ambulance Association. But outside his profession his main interest was in local history. His association with the Yorkshire Archaeological Society, of which he was the oldest member, dated back to 1882, and in 1924 he was elected a vice-president, later becoming president. He was also a member of the council of the society and had been its records secretary. The Wakefield Historical Society also paid him the honour of electing him its president. In his book, *Robin Hood Identified*, published in 1946, he endeavoured to prove that the Sherwood Forest outlaw was a certain Robert Hood, of Wakefield. He also wrote several other books and monographs, including *The Cathedral Church of Wakefield* (1888), *Handbook for Yorkshire* (1904), *The Church Plate of Berkshire* (1927), and *Wakefield, Its History and People*, a book which required a second edition in 1939. Mr. Walker retired from practice in 1921, and then lived in Berkshire, where he joined the Berkshire Archaeological Society and served on its council. After a move to Cheshire he finally settled at Churchill Court, near Bristol, where he died. He married Miss Constance E. Holdsworth, daughter of Samuel Holdsworth, J.P., in 1885, and in 1945 they had the satisfaction of celebrating their diamond wedding. Mr. Walker is survived by his two sons and two daughters.

By the death of Dr. J. G. BENNETT at his home at Woodley, Cheshire, on March 11 in his 64th year, the profession has lost a member of extensive experience, both as a general practitioner and as an officer in the public health service. John George Bennett was born on November 14, 1888, and he received his medical education at the University of Manchester, graduating M.B., Ch.B. in 1913, having gained the Tom Jones scholarship in anatomy and a distinction in medicine. His immediate postgraduate training included

the holding of posts as house-surgeon at the Manchester Royal Infirmary and at Pendlebury Children's Hospital. He then entered the R.A.M.C. and served throughout the war of 1914-18, being sent first to France and then to India and Mesopotamia. For his services he was awarded the Military Cross in 1919. Upon his return to civil life he was appointed assistant lecturer in the anatomy and physiology department of Manchester University, and in 1920 he proceeded to the degree of M.D. after writing a thesis describing his investigations into the embryological and pathological relationships of the lesser sac in the newborn. He also served for a short period as chairman of a pensions board, for which his experience in tropical diseases was particularly valuable. In 1922 Dr. Bennett married Miss Kathleen Ward Siddell, and in the following year he began his career as a general practitioner at Hyde. His general good will towards his patients and his keen interest in their well-being soon enabled him to build up the extensive practice which he conducted for 17 years. During this stage of his career he was a complete success, being held in high regard both by his patients and by his professional colleagues who elected him chairman of the Hyde Division of the British Medical Association from 1937 to 1939. After many years of strenuous work he retired from general practice for reasons of health just before the last war. But when the need for medical men became so essential, he was eager to serve his country again and found scope for his enthusiasm by acting as a medical referee, as a member of the recruitment medical board at Stockport, and as chairman of the pensions board at Manchester. During the last nine years of his life he turned his attention to preventive medicine by accepting the appointment of assistant medical officer of health to the Borough of Hyde, where his work was that of a clinician in the maternity and child welfare and school medical field, and as deputy superintendent at the Hyde Isolation Hospital. With the inauguration of the National Health Service his post was redesignated as that of assistant county medical officer in Cheshire, an appointment which enabled him to continue in the same field of operations. His work in the public health service, like his earlier work as a general practitioner, was most impressive. He was a grand colleague and a good man, and his death has left his associates with a sense of personal loss. His last illness was of short duration, rendered more short through a great determination to remain at duty upon many occasions when most men would have taken the easier course of obtaining a much-needed rest. He died in harness, as seemed to be his intent. Apart from his work, Jack Bennett had a keen interest in gardening and in painting water colours, and he loved a day's shooting. He is survived by a widow and a daughter, Mrs. Mary Howard, wife of Dr. Brian Howard, and to them we offer our deepest sympathy. —F. W. C. B.

Dr. HERMAN BARUCH, a former United States Ambassador to the Netherlands and to Portugal, and brother of Mr. Bernard Baruch, the statesman, died in Long Island on March 15. Herman Benjamin Baruch was born on April 28, 1872, the son of Simon Baruch (1840-1921), a well-known surgeon. He qualified in medicine at Columbia University, New York, in 1895, and spent the next eight years in general practice. He forsook medicine for finance in 1903 when he joined the New York stock exchange as a member of the firm of Baruch Brothers. During the last war he was appointed special representative of the Board of Economic Warfare in Brazil and special economic adviser to the U.S. Ambassador to Brazil. From 1945 to 1947 he was U.S. Ambassador to Portugal, and from 1947 to 1949 Ambassador to the Netherlands. He then retired from the diplomatic service. He was president of the Simon Baruch Foundation (so named in honour of his father), and he devoted the last years of his life to directing the Foundation's research into the aetiology and treatment of poliomyelitis.

Medico-Legal

DRUNK IN CHARGE

BY

A. E. M. HARTLEY, M.B., B.Ch.

The examination of the alleged drunk in charge usually falls to the general practitioner. To many it is one of the nightmares of general practice. It occurs so seldom that occasionally the doctor is not prepared for it, and his examination at the time may be incomplete so far as the law is concerned. He may therefore be cross-examined at length both in the magistrates' court and later at the quarter sessions. Bitter experience of this has prompted me to compile the proforma below. If properly completed at the time of the examination it should ensure that the examining doctor is standing on firm ground at any subsequent cross-examination.

I have had a number of these proformas duplicated by the police, and they are kept at the police station. Whenever a case turns up, one of these forms is produced for me at the time and my notes are made on it. These I am allowed to produce in court. I submit this form in the hope that it may be of some use to those practitioners who see little of this type of medico-legal work, and also in the hope that anyone who can suggest any improvement to it will write to me. Is it too much to suggest that this or some similar form should be available at every police station in the country for the use of examining doctors? The spacing on the form allows for short notes to be made at the time.

OXFORDSHIRE CONSTABULARY

Examination at:

Date:

Time arrived:

Time called:

Warning: (Tell him who you are and inform him that he is entitled to call his own doctor if he wishes. Obtain his consent to the examination.)

Name and address of person examined:

Essential Questions

1. Ask him date and time.
2. History for the day. (Note memory for recent events.)
3. What drinks? Type, amount, and time of consumption.
4. What food? When and where consumed? What did he eat?
5. Medical history:
 - (a) Any serious illnesses. (Diabetes, heart, blackouts, epilepsy.)
 - (b) Any recent illness.
 - (c) Any operation.
 - (d) Any deformity; spine or joints.
 - (e) Any loss of member; arm, leg, eye.
 - (f) Does he take drugs (1) habitually, (2) that day?
 - (g) Is his eyesight normally good? Does he wear glasses?
 - (h) Has he vomited?
 - (i) Does he wear dentures? Are they in place?
 - (j) Has he suffered any injury that day? Blow on head?

Examination

1. Take specimen of handwriting. Separate sheet to be used as exhibit.
2. Visual acuity. With glasses if worn.
 - (a) Snellen's Types.
 - (b) Newsprint.
3. Eyes:
 - (a) Bloodshot.
 - (b) State of pupils.
 - (c) Reaction to light.
 - (d) Accommodation.
 - (e) Ocular movements.
4. Smell of breath:
 - (a) Alcohol.
 - (b) Disease.
5. State of tongue.
6. Teeth and throat.

7. Facies:
 - (a) Flushed.
 - (b) Pale.
 - (c) Cyanosed.
 - (d) Sweating.
8. General demeanour (abusive, hilarious, talkative, truculent). Disorder of dress. Signs of vomit.
9. Specimen of urine: albumin, sugar, blood, alcohol, or drugs.
10. Signs of shock.

General Medical Examination

1. Pulse: rate, character, rhythm.
2. Temperature.
3. Respirations; rate and type.
4. Blood pressure.
5. Heart: signs of disease.
6. Lungs: signs of disease.
7. Abdomen: scars or signs of disease.
8. Deformity or artificial limb or eye.
9. Scalp and head. Any injury, old or recent.

Special Tests for Co-ordination

1. Tip of nose test.
2. Romberg's test.
3. Walking a line.
4. Speech: mumbling, slow, indistinct, slurred, or shouting. Read short paragraph aloud. Simple spelling test.
5. Picking up coins:
 - (a) Distinguish them.
 - (b) Count number of coins.
 - (c) Add to correct amount.

Opinion

Inform him of your opinion at the time and tell him again that he is entitled to call his own doctor.

Note.—See that the examination is carried out in a quiet room with good light and always in the presence of a police officer.

Medical Notes in Parliament

Smoking and Cancer

Mr. HARRY HYND used the adjournment motion in the House of Commons on March 19 to discuss the relationship between smoking and lung cancer, and to seek some authoritative pronouncement from the Ministry of Health on the subject.

He based his argument on the investigations carried out by Dr. Richard Doll and Professor Bradford Hill, whose reports in 1950 and December, 1952, were published in the *British Medical Journal*, and quoted the comment of the *British Medical Journal* (December 13, 1952, p. 1299) in a leading article: "Tobacco has been incriminated as the vehicle conveying an agent responsible for a large proportion of the cases. Out of any random sample of 400 men now aged about 55, at least 10 must be expected to die of cancer of the lung within the next 20 years. Intensive research on the chemical constituents of tobacco and tobacco smoke is now needed." This, Mr. Hynd said, was bad enough, but similar investigations in Germany and the U.S. had led to similar conclusions. The stage had been reached when the medical profession must make up its mind about the cause of this dread disease, and whether it really was related to smoking; and it was part of the responsibilities of the Ministry of Health to guide the public in these matters.

Miss HORNSBY-SMITH, Parliamentary Secretary to the Ministry of Health, acknowledged that the subject was one of great public concern, and quoted from the 1950 report of the Chief Medical Officer of the Ministry that "cancer, and especially cancer of the lung, remains the greatest problem of medicine." But the figures given by Mr. Hynd of the rise in the number of cases of cancer of the lung from 2,281 in 1931 to 13,247 in 1951 must be qualified by taking account of the vastly improved diagnosis, the universal use of x rays, and the increased education of prac-

tioners on cancer work which had taken place during those 20 years. In view of the gravity of the statistical evidence the Ministry and the Medical Research Council were examining carefully what lines of research into the incidence and causative factors were most promising and should be encouraged, and had also taken the initiative in stimulating new lines of research.

The information so far received from the advisory committee of the Medical Research Council showed that, while it accepted that research had shown a statistical relationship between tobacco smoking and lung cancer, it did not necessarily accept that that relationship meant a causal relationship also.

She gave a résumé of the research activity that was in progress. An example of the new lines of research was the experiments in nuclear physics. A new cobalt-60 beam unit, a generous gift from Canada, had been accepted a few days previously by the British Empire Cancer Campaign (see *Journal*, March 21, pp. 666 and 669). In the N.H.S. hospitals there was intensive research. It was going on in the Royal Cancer Hospital and the Chester Beatty Research Institute, the Christie Hospital and the Holt Radium Institute, and in the Hammersmith Hospital, where some of the most modern equipment was being used to find a new means of diagnosis and cure. At St. Bartholomew's Hospital Sir Ernest Kennaway was examining the ingredients of tobacco smoke for cancer-producing substances. At the Pneumoconiosis Research Institute in Cardiff the Medical Research Council was carrying out experiments on the effect on mice of living for long periods in tobacco smoke. At the cancer research unit of the Royal Beaton Memorial Hospital in Glasgow further extensive research was in progress into cancer-producing agents, again related to tobacco smoke, and the possible carcinogenicity of alkaloids in tobacco or its smoke. Similar research was being conducted in America. Fortunately there was no iron curtain in research on this subject, and the best brains throughout the world were co-ordinating their work. In regard to atmospheric pollution and its relation to cancer of the lung, Dr. Percy Stocks was conducting an investigation for the Medical Research Council. The difference between the incidence of cancer of the lung in rural areas and in densely populated industrial areas was dramatic. All the evidence so far on the arsenic content of some tobaccos as a causation of lung cancer showed that the amount was too small to be effective in carcinoma.

She concluded that they must see that nothing was done to panic the public, while assuring them that everything was being done to find a cure for this disease. Research had not been abandoned into exhaust gases from petrol and diesel engines as a possible source contributing to lung cancer. The Ministry's attitude was that it could act only on the best medical advice available, and while the advisory committee had not come to any conclusion going beyond the correlation between tobacco smoke and cancer of the lung the Ministry could only be non-committal. Research was proceeding all the time. It was a long-term matter requiring careful sifting of results and highly complicated experimental work over a long period and the collection of vital statistical data.

The Medical Research Council would have no hesitation in carrying further research into any line which showed promise, and would do everything in its power to find a solution and a cure of this dread disease.

Group Practices

Mr. HILARY MARQUAND on March 19 asked the Minister of Health whether he had drawn the attention of executive councils and their medical committees to the fact that both he and the General Medical Services Committee had accepted the encouragement of group practice as a desirable objective. Mr. IAIN MACLEOD replied that he had received advice from the Central Health Services Council on the definition of group practice, and proposed shortly to discuss with representatives of the medical profession how best to implement the recommendation on group practice of the

Working Party on the distribution of remuneration of general practitioners. He added that he had received the report only the previous night, and he would consider what publicity should be given to the committee's conclusions.

Medical Auxiliaries

Mr. M. TURNER-SAMUELS asked the Minister of Health on March 19 if he would make a statement at an early date on the implementation or otherwise of the Cope Report. Mr. IAIN MACLEOD stated that, following discussions with the professional bodies of medical auxiliaries, the Secretary of State for Scotland and he were satisfied that there was insufficient agreement on fundamental matters to proceed with statutory registration on the lines proposed by the Cope Committees. They intended, therefore, as soon as possible to make regulations using the power of Section 66 of the National Health Service Act, 1946, and Section 65 of the National Health Service (Scotland) Act, 1947, to prescribe qualifications for medical auxiliaries for the purpose of employment in the National Health Service. They would shortly give the professional and other bodies concerned an opportunity to comment on an outline of the regulations proposed. He added that he intended when making the regulations to withdraw the temporary instructions given in August, 1951. He would do everything he could to see that the regulations he proposed were fair to all the associations concerned.

Sickness in the Post Office

Mr. C. OSBORNE asked the Assistant Postmaster-General on March 18 what had been the sick rate amongst Post Office employees in terms of days' absence per person for the years 1952 and 1951, and how this compared with the pre-war figure. Mr. L. D. GAMMANS informed him that the average number of days' sick absence per person for non-disabled established staff was as follows: In 1938, 8.1 days for men and 9.3 for women; in 1951, 15.0 days for men and 18.4 for women. The corresponding figures for 1952 were not yet available. Mr. Gammans added that successive administrations had been disturbed about this alarming increase. It was estimated that if the figures were the same as before the war there would be a saving in staff of at least 6,500. Before the war the Post Office had its own doctors, whereas now the staff came under the National Health Service. He also said that the matter was under careful consideration in co-operation with the trade unions.

Prescription Costs

Mr. A. BLENKINSOP on March 19 asked the Minister of Health what was the estimated average number of prescriptions on each form and the average cost of each prescription at the latest available date, and how these figures compared with those before the introduction of the prescription charge. Miss PAT HORNSBY-SMITH replied that in England and Wales the estimated average number per form was 1.71 in February, 1953, 1.57 in May, 1952, and 1.59 in February, 1952. The estimated average cost was about 4s. 2½d. in December, 1952, compared with an average cost of 4s. 1½d. in May, 1952, and 3s. 10½d. in December, 1951.

Mr. BLENKINSOP suggested that the figures implied that the prescription charge had added to the cost per prescription in many cases, and had encouraged doctors, for understandable reasons, to add to the amount of drugs prescribed, and thereby increased considerably the amount of wastage. Miss HORNSBY-SMITH said the Minister could not accept that as the sole explanation. The main cause was increasing prescribing and expensive new drugs.

Mr. LESLIE HALE asked the Minister of Health on March 17 what was the estimated total net saving to the Exchequer, after making allowances for administrative costs and for the extra cost to the National Assistance Board, both direct and administrative, of the charge of 1s. on prescriptions from the time of its introduction to the nearest most convenient date for computation.

Mr. IAIN MACLEOD replied that the estimated net saving to the Exchequer from the prescription charges paid by patients in England and Wales between June 1 and

December 31, 1952, after the deduction of refunds made by the National Assistance Board, was about £2½m. Administrative costs, though not known in detail, would not materially affect this estimate. In addition there was a saving to the Exchequer during this period of about £1½m. because fewer prescriptions were dispensed than would have been expected if charges had not been introduced, though it was possible that other factors contributed to this decrease.

Doctors' Surgeries

Mr. A. BLENKINSOP on March 19 asked the Minister of Health what action he was taking to secure an improvement in the condition and equipment of general practitioners' surgeries. Dr. SANTO JEGGER also asked the Minister what regulations he had made on the standard of surgery and waiting-room accommodation in doctors' premises under the National Health Service, how many had been inspected by executive councils, and how many had been declared unsuitable.

Miss PAT HORNSBY-SMITH, the Parliamentary Secretary, informed them that the relevant regulation was paragraph 7(4) and (5) of Part I of the First Schedule to Statutory Instrument 1948, No. 506. The Minister had no details of inspections by executive councils. He was, however, hoping shortly to discuss the best way of securing an improvement, where necessary, in the condition and equipment of general practitioners' surgeries and waiting-rooms with representatives of the medical profession.

Provision for Mental Hospitals

Mr. KENNETH ROBINSON asked the Minister of Health on March 19 what special capital allocation he was making for the coming financial year to meet the needs of the mental hospitals.

Mr. IAIN MACLEOD stated that it was for regional hospital boards to decide what particular projects should be included in their capital programmes, but he had again asked them to devote at least 20% of their allocations to mental health projects. In addition, two major mental health schemes were being financed from a special central reserve.

Mr. ROBINSON insisted that 20% was quite insufficient. Mr. MACLEOD agreed that this was probably the most serious problem facing the National Health Service, and it was precisely for that reason that he had insisted on the minimum figure he had given. The position would have been a great deal easier if in the first year or two of the Service a larger proportion of the resources had been devoted to mental health purposes.

Students' Suicides

Lieutenant-Colonel M. LIPTON on March 19 asked the Minister of Health whether he would appoint a committee of medical and other experts to investigate the high number of suicides in recent years among schoolboys and undergraduates. Mr. IAIN MACLEOD replied that the figures for suicides among boys between 10 and 14 were too small to be statistically significant. Separate figures for older students were not available. He was, however, aware of the concern about this problem, and, while he did not think it would be appropriate for him to set up a special committee, he was sure the problem would be carefully watched by all concerned.

He said in a further reply that the general suicide rate for boys and men between 15 and 24 was lower than the general rate and had been falling in recent years. The fullest facilities were available to universities for dealing with the general problem, and he thought the matter was best left to them. If they asked for his help he would be delighted to assist.

The Committee on the Disabled set up by the Ministers of Labour and Health and the Secretary of State for Scotland has two medical men as members, Sir Claude Frankau and Dr. C. G. Magee.

Help for Disabled.—Sixty-five local authorities in England and Wales have submitted schemes for promoting the welfare of physically handicapped persons. Other schemes are still coming in, and the Minister of Health does not propose to issue directions to authorities yet.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending March 7 (No. 9) and corresponding week 1952.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenza pneumonia.

§ Includes puerperal pyrexia.

Vital Statistics

Smallpox in the North Country

The outbreak of smallpox which began earlier this month in Todmorden M.B. (Yorkshire, West Riding) and Bacup M.B. (Lancashire)—see last week's *Journal* (p. 682)—is continuing. Up to March 23 11 cases have been diagnosed. The districts affected are as follows:

TODMORDEN M.B.

There have been 9 cases with 1 death (on March 20). In addition to the 3 cases mentioned last week there have been 6 more secondary cases, all in the two households originally involved. These 6 patients were all under surveillance when they sickened and were promptly removed to hospital. Details of these cases are as follows:

Case 5. Female aged 13, daughter of Case 1. Unvaccinated until March 13. Illness began on March 17, and she was admitted to hospital on the following day. The rash appeared on March 20.

Case 6. Female aged 40, wife of Case 1. Vaccinated in infancy and revaccinated on March 13. Onset of illness on March 19 and admitted to hospital on that day. The rash appeared on March 20.

Case 7. Female aged 35. Lodged with Cases 2 and 3. Unvaccinated. Primary vaccination on March 15 and revaccinated on March 18. Onset of illness March 19 and admitted to hospital same day.

Case 8. Male, 19, son of Cases 2 and 3. Unvaccinated. Primary vaccination on March 15. Onset of illness on March 19 and admitted to hospital same day.

Case 9. Male, 14, son of Cases 2 and 3. Unvaccinated. Primary vaccination on March 15. Onset of illness March 19 and admitted to hospital same day.

Case 11. Male, 53. Contact with Case 1 for 30 minutes on March 11. Vaccinated in infancy and during 1914-18 war. Revaccinated on March 13. Onset of illness on March 21 and admitted to hospital on the following day.

BACUP M.B.

There have been no further cases since the first case reported last week. This patient died on March 13 in the Florence Nightingale Hospital, Bury C.B., and there have been no reports of illness among contacts under surveillance at Bury.

OLDHAM C.B.

An unvaccinated man of 26 living in this district and working as a cotton operative at Hollingwood, Chadderton M.B., fell ill on March 13. A rash developed on March 18 and he was admitted to hospital with smallpox on March 20 (Case 10). So far no human link with the other cases has been found. The mill in which this man worked may have received cotton waste or part of a consignment of raw cotton from the Todmorden mill at which the first 3 patients were employed, but it is too soon to say whether or not an extra-human source of infection is involved. This patient was living in a lodging-house in Oldham and unprotected contacts are numerous.

Of the 9 patients at present in hospital 2 are recovering and 3 are seriously ill. Eight are in the Oakwell Smallpox Hospital and 1 is in hospital at Ainsworth, near Bury. So far there are no reports of illness among contacts under surveillance at Halifax. The first of the Todmorden patients was originally admitted to the Halifax General Hospital.

Week Ending March 14

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,675, whooping-cough 3,072, diphtheria 31, measles 26,924, acute poliomyelitis 17, dysentery 362, paratyphoid fever 6, and typhoid fever 1.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1944-52 are shown thus -----, the figures for 1953 thus ————. Except for the curves showing notifications in 1953, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The only large variations in the trends of infectious diseases in England and Wales during the week ending March 7 were falls of 3,246 in the notifications of measles, from 30,884 to 27,638, 596 for acute pneumonia, from 1,897 to 1,301, and a rise of 79 for scarlet fever, from 1,455 to 1,534.

The largest decline in the number of notifications of measles was 374 in Lancashire, from 1,829 to 1,455. In seven other counties a decrease of over 200 was recorded. Only small variations were recorded in the local trends of scarlet fever. The notifications of whooping-cough were 12 more than in the preceding week, rising from 2,746 to 2,758. With the exception of a fall of 145 in Lancashire, from 682 to 537, only small fluctuations occurred in the local trends of whooping-cough. 22 cases of diphtheria were notified during the week, being 5 fewer than in the previous week. The chief feature of the returns for diphtheria was a decline from 4 to 1 in both the counties of Devonshire and Warwickshire. The largest falls in acute pneumonia were 78 in Warwickshire, from 155 to 82, and 58 in Middlesex, from 104 to 46.

17 cases of acute poliomyelitis were notified during the week. Paralytic cases numbered the same and non-paralytic cases 4 more than in the preceding week. 3 cases were notified in the counties of Surrey and Huntingdon.

The notifications of dysentery, 289, were 37 more than in the preceding week. This rise was mainly due to an increase of 33 in Lancashire, from 58 to 91. The chief centres of infection in this county were Preston R.D. 53 and Liverpool C.B. 22. The other large returns were London 39 and Yorkshire West Riding 23 (Leeds C.B. 11). Only 5 cases of dysentery were notified during the week in Grimsby C.B., where 533 cases have been reported since September.

193 deaths from influenza were registered in the great towns, 120 fewer than in the previous week.

Medical News

Local Medical Societies.—Recent meetings have included the following: *Manchester Medical Society.*—On February 4 Dr. J. H. Kellgren opened a discussion in the section of medicine on "Clinical Uses of Cortisone and A.C.T.H." He was followed by Dr. S. Oleesky, and by Mr. A. S. Scott, who considered ophthalmic conditions. On February 5 Dr. R. G. Gordon Jones read a paper to the section of anaesthetics on "Epidural Anaesthesia." Multiple paravertebral blocks, he said, could be produced with a single injection of local analgesic into the epidural space. The solution escaped through the intervertebral foraminae into the paravertebral spaces, where it produced its effect on the spinal nerves. Dr. P. D. Kelsall followed with a paper on anaesthesia for bronchoscopy, and Dr. J. P. Payne with one on arteriotomy in neurosurgery. On February 25 Dr. C. M. Fletcher read a paper to the section of medicine on research into occupational dust disease, discussing the investigations carried out by the Medical Research Council's Pneumoconiosis Research Unit since it was set up in 1945. He said that two outstanding lessons had been learned: (1) the great importance of observer error in all clinical and radiological estimates of the severity of any disease; and (2) the distorted picture of the prevalence and the severity of a disease given by a hospital population compared with of a disease given by the same disease outside hospitals. *Liverpool Medical Institution.*—At a meeting on February 19 Dr. J. Berkson discussed "Oxygen, the Premature Baby, and Retrolental Fibroplasia." He suggested that as oxygen was a drug with certain toxic effects it should be given only in the lowest concentration required by the particular

patient. The discussion was continued by Mr. A. MacGregor, Reid and Dr. E. Dunsby. Mr. A. Sutcliffe Kerr then read a paper on "Unilateral Proptosis." *Chelsea Clinical Society.*—The sixth meeting of the 56th session was held on March 10 with the president, Mr. Eric Steeler, in the chair. A discussion on "The Medical Aspects of Road Accidents" was opened by Mr. K. L. Kelly, deputy secretary of the Automobile Association, and was continued by Sir Hugh Griffiths and Drs. L. G. Norman, David Matthews, Simpson Harvey, Skene Keith, and Brunton Blaikie. The date of the annual dinner was announced for May 12.

Sport and Medicine.—The British Association of Sport and Medicine had its first general meeting on February 27, with Sir Arthur Porritt in the chair. The president, Sir Adolphe Abrahams, told the meeting that the association, had been founded with the aim of making it the authoritative body on every medical aspect of athletics and exercise. It would advise on all the general principles of athletic training and on the various medical conditions which would and would not prohibit participation in sport. It would have to study the inevitable injuries of sport and its dangers, with particular reference to such problems as the effect of violent exercise during the incubation period of poliomyelitis and other infections, and the dangers of boxing, since so many fatalities in the ring had given rise to some alarm. Research would play an important part in the association's activities, and he hoped that this would break new ground—as, for example, the biopsy of the muscles of athletes.

Family Doctor.—A wide variety of interests are catered for in the April issue of *Family Doctor*, which is now on sale. The opening article presents the facts about smoking and health fairly and squarely: the reader can draw his own conclusions from them. Other informative and helpful articles are about the eyes (by Professor A. M. Low), tuberculosis (by Dr. Harley Williams), the chemistry of life (by Dr. J. Gordon Cook), accidents to children (by Professor John Craig and Dr. M. S. Fraser), toothpastes (by Mr. A. B. MacGregor), and "good health" (by Dr. Cuthbert Dukes). As usual there are a number of articles of special interest to mothers, besides the popular features—such as "Expert Advice," "Beauty and Health," "Family Doctor Speaking"—which now have an established place in the magazine. On nearly every page of the April issue there is useful information on subjects, of one sort or another, about which patients are so often inclined to ask questions of their doctor.

Faculty of Anaesthetists.—The Dean, Dr. Bernard Johnson, presided at the fifth anniversary dinner of the Faculty which was held at the Royal College of Surgeons on March 18. The Minister of Health, Mr. Iain Macleod, proposed the toast of "The Faculty," and drew attention to the great advances made in the art of anaesthesia. Anaesthesia, he said, was no longer the handmaiden of surgery but a true partner. The Dean, replying, referred to the great value of postgraduate teaching in anaesthetics in Britain. He announced that £5,000 had been given to the Faculty by John Wyeth & Brother to be used as scholarships for any overseas students in need of financial assistance. Dr. Johnson made a plea for a research department in anaesthesia which would be free from any other demands on its time. The toast of "The Guests," proposed by Dr. T. Cecil Gray, vice-dean of the Faculty, was acknowledged by Mr. A. A. Gemmell, P.R.C.O.G., and Mr. L. Farrer-Brown, secretary of the Nuffield Foundation.

Aetiology of Rheumatoid Arthritis.—A few copies of *The Aetiological Factors Associated With Rheumatoid Arthritis*, a report of the Empire Rheumatism Council Scientific Advisory Committee, are still available at the original price of 7s. 6d. It was published as a supplement to the *Annals of the Rheumatic Diseases*. Copies may be had on application to the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1. The report was prepared under the supervision of Dr. E. Lewis-Faning, statistician to the department of preventive medicine in the University of Wales. It is arranged in two parts—etiological factors and clinical

pattern. The conclusions are based on a total of 532 questionnaires completed at nine centres in England and Scotland, each patient being paired with a control subject of similar age, sex, and marital status. Other investigations carried out on large series of arthritic patients in Great Britain and abroad may usefully be compared with this national undertaking.

COMING EVENTS

Wessex Rahere Club.—The Spring Dinner of the Wessex Rahere Club will take place at the Castle Hotel, Taunton, on April 18. Further details may be obtained from the hon. secretary, Mr. A. Daunt Bateman, 3, The Circus, Bath.

British Association of Physical Medicine.—Annual meeting at University College Hospital Medical School, Gower Street, London, W.C.1, on April 17-18, 10.30 a.m. to 4.30 p.m. Lunch available each day (5s. 6d.). Annual dinner at Royal College of Surgeons on the Friday (tickets 35s.). Tickets must be applied for by April 4.

The Biochemical Society.—The 317th Meeting of the Biochemical Society will be a joint meeting with the Société Belge de Biochimie and will be held in the Faculty of Medicine, Brussels University, 115, Boulevard de Waterloo, Brussels, at 9 a.m. on April 11, when scientific papers will be read.

NEW ISSUES

Thorax.—The next issue (Vol. 8, No. 1) will be available in a week's time. The contents include:

- A STUDY OF THE ORIGIN AND DEVELOPMENT OF LUNG CANCER. C. Raeburn and H. Spencer.
CARCINOMATOUS ABSCESS OF THE LUNG. C. Strang and J. A. Simpson.
CERTAIN UNUSUAL RADIOLOGICAL APPEARANCES IN THE CHEST OF COAL-MINERS SUFFERING FROM RHEUMATOID ARTHRITIS. Anthony Caplan.
THE PHYSIOLOGICAL BASIS OF REFLEX OESOPHAGITIS IN SLIDING HIATAL DIAPHRAGMATIC HERNIA. John A. Aylwin.
THE BRONCHIAL ARTERIES IN PULMONARY EMPHYSEMA. L. Cudkovic and J. B. Armstrong.
FARMER'S LUNG: A REVIEW OF PRESENT KNOWLEDGE. C. J. Fuller.
ANOMALOUS PULMONARY VENOUS DRAINAGE. Alan R. Muir.
THE INFLUENCE OF STREPTOMYCIN ON THE INCIDENCE OF PLEURAL EFFUSION COMPLICATING THE DIVISION OF ADHESIONS. D. C. Beatty and A. Wiener.
A PRACTICAL MEASURE OF THE MAXIMUM VENTILATORY CAPACITY IN HEALTH AND DISEASE. M. C. S. Kennedy.

Published quarterly; annual subscription £2 2s., single copy 12s. 6d.

Annals of the Rheumatic Diseases.—The next issue (Vol. 12, No. 1) will be available in a week's time. The contents include:

- RHEUMATIC COMPLAINTS IN AN URBAN POPULATION. J. H. Kellgren, J. S. Lawrence, and Jean Aitken-Swan.
INTRAVENOUS COLCHICINE IN THE MANAGEMENT OF GOUTY ARTHRITIS. W. Graham and J. B. Roberts.
CLINICAL STUDIES OF PHENYLBUTAZONE (BUTAZOLIDIN) AND BUTAPYRIN IN RHEUMATOID ARTHRITIS, RHEUMATOID SPONDYLITIS, AND GOUT. E. G. Kidd, K. C. Boyce, and R. H. Freyberg.
RADIOTHERAPY IN ARTHRITIS. M. H. L. Desmarais.
GOLD, SODIUM, AND LIVER PUNCTION IN RHEUMATOID ARTHRITIS. G. D. Kersley, L. Mandel, and M. R. Jeffrey.
RHEUMATOID ARTHRITIS TREATED WITH "IRGAPYRIN." ANALYSIS OF TWENTY CASES. G. Achari, B. Mukopadhyay, and P. Sengupta.
PROSEPTASINE IN THE TREATMENT OF RHEUMATOID ARTHRITIS. L. J. Barford.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, March 30

- HUNTERIAN SOCIETY.—At Talbot Restaurant, 7 for 7.30 p.m., dinner meeting. Discussion to be opened by Dr. Keith Simpson, Dr. Robert Forbes, and Mr. D. C. Norris: Professional Pitfalls.
ROYAL EYE HOSPITAL.—5.15 p.m., Dr. T. H. Whittington: Myopia and the Care of the Myopic Patient.

Tuesday, March 31

- INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. D. F. O'Neill: Diagnosis and Management of Stress Disorders of the Skin.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor F. A. Henley: Gastrectomy with Replacement.

Wednesday, April 1

- INSTITUTE OF UROLOGY.—At St. Paul's Hospital, W.C., 4.30 for 5 p.m., Dr. W. N. MacCall: Diagnosis and Treatment of Gonorrhoea.

APPOINTMENTS

COLLINS, MICHAEL JOSEPH, M.B., B.Ch., D.P.H., Deputy Medical Officer of Health, County Borough of Doncaster.

EAST ANGLIAN REGIONAL HOSPITAL BOARD.—R. Lindsay, M.B., Ch.B., Anaesthetic Registrar, Norfolk and Norwich Hospital; Alice M. Creamer, M.B., B.Ch., D.P.H., D.P.M., Registrar in Psychiatry, Fulbourn Mental Hospital and Psychiatric Department, Addenbrooke's Hospital; J. Littlejohn, L.R.C.P.S.Ed., Registrar in Psychiatry, Fulbourn Mental Hospital; P. R. B. Noel, M.B., B.S., Medical Registrar, East Suffolk and Ipswich Hospital and Ipswich Borough General Hospital; D. J. Brewer, M.B., B.S., Medical Registrar, Foxhall Hospital, Ipswich; P. H. Cima, M.B., B.S., Medical Registrar, North Cambridgeshire Hospital and Clarkson Hospital, Wisbech.

HALL, T. S., M.D., D.P.H., D.Obst.R.C.O.G., County Medical Officer of Health and School Medical Officer, Shropshire County Council.

HELLER, ARTHUR DAVID, M.D., D.P.M., Assistant Psychiatrist, Deputy Medical Superintendent (Senior Hospital Medical Officer), Prudhoe and Monkton Hospital, Northumberland.

LAIDLAW, ALLAN JAMES, L.R.C.P.&S.Ed., L.R.F.P.S., Police Surgeon, City of Worcester.

NORTH-EAST METROPOLITAN REGIONAL HOSPITAL BOARD.—The following consultant appointments at the hospitals indicated in parentheses are announced: F. E. McLaughlin, L.R.C.P.&S.I., D.O.M.S., Part-time Ophthalmic Surgeon (Tilbury and Riverside); W. A. Hamer, M.B., B.S., F.R.C.S., Part-time Surgeon, and H. A. Pearce, M.B., B.S., F.R.C.S., Part-time Orthopaedic Surgeon (South-east Essex Group of Hospitals); J. N. T. Hutton, M.B., B.S., D.A., and H. R. Blades, M.R.C.S., L.R.C.P., D.A., Part-time Anaesthetists (St. Leonard's and St. Matthew's); Elizabeth H. Milne, M.B., Ch.B., D.A., Part-time Anaesthetist, St. Margaret's Hospital, Epping; Elizabeth D. S. Stephen, M.B., Ch.B., D.A., Part-time Anaesthetist, Broomfield Hospital, near Chelmsford; L. Citron, M.B., B.S., F.R.C.S., D.L.O., Part-time Ear, Nose, and Throat Surgeon, Chase Farm and other hospitals in Enfield Group; C. S. Savage, F.R.C.S., Part-time Ear, Nose, and Throat Surgeon, Southend-on-Sea Group of Hospitals; D. C. Arnott, M.B., B.S., D.C.H., D.Phys.Med., Part-time Physician in Physical Medicine, Queen Elizabeth Hospital for Children, London, E.

WARWICK, ELSPETH MARGARET, M.B., Ch.B., D.P.H., Deputy Medical Officer of Health, County Borough of Nottingham.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

- Brearley.—On March 17, 1953, at Mill Road Hospital, Liverpool, to Joyce Mary (formerly Hewitt) and Roger Brearley, F.R.C.S., of 55, Meadow Lane, West Derby, Liverpool, a son.
Green.—On March 7, 1953, to Dr. Elizabeth (formerly White), wife of Dr. D. M. Green, 3, Coupar Angus Road, Dundee, a daughter.
Jackson.—On March 15, 1953, at Glasgow, to Barbara, wife of C. R. S. Jackson, F.R.C.S., a son.
McCrath.—On March 18, 1953, at Freedom Fields Hospital, Plymouth, to Isabel (formerly McDonald), wife of Dr. John Anthony McCraith, a son—Nicholas Stuart.
Power.—On March 19, 1953, at Radley Lodge, Wimbledon, London, S.W., to Joy (formerly Parkes), wife of Dr. Norman Power, a second son.

MARRIAGES

- News.—Christmas.—On February 28, 1953, in Norwich, Norfolk, George Reginald News, M.B., M.R.C.P., to Patricia Mary Christmas, M.C.S.P.
Straschnov.—Hodgson.—On March 26, 1953, at St. Hilda's Church, York, George J. Straschnov, M.R.C.S., L.R.C.P., R.A.F., St. Eval, Cornwall, to Pauline M. Hodgson, S.R.N., of 25, Millfield Lane, Hull Road, York.

DEATHS

- Bartholomew.—On March 2, 1953, in a nursing-home, Francis Bartholomew, F.R.C.S.Ed., of Khartoum, Sudan.
Fielding.—On February 17, 1953, at Kelsall, Cheshire, Charles Robert Fielding, M.B., Ch.B., aged 56.
Horne.—On March 7, 1953, Walter Jobson Horne, M.D., M.R.C.P., of Highlands, Mereworth, Kent, formerly of Harley Street, London, W., aged 87.
Hutchinson.—On March 4, 1953, at Laverstock Nursing Home, Kingswood Road, Tunbridge Wells, Kent, Samuel Hutchinson, M.R.C.S., L.R.C.P., Hon. D.A., aged 70.
Lewellyn.—On February 25, 1953, at Manor Farm, Sutton Mandeville, Wilts, John Woodruff Lewellyn, M.R.C.S., L.R.C.P., formerly of Kingswood, Bristol, aged 74.
Lomax.—On March 6, 1953, at the Royal Infirmary, Liverpool, Harold Aloysius Lomax, M.B., Ch.B., J.P., of Bute House, St. Helens, Lancs.
McBean.—On March 3, 1953, at 352, Upper Richmond Road, Putney, London, S.W., Samuel Leslie McBean, M.B., B.S., aged 70.
MacDonald.—On March 1, 1953, in a nursing-home, Edinburgh, William Fraser MacDonald, M.B., Ch.B., of Olive Lodge, 42, Polwarth Terrace, Edinburgh.
Mason.—On February 28, 1953, Maurice Charles Mason, M.R.C.S., L.R.C.P., D.O.M.S., Surgeon Commander, R.N., retired, of Quarry Cottage, St. Leonards-on-Sea, Sussex, aged 67.
Moorhead.—On March 1, 1953, at Chipping Campden, Glos, the result of an accident, Charles Edward Moorhead, O.B.E., M.B., Ch.B.
Popham.—On March 1, 1953, at The Croft, Wrekenton, Co. Durham, Henry Nicholas Popham, M.B., B.S.
Russell.—On March 5, 1953, at Northcote House, Blackwater, Camberley, Surrey, Walter Ralph Russell, M.R.C.S., L.R.C.P., D.Obst.R.C.O.G., D.C.H.
Sawyer.—On February 22, 1953, James Edward Hill Sawyer, M.D., M.R.C.P., Lieutenant-Colonel, R.A.M.C., T.A.R.O., retired, of Little Holton, Burwash, Sussex, aged 78.
Skrimshire.—On March 2, 1953, at Hill House, Holt, Norfolk, Henry Finch Skrimshire, M.R.C.S., L.R.C.P., aged 79.
Star.—On February 19, 1953, Paul Hohling Mills Star, O.B.E., M.R.C.S., L.R.C.P., Surgeon Captain, R.N., retired, of Long Ashton, Somerset, aged 82.
Trimmer.—On February 27, 1953, at Orplington Hospital, Kent, Francis Inman Trimmer, M.R.C.S., L.R.C.P., late of 22, Sherard Road, Eltham, London, S.E.
Willcox.—On February 25, 1953, in a Glasgow nursing-home, Leonard Stephen Willcox, M.D., D.P.H., of Leabank, Dumbarton.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Wassermann Test in Infancy

Q.—What is the earliest age at which the result of a Wassermann test on a newly born infant can be regarded as conclusive? This is a problem when babies are offered for adoption.

A.—It is assumed from the question that the child's mother has suffered from syphilis. If this is the case, the result of one blood test would not be conclusive evidence. If a Wassermann reaction done within a week of birth is negative, it is almost certain to remain so when tested later. Nevertheless, a second test should invariably be carried out when the child is 3 months old.

If the first test is positive it may be due to: (1) A "carry over" of reagin from the mother, in which case the child's Wassermann titre will usually be lower than its mother's. On serial quantitative testing the positive serum titre of the child will show a progressive and uninterrupted fall, until it finally becomes negative at about 1 to 3 months, depending on the amount of reagin present at the time of the first test and the sensitivity of the serum tests employed. (2) Infection: in this case the Wassermann titre of the child's serum will remain stationary or rise during the course of a series of fortnightly quantitative blood tests.

Specimens of cord blood should never be sent to a laboratory for testing, because a positive result may be of no significance owing to the presence of its mother's reagin; also, many such specimens have an anticomplementary action due in most cases to infection, but in some to an inherent property of this type of serum.

Iodine for Water Sterilization in the Field

Q.—I understand that American forces in Korea have been using iodoglobulin for water sterilization. Please describe the method and compare its advantages and disadvantages with chlorination.

A.—The American specification (Mil-T-283A, dated December 7, 1950) for "Tablets, Water Purification, Individual, Iodine" requires each tablet to weigh not more than 120 mg. The tablets are to contain tetraglycine hydroperiodide 19.3 to 21.3 mg., sodium acid pyrophosphate 82.5 to 92.3 mg., and inert materials to be not more than 5% by weight. Each tablet must contain between 7.6 and 9.0 mg. of titratable iodine. The instructions for use require the addition of one tablet to a quart (about a litre) of water, and a wait of 10 minutes, or 20 minutes if very cold, before drinking. Two tablets are used instead of one if the water is dirty and discoloured. The tablets are packed in bottles of six, twenty-five, or fifty. So far as we are aware no other iodine preparations are being supplied to the American Army.

The advantages of iodine compared with chlorine are: (a) it does not form with ammonia slow-acting (on organisms) ammonia compounds—for example, chloramine; (b) it is not affected in its sterilizing properties by the reaction (pH value) of the water; (c) it is not so easily deviated by organic and other constituents of the water as is chlorine; and (d) it is reported to be more lethal to cysts of *Entamoeba histolytica* than chlorine.

Neither chlorine nor iodine has any bad physiological action when consumed in small quantities. Recent human feeding tests by the Americans have shown that a human being can tolerate 70 mg. of iodine daily without untoward effects. Iodine has the disadvantages that it is expensive and it colours the water yellow. This is regarded as an advantage by some people, as it shows that the water has been treated with iodine and is presumably safe to drink.

Exercises in Bed after Operation

Q.—What routine bed-exercises are recommended to forestall thrombotic and pulmonary complications in patients after abdominal and thoracic operations, from the operation to the fourteenth day?

A.—Post-operative bed-exercises can be divided into three main groups—breathing, leg, and abdominal. These are sometimes supplemented by arm and back exercises, but the latter will not be described here.

The details of treatment must obviously be varied according to the general condition and age of the patient. With a really ill patient the usual routine is: breathing; ankle, foot, and quadriceps exercise; further breathing; gentle hip and knee exercises; final breathing, with percussion if needed. For a recovering patient this routine is made gradually more vigorous up to the convalescent stage. The three main groups of exercises are carried out as follows:

Breathing.—The physiotherapist gives three types of breathing exercise—abdominal, lower thoracic, and upper thoracic. The first two increase diaphragmatic movement, and by giving the exercise against manual resistance the physiotherapist encourages the patient to "feel" the type of movement required. Breathing must be done slowly and deeply about six times and followed by a rest. The patient should concentrate upon the fullest possible inspiration and expiration. This is of real value in assisting the venous return as well as in preventing pulmonary collapse. Coughing should be encouraged, especially if there is any sputum, early rise of temperature, or other signs of pulmonary collapse. Springing the chest smartly (with hands on the ribs at each side, or with one hand over the sternum), especially during expiration, assists in expulsion of the bronchial secretions. It is best for the patient to sit up, leaning slightly forward and supporting the abdominal wound with his own hands. An alternative to springing the chest is clapping over the back with cupped and relaxed hands. Slapping the back can be painful and may cause the patient to tense his muscles. The great secret of all these coughing and springing exercises is to work away at them gradually until the patient attains confidence. There is little difference in the management of cases with abdominal or thoracic wounds, although special posturing and intensified physiotherapy may be needed in certain chest cases, such as following pulmonary resection for bronchiectasis.

Leg Exercises.—In the ill patient these are limited to bending and stretching of toes, pedalling the feet up and down, and ankle-rolling exercises. This may be followed by simple quadriceps drill: alternate lifting of the legs off the bed with knees straight, and sliding the heels up to the buttocks and down again. In the recovering patient these exercises are increased in range and vigour to include leg raising and circling, elevation and abduction of the straight leg, and sitting over the edge of the bed with legs swinging.

Abdominal Exercises.—Gentle exercises are done with the patient supine and the knees crooked up: the head and shoulders are then gently raised and lowered. More vigorous exercise of the oblique muscles is given by trunk-turning with arms stretched out sideways, and the patient then alternately touches each side of the bed with his hands. These can be supplemented by lateral bending of the trunk and back arching in the supine position.

The questioner has asked for information about bed-exercises from the operation to the fourteenth day, but it should be emphasized that it is of the utmost importance to train the patient before the operation. The amount of training required will vary both with the individual patient and with the operation. Full instruction in breathing exercises, and especially the diaphragmatic ones, is extremely important for male patients.

No answer would be complete without reference to the value of early ambulation as a supplement to these bed-exercises. The patient must, however, be up and active. It is certainly better for an ill patient to remain warm and gently exercising in bed than to be got up and allowed to slump in an armchair with bent and inactive legs. Although there is some difference of opinion about the value of early ambulation in preventing thrombo-embolic complications, there can be no doubt about its general moral and physical value to the patient. It is doubtful whether fatal embolism is much reduced, but troublesome leg thromboses are probably less frequent. In general, rising should begin between the second and fourth post-operative days; there is no

real virtue in immediate ambulation after operation. The subject of early ambulation was fully discussed in a leading article (*British Medical Journal*, 1948, 2, 1026).

Mixtures of Antibiotics

Q.—What mixtures of antibiotics can be given at the same time? Are any pharmacologically incompatible, and do the antibacterial actions of some neutralize those of others?

A.—There is no incompatibility between antibiotics in a pharmaceutical sense, but if by "pharmacologically" is meant an interference by one with the action of another this undoubtedly can occur. Such effects can readily be demonstrated *in vitro* and in some conditions experimentally *in vivo* when an antibiotic the action of which is mainly bacteriostatic or growth-inhibitory (aureomycin, chloramphenicol, or terramycin) is added to one which is bactericidal or directly lethal to bacteria (penicillin or streptomycin). Antibiotics of the latter class act only on multiplying bacteria, and if multiplication is prevented by the presence of a bacteriostatic substance their lethal effect is naturally delayed. This interference is closely conditioned by antibiotic concentration, bacterial sensitivity, and dose-time relationships, and it is uncertain how often it operates in the clinical field. A clear example of interference seems to be afforded by the experience of Lepper and Dowling,¹ who treated 43 patients with pneumococcal meningitis with large doses of penicillin only, of whom only 13 died (30%); of 14 patients also given aureomycin, 11 died (79%).

Cats at Night

Q.—How do cats see in the dark?

A.—No animal, not even a cat, can see in the dark, because if visual rays are completely absent the retinae cannot receive adequate stimulation. At the same time it must be admitted that many animals may be able to see under conditions which would not permit a human observer to do so. A number of different factors may act in combination in producing this difference. Of all the light which falls on the front of the eye from external objects probably little more than one-tenth finds its way in through the human iris even when this is widely dilated. This is because the F value (the ratio of focal length to aperture) in man seldom exceeds two. In cats, on the contrary, it may equal one, and, since the brightness of the image on the retina is inversely proportional to the square of the F value, it follows that in a cat this may be four times as bright as in a man. Having passed in at the pupil, a certain proportion of the light is absorbed by the crystalline lens and by the vitreous humour. In those animals which have small eyes with short paths through crystalline and vitreous these losses are less than they are in a human eye. Thus in this respect a cat is better off than a man and a mouse better off than either. It is possible that rays at the extreme ends of the spectrum, that is in the red and in the violet, may be made use of by small animals for visual purposes, whereas to a man they are practically useless because of their low intensity. In this connexion it may be of interest to recall the fact that patients who have had to suffer the loss of a crystalline lens are compensated to some extent by being able to see by means of violet and even by ultra-violet rays, which they were never able to do while the eye was intact. Having reached the human retina, most of the light is absorbed, in part by the photosensitive pigments, such as visual purple, on which sight depends, and in part by the pigment in the outermost layer of the retina. In many animals this layer constitutes a reflecting screen, or tapetum, by means of which the light is returned through the retina a second time. It is thought that this increases sensitivity to light at the expense of fine definition. Theoretically there are two other ways in which the retina could be made more sensitive still, by concentration of the photosensitive pigments, and by linking more receptor cells to each of the optic nerve fibres. Now, suppose that all these modi-

fications are to be found in the eyes of a particular category of animal, to what extent should we expect its eyes to show an improvement in performance? Only a very rough guess is possible—namely, that the animal in question may require no more than one-tenth of light than is required by a man for the same visual performance under twilight conditions. It should be emphasized that this advantage is not obtained without the introduction of disabilities. Usually it is visual acuity which is sacrificed. Thus the employment of a large F value means that the more peripheral zones of the lens system are brought into use, and these have more marked aberrations than the central zones, thus reducing visual acuity. The situation may perhaps be summed up as follows: In the design of the human eye resolving power has been given prior consideration, but in the design of other eyes other factors appear to have been more important. In the case of cats this seems to have been the ability to see in very poor light.

Efficacy of Abortifacient Drugs

Q.—How effective are the drugs commonly used in criminal attempts to secure abortion, in particular extract of ergot?

A.—Drugs such as strong aperients, lead, quinine, oxytocin and ergot preparations are almost completely ineffective as abortifacients in normal women, although they might disturb a pregnancy in a woman who has an unusual susceptibility to abortion. The ineffectiveness of such preparations by themselves is well illustrated by the fact that they are now rarely, if ever, even tried when therapeutic abortion is indicated. Moreover, it was not uncommon in the past to see pregnancy continue unaffected in women who had taken so much in the way of drugs that they themselves suffered from lead, quinine, or ergot poisoning. Again, quinine is given with impunity in malaria-infested countries, and ergot preparations can be safely used for migraine up to the last few weeks of pregnancy.

The oxytocics mentioned become more effective if they are used as supplements to local interference in the uterus—for example, rupture of the membranes, dilatation of the cervix, or intrauterine injections.

Safety of the Safe Period

Q.—What are the chances of conception occurring as a result of intercourse during the "safe period" in a young married woman with a regular menstrual cycle?

A.—In such circumstances conception is very unlikely, but it is always possible. The chances cannot be stated statistically, and they may, well vary according to the exact day in the "safe period" on which coitus takes place.

NOTES AND COMMENTS

Corrections.—Dr. J. R. HINDMARSH writes to say that in the article by him and Dr. D. Emslie-Smith (March 14, p. 593) the second paragraph should read: "Uncomplicated leukaemia presenting as acute polyarthritis has been described by many authors, and its rarity outside childhood . . ." not "in childhood."

The *Textbook of Medical Treatment* edited by Dunlop, Davidson, and McNee referred to in our review columns in the issue of March 21 (p. 661) was incorrectly entitled *Textbook of Medical Practice*.

THE SURGEON AND ISCHAEMIA*

BY

Sir JAMES LEARMONTH, K.C.V.O., C.B.E., Ch.M., F.R.C.S.Ed.

Regius Professor of Clinical Surgery and Professor of Surgery, University of Edinburgh

I am very conscious of the honour which the Horsley Trustees have done me in inviting me to deliver this Horsley Memorial Lecture. I have always regarded Victor Horsley as an Olympian. Indeed, I have a curious second-hand knowledge of him, for on more than one occasion the late Sir Charles Ballance, who assisted Horsley at the operation, recounted to me the dramatic story of the first removal of a tumour of the spinal cord. When I began to practise neurological surgery, many years ago, this led me to peruse Horsley's account of the operation, which was and is a model of orderly reasoning from physiological principles to practical therapeutics: to-day I can think of no better intellectual exercise for a student in the transitional period from preclinical to clinical work than a study of Horsley's procedure on that occasion, and of his reflections upon his own diagnostic problem and upon the technique which he used. That report exemplifies the aspect of Horsley's outlook and life's work which has always appealed to me most: his insistence that physiological hypotheses, and so far as possible operative procedures, should be tested experimentally before being incorporated into surgical techniques. How characteristic of him is the comment in his report that the choice between stitching the spinal dura and leaving it open is one which "requires experimental investigation at the present time." Here was a problem: it must be attacked—and when Horsley was concerned attacked is the right word—without any delay.

I deprecate any tendency to consider Horsley's great contributions to medicine as twofold—the physiological and the surgical. There was no dividing-line between the two. He passed from laboratory problem to clinical problem, and from clinical problem to laboratory problem, with the confident ease of one who was equally talented and equally skilled in both spheres. Possibly the only matters to which he did not apply the rigorous tests of the experimental method were certain of his own passionately cherished beliefs. That is the way of crusaders; and Horsley died, as he might well have chosen, in the midst of a crusade.

Perhaps it would have been more appropriate if I could have selected as the subject of this lecture some neurological topic. On the other hand, it seemed to me that Horsley would not have disapproved of my choosing to speak of some practical aspects of the vascular supply of tissues, to the clarifying of which contributions

have been made from laboratory, ward, and operating theatre. It seemed to me also that I might most conveniently approach my subject by considering first that ischaemia which is desirable.

DESIRABLE ISCHAEMIA

The objective of checking bleeding from injured tissues is quite understandably older than any attempt to provide the surgeon with a bloodless field for a planned intervention, and efforts to secure it did not necessarily depend upon a knowledge of the circulation of the blood. About the second century A.D., Heliodorus applied a bandage above the level of an amputation for gangrene in order to compress the vessels of the limb. This innovation could not have been based on pathological principles, for at the time the accepted technique was to amputate through the gangrenous and therefore presumably bloodless part of the limb. Probably about the beginning of the sixteenth century the site of amputation of a gangrenous extremity was moved to be proximal to the line of demarcation, a change in technique which soon produced the first of the special tourniquets (designed by Fabry) for use at amputations, and this original tourniquet has had many ingenious mechanical successors.

However, until the middle of the nineteenth century the tourniquet was merely a constricting band, and sometimes a destructive one at that. In order to provide a field in which the surgeon could operate upon an extremity unhampered by bleeding, in the eighteenth century Esmarch introduced his method of forcing the blood out of a limb by the centripetal application of an elastic bandage and the application of a second similar bandage at the root of the limb before the first was removed. This was, of course, a highly effective method of providing a bloodless field; but it was a purely mechanical one. An alternative method based on physiological principles deduced from both animal and hominal experiments was introduced about the same time by Lister (1879). Lister showed that on elevation of a limb its veins emptied by gravity and that after a few minutes its arteries underwent reflex contraction, so that the volume of blood entering the extremity was minimal; a tourniquet was then applied to the root of the limb. This was the kind of preliminary physiological investigation of a problem, carried out both in man and in animals, which finds many parallels in Horsley's investigations.

* Victor Horsley Memorial Lecture delivered at B.M.A. House December 11, 1952.

Tourniquet Paralysis

The occasional occurrence of paralysis after the application of tourniquets became too high a price for a proportion of the patients to pay for the surgeon's bloodless field, and posed the problem of the causation of the paralysis. The time during which it is possible to occlude the circulation to a limb without pathological consequences in the tissues distal to the constricting band might appear to be a figure which could be determined by a series of experimental observations on normal individuals; and indeed much work has been done on the subject. The times recorded by different workers, under different conditions, have been so variable that this is a problem to which the experimental method has not as yet provided a uniform solution.

In most of the reported cases of tourniquet paralysis the arm has been the site of application, at a level where the radial nerve is unusually exposed to pressure, and the pressure had often been concentrated by the use of too narrow a constricting band, which introduced the possibility of direct physical trauma to the underlying nerves. It seems to me of great significance that in those cases of tourniquet paralysis which have been investigated by surgical exploration the band employed has been narrow and unyielding, and that the operations have disclosed neuromata at the site of pressure (e.g., Speigel and Lewin, 1945).

Lewis stated that a nerve could withstand total ischaemia for at least 12 hours and possibly even for 20 hours, a period much in excess of that required for any operative procedure on the limbs; and I have seen complete recovery of the nerves of the lower limbs after acute aortic obstruction had existed for nine hours. It might be surmised that nerves which possessed an arteria comitans (median, sciatic) would be particularly vulnerable to ischaemia, and, indeed, in the arm Sinclair (1948) found the sensory territory of the median nerve to be first affected; but tourniquet paralysis of the sciatic nerve is rare, possibly owing to the diffuse pad provided for it by the overlying muscles. After the release of the cuff of a sphygmomanometer which has been inflated to above systolic pressure for periods up to at least 30 minutes, return of function in the nerves of the arm is usually rapid (within a minute or so); but, as I have said, there are considerable differences between patients in the effect of ischaemia upon nerves, so that individual susceptibilities, which cannot be assessed in advance, may lead to considerable divergences from this average figure.

Reactive Hyperaemia

There is a practical objection to the use of any tourniquet. After its release, and, as shown by Lister, whether the limb is elevated or not, there ensues in the distal part of the limb a period of reactive hyperaemia during which free bleeding occurs from innumerable tiny dilated vessels which do not lend themselves to forcipressure or ligation. Thus, at the end of an operation during which a tourniquet has been constantly applied, time must be allowed for this reaction to disappear, and for the effect of such simple haemostatic measures as the gentle pressure of warm moist packs. Because of the possibility of ischaemic lesions after the application of tourniquets, it is natural that techniques have been suggested by which the cessation of circulation in a limb is made intermittent by the timed removal and reapplication of the constricting band. But there are then a series of episodes of reactive hyperaemia, and a further serious objection to this method is provided by the observation of Barlow and Pochin (1948) that a

second subsequent period of ischaemia induced by reapplication of a tourniquet appears to interfere (even after a short—25 minutes—period) with the complete recovery of conduction in the nerves under the band.

Another objection to interrupting the time during which a limb is constricted by a tourniquet is one which has given me some thought. It is that at ordinary temperatures adequate metabolic exchange is maintained in a part only while flow is occurring in its capillaries. Temporary release of a tourniquet can be effective in supplying only one physiological requirement—the removal of accumulated metabolites; these must reaccumulate as the haemoglobin brought by the second and subsequent releases is reduced. I have come to hold the view that if the possibility of local trauma to nerves can be eliminated by the selection of a suitable tourniquet it is best to complete an operative procedure without releasing it, provided that at the termination of the operation time is allowed for the disappearance of reactionary hyperaemia before haemostasis is considered to be satisfactory and the wound is closed. The broad, soft segment of compression provided by the cuff of a sphygmomanometer is the method of choice. My experience leads me to believe that, provided that the tourniquet be properly selected and provided that the patient's arteries are normal, any undesirable after-effects of its use are due to ischaemia. They will occur only if the survival time for any tissue cut off from its blood supply is exceeded, and therefore should not happen after operations upon the limbs. In many peripheral operations a tourniquet is extremely useful, and sometimes it is indispensable.

Partial Ischaemia

The practice of securing *partial* ischaemia for operative procedures was sanctioned by Paré, who had the idea from Galen. Paré directed that vessels should be tied towards their "roots," and the technique was developed by various surgeons who had found that aneurysms could often be dealt with by tying the affected artery on the cardiac side of the aneurysm: in this matter surgical practice preceded physiological knowledge of the circulation of the blood. After the discovery of the collateral arterial circulation it was inevitable that attempts should be made to devise instruments which could compress percutaneously the artery feeding an aneurysm, without constricting the remainder of the extremity and so obstructing alternative arterial routes. This was obviously a technique which could be put to the test of experiment; and it was soon shown that local pressure exerted for four hours upon the radial artery of the horse led to the obliteration of the vessel by periarterial exudate.

This knowledge was applied to the treatment of aneurysms in man; but it has always been incomprehensible to me that it did not occur to anyone to test, on man, one very practical point—whether such concentrated local pressure could be endured. The literature abounds with reports of cases in which the method had to be abandoned because of the torture it occasioned. This is hardly surprising: one such instrument, employed by Sir William Blizard, was supported on "the outer part of the knee and the great trochanter, a piece of steel passing from the one to the other; and to the middle of this a semicircular piece of iron was fixed, which projected over the femoral artery, having a pad at its end moved by a screw, by turning which the artery was readily compressed and the pulsation in the aneurysm stopped, without any interruption to the circulation in the smaller vessels. But, although this patient possessed unusual fortitude of mind and indifference to pain, he was incapable of supporting the pressure of the instrument longer than nine hours."

The method of proximal arterial occlusion by ligature or by clamp was subsequently adapted to the temporary control of arterial flow when a lesion requiring operation was so near the root of a limb that the application of a tourniquet was impossible; but as a method of providing a bloodless field it suffered from the considerable disadvan-

tage that, when a collateral circulation was well developed, even high temporary proximal arterial occlusion might not secure a worth-while diminution in total arterial flow: and it was in these very cases—for example, proximal arteriovenous fistulae in the limb—that a bloodless field was always desirable and indeed often indispensable. When a tourniquet could not be applied to a limb there was until recently only one satisfactory alternative method, and it was applicable only to the lower limbs: on several occasions in the treatment of both urgent and chronic vascular lesions I have used with complete success Macewen's method of compression of the abdominal aorta by the pressure of the closed fist of an assistant, a manoeuvre which allows one to deal without haste with lesions involving the great vessels supplying the lower extremity.

Advantages of Induced Hypotension

It is not surprising that efforts have been made to secure ischaemic or partly ischaemic operative fields in the head and neck and in the trunk. My own experience has been confined to testing the usefulness of these efforts during operations on the trunk. It is obvious that in this region a relatively bloodless field can be produced only by some technique other than local—for example, by lowering the systemic blood pressure. Before describing briefly the technique evolved by my colleagues in anaesthesia, Dr. Gillies and his staff, I must first examine the question whether such hypotension is in the interests of the patient. There is no doubt that in the ischaemic field provided by induced hypotension the surgeon can perform an operation with great precision and speed, as a result of the ease with which structures can be displayed and identified. This is naturally for the good of the patient, who spends a shorter period with both *milieu intérieur* and *milieu extérieur* abnormal. Tissues can be disturbed with the maximum gentleness, and loss of blood is reduced to the minimum. On the other hand, before adopting any such hypotensive technique, the surgeon must be equally sure that certain hypothetical undesirable sequels will not occur.

First he must be certain that systemic hypotension of the duration proposed will not impair, temporarily or permanently, the function of any organ or any tissue, and particularly of any essential organ or tissue which is known to be unduly sensitive to ischaemia, such as the central nervous system, the heart, the liver, and the kidneys. Secondly, he must know that, after the period of hypotension is over, the return to normal of systemic blood pressure will not be followed by reactionary bleeding. It will be convenient to dispose of this second point by saying that in my experience the very bloodlessness of the field makes it easy to secure any vessel which may require occlusion, and that reactionary bleeding of sufficient degree to call for reintervention, or to complicate convalescence, has occurred in only 4 out of a total of 802 operations; in one case (haemorrhage from the middle sacral artery after excision of the rectum) it was fatal.

Thirdly—and Mr. Julian Taylor called my attention to this point—he must know that, especially in procedures which require large operative fields, sufficient circulation will be soon enough established after the wound is closed to provide adequate humoral defence-mechanisms against the multiplication and invasion of any stray organisms (whatever their origin) which may have gained access to it. In the method we use, the period of hypotension can be regulated by the anaesthetist, and can be shortened, if it be desirable, by the administration of such a drug as methylamphetamine hydrochloride. The total duration of the designed period has never exceeded three hours.

The first point—the general and local effects of hypotension—is of fundamental physiological importance. The integrity of any tissue depends upon its receiving an adequate quantitative and qualitative supply of blood. This is primarily a function of the cardiac output, which depends among other factors upon the maintenance of adequate total blood volume, a sufficient proportion of which reaches the

heart through the great veins. Fortunately there is now a large body of evidence, derived from both laboratory and operating theatre, that, at least for the periods required for the completion of most ordinary procedures, the fall of blood pressure and reduction in cardiac output do not result in impairment of function of vital tissue, provided that full oxygenation is maintained: with the stipulation that one has—as I am fortunate to have—anaesthetists of physiological outlook and of great skill.

The Hypotensive Technique

In my unit the method employed by Dr. Gillies and his staff to secure hypotension has been the production of generalized vasodilatation by paralysing, with a spinal anaesthetic, the preganglionic fibres of the whole thoracolumbar sympathetic outflow; the precise details of the method have been recorded (Griffiths and Gillies, 1948; Gillies, 1950). This method has the advantages of combining analgesia and muscular relaxation with the hypotensive state.

The association of hypotension with extensive spinal anaesthesia was noted as long ago as 1928 by Koster, so that the method is not a new one, but one which, as so often happens, represents the application of an old technique refined by the methods so often used by Horsley—laboratory experiment and clinical trial. First, the effect on the experimental animal of ablation of the spinal cord, segment by segment from its caudal towards its cranial end, has been studied from the points of view of increase in local circulation in the limbs and of reduction in systemic blood pressure (Hermann *et al.*, 1936). The former occurs when the segments supplying preganglionic fibres for the respective limbs are removed, the latter when the destruction of these segments is nearing completion. Secondly, it is now known that preganglionic sympathetic fibres emerging from the spinal cord in its anterior roots can be blocked by a concentration of anaesthetic—for example, procaine—approximately one-tenth of that required to paralyse the motor fibres with which they mingle; thus it can be easily arranged that sympathetic paralysis is more extensive than the anaesthesia and muscular relaxation actually required for any given operation.

Peripheral circulation in the limbs and reduction in blood pressure have also been investigated in man by noting their values at suitable intervals while the level of analgesia induced by lumbar puncture was allowed to spread cranially (Sarnoff and Arrowood, 1946; personal observations). Sarnoff and Arrowood added the important observation that the fall in blood pressure was not increased by any procedure which paralysed the skeletal muscles. The fall in blood pressure is the result of vasodilatation, which affects both arteries and veins. Arteriolar vasodilatation reduces total peripheral resistance; venous vasodilatation increases venous capacity, reduces return flow to the right heart, and diminishes cardiac output (Shackman *et al.*, 1952). Whether this is of itself deleterious depends upon its effect upon the flow in the capillaries, which since Krogh's time has been recognized to be the essential nourishing and oxygenating stage in the circulation of the blood. When hypotension is not the result of loss of blood or of plasma—that is, when the blood volume remains at a normal level—it does not affect capillary circulation adversely: indeed, our anaesthetists find that the rapidity with which cutaneous capillary circulation is restored after local pressure is one reliable index of the general condition of the patient.

It has been shown in our unit that the oxygen requirements of the tissues are related to the state of unconsciousness, and not to the plane of anaesthesia, and that when the cardiac output is lowered during the period of hypotension it is still sufficient to provide an adequate supply of oxygen. Moreover, the dilatation of the smaller arteries and arterioles prevents the occurrence of the phenomenon termed by Krogh (1922) "plasma skimming," in which during contraction of the vessels their branches receive only the

peripheral flow of plasma, the erythrocytes as they pass in the axial stream escaping the mouths of lateral branches. Plasma skimming results in local anoxia.

The intracranial structures can be selectively protected from the effects of hypotension by maintaining a "head-down" position. The veins in the field of operation can be emptied by gravity by so placing the patient upon the operating table that this area is at a higher level than the rest of the body. A further diminution of blood pressure may be secured by arranging the patient in such a posture that blood is "pooled" in the legs: an advantage of this arrangement is that, if the need arises, by elevating the limbs some or all of this pooled blood can be rapidly returned to the circulating component of the blood volume.

The orthodox view is that filling of the coronary arteries is maintained at a pressure which is the mean of systolic and diastolic pressures. In the hypotensive stage, in which we aim at a systolic pressure of approximately 60 mm. of mercury, the pressure available to fill the coronary arteries is greatly reduced; and, when atropine is not given before operation, paralysis of their sympathetic innervation exposes them to the unopposed constrictor action of the vagus nerves. Nevertheless, we have never found any clinical evidence at or after operation that, at least after periods of hypotension lasting up to three hours, the myocardium suffers any damage. Nor have we seen clinical evidence of hepatic damage; we realize that it is difficult to be sure of this, and consequently have seldom used the hypotensive technique in cases of known or suspected hepatic insufficiency. On four occasions we have encountered oliguria for 36 hours, after which normal urinary output was restored. We encountered four fatal cerebrovascular complications in a series of 16 patients who were operated upon for malignant hypertension; these operations were undertaken as a last resort. It is quite possible and even probable that the hypotension contributed to this complication, but not absolutely certain; we have had a similar complication appear in cases operated upon under a different technique of anaesthesia, by which every care was taken to maintain the blood pressure during operation at its preoperative level.

Other Ways of Producing the Hypotensive State

The hypotensive state may be induced by certain other methods. Hypotension follows the administration of suitable doses of ganglion-blocking drugs such as hexamethonium (Paton, 1952); the state produced is somewhat similar to that after the spinal blockade of preganglionic fibres, in that the blood volume is not reduced. In ganglion-blockade hypotension the blood pressure may be influenced by changes in posture and by the administration of sympathetomimetic drugs such as *noradrenaline*; obviously, additional provision must be made for analgesia and for adequate muscular relaxation. According to another technique, blood is removed by arteriotomy and returned to the circulation by intra-arterial transfusion as and when required (Gardner, 1946). In this method bleeding in the field of operation is reduced as a result of the general vasoconstriction which follows the abstraction of large quantities of blood from the circulation; in my view intense general vasoconstriction increases anoxia as a result of plasma skimming by the terminal arterioles.

The production of an ischaemic field in the trunk by the employment of a hypotensive technique should not be routine even when both anaesthetist and surgeon are familiar with it, although it provides conditions so favourable that I for one must regularly remind myself of this. It is unsuitable for the elderly and for those suffering from organic cardiac disease. The surgeon must take the greatest care to control what bleeding there is, and must remember that any loss of blood is badly borne by patients in the hypotensive state, especially if it be a rapid loss consequent on some unforeseen operative complication. Any such loss should be at once replaced by transfusion: usually transfusion is not required, and indeed one advantage of the method is that

it reduces demands upon the transfusion service. I regard hypotensive anaesthesia, when used with judgment, as a major contribution comparable to the introduction of the safe tourniquet.

Cooling Technique

Earlier I emphasized that in ordinary conditions and at ordinary temperatures each tissue had a minimum requirement of oxygen. This oxygen requirement is not always a fixed one: thus in man it can be lowered by producing a state of unconsciousness, and in many other animals it is drastically reduced during states of hibernation. It would be of great physiological interest, and possibly of clinical importance, if methods could be devised by which an organism could be brought into a condition in which its requirements of oxygen were reduced to a level so low that its tissues would withstand abnormally long periods of ischaemia without any subsequent interference with function. The first stages of an investigation of this speculative kind must obviously be carried out in the experimental laboratory; and a possible approach is the application of the knowledge that the speed at which physico-chemical reactions (and therefore metabolic processes) are completed is retarded by reducing the temperature at which they are occurring. Much highly important fundamental work on these lines has been originated in Toronto by Bigelow and his co-workers (1950), who have subjected dogs to surface cooling; they found that their animals did not develop an oxygen debt.

In the Wilkie Surgical Research Laboratory in Edinburgh, Dr. Delorme (1952) has cooled dogs by passing arterial blood through an extracorporeal cooling system and returning the cooled blood to a vein. By this procedure the temperatures of the animals were stabilized at between 22 and 26° C., the normal temperature of the dog being 38° C. At temperatures of this order he found that tissues such as those of the central nervous system and the viscera could be completely deprived of their blood supply, as by a tourniquet, for periods in excess of those lethal at normal temperatures, and that without any transient or permanent evidence of loss of function. As Delorme remarks, a combination of the hypotensive and cooling techniques has many possibilities in facilitating and extending surgical procedures, particularly perhaps those employed in cardiac surgery. This work is continuing: there are some technical problems and clearly many physiological problems still to be investigated.

These, then, are some aspects of desirable ischaemia. Some are long-established as useful, some only recently so: still others have to prove their applicability to practical surgery. All have lent themselves to the combination of investigation and trial in both laboratory and clinic which was so faithfully pursued by Horsley throughout his professional life.

UNDESIRABLE ISCHAEMIA

For the remainder of this lecture I shall deal with certain aspects of ischaemia which are known or suspected clinically, and about the genesis of which fundamental information is almost completely lacking. Any observations I make must therefore be highly speculative, and confined to generalities.

It is well known that the local reaction of any tissue to noxious stimuli—which include incisions made by the surgeon's knife—is made up of two main components (Lewis, 1927). These are: (1) at the site of application of the stimulus, dilatation of minute vessels and swelling which results from the outpouring of plasma from capillaries; and (2), in the vicinity of the site of the stimulus, a "flare" which results from dilatation of the neighbouring arterioles, a dilatation mediated through an axon reflex involving local sensory nerve fibres. Both these components are factors in the humoral mechanism of tissue-defence and tissue-repair. When the lower sensory neurones supplying an area have been interrupted—or, to be more accurate, after they have

undergone Wallerian degeneration—the flare no longer occurs when a stimulus is applied to the denervated area. Thus even when the blood supply to such an area is intact its tissues may be regarded as relatively ischaemic so far as local defence and local repair are concerned*; and this is the minimum degree of ischaemia which can be recognized clinically.

This lack of completeness of the local vascular reaction no doubt accounts for the indolent appearance so characteristic of the small cutaneous lesions which may occur in an area of anaesthesia resulting from the division of a peripheral nerve. The same appearance is seen in the ulcers of the face which may occur after section of the posterior root of the trigeminal nerve, although in such circumstances the peripheral sensory axones are still in continuity with their parent cells in the Gasserian ganglion: it would seem that, in these circumstances also, the functional capacity of peripheral axones is seriously impaired, if not abolished (N. M. Dott, 1952, personal communication). Professor Dott has found that the appearance of such facial ulcers may be prevented by preliminary cervical sympathectomy, and that, if one is present, rapid and permanent healing is assured after cervical sympathectomy. In such cases the primary operation of posterior root section does not interrupt the vasoconstrictor fibres destined for the face, which reach the skin supplied by the trigeminal nerve by way of the periarterial plexuses round the branches of the external carotid artery. On the other hand, when a peripheral nerve is divided, the vasoconstrictor fibres which are ultimately distributed by way of its sensory branches are interrupted: the denervated part remains warm until Wallerian degeneration has occurred, and thereafter is consistently colder than normally (Richards, 1951).

This peripheral sympathectomy does not seem to reduce the incidence of cutaneous lesions in the denervated area or to favour their repair. In such an anaesthetic area, what modification, if any, occurs in the healing of lesions, accidental or made by the surgeon, as a result of the curtailing of the vascular response to injury? From a not inconsiderable experience of such cases I agree with the view that the process of repair is retarded. A somewhat similar problem is posed when amputation becomes necessary in a lower limb, the distal parts of which are anaesthetic as a consequence of congenital lesions of the cauda equina. In such cases it is, I believe, wise not to include anaesthetic skin in the flaps. I do not base this view on the inevitable instability of the anaesthetic skin when it is ultimately sheathed in a prosthesis. Even when complete protection is afforded to the original wound by encasing the stump in plaster-of-Paris, its union is slower than normally, and its edges are more apt to show localized patches of necrosis in the neighbourhood of stitches. Lumbar sympathectomy will improve the blood supply to such anaesthetic areas, because their vasoconstrictor fibres join the peripheral nerves which supply them distal to the level of interruption of their sensory fibres.

Although we may attribute them to relative ischaemia, we are quite ignorant of the ultimate cause of these variations in healing, and even of the stage or stages at which the delay in healing occurs. Thus it may be that the initiation of the process of repair is delayed, or that the ultimate production of collagen fibrils and the return of fibroblasts to the resting phase is postponed. It is true that in man (although not in many other animals) the end-stage of repair of many tissues is often fibrosis; but in the majority of clinical cases this is the direct result of impairment of blood supply from organic arterial disease, whereas in the conditions to which I have been referring the vascular tree is normal, although its response to a demand for tissue repair is incomplete. Defects in a process so species-specific should obviously be studied by observations on man.

*Nevertheless accurate measurements of the temperature of the skin around such lesions (Doupe and Cullen, 1943) have shown that the purely local reaction leads to increased warmth.

Some Problems

There are many gaps in our knowledge of the more common problems which may confront surgeons in those forms of ischaemia which are due to definitive lesions of arteries—problems so numerous that I shall have to select some which have interested me most. First let me consider one aspect of acute diminutions of arterial supply. It has seemed to me that when there is no organic disease of the arterial tree the most striking recoveries after surgical relief from potentially dangerous situations have occurred in patients who have not ceased to grow, or have only lately ceased to grow: and in addition I should place in this favourable group young women who have recently borne children. This is a personal view, and a clinical view at that, and I realize that I cannot offer you scientific proof of it. Nevertheless I believe that it is not outside the bounds of possibility that these patients have something—call it what you will—circulating in their blood which potentiates the recovery and repair of ischaemic tissues to a degree not found in other groups; including, for example, the reduction of loss of tissue to an unexpected minimum and the taking of skin grafts placed upon indubitably ischaemic areas. This is the sort of hypothesis that might come to trial; and, if it prove to be soundly based, might be found to depend upon some asset of a general biological nature common to animals—including man—at these stages of life.

When I come to consider chronic and acute-on-chronic ischaemia I must confess that again we lack much fundamental information. In most situations man is so overarterialized that arterial obstruction may progress unnoticed until—and perhaps suddenly—the supply of blood is reduced below minimal requirements. The results of this reduction range widely from death of the individual to death of a small block of tissue. We are still two stages distant from having complete knowledge of the whole process.

The penultimate stage is the ability to recognize ischaemia before it is clinically evident. It is true that in the case of the limbs, which are the most accessible for such measurements, we now have instruments of precision such as plethysmographs which greatly increase the delicacy of estimations of the blood flow. Yet we have still to apply to the problem the method of mass observation, introduced to the profession by Jenner, in which a sufficient sample of the population would be observed over a sufficient length of time in order to determine the earliest change measurable by the apparatus at present available.

The ultimate stage, which may and probably does follow the penultimate after a considerable interval, is the determination of the pathological physiology which initiates obliterative processes in the arterial tree, the established morphological details of which are well enough known. As Leriche has said, the initial changes are so minute that they are probably of an order at present undetectable. Indeed, the search must be to some extent a blind one, for we do not really know what to look for. Any investigation on these lines must also take cognizance of many variables—for example, the appearance of degenerative processes in infancy, the beginnings of which must be during intra-uterine life; and the strange immunity to degenerative changes possessed by certain vessels, such as the peroneal artery of the leg and the interosseous arteries of the forearm, whose ageing, if ageing it be, is so much slower than that of arteries running within a centimetre or two of them. When we acquire this information, our next objective should be to find some way of preventing the changes in the walls of arteries which sooner or later lead to the presentation to blood, as it circulates, of mural areas which favour thrombosis, with all its possible disastrous sequels—loss of intellect and power, loss of cardiac muscle, loss of limb.

Although this must remain the correct objective, if we were able to detect pre-ischaemia, and if we had the opportunity of looking for examples of it in the population, we might possibly reduce the number of clinically evident cases,

and mitigate the severity of those which do occur, by bypassing the morphological issue and, as an expedient, raising to prophylactic levels the amount of anticoagulant substance derived from humoral sources normally circulating in the blood. At the present time this is possible experimentally: when introduced into the portal circulation, curare increases the output of heparin from the liver. Unfortunately, even if a suitable pharmacological preparation were available, therapy of this kind would need to be continuous, for we do not know whether a tendency to clotting—"pre-clotting"—precedes episodes of thrombosis by a long period or a short one. Moreover, investigation along such lines might not commend itself, because on occasion clotting is a valuable protective mechanism, and to suggest its abolition transgresses a clinical precept which is usually sound enough—that one must never try to correct one pathological process by substituting another; although in this particular problem I should not subscribe to that view.

Conclusion

I fear that, by selecting so vast a subject as ischaemia to be the topic of this Memorial Lecture, I have been constrained to be so eclectic that it may seem to lack continuity. If that be so, the fault is mine.

While I was engaged in preparing the address, more than once I had the feeling that here was a matter on which I should have liked to enlist Horsley's advice and help. I venture to repeat that the lecture has been designed to illustrate that oneness of the laboratory, the ward, and the operating theatre so well exemplified by Horsley's life's work. Indeed, there is something more than oneness. For there is holism in surgery as well as in philosophy—the tendency for the final accomplishment to be greater than the sum of the contributions from each of these three arbitrary divisions of our efforts.

To few in our profession have been given those twin gifts without price: the genius to produce ideas, and the steadfastness of purpose to pursue their ideas as ideals. Such a one was Victor Horsley.

Two new American journals were published in January, —*Applied Microbiology* and the *Journal of Histochemistry and Cytochemistry*. The agents in this country are Messrs. Baillière, Tindall and Cox, and orders for the journals may be sent direct to them or placed with any bookseller. Annual subscription for *Applied Microbiology* is 63s. post free, and the journal will be published bi-monthly. The other journal is the official organ of the Histochemical Society of America, costs 60s. per annum, and will also appear bi-monthly. The *American Surgeon* is the new name given to the *Southern Surgeon*, official publication of the South-eastern Surgical Congress of America, to mark its widened scope as a general surgical journal. It is published monthly, annual subscription 82s. Messrs. Baillière, Tindall and Cox are the British agents.

HEALTH OF PREMATURE CHILDREN FROM BIRTH TO FOUR YEARS*

BY

J. W. B. DOUGLAS, B.M.

AND

C. MOGFORD, B.Sc.

This paper describes the health of a national sample of premature children who have been observed during the first four years of their lives and compared with a carefully chosen group of "controls." Details of their growth and development will be published in subsequent papers.

Some 40,000 of the babies born each year in Great Britain weigh at birth 5½ lb. (2.5 kg.) or less, and by international agreement are classed for statistical purposes as premature. Approximately a quarter of them die before they are a month old, and it has been claimed that many of the survivors, as a consequence of prematurity itself or of the antenatal conditions leading to it, are sickly, stunted, or mentally retarded. It is probable that in the future we will be able to save the lives of more of these babies, and it is important to know how large a proportion will be handicapped in later life and what institutional or other special care they will need.

At first sight it seems that these questions could be easily and directly answered by tracing in later life children who had been prematurely born. Many studies of this type have in fact been made, the majority being concerned with growth and development rather than with health. But the results have been conflicting. Some reveal prematurity as a major cause of mental backwardness and dwarfed growth, whereas others show premature children as retarded only to the extent that they were born before term.

The difficulties of tracing children after a lapse of years are great, and few investigators have found more than half the survivors for whom they were looking. Moreover, depending on the channels through which they have had to work, some appear to have been more successful in tracing the abnormal children and others in tracing the normal ones. They have also, in general, been content to compare the health and development of premature children with "national averages," often obtained many years earlier from highly selected groups and by methods differing widely from those used in their own inquiries. A few have compared premature children with a random sample of children born at term during the period of their inquiry, and others have compared each premature child with its sibs. None of these methods is satisfactory, because prematurity is not distributed at random in a series of births. Premature children tend to be female, to be first-born, to come from the poorer classes, and to have mothers who are above the average age for child-bearing. And unless they are

*This follow-up survey of premature children is being made by a joint committee of the Institute of Child Health (University of London), the Society of Medical Officers of Health, and the Population Investigation Committee. The chairman of the Committee is Professor James Young, the vice-chairman Professor A. A. Moncrieff, and the secretary Professor D. V. Glass. The Nuffield Foundation has financed this inquiry during the pre-school years, and a grant for continuing it in the primary school period has been made by the Board of the Hospital for Sick Children, Great Ormond Street, through the Institute of Child Health.

compared with mature children chosen to conform to this pattern it is doubtful what weight can be attached to any differences in growth or health that are observed. It is likely, then, that the conflicting results of previous studies have arisen from the difficulties of obtaining an adequate sample of prematurely born children and of finding a suitable group of children born at term to compare them with.

Description of the Present Survey

We have had the good fortune to follow up over a period of four years the health and development of a national sample of children who weighed at birth 5½ lb. (2.5 kg.) or less and to compare them with a carefully selected group of children who were heavier at birth.

This sample was obtained in 1946, when a Joint Committee of the Royal College of Obstetricians and Gynaecologists and the Population Investigation Committee, with the help of medical officers of health and health visitors throughout the country, investigated all confinements taking place in England, Wales, and Scotland during the first week in March of that year. Out of a total of 458 maternity and child welfare authorities, 424 took part in this inquiry, and detailed medical and social information was obtained about 91% of the births notified in these authorities during the chosen week. In all, 13,687 women were interviewed by health visitors eight weeks after the birth of their babies. The information given by them and obtained from their records formed the basis of a report on the maternity services (Royal College of Obstetricians and Gynaecologists, 1948).

We have chosen as our sample of premature children all legitimate singletons who were notified to us during the survey week and who weighed 5½ lb. or less at birth. We are, of course, aware that not all babies of this weight are premature in the sense that they are born before term. But the weight standard of prematurity is generally accepted, and has been used in the more recent studies of the health, growth, and development of premature children; and it would be foolish to present our material in a form that could not be compared with the results of many of the studies that had preceded it. To talk about "children weighing 5½ lb. or less at birth" is clumsy, and we have preferred to use the term "premature" to describe them, since, although inaccurate, it is established by long usage. For the same reason we have not attempted to use different weight standards of prematurity for the two sexes.

Each premature child in the sample was paired with another child selected from the remaining legitimate single-born children in the sample, who was of the same sex, age, and place in the family, who came from the same type of home background, lived in the same locality, and had parents of the same age and social class. We have been able to match the majority of the pairs very closely owing to the large numbers of children from whom we could draw; even so, a perfect match was not always forthcoming, and a certain latitude has been allowed. For example, if a suitable match for a premature child could not be found within the area of the authority where he was born, the search was extended to other similar authorities in the same geographical region; 17% of the pairs were matched from different authorities. It was also not always possible to match exactly for birth order. While first births were always paired with first, second births might be paired with third, and third births with second or

fourth, etc. During the course of the inquiry a few mistakes in matching were found, and then the original control was discarded and a new one chosen. A premature child was also re-matched when his paired control had left the country; but when either member of a pair had died the survivor was retained in the survey.

Health visitors saw these children and interviewed their mothers on three occasions—when they were 2 months, 2 years, and 4½ years old. At these interviews information was obtained on home conditions, hospital admissions, colds, and certain specified illnesses, and arrangements were made to weigh and measure the children at welfare centres. Information about the course and duration of pregnancy and the care given to the child after birth was obtained from the records of hospitals and midwives.

This comparative study of children born prematurely and at term is part of a much larger inquiry into the health, growth, and development of a national sample of children. This larger inquiry (which will be referred to as the "main survey") is mentioned here because it provides figures on deaths and illnesses which are referred to in this paper. The detailed planning of it has been described elsewhere (Douglas, 1951).

Loss from the Sample

Birth weights of 5½ lb. or less were recorded for 851 single-born children in the 1946 sample, of whom 67 were stillborn and 72 were illegitimate, and accordingly excluded from further study. Five of the remaining 712 children were later found to have weighed more than 5½ lb. at birth, and a further 31 were excluded because so little was known of their home backgrounds that they could not be satisfactorily paired with controls. In retrospect we feel it was a mistake to exclude these 31 children, since much of the missing information would have been obtained during the later surveys. We were left with 676 premature children and 676 paired controls, and we have had considerable success in tracing the survivors (Table I).

TABLE I.—Losses of Premature and Control Pairs, 1946–50

		No. of Pairs
Unavoidable loss	Death	173
	Emigration (1946–8)	21*
Avoidable loss	Refusal	6†
	Untraced	2†
Still in survey		464

* Alive at time of emigration.
† All known to be living in 1950.

In this paper our main interest is in the 472 pairs both members of which were still living in this country in June, 1950, when they were 4½ years old, and the 10 pairs emigrating in 1948–50. Of these 482 pairs, 474 (98.3%) have been successfully retained in the sample, and we have been able to check from official sources that the two children who could not be traced and the six children whose parents refused to help were still living at the time of the last survey. The losses through death and emigration are heavy, but represent a natural decrease in the sample which can hardly be said to have biased it. There is, moreover, no reason to believe that the children who emigrated with their families left this country owing to ill-health; on the contrary, they are likely to be a particularly healthy sample, as all emigrants, including babies, undergo a strict medical examination.

The actual loss of information is rather greater than the figures in Table I suggest. When their mothers were ill or working, the forms for some children were only partly filled in. Other mothers were unable or unwilling to answer certain questions. The loss from these causes varies from table to table, as will be seen below, but for most illnesses it is small.

Survival and Health

(a) Survival

Before describing the illnesses encountered by the 474 pairs of children surviving at 4½ years, it is appropriate to make a brief comparison of the mortality rates in the premature and control samples. These are shown in Table II, which also gives the equivalent rates for all children in the "main survey sample" who weighed over 5½ lb. This further comparison is required because the mortality rates for the controls, being based on few deaths, are of low precision; but in fact they are similar to and not significantly different from the rates derived from the larger sample.

TABLE II.—*Death Rates of Premature Children, Their Controls, and Mature Children in the "Main Survey"*

Age	Monthly Death Rates per 1,000 Survivors			Significance (n=1)
	Premature Live Births (676)	Control Live Births (676)	Live-born Mature Singletons in "Main Survey" (5,033)	
Neonatal ..	211.84*	9.11	10.79	0.02-0.01
1-12 months ..	3.37	1.81	1.09	
13 months-4½ years ..	0.36	0.15	0.19	

* Comparing premature children and controls.
For neonatal deaths, $\chi^2=139.34$, $n=1$, $P<0.001$.
For later deaths, $\chi^2=5.27$, $n=1$, $0.05>P>0.02$.

These figures support the view that the high mortality of premature children extends beyond the first month of life. At ages between 1 month and 4½ years these children appear to be abnormally likely to die from lower respiratory infections, congenital defects, and nephritis, as Table III shows. They are compared, in this table, with the mature children of the main sample and not with their controls, in order to have a greater number of deaths on which to base the comparison. Even so, the numbers are relatively small and the differences in death rates, though statistically significant, need confirmation.

TABLE III.—*Causes of Death Between 1 Month and 4½ Years*

Causes of Death	Yearly Death Rates per 1,000 Survivors			Significance (n=1)
	Premature Children (543 Surviving at 1 Month)	"Main Sample" (4,979 Mature Singletons Surviving at 1 Month)		
Bronchitis and pneumonia ..	4.88	1.35	10.90	<0.01
Other infections ..	2.17	1.83	0.002	
Congenital defects ..	4.33	0.58	23.00	<0.01
Nephritis ..	1.08	0.05	7.00	
Other causes ..	1.62	0.63	1.18	0.3-0.2

(b) Nature and Reliability of Our Information on Sickness

Our information on the illnesses of these children was obtained during interviews with their mothers when they were 2 years and 4½ years old. No comprehensive account of ill-health could be expected to result from this method of approach, and our inquiries were confined to certain specified events and conditions that the mothers would be likely to remember. The following information was asked for and has been used in this paper:

(1) Details of all accidents or illnesses that resulted in admission to a hospital or nursing-home. Mothers were asked to give the reason for admission, the age of the child when admitted, the length of stay, and the name and address of the hospital or nursing-home.

(2) Details of all lower respiratory infections and infectious diseases of childhood which were treated by the family doctor or in an out-patient department of a hospital.

(3) Estimates of the number of colds experienced by each child during the months immediately preceding each interview.

The questionnaire method is open to several sources of error. Events may be forgotten or they may be so garbled that no useful purpose is served by recording

them. They may be remembered but wrongly dated, or they may be attributed, in large families, to the wrong child. We are fortunate in having, for illness resulting in hospital or nursing-home admissions, an absolute check on the extent of these different types of error. During the survey the mothers were asked to give the names of the institutions to which their children were admitted, and we have been able to trace the records of 151 out of the 186 admissions of children in the premature and control sample. Some hospitals had destroyed their records, some have not yet replied, and the addresses of a few others were indecipherable; but the 35 admissions which were not directly checked with the hospitals for these reasons have been confirmed again by further questioning of the mothers, and we are satisfied that the information relating to them is now correct.

When the hospital and nursing-home records are compared with the accounts given by the mothers of the 151 children admitted to them, it appears that 70% of dates were remembered correctly to within a month of the actual time of admission. A further 19% were between two and six months out, and 11% were less accurate than this. A cluster of errors of twelve months suggests that some of the larger discrepancies arose from verbal or recording mistakes rather than from faulty memories. The admissions were as often antedated as post-dated, and Table IV shows that

TABLE IV.—*Ages of Admission to Hospital and Nursing-home*

Source of Information	Age at Admission (Months)				Total
	0-13	14-25	26-37	38-51	
Mother* ..	42	38	28	43	151
Records† ..	42	35	32	42	151

* As remembered by the mothers.

† As given by the institutions.

there is a remarkable similarity between the age distribution of admissions obtained for the same children from the records and from the mothers themselves.

The analysis of hospital admissions given in the next section was based in the first place on the mother's information. It was then repeated when the hospital records became available. None of the original conclusions has had to be altered in the light of this re-analysis, and it would seem that for relatively large samples of children satisfactory information on major conditions of ill-health may be collected by the questionnaire methods used in this survey. On the other hand, it would clearly be unwise to base discussions of the health of an individual child on information of this type.

The admission of a child to hospital is a major event in his life and in the life of his family, and it may be that less serious events are less well remembered. But for the information we have been able to check (covering such diverse subjects as weaning from the breast, immunization, and post-natal examinations) it seems that we can rely on mothers' memories to bridge even a two-year gap (Rowntree, 1950; Douglas, 1951).

(c) Hospital and Nursing-home Admissions

This analysis is limited to the hospital and nursing-home admissions of the surviving children. Those who died were excluded because it was seldom possible after their death to question their parents about their past illnesses. Thirty-nine of the surviving pairs also were left out because information was lacking for one or both of them; among those excluded were five premature children and three controls who had been admitted to hospital but were paired with children whose mothers failed to answer the questions on hospital care. Accordingly there are 435 surviving pairs for whom we have information.

The fact that premature children are often retained in maternity hospitals for several weeks after birth is well known. In the present sample 39% of the surviving premature children, as compared with 11% of their controls,

were kept in hospital until they were more than 14 days old, the mean lengths of stay for all those born in hospital being respectively 17.7 days and 12.6 days ($t=6.91$, $n=593$, $P<0.001$). At this time maternity beds were in short supply, and it may be a reflection of this shortage that as many as 26% of the premature children sent home during the first fourteen days after birth weighed 5 lb. (2.3 kg.) or less on leaving hospital. For this reason it is likely that the mean stay of 18 days found for premature children in this survey is an underestimate of their need for hospital care in the immediate post-natal period. Hospital stay directly related to labour or the special nursing needs of infants during the early weeks has been excluded from the following discussion for obvious reasons, and the figures given below refer with four exceptions (two premature children and two controls) to admissions occurring after the neonatal period.

Ninety-one premature children (21%) and 64 controls (15%) were admitted to hospital on at least one occasion during the first 4½ years of their lives ($\chi^2=5.75$, $n=1$, $0.02>P>0.01$). If the number of admissions is counted instead of the number of children admitted, then the proportions are respectively 26% and 17% in the two groups ($\chi^2=9.87$, $n=1$, $P<0.01$). In each instance the admission rates are significantly higher for premature children. Three of the premature children, but none of the controls, spent a great part of their first four years in hospital. (See footnote to Table XV.) One is a spastic microcephalic who was kept in hospital because there was nowhere else for him to go; the second has pulmonary tuberculosis; and the third has bilateral cataracts and is now totally blind. These three children alone received 1,520 days of hospital care, which is more than the total number of days spent in hospital by all the controls during the same period. It is also nearly half the total amount of care given to all the premature children. For the following description of hospital care we propose to exclude these three children, since the extent of their disabilities would otherwise obscure the pattern of hospital care among those who were less handicapped.

Table V shows the average number of days spent in hospital during different age periods by premature children and their controls.

TABLE V.—*Average Number of Days per Child Spent in Hospital at Different Ages (Excluding Maternity Care)**

Age (in Months)	Average No. of Days per Child (432 Pairs)		Significance (n=862)	
	Premature Children	Controls	t	P
0-12	1.54	0.39	2.59	<0.01
13-24	1.42	0.44	2.82	<0.01
25-36	0.62	0.68	0.21	0.9-0.8
37-51	0.79	0.69	0.39	0.7-0.6

* Three premature children permanently in institutions have also been excluded (see text).

During the first two years premature children spend on the average three and a half times as many days in hospital as their controls do, a total of 1,269 days as compared with 359 for the controls. In the third and fourth years there is no difference between them, the total stay being respectively 608 days and 595 days.

The average stay per illness tends to be greater among premature children; 48% of those admitted to hospital stayed there for more than two weeks, as compared with 36% of the controls ($\chi^2=4.40$, $n=1$, $0.05>P>0.02$). Moreover, the premature children during the first two years show a much greater variability in the time they spend in hospital. In the third and fourth year, on the other hand, there are no significant differences either in the average stay or in the range of variation of the length of stay for each illness. For the remainder of this section, therefore, we will consider only admissions in the first two years of life.

*For convenience the term "hospital admission" is used to include both hospital and nursing-home admissions.

Table VI shows that there is a marked relationship between the birth weight of premature children and the likelihood of their being admitted to hospital.

TABLE VI.—*Hospital Admissions in First Two Years by Birth Weight of Premature Child*

Birth Weight of Premature Child	% Admitted to Hospital			Significance (n=1)	
	Premature Children	Controls	No. of Pairs	χ^2	P
4½ lb. (2 kg.) or less	19.05	5.95	84	5.44	0.02-0.01
4½-5 lb. (2-2.3 kg.)	15.52	5.17	116	5.62	0.02-0.01
5-5½ lb. (2.3-2.5 kg.)	9.36	7.23	235	0.70	0.5-0.3

In each group the admission rate is lower for the controls, but the differences are significant only for premature children weighing 5 lb. (2.3 kg.) or less.

In Table VII the hospital admission rates of male and female pairs are shown separately. While premature

TABLE VII.—*Hospital Admissions in First Two Years by Sex*

Sex	Hospital Admissions in First Two Years			Significance (n=1)	
	Premature Children %	Controls %	No. of Pairs	χ^2	P
Male ..	17.98	7.87	178	8.07	<0.01
Female ..	9.34	5.45	257	3.05	0.1-0.05

children of both sexes tend to be admitted to hospital more often than their controls, the difference is significant only for the males. It is of interest that females, both premature and controls, are less likely to be admitted than are males.

The excess of hospital admissions among premature children is no greater when they have resulted from pregnancies complicated by toxæmia or ante-partum haemorrhage. Nor is it greater among those born more than two weeks early than among those born nearer term.

Table VIII shows the causes of admission to hospital among premature children and their controls. In preparing

TABLE VIII.—*Causes of Admission to Hospital During the First Two Years*

	% Admitted for Specified Illnesses (435 Pairs)			Significance (n=1)
	Premature Children	Controls		
Bronchitis and pneumonia ..	3.22	0.69	$\chi^2=6.06$, $n=1$, $P<0.01$	
Other infections ..	2.99	2.76		
Cataract ..	0.69	Nil	$\chi^2=2.28$, $n=1$, $0.2>P>0.1$	
Inguinal hernia ..	1.38	0.23		
Epilepsy and convulsions ..	0.46	Nil		
All other illnesses ..	2.99	2.30		
Accidents ..	0.92	0.69		

this table successive attacks of the same type of disease—for example, pneumonia—were counted separately, whereas repeated admissions for continuing disabilities—for example, cataract, congenital dislocation of the hip—were treated as single incidents.

A number of conditions are more common among the premature children than among the controls, but, considering them individually, only lower respiratory infections are significantly more common, 42% of the excess of hospital admissions being attributable to infections of this type. The greater occurrence in the sample of premature children with cataract, hernia, and convulsions is of interest in the light of previous work, but a very much larger inquiry would be needed for a profitable statistical analysis to be made.

The higher incidence of lower respiratory infections among premature children admitted to hospital does not necessarily imply that they are, as a group, more likely to contract these diseases. It might mean, for example, that

once they fell ill they were more severely affected. In the following sections, therefore, we will consider the total incidence of upper and lower respiratory infections, whooping-cough, and measles.

(d) Infections of the Upper Respiratory Tract

Our information on upper respiratory infection is limited to an estimate of the number of colds caught by the survey children in the three months preceding their second birthday and in the six months centring on their fourth birthday. These estimates, which were made by their mothers, are of unknown accuracy and have therefore been used only to separate those with reputedly constant or frequent colds from those who seldom or never had them.

Table IX shows that at both 2 and 4 years prematurely born children tend to have more frequent colds than their controls, though the difference is significant only in the

TABLE IX.—Proportion of Children with Frequent Colds

	Premature Children %	Controls %	No. of Pairs	Significance (n=1)	
				χ^2	P
More than 2 colds between Dec., 1947, and Feb., 1948	20.3	14.4	395	4.67	0.05-0.02
More than 3 colds between Dec., 1949, and May, 1950	18.6	15.4	408	1.47	0.2-0.1
Frequent colds in both periods	6.4	3.8	344	2.44	0.2-0.1

younger age group. There are, moreover, among the premature children nearly twice as many who suffered from frequent colds in both years.

(e) Lower Respiratory Infections

Our information on lower respiratory infections covers only the incidence of first attacks during the first two years of life which were treated by a doctor at home or in hospital. Accordingly the following figures are not directly comparable with those given for hospital admissions which include as separate illnesses successive attacks in the same child. Table X shows the mean incidence of first attacks of lower respiratory infections at different ages.

TABLE X.—First Attacks of Lower Respiratory Infections Treated Either by a Doctor at Home or in a Nursing-home or Hospital

Age at Attack (in Months)	Mean Monthly Rate per 1,000 Children Exposed (445 Pairs)		Significance (n=1)	
	Premature Children	Controls	χ^2	P
0-7	16.64	8.26	8.49	<0.01
8-13	33.33	18.43	9.92	<0.01
14-24	10.06	7.55	1.33	0.3-0.2
All ages	17.58	10.53	17.28	<0.01

During the whole of the first year there is an excess of bronchitis and pneumonia among premature children; in the second year the same trend is apparent but the differences are not statistically significant. Further subdivision according to the birth weight of the premature member of each pair (Table XI) shows that the greatest difference

TABLE XI.—Lower Respiratory Infections by Birth Weight of Premature Child

Birth Weight	Mean Monthly Rate per 1,000 Exposed for First Two Years		Significance (n=1)	
	Premature Children	Controls	χ^2	P
4½ lb. (2 kg.) or less	27.78	7.94	92	21.88
4½-5 lb. (2-2.3 kg.)	15.49	9.87	118	3.15
5-5½ lb. (2.3-2.5 kg.)	14.58	11.96	235	1.29

between the premature children and their controls is found in the groups of lightest weight. This relationship is of the same order as that found for hospital admissions.

Sex differences in the incidence of lower respiratory infections (Table XII) are similar to those for hospital admissions. In both sexes there is a higher incidence among the premature children, the difference being smaller for females.

TABLE XII.—Lower Respiratory Infections by Sex

Sex	Mean Monthly Rate per 1,000 Exposed for First Two Years		No. of Pairs Exposed	Significance (n=1)	
	Premature Children	Controls		χ^2	P
Male	19.52	10.83	187	9.89	<0.01
Female	15.75	10.35	258	6.32	<0.01

Lastly, we have related the incidence of lower respiratory infections to the length of gestation, and found that the excess of these diseases among premature children was just as great among those delivered two or more weeks early as among those delivered later than this.

(f) Whooping-cough and Measles

The proportions of children who during the first four and a quarter years of life suffered from whooping-cough or measles are shown in Table XIII. From these figures it

TABLE XIII.—Incidence of Whooping-cough and Measles

	% Falling Ill During the First 4½ Years		No. of Pairs Exposed	Significance (n=1)	
	Premature Children	Controls		χ^2	P
Whooping-cough	30.43	28.38	437	0.45	0.7-0.5
Measles	41.76	45.24	431	1.06	0.5-0.3

appears that premature children are no more likely to contract these two diseases; nor does a closer examination of the data suggest that they are more susceptible than the controls to either of these diseases in early infancy.

Discussion

While many papers on the physical growth and mental development of premature children have been published, few studies have been made of their health. Capper (1928) thought that during the first year a premature child has little resistance to infection of the respiratory tract, whereas after the first year his resistance is not unlike that of a mature child. Mohr and Bartelme (1934) likewise noted the frequent occurrence of respiratory infections, particularly colds, among the prematurely born. But in neither of these inquiries was there an adequate group with which to compare the premature children, though Mohr and Bartelme attempted to use brothers and sisters as controls. Owing to the difference in age between the siblings, however, no useful comparisons could be made.

Drillien (1948), studying a series of premature deliveries, found that the smaller premature infants were particularly susceptible to septic skin infections and discharging eyes. She followed up some of these children when they were age 1½-4½ years and compared their illnesses with those of a sample of children born in the same hospital at term. Her analysis is complicated by the varying ages of the children, and by the fact that she was able to trace only 40% of them. It remains, however, the most serious general study of the health of premature children that has so far been made. Nasopharyngeal and respiratory infections were found to be more common among premature children, who also had a significantly higher incidence of pneumonia and whooping-cough than their controls. For

measles and discharging ears, on the other hand, the controls were apparently the more susceptible. These differences were greatest in the first year and of little importance in the second.

Ferguson, Brown, and Ferguson (1952) report that nearly 25% of premature children in Glasgow received hospital treatment during the pre-school period, for conditions other than prematurity. The amount of hospital treatment was "high among infants who had weighed not more than 4½ lb. (2 kg.) at birth." It is difficult to interpret these observations, because corresponding figures for children born at term are not given, the losses from the premature sample are not stated, and the standard of prematurity adopted appears to have been length of gestation rather than birth weight.

A specific defect that has been receiving increasing attention during recent years is retrolental fibroplasia, first described by Terry in 1952. It is said to affect 12% of surviving children of birth weight of 3 lb. (1.36 kg.) or less (Terry, 1945) and to account for more than a third of the blindness in young children in the U.S.A. (Reese, 1949). Its incidence is increasing and seems to be associated with changes in the post-natal care of small premature babies. In England few cases were recorded before 1949, and most of those recorded since have been among children cared for in premature baby units. There is some evidence that the increased use of oxygen is associated with this condition (Kinsey and Zacharias, 1949; Crosse and Evans, 1952). In the present series of premature children no instance of retrolental fibroplasia was recorded, and the three children with grossly defective sight were all of too high a birth weight for this condition to be a likely alternative diagnosis.

The results of the present inquiry confirm these earlier studies by showing that hospital admissions and both upper and lower respiratory infections are proportionately more common among premature children. They also answer the criticism that, since premature children are on the average drawn from poorer homes, the greater morbidity among them is a reflection of their environment rather than of any physiological or immunological deficiency. They show that these differences in ill-health persist even when the premature children are compared with controls drawn from similar homes. Moreover, the differences are just as pronounced among those who have been brought up in relatively favourable home environments. Thus it will be seen in Table XIV that the excess of colds and lower

TABLE XIV.—Upper and Lower Respiratory Infection Among Premature Children and Their Controls in Two Social Groups

Occupation of Father	% With Frequent Colds at 2 Years		% With Lower Respiratory Infections in First 2 Years	
	Premature	Control	Premature	Control
Professional or clerical worker	19.6	12.8	25.7	13.6
Manual worker	20.5	15.0	33.5	17.9

respiratory infections is as great among premature children coming from the families of professional and clerical workers as among those from the families of manual workers.

Upper and lower respiratory infections, as would be expected from previous studies, are more common among the children of manual workers, whether they are prematurely born or not; but the excess of illness among the premature children is of the same order of size in each type of family.

This inquiry also enables us to state in roughly quantitative terms the burden that premature children throw on the hospital services. Table XV gives the actual number of days spent in hospital by premature and control children of different ages.

While it is evident that in the first two years premature children need considerably more care than those born at

TABLE XV.—Number of Days Spent in Hospital at Different Ages (Premature Children and Controls)*

Age	Premature Children	Controls	Difference
1st year { Maternity ..	5,279	4,016	+1,263
{ Other ..	657	169	+488
2nd year ..	612	190	+422
3rd ..	266	296	-30
4th ..	342	299	+43

* Three premature children who spent a great part of their first four years in hospital have been omitted, = 1,520 hospital days (see p. 751).

term, they do not, in fact, make any great call on the hospital services. Related to the whole survey population and not only to their controls, they received approximately 8% of the total maternity hospital care, 11% of all hospital care in the first two years, and 3% in later years.

The above figures do not fully describe the special needs of premature children, for there are a number who, although living at home, are to a varying extent incapacitated and likely to be an enduring burden on their parents and the community. The question of mental defect and epilepsy will be considered in a later paper; we are here concerned only with physical defects. It may well be that some potentially disabling conditions have been missed by the relatively crude methods used in this survey and, if so, we may hope to make a more accurate statement of the disabilities of these children when the results of the school clinical examinations are available. In the meantime it appears that the only serious physical defect that is more common among premature children is impaired vision. While there is no child in this series of births suffering from retrolental fibroplasia—perhaps owing to the rarity in 1946 of oxygen therapy—there are three with congenital cataract, all of whom weighed more than 4½ lb. (2 kg.) at birth. Two of these children are now completely blind and the third has some sight. Among the control children, on the other hand, there is no instance of blindness or grossly defective sight. Gross congenital defects, other than cataract, are equally common among the surviving premature children and their controls. Of the former, two had spina bifida and one transposition of the viscera; of the latter, one had spina bifida, one a congenital heart lesion, and one congenital dislocation of the hip. Less severe congenital defects, such as hare-lip, webbed toes, etc., were also found as often in the one group as in the other. In view of the high mortality from congenital defects among premature children, this similar incidence in the premature and control pairs is unexpected.

Summary

676 live-born premature singletons drawn from one week's births in 1946 in 424 maternity and child welfare authorities have been matched with 676 children born at term during the same week and drawn from similar home environments. This paper describes the health and survival of these children during the first four years of their lives.

Apart from unavoidable losses from death and emigration, only eight pairs have fallen out of the inquiry.

The high mortality of premature children extends beyond the first month of life, and between the ages of 1 month and 4 years is largely accounted for by deaths from congenital defects and lower respiratory infections.

During the first two years premature children show a higher incidence of hospital admissions, many of which are for bronchitis and pneumonia. At later ages they are no more likely to be admitted than are children born at term.

Upper and lower respiratory infections, including those treated at home as well as those treated in hospital, are more common among premature children

during the first two years. This greater susceptibility to infection is found among premature children even when they are reared in an apparently favourable home environment.

In general, premature children—after they have reached the age of 2—appear to be as healthy as those born at term.

We wish to thank the chairman and members of the Joint Committee for their help and advice, especially Professor Aubrey Lewis, Professor I. G. Davies, and Professor R. M. Titmuss; the medical officers of health and the health visitors whose generous co-operation made this survey possible; and the mothers in all parts of the country who willingly answered numerous and detailed questions on their children's health.

REPORT OF TUBERCULIN SURVEY IN THE RHONDDA FACH

BY

T. FRANCIS JARMAN, M.D.

Medical Director, Mass Radiography Service, Welsh
Regional Hospital Board

The tuberculin test has long been recognized not only as a useful measure in clinical diagnosis but as an essential part of epidemiological investigations appertaining to tuberculosis (Ustvedt, 1942). Myers (1946) declares that "as an epidemiological agent, the test excels every other procedure of examination," and he regards repeated testing of special groups as an excellent method of determining the effectiveness of a tuberculosis control programme. Though a more accurate index of the success of such control measures is undoubtedly the number of new cases of tuberculosis occurring in a community subject to intensive and repeated mass x-ray surveys, the tuberculin-testing of large groups does provide evidence on the existing degree of total communal infectivity. It was therefore decided to carry out skin tuberculin-testing of the school population in the Rhondda Fach as an integral part of the research scheme.

This scheme has as one of its main objectives the determination of the total prevalence of pulmonary tuberculosis in a defined community, the isolation and treatment of all known active cases, and the estimation of the rate of occurrence of new cases subsequent to the application of such measures (Cochrane, Cox, and Jarman, 1952).

The schoolchildren in the Rhondda Fach were tuberculin-tested during the months of February, March, and April, 1951, and a sample of the schoolchildren in another valley were tested during September, 1951. When the Rhondda Fach is resurveyed radiographically in 1953 the school population will again be

tuberculin-tested and the results of such retesting will be compared with those of the 1951 survey. A sample of the schoolchildren in the "control" valley, drawn from the same schools as were those in this 1951 survey, will also be retested in 1953, and the results will serve for comparison with those obtained from the Rhondda Fach.

Such retesting will be combined with a follow-up study of children who were tuberculin-negative in 1951, and this will permit a determination of the attack rate of infection in the two valleys.

Method of Testing

In 2,301 cases the usual Mantoux technique was employed: 0.1 ml. of a 1/10,000 dilution of standardized O.T.—that is, 1 T.U.—was injected intradermally, and all negative reactors were retested with 0.1 ml. of a 1/100 dilution—that is, 100 T.U. The criteria adopted for the reading of these tests was that any reaction producing less than 5 mm. diameter of induration was regarded as negative. The reactions were recorded as measurements in millimetres of induration wherever this was possible, even when they were less than 5 mm. and, qualitatively, negative tests.

In 1,109 cases the initial test used was the multiple puncture test, employing standardized, adrenaized O.T. This is a modification of the Finnish Trambusti (1928) test and that described by Chester Stewart (1928). The reason for using this method, and the possible source of error involved, are discussed later.

A preliminary report on the multiple puncture test has been made recently (Heaf, 1951). The test is performed as follows: a drop of undiluted adrenaized O.T. is spread over an area on the forearm about the size of a shilling by means of a sterilized platinum loop; the multiple puncture instrument is then applied and pressed home; any excess of O.T. is wiped away with cotton-wool and the test is read at the end of 48 hours. The criteria adopted for the reading of this test were as follows: 0=no reaction,

TABLE I.—Results of Tuberculin-testing of School Children

Age in Years	No. who Completed Tests	No. Positive to 1/10,000 O.T.	No. Positive to 1/100 O.T.	No. Positive to Multiple Puncture Only	Total Positive	% Positive

or small points of trauma or commencing induration; 1=larger but discrete circles of induration; 2=a ring of induration; 3=a plaque of induration. Reactions up to and including category 1 were regarded as negative and retested with an intradermal injection of 0.1 ml. of 1/100 dilution of O.T. (100 T.U.).

Results.—The results of tuberculin-testing in the Rhondda Fach are summarized in Table 1 (a) and represented graphically in Fig. 1. The tuberculin-testing carried out in

FIG. 1.—Results of tuberculin-testing in the Rhondda Fach, compared with those of a similar valley in South Wales.

another mining valley comparable to that of the Rhondda Fach, but in which no intensive survey technique is being carried out, is summarized in Table 1 (b) and represented graphically in Fig. 1, and the results serve for comparison with those obtained in the Rhondda Fach.

Number Tested and Analysis of Lapses

It was ascertained that 4,743 schoolchildren were on the school register in the Rhondda Fach area. Of these, 4,522 (95.3%) were x-rayed, but only 3,410 (71.9%) completed the tests. This illustrates the difficulties encountered during mass tuberculin surveys. The lapses resulting from absenteeism occurred at all stages of the survey. It should be noted here that most of the tuberculin-testing was done during the winter months, when thick snow lay on the ground.

Many children who were absent for the reading of the second test were visited at home for this purpose. The

TABLE II.—Stages at Which Lapses Occurred During Tuberculin Survey. Number of Children on School Register, 4,743

Reason for Lapsing	No. Not Tested	No. Remaining	%
Absent from school ..	259	4,484	4.9
Test refused	480	4,004	10.5
Absent at reading of first test	287	3,717	6.5
Absent at reading of second test (excluding those positive at the first test)	307	3,410	6.2
Completed tests		3,410	
Total	1,333 (28.1%)	3,410 (71.9%)	(28.1%)

stages at which lapses occurred during the survey are summarized in Table II. The 480 children who were x-rayed but not skin-tested represent parents' refusals.

The ages of the 259 who were absent for the first test were unfortunately not ascertained at the time of the survey, but it can be stated that they are distributed in a relatively equal manner throughout every type of school, and were therefore not confined mainly to one or two age groups.

The ages of the remaining 1,074 who lapsed are known, and the percentages of those available for the initial skin test who completed each stage of the course are represented graphically by age groups in Fig. 2.

FIG. 2.—Percentage of children available for first test who completed each stage of the course.

Reference to this graph shows that most of the lapses occurred in the age group 5 to 6, and it would appear that the refusal of parents to have their children skin-tested is mainly determined by the age of the child. It is interesting that the percentage lapse rate of those available for skin-testing is fairly equally distributed between each stage of the course and between the different age groups. This suggests that the 3,410 children who completed the test do represent a truly random sample.

Comparison between Tuberculin-testing in the Rhondda Fach and the M.R.C. Surveys of England and Wales

Fig. 3 shows the comparison between the prevalence of positive tuberculin reactions among schoolchildren in the Rhondda Fach and those in the M.R.C. surveys in England and Wales (Daniels, 1952). This comparison suggests that if tuberculin surveys do in fact reflect the total amount of human tuberculous infectivity in a community the amount of such infectivity in the Rhondda Fach is rather less than that in the urban areas of Northern England and Wales and rather more than that in the urban area of Southern England. As the total prevalence of cases of active tuberculosis among those over 15 years of age in the Rhondda Fach was found to be 12 per 1,000, out of which 6 per 1,000 were infectious, the conclusion might reasonably be drawn that estimated prevalence figures for active disease in England and Wales based on these findings are likely to be nearer the truth than those based on findings in routine mass radiography surveys (Cochrane, 1952). Such an estimated prevalence rate, based on a population at June 30, 1952, of 34,000,000 persons over 15 years of age, would mean that there are about 400,000 cases of active tuberculosis in England and Wales, of which 200,000 are infectious.

FIG. 3.—Results of tuberculin-testing in the Rhondda Fach compared with those of the M.R.C. surveys in England and Wales.

The Rhondda Fach and the Control Valley

Fig. 1 shows the prevalence of positive reactors among schoolchildren in the Rhondda Fach and in the control valley, and this reveals that there is a somewhat lower rate of conversion at comparable age groups in the control valley. Presumably there is rather less tuberculosis in this valley than in the Rhondda Fach. It will be noted that there is a sharp drop in the percentage of reactors in the Rhondda Fach at age 8. It is possible that this may be due to some error the nature of which has not been ascertained. Several re-checks on the sorting and counting of the appropriate cards were carried out in this connexion. Table I (a) shows, however, that more children were tested in this age group than in any other, while Fig. 2 shows that the percentage of lapses which occurred at this age is about the average of all age groups from 6 to 16 years. The source of error, therefore, if such exists, remains unexplained.

Sources of Error

(1) Observer Error

Error can arise in the performance and reading of the tests. It has been shown (Meyer *et al.*, 1951) that in duplicate Mantoux tests performed on the right and left arms in which the reactions were read independently but by one person there was disparity in the reading of negative and positive tests in 8% of cases. Sources of error here, however, were both in the performance of separate tests and in the reading of them. In the present survey the only error studied was that involved in the qualitative reading of single tests given by one person.

Double-observer readings were carried out in a sample of Mantoux tests in order to ascertain whether two observers would be necessary throughout the whole survey in order to achieve scientific accuracy. A total of 1,228 Mantoux tests were read by two observers (Dr. V. W. J. Hetreed and myself) reading independently and using the agreed criteria of 5 mm. or more of induration to indicate a positive reaction. The two observers were in a large room out of earshot from each other and seated back to back. The examinee approached the first observer, whose reading was recorded by the clerk attending him. This was recorded in red on the record card and the card was then handed back to the examinee, who proceeded to the second observer.

The record card was taken by the clerk attending the second observer in a way which precluded him from inadvertently seeing what was already recorded on it by the first observer. The second observer then made his reading, and this was recorded in blue by the attending clerk. Any examinee whose test was recorded as negative or doubtful by either observer was retested with 0.1 ml. of 1/100 O.T.—that is, 100 T.U. The final tests were also read by the two observers. The results are summarized in Table III.

TABLE III.—Summary of Double-observer Readings

1st Test, 1/10,000 O.T.	No.	2nd Test, 1/100 O.T.			No Second Test
		Neg.-Neg.	Neg.-Pos.	Pos.-Pos.	
Neg.-neg.	990	912	1	77	
Neg.-doubtful	16			16	
Neg.-pos.	9			9	
Doubtful-doubtful	38			38	
Doubtful-pos.	23			23	
Pos.-pos.	152				
Total	1,228	912	1	163	152

Only qualitative differences in reading the tests are shown, though both qualitative and quantitative—that is, differences in millimetres of induration measured—differences were noted.

There are only two categories of double-observer readings: those of “negative-positive” and “doubtful-positive,” which include examinees who may not have been given a second test had there been only one observer. There are nine in the category “negative-positive” and 23 in the category “doubtful-positive.” All of these reacted positively to the second test. Thus had these 32 cases not been retested because a single observer had read them as positive on the first test this would have made no difference to the final figures of positive and negative reactors.

It was concluded from these results that no appreciable error was likely to arise through the qualitative reading of the tuberculin tests by one experienced person. One and the same reader only was therefore employed during the rest of the survey.

(2) Non-specific Reactions

Attention has been drawn (Palmer, Ferebee, and Petersen, 1950) to the possible occurrence of reactions of a non-specific character when using the larger doses of tuberculin. Positive reactors to a low dose of tuberculin among 10,000 white student nurses in the U.S.A., arranged according to lifetime residency in different States, occurred with a frequency which corresponded to known geographic variations in the prevalence of tuberculosis, whereas positive reactors to a higher dose showed a peculiar geographic distribution unrelated to known prevalence. This suggested “a local widespread non-specific sensitivity to tuberculin.”

This possible source of error is fully discussed in the M.R.C. tuberculin survey (Daniels, 1952). The conclusion is drawn that there is no evidence that with a dose of 100 T.U. the proportion of non-specific reactions is so high in this country as to warrant ignoring those positive only to doses greater than 10 T.U.—that is, 0.1 ml. of 1/1,000.

(3) Bovine Infection

Another possible source of error in using the results of a tuberculin survey as an index of total communal infection from human pulmonary sources is the existence in the community of the bovine type of infection. By comparing the percentage of positive reactors among children in an area in which tuberculosis in cattle was non-existent with that among children of similar age groups in an area where infection in cattle was frequent, it has been shown (Madsen, Holm, and Jensen, 1942) that infection with bovine bacilli may influence the results of tuberculin-testing surveys. That this may be a factor influencing the results is also borne out by the differences in percentages of positive reactors among children of school entry age from rural and urban areas in England and Wales (Daniels, 1952).

So far as the Rhondda Fach is concerned the proportion of notified cases of tuberculosis which are designated as non-pulmonary may give some indication of the prevalence of bovine tuberculous infection.

Table IV shows the number of respiratory and non-respiratory cases of tuberculosis notified during the years 1949, 1950, and 1951 in the Rhondda Fach area. The sharp

TABLE IV.—Notified Cases of Respiratory and Non-respiratory Tuberculosis in the Rhondda Fach

Year	Respiratory Tuberculosis	Non-respiratory Tuberculosis	Meningitis
1949	59	6	—
1950	87	9	2
1951	66	5	2
Total	212	20	4

increase in the notifications for 1950 reflects the discovery of an abnormally large number of early cases of pulmonary tuberculosis through the intensive mass radiographic survey carried out in connexion with the research scheme.

In the four cases of meningitis human-type bacilli were recovered from the cerebrospinal fluid. In 9 out of the 20 cases of non-respiratory tuberculosis, tissue fluid was available for examination; in five of these, cultures were positive for tubercle bacilli and all were of human type (J. Glyn Cox, 1952, personal communication).

Information supplied by the Central Tuberculosis Laboratory of the Welsh Regional Hospital Board (J. Marks, 1952, personal communication), shows (Table V) that since 1943

TABLE V.—Isolations of Human and Bovine Type of Tubercle Bacilli from Tuberculous Patients in Wales

Year	Total Positive Cultures	Human Type	Bovine Type
1943	554	499	55
1944	511	463	48
1945	484	453	31
1946	442	416	26
1947	536	519	17
1948	569	541	28
1949	1,041*	1,026	15
1950	1,539*	1,534	5

* The increase in positive cultures reflects wider use of the laboratory.

there has been a steady decrease in the number of isolations of the bovine type of bacillus, suggesting that infection with this type has been responsible for only a small and steadily decreasing proportion of the total number of cases of tuberculosis.

This laboratory receives specimens from all over Wales, though about three-quarters of them come from the South Wales area, which includes the more densely populated counties of Monmouth and Glamorgan.

In Glan Ely Hospital, Fairwater, there are 110 beds for non-pulmonary tuberculosis, and most of such cases occurring in the South Wales area, including the Rhondda Fach, are admitted to this hospital. Information was made available by the medical superintendent (V. Emrys Jones, 1952, personal communication) to the effect that during the past five years not one of the large number of cases yielding positive cultures was due to a bovine infection.

The likelihood of bovine infection affecting the percentage of positive reactors in different age groups amongst the schoolchildren of the Rhondda Fach can also be related to the sources of milk supply to the school and homes. From information supplied by the Rhondda Urban District Council Health Department (D. J. Thomas, 1952, personal communication) it has been ascertained that licensed retail distributors of milk in the Rhondda Fach area obtain their supplies from four main wholesale sources. All of the milk so supplied is sterilized, pasteurized, or from tuberculin-tested herds. Of the 25 distributors, 23 supply milk which is from tuberculin-tested herds and pasteurized as well, and

the remaining two supply milk which is pasteurized or sterilized. These conditions of milk supply have been in existence in the Rhondda Fach for at least ten years, with the exception of three small farms which supplied raw milk in small localized areas until five years ago. One distributor, however, who possesses a small farm, produces about 8 gallons (36.4 litres) of milk a day, and this he retails intermittently in a very small locality. The sale of 8 gallons (36.4 litres) of untreated milk represents about 0.8% of the total milk sold daily in the entire valley. The bulk of the milk has for decades been imported into the district and, on account of the method of milk marketing during the past 20 years, heat treatment has been a commercial necessity.

It is therefore reasonable to conclude that bovine infection is unlikely to contribute to the number of positive reactors amongst the Rhondda Fach schoolchildren to an extent which would invalidate tuberculin surveys as an index of human tuberculous infectivity in that community.

A contrast is provided by the survey carried out in the Calder Valley in the county of Yorkshire (Keidan *et al.*, 1952). Out of a total school population of 6,532 in the Calder Valley 85% completed the skin-testing programme. A high prevalence of positive tuberculin reactors was found amongst the schoolchildren in this rural area when compared with those from Hull and Leeds. The reactor rates from Hull and Leeds closely approximate to those from the Rhondda Fach and to those from the urban areas of England and Wales, whereas the rates from the Calder Valley are much higher at every age group and exceed also the rates for rural England and Wales (Fig. 4). Table VI

FIG. 4.—Results of tuberculin-testing in the Rhondda Fach compared with those of the Calder Valley and Leeds.

TABLE VI.—Tuberculosis Morbidity in the Calder Valley and in the Rhondda Fach

	Total Cases Notified, All Types, per 100,000	Non-respiratory Cases Notified per 100,000	Percentage of Cases Non-respiratory
Calder Valley, 1948	460	215	46.7
Rhondda Fach, 1949	244	24	9.8

shows that the greater total morbidity from tuberculosis in the Calder Valley compared with that in the Rhondda Fach is almost entirely accounted for by the much higher proportion of non-respiratory cases notified in the former valley. These figures suggest, moreover, that the higher incidence of positive reactors found in the Calder Valley might be attributed to an excessive amount of bovine infection, a supposition which is supported by other direct evidence. The conditions appertaining to the supply of milk in the Calder Valley are in marked contrast to those in the Rhondda Fach, Hull, and Leeds. As much as 80% of all milk consumed in the Calder Valley is untreated, and about 40% of the cows in the area are positive tuberculin reactors. These findings therefore amount to strong circumstantial evidence that the difference in prevalence of positive tuberculin reactors in the Calder Valley and in the Rhondda Fach is related to a high incidence of bovine infection in the former and a low incidence in the latter.

(4) The Negative Reaction

Attention has been drawn (Rich, 1951) to the fact that a negative tuberculin test is not necessarily proof that a person has not been infected. He quotes many workers who have demonstrated the phenomenon of "reversion" from a positive to a negative test and have shown that such reversion can occur in as short a time as two years. He suggests that, in the past, available evidence tended to support the view that only in exceptional cases will the test be negative in healthy persons who have been previously infected, but that in the face of greatly changed conditions "it becomes possible that the results of the tuberculin test in present-day surveys no longer mirror so well the actual incidence of infection." The average duration of tuberculin sensitivity following a slight well-resisted infection is not known.

It is believed that reversion tends to occur only where the incidence of active disease, and therefore the chance of reinfection or superinfection, is very low. It may therefore influence the figures in schoolchildren living in rural and semi-rural areas with a milk supply free from infection, but it is less likely to affect those resulting from a survey in an urban area such as the Rhondda Fach.

(5) Use of the Multiple-puncture Test

It was recognized during the early stages of the survey that a number of children were "lost" on account of absenteeism during the routine of first testing, reading, retesting, and again reading. Needle-puncture methods of tuberculin-testing have been described (Trambusti, 1928; Stewart, 1928) which presumably possess a number of advantages over Mantoux testing in mass surveys, chief of which are that it is a single procedure and that only 1% of complicated reactions occur, in contrast to 10% produced by Mantoux testing with 1/1,000 O.T. (Edwards and Savonen, 1951).

In order to ascertain whether a needle-puncture technique similar to the Trambusti test but employing multiple punctures and using undiluted adrenaized O.T. might prove to be a satisfactory single test, it was used in 1,109 cases as the initial test. The method and criteria adopted have already been described.

To ascertain whether the results in these cases could be included in the total figures, a comparability study between the multiple-puncture test and the accepted intradermal routine was undertaken in 692 cases.

Method of Comparability Study.—A multiple-puncture test was performed on the right arm and at the same time an intradermal test with 0.1 ml. of 1/10,000 O.T. was performed on the left arm. The tests were read 48 hours later in groups of 20 in the following way. The right arm of each examinee was exposed, the left arm being placed behind the back. The observer read the multiple-puncture test, keeping his attention deliberately and strictly only on the arm of the examinee. Whilst the observer left the room

the whole group was "shuffled." The right arm was now placed behind the back and the result of the intradermal test on the left arm was then read. Cases in which either test was read as negative were retested with 1/100 O.T.

Results of the Comparability Study.—It will be noted from Table VII that one false positive occurs in Category 2 multiple-puncture reactions and none in Category 3. Thus in 102 cases that would have been read as positive if multiple puncture alone had been used as the initial test, one would have been in error. Reference to Table I (a) shows that 231 cases were read as positive to the initial multiple-puncture test and were not retested. Two of these may have been "false positives"—an error which does not affect the validity of the total results.

It should be noted (Table VII) that, had the multiple-puncture test been used as a single test only, the Category 2 reaction would have been too high for reading a positive

TABLE VII.—Comparison Between Results of Multiple Puncture and Intradermal Tuberculin Testing in School Children

Reactions to Multiple-puncture Test			Reactions to Mantoux Tests

test, since out of 29 reactions designated as Category 1 as many as 21 were positive to Mantoux testing. If, however, Category 1 reactions had been accepted as positive then 8 out of the 29 would have been in error. This is preliminary work with this test, and further investigations on the reading of the lowest category of reaction that can be regarded as positive is necessary before the multiple-puncture test can be used as a satisfactory single test in survey work requiring scientific accuracy.

Criteria for Reading a Positive Reaction

Although qualitative results only are shown in Table I, any measurable induration was recorded. The results on retesting cases which were read as qualitatively negative but in which some measurable induration was present are shown in Table VIII. Since only 12 out of 124 of such

TABLE VIII.—Results of Retesting with 1/100 Intradermal O.T. a Sample of Cases Designated after the First Test as "Negative," but Showing Some Measurable Induration

Reaction to 1st Test with 1/10,000 O.T.	Reaction to 2nd Test with 1/100 O.T. Induration Measured in mm.					
	0-5 mm.	5-10 mm.	10-20 mm.	20-30 mm.	30-40 mm.	40+ mm.
Negative "with measurement" .. 51	12		6	23	7	3
Doubtful "with measurement" .. 73			8	41	21	3
Total .. 124	12		14	64	28	6

cases proved negative on second testing with 1/100 O.T. and the measured induration of those reacting positively was high, the results suggest that the criterion of 5 mm. of induration for a positive test with 0.01 mg. of O.T. is probably too high.

Summary and Conclusions

Of the children on the school registers in the Rhondda Fach area, 71.9% were tuberculin-tested. The stages at which lapses occurred are presented and three-quarters of the total lapses are analysed by age groups.

Evidence is presented which suggests that the sample is adequate for the results to be considered as an accurate reflection of the total tuberculous infection in the community.

The trend of conversion rates at different age groups in the Rhondda Fach and in another valley are presented. These form a satisfactory basis for later comparison applicable to the studies which are to be continued in the future to ascertain the effect of the control of tuberculous infectivity in the Rhondda Fach.

Possible sources of error have been considered, including that of error in the qualitative reading of tuberculin tests by experienced observers, and none of these are regarded as invalidating the results and purpose of the survey.

A comparability study was carried out in 692 cases between the multiple-puncture method of tuberculin-testing and the normal intradermal method. The inclusion of figures obtained by the use of the multiple-puncture method of testing does not invalidate the results or conclusions drawn from the study. As yet the multiple-puncture test cannot be regarded as a satisfactory single test for survey work requiring scientific accuracy.

Evidence is presented that the criterion of 5 mm. of induration for the reading of a positive test with 0.01 mg. of O.T. is probably too high.

I am grateful to Dr. V. W. J. Hetreed for his ready co-operation in the work on double-observer reading of the tests and to Mr. John H. Phillips, Administrative Officer of the Mass Radiography Service in Wales, for the organization of the survey and in the preparation of the statistical tables. I am indebted to the Medical Research Council, London, for the material and equipment used in this study and to the Cardiff Public Health Laboratory for its preparation and sterilization; to Professor F. Heaf, of the Department of Tuberculosis in the Welsh National School of Medicine, to Dr. Norman Tattersall, late Regional Tuberculosis Physician, Welsh Regional Hospital Board, to Mr. Peter Oldham and Dr. A. L. Cochrane, of the Pneumoconiosis Research Unit, and to Dr. J. B. Atkins, H.M. Inspector of Mines, for generous and helpful criticism.

Dr. Max J. Miller, of the Institute of Parasitology, McGill University, has recently been appointed Research Director of the Liberian Institute of the American Foundation for Tropical Medicine. The Foundation was incorporated in 1934, and is associated with the American Society of Tropical Medicine and the American Academy of Tropical Medicine. The Foundation supports the teaching of tropical medicine in medical schools and promotes research into tropical disorders. The Liberian Institute was established in 1946 to carry on comprehensive research on the origins, treatment, and control of tropical diseases. The Institute's immediate objective is to provide an international laboratory centre where medical, governmental, educational, and industrial scientists of all nationalities can unite in a common attack on diseases of man and domestic animals, and on the production of balanced food crops for both man and animals.

CHLORAMPHENICOL TREATMENT OF THE NEWBORN

BY

R. M. CALMAN, M.B.
Bacteriologist

AND

JOHN MURRAY, M.D.
Director of Pathology

(Bernhard Baron Memorial Research Laboratories, Queen Charlotte's Maternity Hospital, London)

The synthesis and large-scale production of chloramphenicol has made available everywhere a valuable antibiotic, effective against a wide range of pathogenic organisms, including strains resistant to penicillin. As the drug can be taken by mouth, vast numbers of patients, old and young, have been treated somewhat empirically, and it is not surprising that some of the hundreds of papers describing successful therapy disclose serious toxic effects. Most of the reports of fatal aplasia of bone marrow are associated with relatively large doses, or prolonged or repeated treatment with the drug (Hawkins and Lederer, 1952; Sturgeon, 1952; Smiley *et al.*, 1952; Claudon and Holbrook, 1952; Wolman, 1952).

It has therefore become necessary that the clinician should know exactly what serum concentration to expect from a recommended dose. In the case of adults this was provided by Ley *et al.* (1948) and by Hewitt and Williams (1950). For children, Kelly *et al.* (1951) have reported blood-serum levels, and shown how long they persist. As their series contained only one baby less than 6 kg. in weight, an investigation was undertaken in order to establish serum levels obtained in babies during the first fortnight of life.

A group of babies suffering from staphylococcal infections was therefore selected for trial with chloramphenicol therapy.

Present Investigation

Methods.—Blood was obtained in sterile Wright's capillaries from heel puncture. With this method quite small quantities of blood yielded enough serum for assay.

Assay.—Numerous different organisms have been used for the biological assay of chloramphenicol levels in blood serum. The organism most commonly recommended is *Sh. sonnei*. We have tested various other bacteria and found that, using the capillary technique of Fleming (1944), one of our strains of Group A beta-haemolytic streptococci (9570) was conveniently inhibited by exactly 1 µg. of chloramphenicol per ml. The use of this strain clearly simplified the estimation of chloramphenicol levels when a result in µg. per ml. of serum was required.

Test.—The results were read after incubation at 37° C. overnight, the end-point being the tube in which the test organism just failed to grow. This was confirmed by Gram-staining where there was any doubt.

Dosage of Drug.—In order to ensure that all of the intended dose was taken by the babies, chloramphenicol was dispensed as a powder, each powder being made up separately in a waxed paper packet, according to the infant's weight. The powder was given by teaspoon, together with a small amount of syrup. By the dosage scheme, only a limited series of weighed powders need be held by the dispensary to meet the requirements of babies of different sizes, and powders of appropriate amount were available at all times of the day and night. As will be seen from the Table, even at the extremes of each weight range the

deviation from the intended dose is very slight. This dosage was calculated on the basis of 100 mg. per lb. (220 mg. per kg.) per day in three separate doses.

As babies do not appear to taste chloramphenicol it was not thought necessary to use the palmitate derivative, the absorption of which might be less certain in the newborn.

Chloramphenicol Dosage According to Weight

Weight of Baby	Individual Dose
1½ lb. (0.68 kg.) and below	50 mg.
2-3 lb. (0.91-1.36 kg.) inclusive	100 "
3½-4½ lb. (1.59-2.04 kg.) "	150 "
5-6 lb. (2.27-2.72 kg.) "	200 "
6½-7½ lb. (2.95-3.40 kg.) "	250 "
8-9 lb. (3.63-4.08 kg.) "	300 "

Where the weight lay between the points on the range, it was taken to the nearest ½ lb., and doubtful ones were placed in the higher group; thus a 7 lb. 10 oz. (3.46 kg.) baby received 250 mg., and a 7 lb. 12 oz. (3.51 kg.) baby received 300 mg. The chloramphenicol was dispensed as a powder.

Results

A preliminary series of tests was made in 17 babies (weight 6 to 9½ lb., 2.7 to 4.3 kg.) to determine the effect of a constant dose of chloramphenicol (100 mg. thrice daily) irrespective of weight. This method was tried, as

CHART: Serum chloramphenicol levels in 24 newborn babies.

Murray and Crawford (1951) had found that with oral penicillin in the newborn a constant dose of 100,000 units gave excellent serum levels for more than six hours. The results with a constant dose of chloramphenicol gave very inconsistent serum levels, and this method was abandoned in favour of dosage by weight.

The serum level of chloramphenicol was traced over a period of 24 hours in 30 babies who received a single dose according to the scheme shown in the Table. In order to exclude the possible presence of inhibitory substances in the serum, in the first half of the cases a control test was made before administration of the drug. In none of these was any inhibitory level found.

In 24 babies chloramphenicol was detected in the serum, whereas in six no serum level was found. In one of these six cases the baby vomited within 30 minutes of receiving the drug, but in the remaining five the causes of the failure to detect a serum level were never elucidated, and in the absence of vomiting must remain open to conjecture, since there is no evidence of failure to absorb the drug. In fact, in one of the five cases the baby received a repeat dose the following day, and levels of 3 µg. were found at one hour, and 6 µg. at seven and a quarter hours after the dose.

It is interesting to note that in Case 30 vomiting occurred one and a quarter hours after the drug was given, and a good serum level was still present at 18 and 24 hours.

The results of these estimations are shown as points in the Chart, and the limits within which they fall appear as a stippled area, which it can be seen forms a smooth curve.

On account of the times at which samples were collected, a calculated mean curve is not presented: it is felt that the band showing the general limits of chloramphenicol levels presents a more useful indication of the results that can be expected from treatment with this drug. Individual cases were followed through, and conformed to the general shape of the curve.

Of the results on the 24 babies shown in the Chart, the first 12 were tested two or three times during the first eight hours in order to establish how rapidly the serum level rose. The remaining cases were used to determine how well the serum level was maintained during the latter part of a 24-hour period. In this group, samples were taken three times—the first at one hour, and the others between 12 and 24 hours after the dose. In only one case in which the chloramphenicol was shown to have been absorbed did the level fall below 4 µg. per ml. serum in under 14 hours.

Discussion

The effect of an antibiotic upon an organism in the body compared with its effect in the test-tube is always a matter of experience and prolonged trial. As this investigation was designed to show the effect of a single dose, no attempt was made to correlate the serum levels with clinical results. However, treatment has proved uniformly satisfactory in cases subsequently treated according to this dosage scheme. The results, however, do show that it is possible to achieve a concentration of chloramphenicol in the serum four to eight times that which is effective in the test-tube. The

Chart shows that in the present series such a level was maintained in almost all cases for more than 12 hours. It would appear, therefore, that for the newborn it should be necessary to give chloramphenicol only in the doses here suggested, twice daily. With any drug given by mouth there is always some risk that it will not be absorbed; this is especially true of babies, for extra care must be taken to ensure that regurgitation does not occur. For this reason it is desirable to keep the babies under strict supervision.

Although the dosage scheme was calculated on the basis of 100 mg. per lb. (220 mg. per kg.) per day, given in three separate doses, the levels achieved have shown that it is unnecessary for the drug to be given so often, since the serum level is maintained so well. We have therefore employed doses of 33 to 50 mg. per lb. (73 to 110 mg. per kg.) per single dose. An odd feature of this investigation is that the levels obtained were nowhere near so high as those found in older children by Kelly *et al.* (1951) using almost half the dose. It is possible that this discrepancy may be accounted for by the difference in method of assay. That used by Kelly *et al.* was a modification of the Osgood turbidimetric method, whereas ours was a biological assay using a standard β -haemolytic streptococcus as a test organism. Whatever the absolute accuracy and relative merits of the two methods may be, the one used in this series has shown that the levels obtained in the serum were very much greater than those necessary to inhibit chloramphenicol-sensitive pathogens in the test-tube, and all the evidence goes to indicate that this drug is at least as active in the body as *in vitro*.

Our dosage, while rather greater than that recommended by the manufacturers, is very similar to that successfully used by Smellie (1950) in the treatment of infantile gastric enteritis. We feel, therefore, that a dosage of between 33 and 50 mg. per lb. (73 and 110 mg. per kg.), given twice in 24 hours, should be adequate in the treatment of suitable infections in the newborn.

Summary

A haemolytic streptococcus sensitive to 1 µg. of chloramphenicol per ml. was used to assay blood-serum concentrations in 47 newborn babies.

Dosage irrespective of weight proved unsatisfactory in 17 cases.

A scheme of dosage based on body weight was applied to 30 babies, 24 of whom showed satisfactory blood levels for at least 12 hours and detectable levels for 24 hours.

No chloramphenicol was detected in the blood serum in six babies, one of whom had vomited half an hour after its dose. No cause for the remaining five negative results was found. Failure of absorption was discounted, as one of these cases showed a reasonable serum level in a repeat test the following day.

We recommend a dosage as set out in the Table: this represents 33-50 mg. per lb. (73-110 mg. per kg.) per dose, given twice daily.

We would like to thank the paediatricians, paediatric registrars, and nursing staff for their co-operation in this investigation. We are also grateful to Messrs. Parke Davis for generous supplies of chloramphenicol.

SUMMER HAY-FEVER AND ASTHMA TREATED WITH ANTIHISTAMINIC DRUGS

BY

A. W. FRANKLAND, M.A., B.M., B.Ch.

AND

R. H. GORRILL, M.D.

The Wright-Fleming Institute of Microbiology,
St. Mary's Hospital Medical School, London, W.2

In the early summer of 1948 a trial of a new antihistaminic drug was carried out in the hay-fever clinic. It has since been named chlorcyclizine hydrochloride ("histantrin"). Each tablet contains 25 mg. of N-methyl-N-(4-chlorobenzhydryl) piperazine dihydrochloride. After this trial it was suggested (Frankland, 1949) that, although antihistamines could help the mild case of hay-fever, they might precipitate the onset of asthma in the more severe cases. This was commented on in the review of hay-fever literature for 1949 (Kaplan and Ehrlich, 1951). It was, however, pointed out that a statistical survey of hay-fever patients treated with antihistamines must be carried out before it could be taken as proved that asthma was more apt to occur in such patients. It is interesting that in another trial (Gay *et al.*, 1948) the high incidence of asthma in hay-fever patients treated with antihistamines had been noted, but not commented upon. There is now fairly widespread belief that hay-fever patients who receive antihistaminic drugs as the only form of therapy are more liable to develop asthma than those who receive no treatment (*British Medical Journal*, 1952).

An experiment was designed to test not only the efficacy in hay-fever and hay-asthma of an untried antihistaminic drug, but also whether there was any statistical difference in the incidence of asthma in treated and untreated hay-fever patients. In the first enthusiasm

that greeted the preparation of many new antihistaminic drugs, the published reports suggested that antihistamines do benefit many cases of asthma. Southwell (1948) commented on the non-critical assessments in many of the published papers from France and America. He concluded as a result of a trial of mepyramine maleate ("anthisan," pyranisamine maleate, or "neo-antergan") in the treatment of asthma that it "conferred no apparent benefit upon 25 specially selected and carefully observed asthmatic patients." Hunter and Dunlop (1948) also concluded that mepyramine maleate was of no value in the prevention of asthma. Frankland (1952) and Watkins (1952) agree with these views.

Scheme of Trial and Methods of Assessment

The patients were treated with three different kinds of tablets: (1) mepyramine maleate, which has had extensive trials and clinical use; (2) a new antihistaminic preparation which has as yet no name and will be referred to as 405-c-49 (chemically it is 3-pyrrolidino-1-(4'-chlorophenyl)-1-(2'-pyridyl) prop-1-ene maleate); and (3) inert tablets. It was considered essential that the box of tablets given by the doctor to the patient should be numbered and not named. The consecutive-numbered boxes were given to the patients in the order they reported. Previously the three kinds of tablets had been allocated to the numbered boxes by use of a random-number table. Twin girls who both received the same tablets were the only exception to this random distribution. Anthisan (mepyramine maleate) is normally coloured green, but for the purposes of the trial Messrs. May & Baker kindly supplied white tablets. The inert tablets, which contained 5 gr. (0.32 g.) of lactose, looked similar to but differed in taste from the antihistamine under trial. Each tablet of 405-c-49 contained 10 mg. of the antihistaminic drug, which was thought to correspond clinically to a dose of the 100-mg. tablet of mepyramine maleate. The doctor did not know which type of tablet he gave to the patient (except for the few patients who asked for a change of tablet). It was not until all the results of treatment had been tabulated that the kind of preparation used was entered on the card. Each patient was given a chart and asked to keep a daily record, from the time the symptoms of hay-fever began, of the number of tablets taken each day, and whether the results were good, moderate, or poor so far as the hay-fever was concerned. The letters G, M, and P were used to designate the daily result of taking the tablets.

The patients were told that they were taking part in a trial of a new drug for hay-fever, and that it was believed that the side-effects, if any, would probably not be annoying, but that the dose was not known. It was suggested that up to four tablets a day was probably the correct dose for relief of symptoms, but more or fewer tablets might be necessary. As a third of all patients were to receive inert tablets when first seen, all of them were told that if they thought the tablets given to them were not effective they could either come back for a stronger tablet or use any other preparation that was considered from previous years' treatment to be more effective.

Normally a patient used the same tablet throughout the hay-fever season, though a few patients who were seen more frequently were given the chance of a change of tablet if they so desired. If a patient did ask for a change of tablet, in each case the new antihistaminic tablet 405-c-49 was given. This allowed a direct comparison with either the inert or the mepyramine maleate tablets. In practice only a few patients came back for what was euphemistically called the stronger tablet.

When the patients were first seen at the beginning of the trial they were accepted as suitable for it so long as their complaint was one of seasonal hay-fever. Before the dis-

nosis could be made, symptoms of irritation of the eyes with rhinorrhoea and sneezing during the month of June had to be present. In many the symptoms lasted longer than one month. In many cases the symptoms began in May and continued until the beginning of August or longer. Interestingly, the daily charts often indicated a season much shorter than had been given at the first interview. Many of the women and nearly all the children were very vague about the week and sometimes even the month of the onset and disappearance of symptoms. Every patient was also carefully questioned at the beginning and at the end of the trial regarding symptoms of asthma. If there was any suggestion of a non-seasonal allergic rhinitis or asthma the patient was excluded from the trial.

During the last week in August and the first week in September the patients were reviewed. They brought back their completed daily charts and any unused tablets. For reasons unconnected with this experiment they had their skin reactions retested. For various reasons, but generally because of distance from London, some of the patients undergoing the trial did not return for the final interview. Each one of these was written to and requested to return the daily chart and answer a questionnaire. The following information was obtained from all patients. They were asked whether the overall results of the treatment were good, moderate, or poor; whether they had noticed any side-effects from the tablets, and, if so, what these were; and whether they preferred the new tablets to any previous antihistamine used.

The daily record of the chart indicated the number of tablets taken and whether they produced good, moderate, or poor relief. If the total number of "good" days exceeded the total number of "moderate" and "poor" together the result was called "good." So, too, if the total number of "poor" days exceeded the "moderate" and "good" days the result was called "poor." Moderate relief as shown from the chart nearly always corresponded to the patient's overall impression of the treatment. The heading includes most of those who obtained good results at the start of the hay-fever season but at the height of the pollen cloud found that the tablets were not effective. When the side-effects from the tablets were such that normal everyday occupations could not be continued the results were designated "poor." In five cases the results according to the chart and to the patient's statement did not correspond. The patient, who in each case was a child, stated that the tablets had not helped, while the chart showed good results. The child's impressions were accepted rather than the wishful thinking of the mother that had caused her to fill in a faulty card. Even so, as is described later, some of the patients did obtain good results from the inert tablets.

The diagnosis of asthma in all the patients was based on subjective observations. Grading of asthma according to severity of symptoms was not carried out.

The clinical diagnosis of summer hay-fever was confirmed in every case by means of skin tests. The method used was to prick through a small amount of testing fluid with a sharp needle so that momentary pain was felt but no blood was produced. It has been shown that under standard conditions about 0.000003 ml. is introduced into the skin (Squire, 1950). For the diagnosis of a grass-pollen sensitivity a mixed pollen extract ("pollacine") of a strength of 20,000 Noon units was used.

Results

In all, 174 patients took part in the trial, and the preliminary analysis shows that the three groups are comparable regarding sex ratio, age, age of onset of hay-fever, and follow-up (Table I). The results of the use of the three different tablets in the treatment of hay-fever, together with the results of those who changed their tablets, are given in Table II. Few patients elected to change their type of

tablet during the trial: the figures show that no patient on 405-c-49 tablets changed, three patients on mepyramine maleate changed and were given 405-c-49, and four patients on control changed and were given 405-c-49 tablets. The results following change of tablet are interesting, but owing to the numbers being so small no statistical analysis can be made.

In each group records were made of the incidence of asthma and the history of previous antihistaminic treatment for hay-fever. The results are shown in Table III. All patients who had had asthma in previous summers developed asthma again in the summer of 1951 except one patient who previously had had a summer hay-fever and associated asthma but had noticed no asthma for the last five years. As will be seen, the results show no evidence for a correlation between drug-taking and asthma. The same number of patients developed asthma for the first time in the summer of 1951 whether they took antihistaminic or control tablets.

TABLE I.—Composition of Three Groups of Cases

		Mepyramine Maleate (55)	405-c-49 (59)	Control (60)

Also when the past history of the asthma cases is compared with the unaffected cases it will be seen that there is no difference in the incidence of asthma whether antihistaminic drugs had or had not been taken previously.

In view of these findings the importance of duration of hay-fever on the onset of asthma was examined. The results are set out in Table IV. It will be seen that in all three groups of patients asthma is more likely to occur with long durations of hay-fever. The figures have accordingly been pooled and analysed, and the results are just significantly different.

The value of treatment of hay-fever by antihistamines might depend upon the presence or absence of hay-asthma. With this in mind the figures in Table V were obtained, and, as each group shows the same trends, two groups of pooled data are also shown. The statistical analysis shows that the results are significantly better in non-asthma cases than in asthma cases. This observation is emphasized by including the control group, which makes the significance much bigger. The explanation is that inert tablets had very little effect in cases with hay-asthma but seemed to have some effect in mild cases not complicated by asthma.

The figures collected in this trial of the incidence of asthma in the three treatment groups allows an investigation into the number affected with asthma and the number with relief of symptoms. There seems to be no difference in results between the two potent antihistamines and lactose in the treatment of hay-asthma (Table VI).

The side-effects from taking the three different kinds of tablets are shown in Table VII. In 10 patients mepyramine maleate caused such a marked soporific effect that hay-fever was preferred. Other patients with less severe side-effects reported that these lessened after the first few days. If the patient complained of any other effect which was believed to be due to the tablets and not to the hay-fever, this was recorded. Some of the patients who developed asthma for the first time when taking tablets not unnaturally blamed the treatment. Two of the patients who attributed

Control	15	27	1	4	10	57

their asthma to the treatment were on control tablets, one was on mepyramine maleate, and two were on the new antihistamine.

Table VIII shows the preference of patients for various kinds of tablets. Ten of the patients preferred control tablets to all other tablets tried because they produced no side-effects. Even so, the control tablets gave such poor results that 27 patients preferred any other tablets. There is little to choose between the preferences of the groups on the two antihistaminic drugs, though Table VII would indicate that because of fewer side-effects the new preparation is preferable.

Conclusions

The purpose of the trial in 1951 was twofold: (1) to carry out a clinical trial of a new antihistaminic drug in cases of hay-fever; and (2) to see whether the incidence of asthma in seasonal cases of hay-fever was altered when symptomatic treatment with antihistaminic drugs was used. This paper is concerned mainly with the latter problem.

The new antihistaminic drug 405-c-49 compared favourably with mepyramine maleate, though weight for weight it was ten times more potent.

The number of patients who had asthma with their seasonal hay-fever for the first time in their life was the same or similar in the three groups, as was the number who never had asthma but who had had previous antihistaminic drugs. In Table III it will be seen that the overall incidence of asthma for the whole group was 42.86%, which compares with a figure of 55% given by Williams (1950) for South Wales. Table VII shows that in each group a few patients thought that their asthmatic symptoms were due to the tablets.

The prognosis in hay-fever is difficult to gauge except to say that Table IV indicates that the longer hay-fever is present the more likely is it that the patient will develop asthma with it. The presence of asthma makes it less likely that antihistamines will help the hay-fever, as shown in Table V, though if specific hyposensitization is given, and this helps the pollen asthma, any remaining hay-fever is helped by antihistamines (Frankland, unpublished work). Finally, it will be seen (Table VI) that, contrary to the observations of the earlier literature on the subject, there is no evidence in a carefully controlled selected group of seasonal (pollen) asthmatic patients that the antihistaminic drugs are of any benefit to the asthma when used as the only form of treatment.

Summary

A clinical trial has been made with antihistaminic drugs in the treatment of seasonal cases of hay-fever and asthma.

Suitable antihistaminic drugs help many of the mild cases of seasonal hay-fever. These drugs do not increase the incidence of asthma, nor do they help the symptom of asthma when it occurs.

PYLEPHLEBITIS AND SEPTICAEMIA TREATED WITH AUREOMYCIN

BY

F. GRAHAM MARSON, M.D., M.R.C.P.

Senior Medical Registrar

AND

M. J. MEYNELL, M.D., M.R.C.P.

Clinical Pathologist

with a Note on the Surgical Findings by

F. WELSH, F.R.C.S.

The General Hospital, Birmingham

Recovery from systemic infection with organisms of the *Bacteroides* group is worth recording in view of the high mortality. In well-established infections the case mortality is over 50% (Topley and Wilson, 1946). Brown *et al.* (1941) reported the recovery of one of fifteen patients with septicaemia due to bacteroides. Comparably poor results were recorded by Thompson and Beaver (1932), Reid *et al.* (1945), Ruys (1947), and McVay *et al.* (1949). The last-named, in their report of six cases, had four deaths despite chemotherapy. The last two cases recovered after large dosage of aureomycin and supportive treatment.

A case of pylephlebitis with septicaemia, from which both *Bacteroides fragilis* and *Streptococcus haemolyticus* were isolated, was recently admitted to this hospital. The patient was originally treated with penicillin, chloramphenicol, and streptomycin with no apparent benefit. The regimen of McVay *et al.* was adopted, with final recovery of the patient.

Topley and Wilson include the bacteroides in the genus *Fusiformis*. They define the latter as follows: "Obligate parasites. Anaerobic or microaerophilic. Cells frequently elongated and fusiform, staining somewhat unevenly. Filaments sometimes formed; non-branching; sometimes highly pleomorphic. Non-motile. No spores. Reaction to Gram variable, but mainly Gram-negative. Growth in laboratory media feeble." They term infections with the genus *Fusiformis* as necrobacillosis.

Bergey (1948) separated the bacteroides from the fusiform bacilli and defined them as motile or non-motile Gram-negative bacilli which are obligate anaerobes.

Beigelman and Rantz (1949) emphasize the ubiquitous character of the group. They state that these organisms have been isolated from gangrenous lesions of practically all the organs of the human body as well as from

normal mucous membranes. They are commonly present in the mouth, tonsils, large bowel, and female genital tract. The general opinion is that they are of low virulence in man and act as secondary invaders. Blood-stream infection is probably not uncommon, but spontaneously terminates as soon as the primary focus is treated. Rarely, a septicaemia arises which ends fatally. It is stated by Reid *et al.* that pylephlebitis of the regional veins draining the primary focus is a common occurrence; arthritis, jaundice, and pulmonary emboli are frequent accompaniments.

Case Report

A man aged 32 was admitted with an illness of one month's duration. Whilst at work he was seized with severe upper abdominal pain, which later radiated to the right iliac fossa. This continued for four days and was accompanied by some diarrhoea. On the fifth day the pain began to abate, but he suffered a rigor. For the three weeks before admission he had two or three rigors a day.

On examination he appeared extremely ill, and was pale, thin, and sallow. His pulse was 120; temperature 102.8° F. (39.3° C.). No abnormality of the cardio-respiratory system was detected apart from a haemic murmur. The upper abdomen was tender; no mass was palpable. The liver and spleen were not palpable. A rectal examination was negative.

The blood count showed: haemoglobin, 54%; red cells, 3,060,000 per c.mm.; white cells, 19,800 per c.mm., 82% being polymorphonuclears. There were many target red cells in the stained films. The other laboratory examinations were negative, apart from a serum alkaline phosphatase of 35 units, and the Van den Bergh was immediate positive. On admission blood cultures in various media, including Robertson's meat, were taken. These were repeated with each rigor for the first 24 hours. From all cultures two organisms were isolated—a β -haemolytic streptococcus belonging to Lancefield's Group A, and *Bacteroides fragilis*. The latter was agglutinated by the patient's serum to a titre of 1 in 250. The streptococcus was fully sensitive to penicillin.

Bact. fragilis, by the ditch-plate method, was insensitive to penicillin but fully sensitive to chloramphenicol and streptomycin. As a result the penicillin treatment which he had had since admission was stopped and chloramphenicol and streptomycin were given. Chloramphenicol was administered as follows: 4 g. the first day and 2 g. daily subsequently. In addition 2 g. of streptomycin in divided doses was given subcutaneously each day. His temperature continued to swing, at times reaching 105° F. (40.6° C.). A laparotomy was performed on the sixth day after admission and an appendicular abscess was found and drained; the necrotic remnant of the appendix was removed. Examination of the pus revealed, in addition to various organisms, a β -haemolytic streptococcus and *Bact. fragilis*. There was no appreciable change in his condition.

Six days after the first operation another laparotomy was performed in order to ligate the ileo-colic vein. The patient's condition was critical and no further procedure was attempted. On this day he was given aureomycin, 1 g. four-hourly by mouth, and all other antibiotic therapy was stopped. In three days, after 18 g. of aureomycin, his temperature fell to normal and remained so. He received a total of 80.5 g. in approximately 14 days. During this period he had 4 pints (2.3 litres) of blood and a high-protein diet with additional vitamins. His only complaints were a slight soreness of the mouth and some difficulty in swallowing.

After all treatment was stopped he became less cadaverous and began to put on weight. For a few days a pseudochylous fluid drained from his operation wound, but this rapidly cleared up. He was discharged to a convalescent home.

Note on Surgical Findings, by Mr. Welsh

The patient presented as a case of septicaemia, with probably a focus of pus in the abdomen which could not be located by clinical or x-ray examination. Laparotomy, by a transverse upper abdominal incision, led to the discovery of a small appendix abscess containing thick greenish-yellow pus in the right iliac fossa. There was a small amount of blood-stained free fluid in the general peritoneal cavity, and the spleen was found to be enlarged.

Appendicectomy, aspiration, and drainage of the abscess were performed. No definite search was made for thrombosed portal-vein tributaries. On the sixth post-operative day it was decided to reopen the abdomen and search for and ligate the ileo-colic vein. The tissues at the root of the mesentery were all matted and oedematous, but a portion of what was believed to be thrombosed vein was removed between ligatures. Subsequent histological examination did not confirm the presence of vein wall in this tissue.

Notes on the Laboratory Findings

The organism, *Bact. fragilis*, was first isolated from Robertson's meat medium. It was subsequently cultured on blood agar under micro-aerophilic conditions. It closely resembled the characters of the organism described by Schwabacher and Mitchison (1947).

The sensitivity results were as follows:—Penicillin: sensitive to 20 units per ml., insensitive to 10 units per ml. Sulphadimidine: sensitive to 5 and 50 mg. per 100 ml. (plate method). Chloramphenicol: sensitive to 5 units per ml., insensitive to 4 units per ml. Streptomycin: sensitive to 25 units per ml. (plate method). Aureomycin: sensitive to 0.1 unit per ml. Terramycin: sensitive to 0.4 unit per ml.

Comment

A case of pylephlebitis and septicaemia is described with recovery on large dosage of aureomycin. It was of great interest for the following reasons: (1) The failure to respond to penicillin, streptomycin, and chloramphenicol. (2) A Gram-negative bacillus of the *Bacteroides* group and *Sr. haemolyticus* were isolated from the blood and the appendix abscess. (3) The relative absence of toxic effects despite the large dosage of aureomycin used. (4) The development, on recovery, of ascites, which was possibly related to pylephlebitis. (5) The long duration of the illness, with complete recovery.

Thanks are due to Professor A. P. Thomson for permission to publish; to Miss V. M. Jones for technical assistance, and to Miss M. N. Ellis for secretarial assistance.

ADDENDUM.—Since this case was seen rules have been formulated for the combined use of antibiotics. A leading article in the *Lancet* (July 26, 1952, p. 173) divides these agents into two groups. Group 1: Bactericidal—for example, penicillin, streptomycin, and bacitracin. Group 2: Bacteriostatic—for example, aureomycin, chloramphenicol, terramycin, and possibly sulphonamides. Where the organism is sensitive to a drug of Group 1 the addition of a bacteriostatic agent may result in antagonism (this may have occurred in the above case when streptomycin and chloramphenicol were given in combination). If the organism is only partially sensitive to the bactericidal agent the combination with a bacteriostatic may result in synergism.

CONGENITAL OBSTRUCTION OF THE SMALL INTESTINE IN TWO PREMATURE INFANTS

BY

W. P. SWEETNAM, M.D., M.R.C.P., D.P.H., D.C.H.
PaediatricianF. W. SHEPHERD, M.D., F.R.C.S.
Surgeon

AND

E. F. MURPHY, M.D., D.C.H.
Senior Paediatric Registrar

The Royal Infirmary, Huddersfield

The neonatal mortality rate has fallen by more than a half over the last 40 years. The rate in England and Wales in 1949 was 19.31 per 1,000 live births. Over half the deaths (10.2 per 1,000 live births) were due either to prematurity or to congenital malformations (Ministry of Health, 1949). This paper describes the successful treatment of two infants presenting both of these two main causes of neonatal death. One was a premature infant with an ileal atresia, the other a premature infant with exomphalos and congenital obstruction of the small intestine.

Wangensteen (1942) estimated the incidence of congenital atresia of the small intestine as 1 in 20,000 births. This estimate is based on necropsies and hospital births, and, although the condition must be considered rare, it is probable that the true incidence is higher. O'Neill *et al.* (1948), in a comprehensive review of the literature, could find only 36 cases of atresia of the small intestine which had been successfully treated by operation. A further case has been described by Stevens (1951). The 37 cases include three premature infants with birth weights of 4 lb. 11 oz. (2.12 kg.) (Stetten, 1940), 4 lb. 11 oz. (2.12 kg.) (Ward and Cooper, 1943), and 4 lb. 8 oz. (2.04 kg.) (Duncan *et al.*, 1943). The 52 babies operated upon by Ladd and Gross (1941) showed a mortality rate of 80% for duodenal, 50% for jejunal, and 91% for ileal atresia.

Exomphalos is commoner. Jarcho (1937) estimated its incidence as 1 in 5,000 deliveries; again this estimate is based solely on hospital births, and the true incidence is probably higher. The chances of survival depend largely on the size of the sac. Gross (1948), in a series of 60 cases, found that with a sac less than 7 cm. in diameter there was about a 75% chance of survival following surgery. When the sac was 7–9 cm. in diameter survivals were cut to about 30%. When the sac was larger than 9 cm. the survivals were reduced to about 15%.

Case 1

The baby, a boy, was born a month prematurely. The birth weight was 4 lb. 6 oz. (1.98 kg.). The mother's pregnancy had been uneventful. She had had one previous pregnancy in 1949, and a three-months miscarriage in 1945. Her blood was Rh-positive; the Kahn test was negative. Delivery was rapid, the mother suffering mild obstetrical shock. The baby was left undisturbed for 24 hours, when a small amount of glucose-water was given and retained. The following day $\frac{1}{2}$ -oz. (14-ml.) feeds of breast milk were given two-hourly, and taken readily. Early on the third day vomiting started, and soon became bile-stained. At about this time a normal meconium stool was passed, no food residue being noted.

The baby showed the usual signs of prematurity and dehydration. The abdomen was slightly and evenly distended and peristaltic waves could be clearly seen over the gastric area, and also up and down each side of the abdomen. The child's weight had fallen by this time to 3 lb. 8 oz. (1.59 kg.), and he had lost a fifth of his birth weight. Radiographs taken of the abdomen with the child in various positions showed several loops of gas-distended small intestine with fluid levels, confirming a small-intestine obstruction (Fig. 1).

Three hours were spent in pre-operative treatment: the stomach was washed out and aspirated half-hourly (an intranasal catheter being kept *in situ*), and 200 ml. of 5% glucose in N/5 saline was given intravenously by continuous drip.

FIG. 1.—Case 1. Radiograph of abdomen showing fluid levels in stomach and small intestine. No air present in large intestine.

A laparotomy was performed 80 hours after birth, by which time the baby's weight must still have been under 4 lb. (1.81 kg.). Atropine, 1/200 gr. (0.32 mg.), was given pre-operatively, and the abdomen was opened through a right paramedian incision, under "vam" and oxygen anaesthesia → ether and oxygen on an open mask (Miss K. M. Watson). There was bile-stained free fluid. Part of the omentum was adherent to the ileum about 12 cm. from the ileo-caecal junction. At this point the lumen appeared to be obstructed by a short imperforate portion, or diaphragm, the ileum above being distended to a diameter of 2 cm., while distally it was collapsed, though probably canalized. No bowel contents could be milked along. The caecum, appendix, and ascending colon were normally developed, though empty.

It was decided that relief of the obstruction could most simply be obtained by making a stoma between the distended ileum and the caecum. The short length of collapsed ileum would then be left as a blind diverticulum draining into the caecum through the ileo-caecal valve. The anastomosis was sutured in two layers with catgut, antiperistaltically, without difficulty. No attempt was made to close the gap in the mesentery or to explore the rest of the abdomen. The abdominal wall was closed in layers. The baby stood the operation very well.

Post-operatively the baby was nursed in an oxygen container with a minimum of clothing; 5% of CO₂ was added for five minutes of each hour. Aspiration of the stomach was continued half-hourly. The intravenous drip of 5% glucose in N/5 saline was continued until the first signs of oedema appeared, by which time a total of 750 ml. of fluids had been given. The drip was then changed to whole fresh blood (from the father), 100 ml. being given in the following two hours. Twenty-four hours after the operation glucose was given by mouth. The next day this was changed to expressed breast milk ½ oz. (14 ml.) two-hourly, slowly increasing to 2 oz. (57 ml.) two-hourly. Streptomycin, 25 mg., and penicillin, 100,000 units, were given intramuscularly four-hourly for four days. The baby's temperature (per rectum) remained between 95 and 96° F. (35 and 35.6° C.) for three days. No attempt was made to raise this. On the fifth day the baby passed a normal stool. The stitches were removed on the tenth day and the baby was

discharged home three weeks after the operation, weighing 6 lb. 8 oz. (2.95 kg.). He was last seen at 3 months of age, by which time he weighed 10 lb. 2 oz. (4.59 kg.), and was having no trouble with breast-feeding or bowel action.

Case 2

This baby, a female, was born six weeks prematurely. The birth weight was 4 lb. 4 oz. (1.93 kg.). The mother's pregnancy had been uneventful. She had had one previous miscarriage, in 1951. Her blood was Rh-positive; the Kahn test was negative. The presentation was a breech with extended arms and legs. An episiotomy was performed under pudendal block and the after-

coming head delivered with forceps. The baby was badly shocked. A small defect was seen in the anterior abdominal wall, through which a translucent rounded mass about 8 cm. across protruded. This mass could be seen to contain intestine. The precarious condition of the child and the danger of rupturing the thin-walled sac precluded any immediate conservative or radical attempts at reduction. The infant was placed in an oxygen container and left undisturbed for 36 hours, when small amounts of glucose-water were given by mouth, followed by ½-oz. (14-ml.) feeds of expressed breast milk. By this time the mass had become opaque and friable. On the fourth day the baby began to vomit. It was apparent that a loop of intestine in the sac had become obstructed. This was confirmed by a plain x-ray film of the abdomen, which showed gaseous distension of the small intestine. The exomphalos was also seen to contain a small loop of intestine (Fig. 2).

FIG. 2.—Case 2. Radiograph of abdomen showing gaseous distension of the stomach and small intestine and a loop of small intestine in exomphalos.

The same pre-operative regime as in Case 1 was followed, 150 ml. of 5% glucose in N/5 saline being given intravenously over two hours. Ninety hours after birth the baby was operated upon. Atropine, 1/200 gr. (0.32 mg.), was given, followed by vam and oxygen → ether and oxygen on an open mask (Miss K. M. Watson). An incision was made over the upper and lower angles of the hernia and the sac opened. A loop of small intestine was seen to have herniated through a small hiatus in the transversalis fascia about 2 cm. in diameter. The sac was excised, the constricting neck divided, and the loop of intestine replaced in the abdomen, which was then closed in layers.

The post-operative regime was the same as in Case 1—a total of 500 ml. of 5% glucose in N/5 saline followed by 75 ml. of fresh blood being given by continuous intravenous drip over the next 36 hours. By the fourth post-operative day the baby was taking 1½ oz. (42 ml.) of expressed breast milk two-hourly. She was discharged home three weeks after the operation.

Discussion

The development of regional neonatal surgical centres for the treatment of congenital malformations has been

strongly advocated (Rickham, 1952). Most paediatricians will agree that certain congenital abnormalities such as oesophageal atresias and genito-urinary malformations require the specialized surgical techniques available only at regional centres. Abdominal malformations of the alimentary tract, particularly obstructions of the small intestine, are probably the most urgent of the remedial congenital malformations. Early diagnosis and immediate pre-operative treatment are required. Available statistics suggest that after 96 hours the operative mortality even in the most capable hands is practically 100%. The delay and disturbance necessarily involved in transferring such cases from outlying hospitals to regional centres is unjustified. Rickham (1952) points out that a surgeon working in one hospital group is unlikely to see more than one or two such cases a year, and therefore unlikely to gather enough experience to deal correctly with the complicated surgical problems. On the other hand, the general surgeon, owing to the development of other surgical specialties, is a specialist in abdominal surgery, and neonatal abdominal surgery should rightly remain within his province.

Summary

Two cases of congenital obstruction of the small intestine in premature infants, with recovery after operation, are reported. The question whether congenital surgical abnormalities in the newborn should be treated locally or at regional centres is discussed. It is suggested that certain congenital abnormalities requiring specialized surgical technique should be transferred to regional centres, and that others, such as obstructive malformations of the small intestines, should be treated locally.

Our thanks are due to Dr. W. S. Dickson, Dr. W. Niven, and Miss K. M. Watson; to the junior medical staff; and to the nursing staff of the Huddersfield Royal Infirmary and the Princess Royal Maternity Home for their invaluable assistance.

In 1911 Dr. M. David Eder read a paper on "A Case of Obsession and Hysteria Treated by the Freud Psychoanalytic Method" to the neurological section at the Annual Meeting of the B.M.A. It was the "first public contribution to clinical psycho-analysis" in Britain to be described publicly, and was later published in this *Journal* (1911, 2, 750). Now, 42 years later, the case has been followed up—which in that respect probably makes it unique in the psychiatric literature, as Drs. Hunter and MacAlpine indicate in the *British Journal of Medical Psychology* (1953, 26, 64). The patient first consulted Dr. Eder in 1910 because he was worried by a dull aching pain in the back of the neck which caused considerable depression. He was treated twice weekly for three months—the technique being based mainly on free associations and dream analysis. At the last session he was hypnotized, and Dr. Eder suggested to him that he was cured. At the age of 68 he still has some symptoms, mainly of intense pain and tension in the head, which he relieves with barbiturates. But on the whole, says the report, he seems to have made a satisfactory adaptation to life, and learned to live with his symptoms. An interesting point mentioned by these authors is that the patient, who was found to have a "mother complex" displaced on to his sister Ada, probably chose Dr. Eder because of the homophony of the names. But this, involving the concept of transference then little appreciated, went unnoticed by Dr. Eder.

SUCCINYLMONOCHOLINE

BY

H. LEHMANN, M.D., Ph.D., F.R.I.C.

Senior Lecturer in Chemical Pathology, St. Bartholomew's Hospital, London

AND

E. SILK, B.Sc.

Research Assistant

Whittaker and Wijesundera (1951) reported that the product of succinylcholine (succinylcholine SDC) hydrolysis by horse serum was succinylmonocholine (SMC). We decided to study this process, using human serum. While this work was in progress another communication by Whittaker and Wijesundera (1952) described work done with a highly concentrated horse pseudo-cholinesterase (33,000 units per ml.) confirming that, in the enzymatic breakdown of SDC, first SMC was formed, but that this was an intermediate which was subsequently hydrolysed to succinic acid and choline: SDC → SMC + choline; SMC → succinic acid + choline. We found the same with human serum, and when using similar concentrations (SDC 1.1, SMC 0.7 mg. active cation per ml.) could show that SDC was at first hydrolysed four to six times as fast as SMC, but that between 40 and 60% hydrolysis point the speed slowed and became identical with that of hydrolysis of pure SMC. Thus, using a highly concentrated human cholinesterase, we found that it contained for one unit SMC hydrolysis six for SDC. One unit equals 1 μl. CO₂/ml./min./37° C. obtained by the bicarbonate method according to McArdle (1940). At higher substrate concentrations the difference falls, and when they reach 15 times the values with which Whittaker and Wijesundera worked the ratio becomes less than 2:1 (see Table I).

TABLE I.—μl. CO₂/min./ml. of Pseudo-cholinesterase (Human, 16,000 Units) Produced at 20% Hydrolysis Point of Succinylcholine and Succinylmonocholine. Total Volume, 3 ml.; Enzyme Dilution, 1:60

Substrate Concentration 10 ⁻³ M	Succinylcholine SDC	Succinylmonocholine SMC
55	580	350
5.5	514	134

Whereas SMC resembles SDC in its response to pseudo-cholinesterase, as a substrate of the true cholinesterase of the red cells it occupies a position midway between acetylcholine and SDC. Table II shows that SMC, like acetylcholine and unlike SDC, is hydrolysed by true cholinesterase at low substrate concentrations. It resembles SDC in inhibiting acetylcholine hydrolysis by the true cholinesterase, but whereas SDC is still effective at very low concentrations (Evans *et al.*, 1952) SMC inhibits only at the high levels at which the acetylcholine itself becomes an inhibitor.

TABLE II.—μl. CO₂/min./ml. of Packed, Washed, and Laked Human Red Cells, 37° C., Bicarbonate Buffer. Substances are Referred to as mg. Active Cation/ml. Total Volume, 3 ml.; Enzyme Dilution, 1:75

	0.7 mg. Acetylcholine	0.9 mg. SMC
—	149 μl.	24 μl.
+7 mg. acetylcholine ..	71 "	71 "
+9 mg. SMC ..	69 "	21 "

Effect on the Rabbit

SMC has been considered pharmacologically inactive by Bovet *et al.* (1951), but nevertheless they noted a "head-drop effect" with 10 mg. of SMC iodide per kg. of rabbit, compared with 0.2 mg. of SDC di-iodide per kg. As there was here a substance which had a pharmacological action and which could be destroyed by cholinesterases, we decided to investigate the effect on the rabbit in the first instance. The animals were females weighing between 2.5 and 3 kg. The dosages represent active cation of SMC injected intravenously in mg./kg. No effect could be seen below 0.8 mg.; 0.8 to 1.2 resulted in slight depolarizing twitches but no paralysis; 1.3 to 1.5 produced a transient head-drop; from 1.5 to 4.5 there was paralysis of increasing duration—150 seconds at 2.5 and 570 seconds at 3.5. At this latter range the breathing was shallow, but there was no apnoea. A dosage above 4.5 could, and above 5 did, regularly cause respiratory paralysis. When given in doses above 7 mg.—that is, twice that producing 10 minutes' relaxation without apnoea—SMC caused a fall in blood pressure followed by a fall in heart rate. There seemed to be a hexamethonium-like effect on the peripheral blood vessels accompanied by "pooling" of blood in dependent parts of the body. It was followed by a depressant effect on the heart, which persisted after severing the vagus. Thus there is a wide range from the head-drop dose of 1.5 to the toxic dose of 7.5. SMC is much longer acting than SDC at similar pharmacological levels—doubtless because it is so much more slowly destroyed by pseudo-cholinesterase than SDC. An injection of 1 ml. of human pseudo-cholinesterase (16,000 units) terminated the effect of SMC as effectively as that of SDC. In fact, such treatment will allow a rabbit (female 2.5–3 kg.) to survive with impunity a threefold lethal dose of both SDC and SMC.

To find whether these results are applicable to man further work will have to be carried out on other mammals. One certainly would not like to embark on the injection of unusually large amounts of a choline derivative into man without ample reassurance. There exist for man a number of long-time relaxants which are readily controlled by neostigmine; nevertheless a long-acting relaxant which could be counteracted by a harmless compound might be a useful addition to the equipment of the anaesthetist. Neostigmine tends to be given in emergencies and to patients who are already at hazard, and there is always a risk of a toxic effect. Be this as it may, at any rate so far as the rabbit is concerned there exists a cholinergic compound which resembles decamethonium in its prolonged curarizing action and succinylcholine in permitting this action to be terminated at will by the injection of pseudo-cholinesterase.

The Function of Pseudo-cholinesterase

It has hitherto not been possible to allot to the pseudo-cholinesterase a function in life, particularly as, unlike true cholinesterase, it can be removed by specific inhibitors in man and animals *in vivo* without notable ill effect. The most important study on the distribution of pseudo-cholinesterase was that carried out by Ord and Thompson (1952) on brain and nerves of man and animals; they demonstrated by the interplay of specific substrates and inhibitors that the pseudo-enzyme is largely in the white matter of the central and peripheral nervous system in close association with the true cholinesterase of the grey substance. There are now at least four compounds which "poison" the true cholinesterase and are destroyed by the pseudo-cholinesterase: acetylcholine and SMC in high concentrations, SDC and suxethonium at high and low concentrations. Except for acetylcholine, the compounds tested have been synthesized *in vitro*, but it is obvious that similar substances must arise in the intermediary metabolism of the body. It may therefore not be unreasonable to suggest that a function of pseudo-cholinesterase is that of protecting true cholinesterase from non-specific inhibitors.

Summary

Succinylmonocholine inhibits true cholinesterase of man and is broken down by the pseudo-cholinesterase. In rabbits at concentrations of 3.5 mg. of active cation per kg. of body weight it produces muscular relaxation of 10 minutes' duration without apnoea; its effect can be terminated at will by the injection of pseudo-cholinesterase. Prior injection of pseudo-cholinesterase will protect rabbits against toxic doses.

It is suggested that a function of pseudo-cholinesterase is that of protecting true cholinesterase against non-specific inhibitors.

We thank Professor D. Bovet and Messrs. May and Baker Ltd. for gifts of succinylmonocholine. We are indebted to Professor K. J. Franklin, who kindly gave us the hospitality of his laboratory for the kymographic recording of blood pressure changes; to Dr. G. Boissard, for assistance in this part of the work; and to Drs. F. T. Evans and P. W. S. Gray for helpful discussions. Dr. E. B. McLean kindly provided us with a concentrated pseudo-cholinesterase solution produced by a further fractionation of Cohn's fraction IV-6-1 with ammonium sulphate. We are grateful to the Medical Research Council for an expenses grant, and for a maintenance grant to one of us (E. S.).

Medical Memorandum

Stevens-Johnson Syndrome

A further case of this rare disease is reported in the hope that the photographs will be of help to others who have not encountered it. Involvement of the nails is a feature that has not been mentioned in previous cases.

CASE REPORT

A boy aged 5 years 3 months had been in good health since the removal of his tonsils and adenoids two months previously on account of frequent attacks of tonsillitis. The only other illnesses were measles at 3, whooping-cough at 5, and several large epistaxes. The family history was not relevant. On September 7, 1949, a slight discharge from both eyes was noticed, and his appetite became poor. This discharge increased rapidly and the lids became oedematous. The next day his lips began to swell, a rash appeared, and he was febrile. He was admitted on September 9. The clinical picture is shown in the photographs taken the next day. The features of the case were:

Bilateral angular conjunctivitis, with a profuse purulent discharge and much irritation, which made him rub the oedematous lids. There was no corneal ulceration.

Haemorrhagic crusting of the lips, strikingly confined to the red margins, extending neither to the mucous membrane inside the lips nor to the relative normal surrounding skin producing by contrast the appearance of circumoral pallor (Fig. 1).

The Rash.—The distribution was general but more pronounced on the face, extensor surface of the forearms palms (but not the soles), and nail margins. On the face the cheeks were the most affected, with fewer lesions round the mouth, on the forehead, and (not shown) behind the pinnae. The penis was involved no more than the trunk and there was no urethritis. The configuration was pleomorphic, the discrete lesions varying from 2 to 5 cm. in diameter and tending to be circular or oval. The lesion

itched and some were in relation to scratch marks (see left forearm in Fig. 2). The early lesions were erythematopapular, later becoming vesiculo-bullous. Breaking of the bullae produced raw areas and haemorrhagic crusting. On the face the lesions were confluent. On the extensor surfaces of the forearms and on the palms, where the lesions

were becoming confluent, the intervening skin was erythematous. Elsewhere the intervening skin was normal. Oedema was confined to the cheeks, mouth, and eyelids. Except at the umbilicus, no lesion was pustular.

In the mouth there were raw areas from lesions on the mucous membranes of the cheeks; the soft palate, fauces, and tonsillar beds escaped. Surprisingly there was no enlargement of the cervical lymph nodes.

The nail beds and skin of the terminal phalanges of both fingers and toes were heavily involved (Fig. 3).

On examination his temperature was 102.6° F. (39.2° C.), pulse 128, and respirations 26. He was miserable and crying, but intelligent and co-operative. The lymph nodes were not enlarged. The cardiovascular and central nervous systems were normal. The respiratory system showed no evidence of infection. The liver and spleen were not palpable.

Swabs from the conjunctival, skin, and mouth lesions were taken before any treatment was given. Cultures in broth and on blood-agar and chocolate-agar (+CO₂) plates were sterile. The blood count and urine were normal.

Treatment.—(1) Aqueous penicillin, 100,000 units six-hourly for six days, then procaine penicillin, 300,000 units (1 ml.) daily for a further six days. (2) Tab. sulphadimidine, 1 g. six-hourly for six days (total 24 g.). (3) Penicillin cream to the broken bullae. (4) The eyes were irrigated every six hours with 1% boric eye lotion, after which penicillin eye drops (1,000 units per ml.) were instilled. (5) Tab. phenobarbiton, ½ gr. (32 mg.) twice daily, during the first ten days.

The patient was afebrile and the pulse rate became normal within 24 hours. There was no further rise in temperature. Also, by the next day, in spite of the alarming appearance, he was feeling well and faced the camera with co-operation and composure. In a week the conjunc-

tivitis had cleared up completely. After a fortnight all the skin lesions had cleared except for a little dry crusting where the larger bullae had been. He was discharged home in good health on October 10 after 31 days in hospital. When seen in January, 1950, he had remained in good health. He had shed all the nails of his fingers and toes twice since discharge from hospital. In November, 1950, he was well and there has been no recurrence of any skin lesions.

COMMENT

This disease was reviewed by Thomas (1950), who regarded it as a severe form of erythema exudativum multiforme (Hebra). Thomas stated: "It occurs to me that simpler appellations would be 'erythema multiforme exudativum major' and 'erythema multiforme exudativum minor.'" Although possibly attractive to the purist, most doctors will prefer to leave this esoteric sesquipedalianism to their dermatological colleagues and continue to call the disease the Stevens-Johnson syndrome.

The clinical picture is pathognomonic and must rank with diseases such as cretinism, mongolism, pink disease, etc., which, once seen, can thereafter be recognized at a glance.

FIG. 1.

FIG. 2.

FIG. 3.

This case satisfied the criteria of the Stevens-Johnson syndrome—namely, a generalized eruption, continued fever (cut short by treatment), inflamed buccal mucosa, and severe purulent conjunctivitis. The marked involvement of the nail beds, with subsequent shedding of the nails twice, is not mentioned in other cases. This boy was never very ill, and within 24 hours of admission became afebrile, improving steadily thereafter. The dangerous complications of corneal ulceration and pneumonia never looked likely to occur, and gave no anxiety. This prompt improvement must be attributed to the energetic treatment, which prevented any secondary infection. It seems to me that, in these days when sulphonamides are more of a food than a medicine, it is difficult to be sure that toxicity to sulphonamides can be a cause of the Stevens-Johnson syndrome. Certainly, except in persons known to be sulphonamide-sensitive, such a consideration should not prevent sulphonamides being given in full doses to prevent secondary infection.

For permission to publish this case I am grateful to Dr. Duncan Brierley, the family doctor, and to Dr. W. H. Macmillan, under whose care the boy was while in hospital. I am indebted to Mr. J. Parkes Foy for the photographs.

The first party of British children to go to Denmark this year under the Anglo-Danish Sanatorium Scheme for British Children (see *Journal*, 1952, **1**, 634) left Northolt Airport recently. The party included a number of Scottish children and also some from Liverpool. About 20 children who have been at Vordingborg Sanatorium through this scheme for several months returned to England on the same day.

Reviews

HANDBOOK OF RADIOTHERAPY

4 *Handbook of Radiotherapy for Senior and Postgraduate Students*. By Walter M. Levitt, M.D., F.R.C.P., F.F.R., D.M.R.E.(Camb.). (Pp. 232; 53 figures. £1 10s.) London: Harvey and Blythe. 1952.

Dr. Levitt has written a book which is admirably composed, giving ideal proportions to its various technical and clinical parts, and filling it with the wisdom that stems from wide experience, acute observation, intellectual synthesis, and profound insight: he has produced a work of art. To refer to such a prosaic-sounding book as this in these terms may seem to be an exaggeration, but, just as in looking at a picture one continually appreciates more and more the artist's thoughts, and, just as the expert in art can see more in the work, so in this book both the students for whom it is written and radiotherapists of whatever experience will find sound information and wise counsel on the application of radiotherapy to disease. There are a few minor errors which will no doubt be corrected in the next edition, and a slight illustration of the case of pituitary basophilism (p. 195) might well have been of the type recovering without any treatment. The work is adorned with apt illustrations and useful and accurate index.

The book follows a natural sequence in its arrangement of chapters, starting with two on physics clearly and evenly written, followed by one on the application of radiation in treatment and another on the effects of radiation on cells, tissues, and organs. Fourteen chapters on clinical radiotherapy follow. Two of these—on principles of treatment and the management of the patient—are admirably written. In the succeeding chapters, which are devoted to systems and organs, the handbook nature of the work becomes more apparent towards the end of each chapter, but the balance of the book is never at fault. Readers wishing to know something of radiotherapy will find it useful, and readers who know something of radiotherapy may find it even more useful.

FRANK ELLIS.

CHALLENGE TO PSYCHIATRISTS

The Philosophy of Psychiatry. By Harold Palmer, M.D. (Pp. 70. \$2.75 or £1 2s.) New York: Philosophical Library. London: H. K. Lewis and Co. 1953.

The development of psychiatry has necessarily been dependent on verbal communication. In the effort to record and discuss the products of mental and cerebral activity, psychiatrists have built up a terminology of their own, often hastily adapted from other disciplines, often based on analogies and theoretical constructs and finally becoming so specialized as to discourage contact with their scientific neighbours. Within this terminology it is possible to discuss the same concepts in different terms—such as those of analytic psychology and cybernetics, for instance—so that the reason for the restriction of communication between schools is mere lack of common language. Further, the means of communication may leave its imprint on the ideas transmitted. There is thus reason for a careful logical scrutiny of the basic terms and assumptions of psychiatric discourse, and such a scrutiny, in Dr. Palmer's view, is essential if any synthesis is to be achieved which will reconcile the different approaches.

It is as the prolegomena to such a unifying system that he has written this book, and with the purpose of encouraging psychiatrists to question the terms and working hypotheses which they use in clinical practice. Assuming that the legitimate subject-matter of psychiatry is mental ill-health as it affects the self, he proceeds to define a group of primary entities—awareness, consciousness, self, thought, and mind—and a secondary group nearer to the clinical

field—personality, character, morale, group, and society. The way is now clear for definition of some of the descriptive categories into which clinical material may fall, but the author does not carry this very far and reminds readers that he claims no more than to clear the way. Readers are now left free to work out the next stage, including the definition of symptoms, for themselves.

The statement of the problem, which occupies most of the book, appeared originally in two articles in *Philosophy* (October, 1951, and January, 1952) and provoked surprisingly little reaction. The author now presents it as a challenge to psychiatrists. The essentially abstract material is discussed with great clarity, although the application of the methods of logic is a little self-conscious. The compass of the book is not as ambitious as the title, and discussion of the relation of brain to mind, for instance, is confined to the field of psychosomatic manifestations. This book deserves serious consideration. It can hardly fail to sow the seeds of healthy scientific doubt in a branch of medicine where the clinician can too easily escape from the philosophical implications of his subject by taking refuge in belief and in mere words.

ALEXANDER KENNEDY.

TRICHLORETHYLENE ANAESTHESIA

Trichlorethylene Anaesthesia. By Gordon Ostlere, M.B., B.Chir., D.A. (Pp. 83; 5 figures. 7s. 6d.) Edinburgh and London: E. and S. Livingstone. 1953.

This little book provides a complete review of all that has been said and written about trichlorethylene. History, pharmacology, and clinical use are all described, each short chapter having a very full list of references at its end. The book will be useful to supplement the chapters on this subject in the standard textbooks and as a reference source for the literature on trichlorethylene.

W. W. MUSHIN.

NO SURRENDER

Disabilities and How to Live with Them. By 55 Patients. (Pp. 243. 10s. 6d.) London: The Lancet Ltd.

Help Yourself to Get Well: A Guide for T.B. Patients and their Families. By Marjorie McDonald Pyle, M.D. With foreword by H. Corwin Hinshaw, M.D. (Pp. 143. 12s. 6d.) London: William Heinemann. 1952.

The well-remembered articles from the *Lancet*, in which patients related their case histories, have now been collected in this remarkable little book. The degree of disability varies, but the authors display a uniformity of courage and an absence of self-pity which is very impressive. Although these sufferers, like Samuel Johnson, might be conquered but would not capitulate, yet the dominating impression on rereading these essays is not one of courage but of the extraordinary adaptability and resource of the human body and mind. Consider, for example, the doctor who, after 20 years of Parkinsonism with increasing difficulty in walking, talking, eating, and writing, found that his left index finger, which he used so laboriously to type the articles which too frequently were returned to him, was at last refusing its essential function. He looks forward to the purchase of an electric American typewriter which will continue to make his work possible. And the woman who, although completely paralysed below the waist, can manage the life of a housewife by the use of four different types of propelling chair.

If the biological lesson to be derived from these essays is that of adaptation, the philosophical conclusion is that, although these patients demonstrate the supreme value of the human will, their reactions to disaster are predetermined. The thinking surgeon with an acute anxiety state found his cure in the probing and painful operations of psychoanalysis as certainly as the turbulent and asthmatic physician rejected the "unscientific" approaches of three psychiatrists.

"Gentleman," as Wilfred Trotter declaimed on a famous occasion, "let us remember the patient," and it is because these essays remind us so vividly of suffering men that the book has an especial value for all doctors. These histories are told with a different emphasis from those we hear in our consulting-rooms. There we see the "stills," but here, as in a film, we are shown the initial rejection, the acceptance, the struggle, and the final triumph.

The family doctor, who already has a sufficiently intimate acquaintance with sick persons, will nevertheless find this book of value. Some of these patients set out the management of their disabilities in considerable detail, and their personal experience of drugs, apparatus, and clothing is worth studying. It is not easy always to draw apposite conclusions from their experience, as in the case of the lady with myasthenia gravis who gives herself an injection of neostigmine every two hours and yet finds it unnecessary either to anoint her skin with ether or to sterilize her syringe more than once a week. It is a good book for the layman, too, but it should not be given to patients indiscriminately. There are as many patterns of disease as there are patients. Not every man with coronary thrombosis should again work as hard as he did 20 years before his attack, and not every diabetic should regard hypoglycaemia so lightly as does one doctor-driver. The book should become a classic.

Help Yourself Get Well is not of the same quality. It is, however, a sensible and encouraging book addressed to the tuberculous patient. It must be a great comfort to the dwellers in sanatoria to know that the auto-therapies of Samuel Smiles are now efficiently supplemented by the hetero-therapies of biochemists and surgeons.

D. V. HUBBLE.

SUICIDE

Der Selbstmord. By Dr. Erwin Ringel. Wiener Beiträge zur Neurologie und Psychiatrie 3. (Pp. 235. M.20.) Vienna: Wilhelm Maudrich. 1952.

Suicide is considered as the outcome of a pathological mental development. 745 patients admitted to the psychiatric clinic at Vienna after attempted suicide in the year 1949 were investigated; 454 were female and 291 male patients. In about half of them unfavourable home conditions in childhood were found. In later life mental trauma figured highly: the traumatic factors were mainly an unhappy married life, childlessness, unfaithfulness of the partner, disappointments, and professional setbacks. The trauma caused a lowering of moral values and produced a devaluation of life itself. One-fifth of the patients were either asocial or delinquent. These were the conditions in the patients' past which prepared the ground for what the author calls the "presuicidal syndrome," consisting in the triad of constriction, aggression, and flight into unreality. Constriction leads to loss of expansive power, stagnation, and regression; aggression creates destructive tendencies culminating in self-destruction; the flight into unreality promotes fantasies which replace reality. No distinction is made between attempted suicide and successful suicide, and the author attaches no significance to the setting and circumstances of the suicidal attempt. The non-psychotic patients form a separate neurotic group, and the therapeutic approach advocated is a short analysis on psycho-analytical lines. In cases of depression the same presuicidal syndrome can be traced, while in schizophrenics the psychotic picture as a whole is held responsible for the tendency to self-destruction. In a chapter on prophylaxis the collaboration of the psychiatrist with lay organizations is stressed.

The book contains some interesting material on the cultural and social background of the suicidal patients. But the general psycho-pathological formula at which the author arrives is sweeping, as can be expected from his simplification of the complex problem.

R. KLEIN.

WATER METABOLISM

Physiologie Normale et Pathologique du Métabolisme de l'Eau. By Professor Jean Hamburger and Dr. Georges Mathé. (Pp. 512; illustrated. 2,850 francs.) Paris: Editions Médicales Flammarion. 1952.

This is a nicely produced book by authors who have themselves made contributions to the subject of water metabolism, and provides a general review of normal and disturbed body-fluid balance. It is in three main parts, dealing respectively with normal physiology, methods of investigation, and pathological states. The presentation is balanced and the expression clear.

As might be expected from the title, the physiological aspects are most fully considered. At the same time, clinical manifestations are clearly described. Advice on treatment is relatively brief, and greater detail would be more helpful to clinicians. The illustrations are well chosen and simple to understand. A feature particularly useful to students of the subject is the very full bibliography of 2,500 references. These include a large number of English and American publications as well as Continental papers. The authors are to be congratulated on producing an excellent book.

H. L. MARRIOTT.

POISONS

Poisoning: A Guide to Clinical Diagnosis and Treatment. By W. F. von Oettingen, M.D., Ph.D. (Pp. 524. £3 10s.) London: William Heinemann. 1952.

The incidence of poisoning, both acute and chronic, is constantly increasing as new chemicals for industrial, domestic, and medicinal use are introduced. In addition there are many plant poisons of concern particularly in rural districts. The purpose of this book is to summarize knowledge of poisoning in a way which will be easily available to the physician in emergencies. The volume is divided into four parts: in the first the author classifies poisons and discusses medico-legal implications; in the second he deals with the clinical diagnosis of poisoning and the diagnostic laboratory tests available; in the third he discusses the principles of treatment; and in the fourth and largest section he lists alphabetically 461 poisons, with, in each case, a short synopsis of the clinical syndrome produced and the treatment advised.

The work gives the impression of having been compiled by a State official from case reports, documents, and literature rather than from personal knowledge acquired by clinical experience. Many of the laboratory tests for poisoning are old-fashioned. Poisoning by aureomycin is described, but poisoning by chloramphenicol is omitted, which in the light of modern experience seems odd. It is surprising to learn that 34% of cases of agranulocytosis due to thiouracil prove fatal, but the surprise becomes less when it is discovered in the next paragraph that the treatment recommended is the administration of sodium pentnucleotide, with no mention of penicillin or blood transfusions.

The descriptions of treatment throughout are insufficiently detailed. For example, the harassed doctor confronted by a case of acute poisoning may not find the laconic statement that "analeptics should be given" very helpful. He might want guidance on dosage and route of administration and might even want to know, if he had not studied the humanities, what an analeptic is.

The considerable expense of American books in this country is often well worth incurring because of the almost invariable excellence of their production and the admirable and up-to-date information which they frequently contain. But it is doubtful if this volume of 524 pages justifies the expenditure of 70s. even by an ardent toxicologist.

D. M. DUNLOP.

BRITISH MEDICAL JOURNAL
LONDON

SATURDAY APRIL 4 1953

QUEEN MARY

Queen Mary, as Queen Consort and Queen Mother, held the affection and respect of the British people in an unusual degree during over forty years of eventful history. This was not because of any superficial glamour or cultivation of the arts and graces of a princess. The head of society for a quarter of a century, she was more like the matron of an ordinary household than a society woman in the usual sense of the term. The public thought of her as a woman of good sense and practical mind, really interested in people and their affairs, and animated by a principle of duty—of duty as the strict mid-Victorians understood it—which, as her son the Duke of Windsor has said, she put before everything else in life.

Those who saw or accompanied Queen Mary on numerous public occasions, on her visits to hospitals, exhibitions, and the like—visits which she continued with great energy into old age—were impressed, sometimes embarrassed, by the thoroughness with which she undertook her task. She made it plain that she was there not to be seen but to see, and she insisted on seeing everything. Her questions, the result of her habit of serious reading, especially of social history, showed that she understood the background. She could certainly be forbidding, and, on occasion, a stickler for etiquette. But that was all part of her rigid schooling and her Hanoverian ancestry. At public ceremonies she had a disconcerting way of departing from schedule. In 1925, on the occasion of the opening of the British Medical Association House in Tavistock Square by George V, the Queen went on by herself ahead of the official procession which was about to leave the Great Hall and found her way into the Hastings Hall, which was untenanted save for one rather frightened junior member of the staff who on her entrance effaced himself behind a pillar. By the time the King and the chief officers of the Association had descended the stairs she had already made a solitary round of the exhibits. It was on her initiative, too, that the royal party on that occasion paid an unexpected visit to the children gathered in the grounds of the Mary Ward Settlement next door. In her visits to hospitals her practical sympathy was shown, not in a few conventional words and a passing smile, but in grave and under-

standing inquiries, followed later in some cases by an appropriate gift or other act of kindness. The great preoccupation of royalty is said to be to avoid the appearance of being bored. Queen Mary had no need to fear lest her countenance betrayed boredom, for her interest was real and sustained.

The first world war gave her the opportunity to demonstrate her practical ability in many directions as the leader of British women in their various endeavours to mitigate suffering. In the seventeen years of reign which followed the Armistice and culminated in the Silver Jubilee—when the public gave a spontaneous manifestation of their feelings towards the King and Queen—her interest in hospitals and nursing was shown on many occasions, notably when she opened the Royal College of Nursing in London, the gift of Lord and Lady Cowdray, in 1926.

During the illnesses of George V the King's doctors and others in court circles remarked on her fortitude and courage and disciplined emotion. She had a never-failing confidence in the medical men who had care of the King—as indeed she had to the end in the doctors of her own household—calmly assuring them that she felt they knew best and protecting them from well-intentioned and fussy interference. She was the ideal “patient's relative.” In the biography of Viscount Dawson of Penn, with whom she was on the friendly terms to which the family doctor is accustomed in any well-conducted household, it is related that Dawson said to his wife on returning from the palace on one occasion, “If only they were all like Queen Mary how much easier it would be.” A story is told of Dawson that during the King's illness in 1928 he wanted more air in the sick-room and suggested that an upper window be lowered and the opening covered with fine moistened muslin. Queen Mary knew at once what was wanted, and took Dawson along corridors and up stairs to a store-room where she asked him to clamber up on a stool and hand down to her a bundle from a high shelf. It proved to be exactly the material needed.

From her own steadfastness and courage in successive bereavements people in all classes of society drew inspiration to sustain them in their own like troubles, and it is a particular grief to the whole nation that she has not lived to see the coronation of her granddaughter, whose reign holds such high promise. Archbishop Lang once told how at the beginning of their reign he accompanied King George V and Queen Mary through an industrial district of South Yorkshire and they overheard one working-man say to another, “He ain't seech a fine man as Teddy” (Edward VII), to which the other replied, “Well, anyway, he's gotten him a fine oop-

standing wife.” It is as a “fine oopstanding” wife, mother, and queen that Queen Mary will be remembered. From the time of her emergence in the public eye as “Princess May,” the bride of 1893, she has strengthened that high standard of family life which in modern times has given the British monarchy, shorn of much of the power and state which it had in the past, an even surer hold on the imagination of the people.

COOLING THE BODY

The physiological changes induced in animals by cooling of the body have interested physiologists for some years, and the importance of these investigations to surgery is referred to by Sir James Learmonth in our opening pages this week. The results of acute hypothermia in dogs were studied by Prec and his colleagues,¹ who caused cooling by means of chipped ice packed round the body. They found that, in the early phases of cooling, thermogenic reflexes produced shivering, which was accompanied by a rise in cardiac output, blood pressure, heart rate, respiration rate, and oxygen consumption. After these reflexes had been inhibited by deep anaesthesia, the effects were reversed if cooling was continued, and there was reduction of the cardiac output, blood pressure, heart rate, respiration rate, and oxygen consumption. Haemoconcentration also occurred, and the electrocardiogram showed an increase in the duration of systole, auriculo-ventricular and intraventricular block, depression of the ST segment, and flattening and inversion of T waves; sometimes ventricular fibrillation occurred. Death appeared to be due to failure of the respiratory and vasomotor centres.

Oxygen transport and consumption were found to be greatly reduced in dogs cooled down to 64.4° F. (18° C.) in a cold room, but no tissue deficit of oxygen resulted, even when they were cooled for as long as four hours, provided full arterial oxygen saturation was maintained by artificial respiration.² Temple Fay³ reported that the rectal temperature in human beings could be lowered to 80° F. (26.7° C.) for many hours without untoward incident, while Talbott,⁴ reviewing the use of hypothermia for the treatment of patients with intractable pain, noted the same cardiovascular changes as those found in animals. It was found possible to lower the general

body temperature to 75° F. (23.9° C.) with subsequent recovery. Auricular fibrillation developed in all cases when the temperature reached 80° F. (26.7° C.), but could be reversed with quinidine, digitalis, and warming up again. The electrocardiogram also showed changes similar to those seen in animals.

Reduced oxygen requirements and lowered metabolism are great advantages when patients with cyanotic congenital heart disease are being operated upon. Especially is this so when they are children, since they can be readily cooled and re-warmed, and tolerate a low temperature far better than a high one. According to Bigler and his colleagues⁵ cooling may be achieved either by packing ice bags round the body or by means of a rubber mattress with water at the desired temperature. The internal temperature of their patients was measured by a rectal thermometer and kept between 94° and 97° F. (34.4° and 36.1° C.). They found that less anaesthetic was required at low temperatures during operations on children with cyanotic congenital heart disease, and that the heart action seemed to be slower and more forceful; the respiration rate was also reduced and fluid loss diminished. In exploratory thoracotomies on such children, in which no procedure to increase the pulmonary blood flow was possible, the mortality was 54% in uncooled cases and 14% in cooled cases. Apart from the fact that cooling reduced the mortality in cases of cyanotic congenital heart disease, Bigler and his associates emphasized its importance in preventing and treating the hyperpyrexia which they observed during operation in 62% of their patients between the ages of 6 months and 13 years, two of whom died as a result of it.

But of even greater interest and importance are the possibilities of intracardiac reconstructive surgery in a relatively bloodless field. At present the cardiac surgeon must confine himself to rapid and “blind” intracardiac manipulation, which limits his scope considerably. To exclude the heart from the circulation for sufficiently long to permit intracardiac procedures under direct vision would be a major advance. It could be accomplished in one of two ways: either some form of artificial circulation could be provided, or the oxygen requirements and metabolism of the tissues could be reduced to a point at which the heart could be excluded from the circulation for the requisite length of time. Bigelow and his colleagues⁶ with this object in view studied the effects of cooling in forty dogs. At 82.4° F. (28° C.) respiration ceased and anaesthesia was no longer required. They noted the same physiological effects as did previous workers, oxygen consumption being reduced to about

¹ *J. clin. Invest.*, 1949, **28**, 293.² Bigelow, W. G., et al., *Amer. J. Physiol.*, 1950, **160**, 125.³ *N.Y. St. J. Med.*, 1940, **40**, 1351.⁴ *New Engl. J. Med.*, 1941, **224**, 281.⁵ *J. 15% of normal, and they found that ventricular fibrillation commonly occurred and caused death at temperatures between 60.8° and 71.6° F. (16° and 22° C.). The central venous pressure showed an initial fall, and then a rise, which was often followed by ventricular fibrillation when the pressure exceeded 6 cm. water. Of great interest was the fact that venesection often caused reversion to sinus rhythm, and was the only measure among many (including mechanical stimulation, massage, and a variety of drugs) which had any effect on the arrhythmia. Other effects of venesection included an increase in heart rate and shortening of the lengthened ST segment of the electrocardiogram.

Boerema and co-workers⁷ maintained dogs at 66.2°–77° F. (19°–25° C.) for periods varying from 20 to 150 minutes. In nineteen dogs the venae cavae and vena azygos were clamped for 10 to 15 minutes and the heart was opened. It was found to be almost bloodless and beating slowly and feebly. An intracardiac operation was performed in eight cases, and in four cases resection of the septum was carried out: two of these animals were alive and well nine months later. In some dogs complete asystole occurred during the period of clamping, but the heart usually began to beat after warmth had been applied. In some cases (the exact number is not given) ventricular fibrillation occurred, and was always fatal. The dogs were slowly warmed again after operation, and many of them developed shock, possibly as a result of peripheral vasodilatation. But shock could be prevented by the intravenous infusion of 5% glucose and of blood. Cookson and others,⁸ conducting similar experiments, noted that after the removal of caval clamps the heart began to beat forcibly and more rapidly, and that in some animals ventricular fibrillation quickly followed. They attributed this to flooding of the heart with a high concentration of adrenaline released from the suprarenal glands as a result of anoxia and dammed back in the caval blood. They were subsequently able to prevent the onset of ventricular fibrillation by means of an adrenolytic drug. Thirty-two dogs were subjected to cardiomy, twenty-seven with caval occlusion for twelve minutes at 78.8° F. (26° C.), of which 80% survived, and five with occlusion for thirty minutes at 62.6° F. (17° C.), of which 40% survived. They attached great importance to the use of digitalis, intravenous glucose, A.C.T.H., adequate ventilation with 100% oxygen, and injection of atropine if marked tachycardia occurred, in addition to measures to maintain blood pressure and to prevent ventricular fibrillation. Delorme⁹ reported survival in dogs after twenty minutes' caval occlusion at 71.6°–78.8° F. (22°–

26° C.) and after other procedures which would have been fatal at normal temperatures.

The work on animals carried out by many investigators indicates that cardiomy under direct vision during hypothermia should be a practical technique applicable to man. Lewis and Taufic,¹⁰ after reporting their ability to make and then close atrial septal defects in dogs under hypothermia, successfully closed an atrioseptal defect in a 5-year-old girl. The patient was anaesthetized and wrapped in refrigerated blankets until, after 130 minutes, her rectal temperature had fallen to 82.4° F. (28° C.). The cardiac inflow was arrested for five and a half minutes, and at the end of the operation, which lasted fifty-eight minutes, the rectal temperature was 78.8° F. (26° C.). Re-warming, and subsequent convalescence, were uneventful.

This technique may pave the way for important new advances in the surgical treatment of congenital heart disease. Of greater significance, however, is the possibility of improving the techniques available for operations on the mitral and aortic valves. For example, the surgical treatment of mitral incompetence is generally conceded to be unsatisfactory, but it might be possible to reconstruct the mitral valve under direct vision, to say nothing of greatly increasing knowledge of the detailed function of the abnormal valve. Clearly there are many problems yet to be solved, the greatest perhaps being the prevention of ventricular fibrillation at low temperatures and on restoration of the venous inflow to the heart, and the comparatively short period available to the surgeon for working inside the heart. The technique should be carried out only in fully equipped centres; accurate estimation of internal temperature must be possible, while continuous electrocardiographic records and measurements of central venous pressure are of great importance. Controlled respiration and administration of 100% oxygen are essential, since spontaneous respiration ceases early in the refrigeration process. Facilities, probably including the use of the electrical defibrillator, must be available for treating ventricular fibrillation if it occurs; venesection and the use of an adrenolytic drug may also be necessary for this. The equipment for producing cooling must not be too cumbersome, must not obstruct the surgeon, and must permit of rapid re-warming. Refrigerated blankets or a rubber mattress filled with cooled water are probably satisfactory. Further reports of the refrigeration technique will be eagerly awaited by cardiologists and cardiac surgeons, many of whom may consider hypothermia to be a valuable alternative to the artificial heart.

THE FATE OF PREMATURE CHILDREN

By international convention an infant is regarded as premature if it weighs 5½ lb. (2.5 kg.) or less at birth. Each year about 40,000 of the infants born in England and Wales fall into this category,¹ and approximately one-quarter of them die before they are a month old. Indeed, nearly half the deaths occurring in this period are associated with prematurity,² and we are only likely to make substantial improvements in neonatal survival if we can reduce the incidence of prematurity and lower the high death rate among those that are prematurely born.

While there are no two opinions about the importance of prematurity as a cause of death, there is no agreement about the fate of those premature children who survive. Some find in prematurity a major source of stunted growth and mental backwardness, whereas others find that premature children are retarded only to the extent that they are born before term. Few would fully agree with Capper's opinion that the premature infant will become "the backward school child, is the potential future psychopathic or neuropathic patient, and even the potential inmate of the home for imbeciles or idiots,"³ or with Sir Robert Hutchison's comment: "I confess I cannot get up much enthusiasm for trying to save these premature arrivals: I have a strong suspicion that, of those who survive, a large proportion turn out defective either physically or mentally or both,"⁴ but the feeling that premature children are likely to remain handicapped is strong. It has been encouraged recently by the discovery that a proportion, perhaps 12%, of the infants weighing 3 lb. (1.4 kg.) or less develop after birth retrolental fibroplasia.^{5,6} This condition is now said to account for more than one-third of blindness in young children in the U.S.A. There is, however, some evidence that its development is related to treatment rather than to prematurity *per se*,⁷ and until more is known about this we should hesitate to include it among the handicaps of prematurity.

it is clearly of importance to know how large a proportion of prematurely born children are mentally or physically retarded in later life and what institutional or other care they need. And the growing interest in this country in the fate of these children makes this a convenient moment to consider why so many careful studies have yielded such inconclusive results. At first sight it would appear simple to take a sample of premature children and trace their health and development in later life; and this is in fact what many have tried to do. There are, however, two major problems to solve before even the most careful study of this type can give meaningful results. First, the children followed up must be either a complete series of prematurely born children or a random sample of such a series of births. Secondly, they must be compared with a suitable group of children born at term. The task of tracing children is no easy one, and few workers have found more than half of those they were looking for.^{8,9,10} Unfortunately it seems that, depending on the channels through which they have had to work, some have traced mainly the abnormal children and others mainly the normal ones. And for this reason alone it is difficult to know what weight to attach to their findings.

Even a perfect sample of prematurely born children would be of little value unless their growth and development could be compared with a similar group of children born at term. This has not always been recognized, and many have been content to compare their figures with national averages often obtained many years earlier from highly selected groups and by methods differing widely from those used in their own inquiries.^{11,12} But even a control sample drawn from a contemporary population^{13,14} fails to meet the needs of the case. Douglas and Mogford remark that premature children tend to be firstborn, to come from poorer families, and to have mothers above the average age for child-bearing; therefore they should be compared with controls chosen to conform to this pattern, otherwise comparison will be difficult. For example, it is often stated that premature infants are particularly likely to suffer from lower respiratory infections, but it has not been established whether this is owing to their prematurity or to their being drawn from the poorest homes. Some, realizing this difficulty, have hoped to eliminate the effects of environment by comparing premature children with their sibs.¹⁵ But this method also is unsatisfactory, for, except with twins, the sibs will have been exposed to very different risks of infection; for example, the history of infection of a firstborn child is likely to be very different from that of his later-born brothers and sisters. Moreover, comparisons of growth and health

are valid only if they are made between children of the same age. Accordingly, when sibs are used as controls the real comparisons will be between children of like age drawn from different families and not between premature children and their own brothers and sisters.

Another approach to the problem is to find out what proportion of children in special schools and institutions of one kind or another were prematurely born.^{16 17} But here again there are difficulties of interpretation. It is still necessary to make allowances for the selective factors in prematurity which have already been mentioned. For example, the generally poorer social level of children of low birth weight might explain part at least of the excess of these children found by Asher and Fraser Roberts¹⁷ among the feeble-minded and borderline defectives.

There is no reason why the handicaps of prematurely born children should not be accurately known, though it is unlikely that the answer will come from studies based on the highly selected child populations of maternity hospitals or special premature baby units. A new approach to the problem has been made by the Joint Committee of the Institute of Child Health (University of London), the Society of Medical Officers of Health, and the Population Investigation Committee, which, with the help of health departments throughout the country, has been following for the last six years all premature children born during a single week in 1946 in England, Wales, and Scotland. Douglas and Mogford's paper presents the results of part of this research. They have been able to compare 676 premature children during the first four and a half years of their lives with the same number of children born at term, matched for sex, social class, and order of birth. Many questions which have been in doubt can now be answered with greater certainty. For instance, the higher mortality among premature children extends beyond the first month of life: up to the age of 4½ years these children appear to run a greater risk of dying from lower respiratory infections, congenital defects, and nephritis. In this series 91 premature children and 64 controls were admitted to hospital at least once during the first four and a half years of their lives. On an average premature children spent three and a half times as many days in hospital during the first two years of their lives as did the controls: in the third and fourth years, however, there was no difference in the time spent in hospital by premature and full-term children. It is clear that the greater morbidity (mainly upper and lower respiratory infections) among premature children is not confined only to those from poor homes.

Owing to the complexity of the causes that may lead to the birth of under-weight children a much larger investigation than this excellent preliminary study of the joint committee is still needed. The Ministry of Health during recent years has shown an increasing interest in the survival of premature children, and it is to be hoped that in the future this interest will be extended to the fate of those who survive.

PRESCRIBING HABITS

The cost of the general pharmaceutical services in Great Britain is approximately £50m. a year, and it is clearly the duty of the medical profession carefully to examine how this large sum is spent. In a paper published in this *Journal* about a year ago Dunlop, Henderson, and Inch¹ analysed 17,307 prescriptions on E.C.10 forms completed during the month of September, 1949, and coming from three different areas in England. Several unexpected facts emerged from their investigation. It appeared that about one-third of all preparations used were sedatives, stomachics, and tonics, and that 21% of all prescriptions were for proprietary drugs. Some drugs which are widely used in hospital practice, such as mersalyl and thiouracil, were very seldom prescribed in general practice. This paper was widely discussed in our correspondence columns, and general practitioners were able to explain some of the curious facts brought out by the survey.

Professor Dunlop and his collaborators have now carried out a more extensive investigation of prescribing, having planned it so as to meet some of the criticisms of the first paper, and their report was published in last week's *Journal* (p. 694). The month of October, 1951, was selected for intensive study, and it seems unlikely that the pattern of prescribing has altered much during the last eighteen months, for the introduction of the shilling charge has not reduced the total cost of the pharmaceutical service as much as was expected.² The month of October was chosen fortuitously, but for some unexplained reason it so happened that more scripts were issued during October than during any other month in the last half of 1951: this fact was taken into account by Professor Dunlop when making general deductions.

The new survey was limited to Scotland: this had the advantage of providing evidence about methods of prescribing in one large section of Great Britain representative of all types of general practice. The results of the investigation, however, are not strictly comparable with those of the earlier one, for differences in prescribing habits might have arisen in the two-year interval between them or there might be differences between Scottish and English prescribing. Thus the proportion of proprietary preparations (30%) is higher than the corresponding figure (21%) for the previous

¹ *British Medical Journal*, 1952, 1, 292.

² See leading article in *British Medical Journal*, 1953, 1, 716.

³ *British Medical Journal*, 1952, 1, 149.

⁴ *British Medical Journal Supplement*, 1952, 1, 50.

survey, and this probably reflects a universal trend in Great Britain. In general, however, the relative frequency with which drugs are ordered is remarkably similar. As Dunlop and his colleagues found in the previous investigation, most drugs are given as mixtures or tablets; powders and injections are little used. About 10% of all prescriptions are for barbiturates, and mild analgesics were prescribed almost as often. Bromides were much less used than in England—which reflects credit on the teaching of pharmacology in the Scottish schools. More than half of all prescriptions are for symptomatic remedies unlikely to affect underlying disease processes. At a conservative estimate the United Kingdom spends through the National Health Service alone £2m. on vitamin preparations. It can hardly be doubted that large quantities of drugs are being prescribed as placebos, which of course may often be justified. But, as we have already pointed out,³ quite apart from the expense, placebos may do actual harm to the patient whose symptoms are associated with anxiety or fear.

Surprising differences exist in prescribing between different parts of England. For example, in each of the last three months of 1950 the average cost of prescriptions per person in Chester was consistently more than twice what it was in Huntingdonshire.⁴ Professor Dunlop and his colleagues have been able to shed some light on these differences. Thus there is a close relationship between three factors—the number of scripts issued per unit of population, the population density, and the average size of the doctor's list. Many more prescriptions are issued in densely populated areas, perhaps because of the greater incidence of disease or the easier availability of the doctor. But another possible explanation might be a greater tendency for workers in an industrial area to report sick and the likelihood that an overworked practitioner will give medicine rather than advice. Further studies of prescribing in different areas should provide answers to some of these questions.

LIVER INJURY BY ANTIBIOTICS

The antibiotics in common use have become popular because they combine a high degree of activity against infecting organisms with low toxicity to the host tissues. But the occasional fatality attributed to their use emphasizes that their low toxicity is relative, and excessive dosage or unusual susceptibility may have unpleasant consequences. Aplastic anaemia resulting from chloramphenicol, although rare, has received wide publicity. Less widely known are some of the hazards of therapy with aureomycin and terramycin.

In their early trials with aureomycin Lepper and his associates¹ were impressed by the evidence of liver damage caused by the combination of oral with intravenous administration. Of eighty-nine cases treated exclusively by the oral route, none showed clinical evidence of hepatic dysfunction, but seven of the fourteen cases in which oral therapy was supplemented by intravenous injections six-hourly of 8 mg. per kg. body

weight or more showed definite clinical signs of liver damage. It was confirmed in one case by biopsy and in five by necropsy. The clinical features were usually hepatomegaly and jaundice, and the morphological change in each case was severe cytoplasmic vacuolation and fragmentation. Since all the cases in this series which showed liver damage were seriously ill before receiving aureomycin, it may reasonably be objected that the hepatic damage resulted from the primary illness and occurred despite the antibiotic therapy. To eliminate this possibility, Lepper and his colleagues² studied the effect of heavy doses of aureomycin in experimental animals. In a large series of mice, changes virtually identical with those in the human cases were caused by parenteral administration of large doses of either aureomycin or terramycin. Only insignificant changes occurred with comparable doses of chloramphenicol, or when the other antibiotics were administered orally.

Further evidence of damage to the liver by intravenous aureomycin in man has recently been presented by Rutenburg and Pinkes.³ They too were impressed by the frequency of hepatomegaly and jaundice, but as in most of their eighty-nine cases, none of whom showed any evidence of disease that might have caused impaired liver function, the drug was given post-operatively for prophylactic purposes, the correlation between the development of liver damage and the exhibition of aureomycin is more convincing than in the series of Lepper and his colleagues.¹ Thirty developed hyperbilirubinaemia three to seven days after operation: in fourteen the serum bilirubin exceeded 2 mg. per 100 ml., and in fifteen clinical jaundice was present. In all cases the values returned to normal within a few days of discontinuing the drug. It has been shown, however, that moderate hepatic injury and dysfunction is common after operations of many kinds, quite independently of antibiotic therapy.⁴ To exclude this possible complication, Rutenburg and Pinkes studied twenty selected patients with no evidence of cardiovascular, renal, or hepatic disease, each of whom received 500 mg. of aureomycin intravenously twice daily for three consecutive days. Serial estimations of serum bilirubin, cephalin flocculation, and bromsulphthalein retention were made in several of these cases before, during, and after the three days of therapy. Nine of these selected patients developed transient hyperbilirubinaemia, and four of the seven tested showed abnormal retention of bromsulphthalein.

This evidence from human and animal studies shows that aureomycin, and probably terramycin, are mildly injurious to the liver when given in large doses, especially parenterally. Even more remarkable perhaps is the absence of such toxicity when these substances are given orally in the usual dosage. In very severe cases of infection the greater antibacterial effect of large doses and intravenous administration must be weighed against the small but real risk of damaging the liver.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

PROLAPSE

BY

A. J. WRIGLEY, M.D., F.R.C.S., F.R.C.O.G.

Obstetric Physician and Lecturer in Midwifery and Diseases of Women, St. Thomas's Hospital, London

Prolapse signifies the descent through the vaginal orifice of any structure lying immediately above the pelvic floor. Thus the term may imply descent, singly or in combination, of the uterus, bladder and urethra, anterior wall of the rectum, or pouch of Douglas. Prolapse is usually found in parous women, and therefore it is assumed that weakening of the pelvic floor muscles and fascia and damage to the transverse cervical ligaments are produced by the birth of a baby. Prolapse is rarely seen in nulliparous women; when this does occur it may be associated with a general weakness on the part of the patient as the result of overenthusiastic fasting, or with some lesion in the central nervous system, usually in the lower part of the spinal cord. Prolapse to the laity means descent of the womb, and this may explain the general expectation, which is present even with a few doctors, that its logical treatment is the removal of this offending organ.

Symptoms and Signs

Nearly all women who suffer from prolapse notice the same symptom and phrase their complaint in the words that they "feel something coming down." It is as rare to find prolapse without this symptom as it is to hear of the symptom and discover no prolapse. Concurrently the patient may state that she easily tires and that she has acquired a low backache that becomes progressively more pronounced as the day wears on and is relieved immediately she lies down. Difficulties with micturition may or may not be present. Quite often a patient in whom there exists a large cystocele states that micturition is normal, whereas another with relatively slight descent of the bladder and urethra may be greatly troubled with stress incontinence of urine or frequency of micturition. Occasionally the patient discovers that emptying of the bladder can be completed only by the digital reduction of a large cystocele. A similar trouble with defaecation is dealt with in a like manner in the case of a large rectocele. When a severe degree of prolapse occurs, the patient's discomfort is great, and it is rare for complete procidentia to be tolerated for any length of time.

Although prolapse may occur directly after childbirth, in the majority of patients it develops at about the time of the menopause. This may be due to a general diminution in muscle tone at about this time in a woman's life or to a considerable increase in weight. Rarely, prolapse is suddenly produced following some severe and perhaps unexpected muscular effort such as the lifting of a heavy weight or an attempt to recover from a slip or fall. Prolapse always becomes worse if the patient becomes pregnant.

The diagnosis of prolapse is easy. The patient should be examined lying on her back with the knees drawn up and well separated. She is then asked to give a violent cough or to bear down hard. Prolapse will then be visible, and it will be possible to discover its exact nature and extent. A faulty diagnosis is rarely made either by the patient or by her doctor. Very occasionally a cyst beneath the anterior vaginal wall suggests a cystocele, or a fibroid polyp may simulate uterine descent.

Prevention

Theoretically it should be possible to do much to prevent prolapse, and, indeed, over the last two or three decades

much has been tried. It must be noted, however, that in spite of conscientious painstaking work on the part of the doctor and midwife, and the enthusiastic co-operation of the patient, the condition seems to be as commonly seen as ever it was. Prenatal physiotherapy by education in muscular relaxation and contraction, the prevention of any expulsive efforts during the first stage of labour, the use of the forceps only during the second stage of labour, and renewed physiotherapy after delivery directed toward re-education of the pelvic floor muscles might with reason have been expected to produce good results. There is no evidence that this is so. Those who advocate that early rising after childbirth will lessen the likelihood of prolapse argue with others who believe that the uterine supports will function better if they are allowed a few days' rest and peace and quiet in which to recover. Of all these various methods, the art of midwifery in the conduct of the actual labour is undoubtedly by far the most important.

Treatment of Prolapse

Unless contraindicated, the treatment of prolapse is by operation. Operation is contraindicated if the condition of the patient is such as to make its performance dangerous. It is not advised if the patient is advanced in years, though recent advances in methods of anaesthesia and improved surgical technique have greatly extended the age of safety. Each patient will be judged individually. Operation is not advised if the patient suffers from some chronic illness, and especially if, following a pelvic floor repair, she is likely to be affected by a persistent or troublesome cough. Operation would not be advised if the prolapse was noticed directly after childbirth, for a considerable degree of improvement should be expected in the course of normal involution aided by symptomatic treatment. Operation would not be advised if the patient was young and intended to become pregnant, and never, of course, during pregnancy. A severe degree of prolapse, however, in a woman in the child-bearing period of her life merits operative repair: such an operation is no contraindication to further pregnancy or to the expectation subsequently of a normal delivery. A recurrence of the prolapse in such a patient is very far from inevitable, and the small risk of such a recurrence is justified because the operative safety of a further pelvic floor repair is very much greater than that of caesarean section, which is the only method of avoiding the risk.

Palliative Treatment

This treatment is now reserved for those patients in whom any operative procedure is inadvisable or who refuse operation. A quarter of a century ago many more patients suffering from prolapse were treated palliatively, and operation was often reserved for those few in whom palliative treatment for some reason was ineffective. The change of outlook that has occurred is probably due to the appreciation by doctors and by their patients of the great benefits that follow a correctly performed pelvic floor repair.

Palliative treatment consists in the insertion into the vagina of a ring pessary of such a size that it is larger than the hernial orifice through which the prolapse occurs. The pessary is usually circular and may be made of rubber or of vulcanite. The rubber pessary is usually employed because it is more easily inserted and removed. Rubber is

much more irritant to the tissues of the vaginal wall than vulcanite, and is therefore more likely to produce an offensive purulent discharge. The correct size of pessary to be used in any particular patient can be determined only by trial and error. It is usually advised that the smallest pessary should be inserted which appears to control the prolapse. Such advice inevitably leads to many errors and many trials, and it is much better in the first instance to insert the largest pessary of whose presence the patient is not aware. The patient who for the first time has been so treated for prolapse must be instructed upon the necessity of regular douching to try to prevent infection, and of regular visits to her doctor or nurse for the removal and cleaning, or changing, of her pessary. Most women hate a pessary life, and with good reason.

Operative Treatment

Many and varied have been the operative procedures suggested for the cure of prolapse. Only one has stood the test of time, and that is the operation first evolved at the beginning of the century by the surgeons in Manchester, notable among whom were Donald and Fothergill. The various parts of this operation are designated anterior colporrhaphy, amputation of the cervix, posterior colporrhaphy, and perineorrhaphy. The use of the word colporrhaphy is unfortunate because it implies the use of the vaginal wall in the cure of the condition. The part played by the vaginal wall is exactly analogous to that of the skin overlying the umbilical hernia. It becomes stretched by the hernial protrusion and redundant skin has to be removed. The essential procedure consists in an exposure of the separated inner margins of the two levatores ani muscles with their adjacent fibromuscular fascia. This necessitates dissection beneath the anterior and posterior vaginal walls and exposure of the transverse cervical ligaments by amputation of the cervix. Thus the reconstruction of the pelvic floor and of the perineum is performed. There is no necessity to open the abdomen. Vaginal hysterectomy can be combined with pelvic floor repair and is especially indicated in the presence of some pathological condition of the uterus. It is undoubtedly a more severe proceeding, but the results are excellent.

Aftercare

The care of a patient on whom the Manchester operation has been performed may be divided into the initial period of her stay in hospital and the following two months when she is at home. In the latter period she will certainly be in the hands of her family doctor, and very often, especially in the smaller hospitals, he is also responsible during the first three weeks. For this reason a brief account will be given of the management of these patients until they are well enough to go home. The operation is followed by a definite, and sometimes considerable, amount of pain and discomfort, and morphine should not be withheld during the first 24-36 hours. Thereafter tab. codein. co. or its equivalent should be sufficient. The patient may be returned to the ward with a self-retaining catheter inserted into the bladder. This should be released by the nursing staff at regular intervals and is usually removed on the third or fourth day. By this time much of the initial and local discomfort will have abated and the patient in consequence is far less likely to have difficulty in micturition. If she is able to pass her water naturally the nursing staff must be instructed to pass a catheter regularly on at least two occasions in each 24 hours after the patient has passed water, in order to discover the presence of, and to remove, any residual urine. When by this means less than 2 oz. (60 ml.) is found to remain in the bladder, catheterization may be discontinued. Cystitis is a frequent and troublesome complication of any pelvic operation. The belief that it is most likely to result from repeated catheterization is probably incorrect. A far more probable explanation is that it is due to temporary imperfect emptying of the bladder and

the infection of a considerable quantity of unsuspected residual and stagnant urine. The routine administration of urinary antiseptics should be left to the discretion of the doctor in charge of the case. Aperients should be ordered as soon as the patient has recovered from the immediate ill-effects of the operation. There is no need to purge the patient, nor is it necessary to order an enema. The Manchester operation is not a dangerous proceeding, but one of the few alarming complications is due to occasional phlebo-thrombosis or even thrombophlebitis. Instruction in post-operative deep breathing exercises and early movements on the part of the patient is of great and proved importance in its prevention. Indeed, no harm seems to result from early ambulation, though this must not prejudice the patient's stay in hospital, which should be from two to three weeks, depending upon the severity and extent of the operative repair. Reactionary bleeding is rare, but secondary haemorrhage following amputation of the cervix does occasionally occur at about the end of the first week. It may be severe and even dangerous. An initial injection of morphine $\frac{1}{2}$ gr. (16 mg.) should be given. The patient should be turned on to her left side into the Sims position and a Sims speculum gently inserted into the vagina. A good light is essential. With dry gauze and a pair of dissecting forceps all blood and clot is removed, and the vagina should be carefully, systematically, and firmly packed with dry sterile gauze. In nearly every case this will deal with the condition and no further bleeding occurs after the removal of the gauze plug at the end of 24 hours. Very occasionally, and if the blood soaks past the gauze, it is necessary to take the patient back to the operating theatre and to deal with the bleeding point or area by the insertion of a catgut stitch. The wounds in the anterior and posterior walls of the vagina and in the vaginal vault rarely heal entirely by first intention, and in consequence many patients following a Manchester repair operation acquire for a few days a noticeable and offensive vaginal discharge. When, and if, this occurs the patient should be ordered a twice daily vaginal irrigation with a dilute solution of some non-irritant antiseptic given at body temperature. A solid douche nozzle must not be used, but the fluid should be run into the vagina through the largest size of rubber catheter. Before the patient leaves hospital a digital examination of the vagina must be made. Occasionally the wound on the anterior wall becomes adherent to the wound on the posterior wall. Two or three weeks after the operation the adhesions will be slight and easily separated by the examining finger.

On return home the patient should be told to use her common sense. Prolonged periods of standing, lifting of heavy weights, straining at stool, and similar exertions will all tend to stretch an insecure wound and to undo the repair. Her return to normal activities should be gradual and she should be able to lead a full and normal life once more about three months from the time of her operation. A final examination made about this time is most advisable in every case, and not until then should a return to married life be contemplated.

Conclusion

Prolapse nearly always occurs in women who have borne children, and often first becomes troublesome about the time of the menopause.

The treatment of prolapse is by operative repair unless contraindications exist. The contraindications to the operation are obvious.

The success of the repair operation depends not only on the surgeon but also on all those who take part in the aftercare of the patient up to the end of the third month.

QUEEN MARY WITH KING GEORGE V AT THE OPENING OF B.M.A. HOUSE, JULY 13, 1925

Escorting the King and Queen are (right) Mr. Basil Hall, President, and Dr. (later Sir) Robert Bolam, Chairman of Council.

Correspondence

Treatment of Ringworm of the Scalp

SIR,—Dr. Bernard A. Thomas (*Journal*, March 7, p. 536) propounds the interesting thesis that cases of tinea tonsurans caused by *Microsporum canis* need neither be treated by x-ray epilation nor be kept from school. Our experience at Goldie Leigh Hospital does not support the former in its entirety. Some cases of infection with *M. canis* are sufficiently persistent to warrant epilation.

I am, however, greatly concerned at two statements in his paper. He states that "in common with others treating ringworm of the scalp" he has had "an occasional case of incomplete regrowth of hair." I had hoped that this unhappy sequela did not occur in these days of precision apparatus. At Goldie Leigh Hospital, in a series of more than 4,300 cases treated during the last thirty years, the last case of incomplete regrowth happened in 1927. This occurred in the bad old days of coil sets, mercury interupters, and Sabouraud pastilles, and since that date in 2,700 epilations I have not had a single case. With modern apparatus and technique properly calibrated by a hospital physicist, overdoses sufficient to cause impaired regrowth should not occur. Indeed, the child's scalp is remarkably

tolerant in this respect. I have seen a child receive two full epilation doses at one week's interval without any permanent damage resulting.

Dr. Thomas also states that "occasionally an anaesthetic had been necessary in toddlers." An anaesthetic is never necessary in toddlers or in other patients. In 1924, and again in 1931¹ and 1944, I described a simple restraining-couch (made by the hospital carpenter for £5) with which it is possible to keep children still during irradiation. It has been used at Goldie Leigh Hospital in over 2,000 cases, including imbeciles up to 15 years of age, and has not yet been found wanting.—I am, etc.,

S. COCHRANE SHANKS.

REFERENCE

¹ Shanks, S. Cochrane, *Brit. J. Derm.*, 1931, 43, 477.

SIR,—I refer to Dr. B. A. Thomas's article on *M. canis* ringworm and loss of schooling (*Journal*, March 7, p. 536). Dr. Thomas states that *M. canis* ringworm of the scalp need never be treated by x-ray therapy because local applications are effective in all cases, and that there is no valid reason for excluding such cases from school. I would disagree with both conclusions. Most authorities agree that topical treatment may prove inadequate in some cases of *M. canis* ringworm. Accordingly, if the lesion is of a non-inflammatory type (and many cases of *M. canis* infec-

tion are non-inflammatory) x-ray epilation is clearly indicated regardless of the particular species of fungus isolated, since in skilled hands it provides the most certain cure within the shortest time.

So far as appears from Dr. Thomas's article, no Wood light examinations of the school groups at risk were carried out, and therefore the possibility of child-to-child transmission cannot be entirely eliminated. The time lapses between the diagnosis of infection in Cases 15, 19, and 25 (attending the same school) in particular are insufficient in themselves as evidence that child-to-child propagation did not in fact occur; in this connexion it should be born in mind that fallen infected hairs may remain contagious for long periods. "Boys will be boys," and the instruction to apply a fungicidal ointment daily and to wear a linen cap constantly would seem to be a fragile therapeutic barrier to place between the infected and the healthy child.

It is to be hoped that education authorities in general will continue to exclude all types of scalp ringworm from school.—I am, etc.,

Treatment of Perforated Peptic Ulcer

SIR,—Dr. Avery Jones and his colleagues (*Journal*, January 17, p. 122) are to be congratulated on their continued follow-up and research on the surgical treatment of perforated peptic ulcer. It is of great interest to me to find that the overall mortality in all their cases is 7.9%, while the mortality in the "operable cases" is 3.3%. These figures are the best results achieved by a method that has been established for 50 years. They are identical with the first results of treatment of the same groups of cases by the regime of continuous gastric aspiration, collected from different hospitals in England, France, and America and published in the *Lancet* (1951, 1, 7). Clearly the method of gastric aspiration can achieve all that can be obtained by the method of surgical closure, but with the not inconsiderable advantages of avoiding an operation. Recurrence of symptoms seems to be about the same with both methods.

There is no doubt, however, that in the patient with a long-standing history of ulcer immediate partial gastrectomy is the treatment of choice if conditions permit. At King George Hospital, however, we are continuing to use the aspiration method wherever possible in order to achieve results beyond statistical criticism. I feel sure that the future regime for the management of perforated ulcer will be the immediate emptying of the stomach when the patient arrives at hospital and the institution of continuous gastric aspiration. In suitable cases where a chronic ulcer has finally perforated, immediate partial gastrectomy is indicated. In all other cases treatment by gastric aspiration should be continued except in air-swallowers, in whom surgical closure of the perforation may be called for. The routine practice of simple closure has an honoured place in surgical history, but modern developments have rendered it obsolete.—I am, etc.,

HERMON TAYLOR.

Dogs and Disease

SIR,—In "Medical Notes in Parliament" (February 14, p. 409) you state that, in answer to a question by Sir William Darling on February 5, Miss Pat Hornsby-Smith replied that "the Minister of Health was advised that there was little evidence that domestic dogs were commonly responsible for any human disease in this country." Has not the Minister been incorrectly advised? Surely dogs are almost invariably responsible for at least one disease in this country.

Cases of hydatid disease are not infrequent in South Wales, and dogs are definitive hosts in the life-cycle of *Taenia echinococcus*. They have also been shown to be one of the sources of infection of the relatively common *Taenia mediocanellata* (Paterson).¹ One hundred and forty-four cases of hydatid disease were admitted to hospitals in Wales during the years 1927–36. The minority came from agrarian

areas, 62% being from the industrial counties of Glamorgan and Monmouth, and it is probable that in these cases infection in the main occurred directly from dogs (Howell).² A series reviewed recently consisted of 71 patients suffering from pulmonary hydatid disease and treated between 1938 and 1952: in 90% the disease had been contracted in the British Isles (Barrett and Thomas),³ and it is probable that pulmonary infection forms only 10–16% of cases of hydatid disease (Dew).⁴ For a demonstration last year, my friend Mr. I. F. Barwell-Clarke had little difficulty in collecting a dozen specimen organs recently affected by hydatid disease. Deaths from hydatid disease from 1931–5 (inclusive) were England 103, Scotland 2, Wales 35 (Wolfe).⁵ The Registrar-General's statistical reports for England and Wales show an average of 17 deaths a year for the last 10 years reviewed.

In Iceland, under the Health Act of 1924, district councils are allowed to forbid the keeping of dogs in large towns. There are now no pet dogs in Reykjavik (Jonsson).⁶ An infestation which in the middle of the last century affected between one-fifth and one-sixth of the population has probably been completely eliminated (Gerault, Hjalalin).⁷

Our city parks are playgrounds for infants. They also serve as excretory areas for many dogs. Though regulations have been made regarding the disposal of offal in abattoirs, little effort seems to have been made to inform the public of the disease, the dangers of contact between children and pet dogs, the need for protective fencing of vegetable gardens and allotments, and the necessity for prompt detection and treatment of cestode disease in dogs. The appalling complacency amongst dog-owners regarding worm infestation is not surprising. As a father not long ago said in this hospital regarding his daughter of 8 years, "She loves dogs and spends much of the day with them." Her cerebral symptoms were found to be due to an intracranial hydatid cyst the size of a golf-ball.—I am, etc.,

Cardiff.

Counting High Pulse Rates

SIR,—Professor Crichton Bramwell's valuable article on tachycardia (February 28, p. 500) prompts me to mention a technique for counting very high pulse and heart rates, for which, of course, I claim no originality. It does not, however, appear to be sufficiently widely known to practitioners, house-officers, and nursing staff. The method is very simple. The watch is disengaged from the wrist or pocket and placed on the bed in a position of good visibility. One hand holds the pulse or the stethoscope, the rate is counted in tens, and the fingers of the free hand are used to add up the series of tens. There is no question that this greatly facilitates counting accurately at high rates.—I am, etc.,

London, N.21.

E. MONTUSCHI.

Mental Hospital Service

SIR,—Drs. R. A. Sandison and A. M. Spencer (March 7, p. 560) rightly plead for a reorganization of the mental hospital service to meet the problem of overcrowding, but the suggestions they offer for improving the present state of affairs are such as to invite challenge. Particularly unacceptable is their statement that "occupational therapy should be developed towards providing active rehabilitation for acute and recent cases rather than for providing occupation for chronic patients." The implied suggestion is that occupation for chronic patients is hardly to be regarded as a

treatment, and that all skilled staff should concentrate their energies on acute, and presumably recoverable, cases.

Again, by the use of the phrase "interesting and recoverable" the writers seem to suggest a lack of interest in the incurable patient. Such an outlook appears to be increasing among present-day mental hospital psychiatrists, and as a consequence juniors regard the acute case as one surrounded by therapeutic glamour and the chronic case as a chore. The result of this attitude is that the poor chronic patient tends to be more and more deprived of the occupational facilities which constitute his only defence against total social rejection. More and more paid staff replace him in the utility departments of the hospital. More and more lay administrators point with pride to the economic efficiency of departments now as compared to the "bad" old days when they were operated with patient labour.

I therefore submit that both patients and the public would be grateful to the psychiatrist if he were to revive his traditional, but now almost moribund, interest in the chronic patient. Instead of appealing to the Minister to dip heavily into the public purse, we mental hospital psychiatrists should set about organizing our vast armies of idle chronic patients to build their own workshops, and to put to collective use their many already acquired trades and skills.—I am, etc.,

Shenley, Herts

OTHO FITZGERALD.

The Metric System

SIR,—The advantages of the metric system are international usage and suitability for scientific work. These are good things to our profession. But the main body of medical men are tied to one locality and are engaged in practical work with patients. They are dependent for the administration and supply of medicines on nurses and dispensers, or their assistants, all of whom, even the doctors, are much more familiar with the old British system than with the metric. The confusion of a change might so easily prove fatal. In the meantime any journal which caters for both scientific and practical aspects, and has some international circulation, does well to foster both systems.

There are some who would abolish one system. In spite of some anomalies and queer terms which are falling out of use, the Imperial and apothecary systems are adapted to everyday requirements and not basically to scientific niceties. It is only to be expected that pharmacologists and scientific committees should advocate the metric system, but it has some serious practical drawbacks and medicine cannot be altogether a pure science. Apart from the risk of error by a mere shift of a point, the only factors of 10 are 2 and 5. Most practical systems cater conveniently for common fractions. It is a pity that the mathematicians who introduced the metric system did not have polydactyly and thus base their system on 12 instead of 10. Such a duodecimal system might then have grown up scientifically and yet have been accepted for everyday use. It has 2, 3, 4, and 6 as factors, is used already in our measure of distance and money, and comes into the universal measurement of time and angles. Hitler attempted to decimalize the last of these, but he failed. However, the time for such an innovation has passed. Mathematicians now go in for a binary system to suit the electronic calculating machines, and it is probable that the brain works on a similar basis as a yes-no problem in several steps.

Both a scientific and a practical system are desirable. It is rather similar to Latin surviving as an international language until comparatively recently, while Italian came to be used in its country of origin. However the controversy goes, I shall continue to use the metric system for my scientific work and to prescribe opiates in vulgar fractions of a grain.—I am, etc.,

London, N.W.2.

JOHN PRIMROSE.

SIR,—My few remarks on this subject (February 21, p. 450) seem to have aroused a good deal of criticism, mainly of an adverse nature. While fully realizing the theoretical advantages of changing over to the metric system,

I was only trying to point out the difficulties that would arise in practice, and even in medicine the old adage still holds good: "14.18 grammes (grams, gm., g., or G.) of practice are worth 0.454 kg. of theory."

Before embarking on a revolution of this magnitude, it seems prudent to consider the history of any similar project which has been actually launched within living memory. and I think that the closest analogy occurs in the attempt to introduce the new terminology into anatomy. It was said at the time by the promoters of this scheme that the new system was scientific and that all errors would be avoided, as the impeccable Latin used was an international language. There is no need to discourse on the confusion which actually resulted, and which indeed still exists after some 20 years. The chief good which accrued was to unexpected people, such as scientific publishers and examination candidates. For instance, in a surgical anatomy viva, a student when asked about a structure of which he is totally ignorant can always say in a rather patronizing voice: "I am sorry, Sir, but it is not called that now." There is always a chance that the eminent surgeon then becomes so confused that he may turn to another subject altogether. Is it improbable that worse muddles would occur on and after the "appointed day" for the metric system?

I am sorry that Mr. A. L. Bacharach (March 14, p. 619) should think that my letter was not meant to be taken seriously. This so affected me that I have been running a temperature of over 36.5° C. ever since, and my feelings can only be expressed by the dire threat of the Victorian father: "Beware lest I thrash you to within 2.54 cm. (approx.) of your life."—I am, etc.,

London, E.C.1.

C. LANGTON HEWER.

Export of Antibiotics to China

SIR,—The letter of Drs. Richard Doll, D. G. Leys, and Douglas McClean, and Professor L. S. Penrose (March 7, p. 563) on the export of antibiotics to China is interesting. It is difficult to imagine on what grounds the sending of British streptomycin to China should be prohibited and other important drugs restricted, especially when we apparently have freely available stocks in this country.

Looked at politically or economically, this action seems foolish; medically it is unethical. I would urge second thoughts. In this country we treat laughingly the epithets applied to us from some countries in the East. It would be a pity if we ever came to deserve them.—I am, etc.,

London, W.5.

N. F. COGHILL.

General Peritonitis and Appendicectomy

SIR,—Mr. N. N. Iovetz-Tereschenko (February 21, p. 454), under the heading "Abuse of Antibiotics" and referring to a letter by Mr. Norman C. Lake (December 13, 1952, p. 1307), states: "Drainage alone in a case of perforation of the appendix is permissible only when a localized abscess is present. In a case in which generalized peritonitis is diagnosed at or before operation the appendix must be removed . . . the actual removal of the offending appendix is absolutely essential to prevent the continuation of infection of the peritoneum."

This is a sweeping statement and, we believe, dangerous teaching, especially when directed to inexperienced operators. About 300 cases of acute appendicitis in children come under our care each year; 25% of these cases have spreading or generalized peritonitis. There has been no mortality during the last two years. When an appendix can be removed without much difficulty this is done, but no determined effort is made to remove an adherent appendix when generalized peritonitis is present. Pre-operatively, rigidity and distension make determination of the position of the appendix difficult or impossible, and these patients are poor subjects for second incisions, widely enlarged incisions, packing off of inflamed small intestine, and retraction. The removal of an adherent appendix, however skillfully performed, may involve opening up tissue planes and

may well leave an oozing surface, an ideal culture medium and area for absorption of toxins. Some of our worst cases of generalized peritonitis result from rupture of an appendix abscess; appendicectomy in these cases would surely be the height of folly.

In the pre-sulphonamide and pre-antibiotic era, when open ether was almost routine for emergency surgery in children, one of us saw many cases of appendix peritonitis with distended and drumlike abdomens. A small incision made with local anaesthesia released pints of pus; apart from inserting a small tube, nothing further was done. Some of these children died, but many recovered. We believe that more extensive surgery would have resulted in a mortality approaching 100%. By the time generalized peritonitis has occurred the appendix distal to the obstruction is often empty, or at least no longer under tension—that is, in many cases a perforated appendix will do so much and no more harm; this is confirmed by the appearance of appendices removed at a later date.

The correct treatment of appendicitis in all its aspects is the most important subject in general surgery, because appendicitis is the commonest condition calling for emergency operation and because, by and large, it affects the young and able-bodied. In deciding to leave an appendix in or to go on and take it out the general condition of the patient and the quality of the anaesthetic, as well as the ease or difficulty of the operation, require consideration. Good judgment is acquired only with experience, and, on the whole, cases of appendicitis are treated by comparatively inexperienced operators.

While all surgeons will probably agree that a perforated, and more especially a gangrenous, appendix is better removed in a case of generalized peritonitis, no firm dictum should be made. Advice, if it may be offered, should be: "When in doubt or difficulty, leave the appendix in.—We are, etc.,

ISABELLA FORSHALL.

A Continuous-feed Aneurysm Needle

SIR,—Since my brief description of the continuous-feed aneurysm needle (*Journal*, November 29, 1952, p. 1201) a number of inquiries have been received from surgeons wishing to know from whom this instrument might be obtained. I should be most grateful if you could publish this letter to let it be known that Messrs. Thackray, of Leeds, have undertaken manufacture of the instrument and are now able to supply it on order.—I am, etc.,

Newcastle-upon-Tyne.

D. J. TIBBS.

Research in General Practice

SIR,—In your leading article on research in general practice (March 14, p. 605) you state that "the first obstacle is the attitude of mind that the sick man expects in his medical attendant—assurance in diagnosis and confidence in prescribing." This statement might stand alone. When linked with the subsequent statement that the practitioner finds it essential "to be dogmatic and assured even when dogmatism is not altogether warranted by the state of current medical knowledge," it becomes a matter for debate. It should be made clear, if only for the sake of self-protection from the publicity columns of the lay press, that "assurance in diagnosis and confidence in prescribing" comprehends the right to withhold diagnosis and treatment at the physician's discretion, if uncertainty exists.

There was a time when dogmatic assurance and confidence were the only useful weapons in the possession of the practitioner. Nowadays the sick man and his relatives tend to expect a degree of intellectual honesty from their doctor because of the widespread medical education of the general public, the increased likelihood of a cross-check of the diagnosis by x-ray examination or laboratory tests (to say nothing of necropsies), and the demand for ethical indications before potent and potentially dangerous drugs are used. I submit that among good doctors there are many who find it unnecessary to be dogmatic and assured. A doctor may safely and with dignity decide to avoid a diagnosis and treat a case expectantly. He may thus keep his mind open for further evidence, and reassure the patient that the root of the disease is still being sought. I do not

deny the right of a doctor on occasion to use the unwarranted dogmatic approach, but I do object to the giving of an impression that the G.P. must spend all his day using such methods. The average patient does not expect superhuman wisdom from his general practitioner, and the great teachers of the "classical" school of clinical medicine were apt to leave a back door open for use should time prove first impressions or treatments to be wrong.

With regard to the scientific approach in general practice, Professor Robert Platt (p. 577) quotes Professor Pickering as having remarked that "doctors are really experimenting every day." The pity is that many do not realize the fact, and it is towards this realization that we must strive if research in general practice is to be advanced.

In conclusion it seems of importance that those practitioners who manage to retain the loyalty of their patients without constant recourse to diagnostic and therapeutic dogmatism should make their numbers known. For this matter leads to consideration of the G.P.'s attitude to over-prescribing and the prescribing of tonics and placebos, in which the pros and cons are subtly balanced, and the pivotal factor is what the sick man expects from his medical attendant.—I am, etc.,

Hornchurch, Essex.

I. H. J. BOURNE.

SIR,—The address by Professor Robert Platt (*Journal*, March 14, p. 577) should be most stimulating to those general practitioners who believe they can contribute something to investigation and research into varied diseases and disorders in the course of their general practice. I hope that, instead of merely applauding the idea, general practitioners themselves will do something about it.

Some years ago a colleague and I wrote a letter to the *British Medical Journal* advocating the formation on a volunteer basis of groups of enthusiastic general practitioners who would, in co-operation with the appropriate consultant and with the assistance of laboratory facilities, undertake investigation into the incidence or special features of some disorder in which they are particularly interested. The teaching hospitals might sponsor several groups of practitioners working in this way, and some central body, perhaps the College of General Practitioners, could co-ordinate these investigations and see that there was no necessary overlapping. I believe that this method would commend itself to the general practitioners far more than merely working at a subject chosen by some central body, and I believe that in the course of a few years really useful information would be made available in this way.—I am, etc.,

Calne.

A. K. JAMES.

SIR,—Professor Robert Platt's interesting remarks on research in general practice (*Journal*, March 14, p. 577) prompt mention of two points which might be suitable subjects for such research.

Some years ago I began treating vomiting in whooping-cough with sodium bicarbonate, on the assumption that vomiting, once started, would be made worse by acidosis. My impression has been that relief of the vomiting has been almost invariable with occasional complete cure. However, I have kept no records, and my impression may well be wrong. Also I have invariably kept such cases in bed, and improvement may have been due to that. Furthermore, there may have been mothers who did not give the bicarbonate regularly or did not keep their children strictly in bed. If so, such cases would form two control series; but in my practice the total number of cases in any one epidemic is too small for statistical analysis.

The other suggested subject is the early diagnosis of lobar pneumonia. The experience of other doctors with whom I have discussed this seems to have been the same as mine—that if an ill child, with no other signs or symptoms than a rise of temperature and grunting respiration, is treated with sulphonamides it is quite well in 24 hours. This happened so regularly that I began to suspect that my diagnosis was a fantasy, until one child, after apparent com-

plete recovery, produced rusty sputum. The difficulty here is that, with this experience, I should not feel justified in withholding the drug and waiting to see if the classical signs would develop, and so, even if I saw enough cases, I would not be able to produce a control series. Such a series would eliminate the snag (there may be others) that grunting respiration and a rise of temperature are a slender foundation for a diagnosis, and that some of the cases might recover as rapidly on expectant treatment only. I do not believe this to be so. I seldom see a case of pneumonia with classical symptoms, and it seems improbable that pneumonia has almost died out in my practice, as would be the position if any considerable proportion of these rapid recoveries were not pneumonias. Obviously, however, belief is not enough for statistical purposes.—I am, etc.,

Bracknell, Berks.

Agranulocytosis

SIR,—The annotation on agranulocytosis (March 7, p. 553) prompts us to record some observations on this condition made over the last three years. During this time we have seen six cases; of these, four have been due to thiouracil, one to amidopyrine, and in one the offending drug was not discovered. Experience of these cases has confirmed the findings of other authors^{1,2} that marrow function will usually return spontaneously within a week, provided the infective processes can be controlled. Further, serial marrow studies suggest that the presence of myelocytes or later cells of the granular series indicates that recovery is already under way.³ It is evident that, in view of the likelihood of spontaneous recovery, only those cases in which the agranulocytosis has lasted longer than one week and which still show no evidence of granulopoiesis in the marrow are of value for assessing a new therapy such as A.C.T.H. or cortisone. One of our cases showed these features.

A woman, aged 21, developed complete agranulocytosis five days after a surgical induction for toxæmia of pregnancy. The patient had received numerous drugs during and after parturition, and the offending drug was not discovered. Aureomycin and, later, chloramphenicol were given to combat the infection, but despite this and other routine measures there was no improvement. Marrow punctures on the first and fourth days showed a complete absence of granulopoiesis, and a further puncture on the eighth day showed a similar picture, though an occasional atypical promyelocyte was seen on prolonged search of the film. On the eleventh day 25 mg. A.C.T.H. was given intramuscularly, six-hourly, for 48 hours, and subsequently 50 mg. per day was given with 25 mg. intravenously in slow drip on alternate days. A marrow puncture on the fourteenth day showed marked granulocytic hyperplasia with abundant myelocytes and an occasional mature polymorph. Granulocytes appeared in the peripheral blood on the fifteenth day and the count rapidly returned to normal.

Because spontaneous recovery cannot be excluded in this case or even in that reported by Hart and his colleagues,⁴ where there was complete agranulocytosis for 13 days before A.C.T.H. was started, these cases suggest that further trials of A.C.T.H. should be conducted in those patients whose marrow punctures still show complete failure of granulopoiesis after several days' observation. Indiscriminate use of A.C.T.H. or other drugs in the early stages of the disease gives no information as to their therapeutic value.

Our thanks are due to Dr. F. T. G. Prunty for permission to record this case.—We are, etc.,

SIR,—In your annotation on agranulocytosis (March 7, p. 553) you state: "The most beneficial single therapeutic measure is to give penicillin as soon as the condition is diagnosed." A recent case in which this was done suggests that this may not be the wisest course. A man of 29, with

agranulocytosis and high fever and sore throat, was treated with penicillin (250,000 units three-hourly) for three days, during which he became increasingly ill and developed metastatic abscesses. Blood culture and throat swab taken on the first day grew *Staphylococcus aureus* resistant to penicillin 10 units per ml., but fully sensitive to aureomycin. When aureomycin was given the temperature began to fall and the patient started to improve.

Barber¹ and others have shown that nearly 60% of strains of staphylococci grown from hospital patients may be resistant to penicillin, and it is clear that when agranulocytosis occurs there is need for an antibiotic of the widest possible range. It is probably unwise to give chloramphenicol in the presence of a damaged bone marrow, but there is no contraindication to aureomycin, and I would suggest that this drug rather than penicillin is the antibiotic of choice in agranulocytosis at the stage before the bacteriology of any intercurrent infection is known.

I am grateful to Dr. C. N. Armstrong, under whose care the patient was admitted, for permission to refer to this case, and to Dr. C. A. Green, who has carried out the bacteriological studies.—I am, etc.,

Newcastle-upon-Tyne.

Intraperitoneal Rupture of the Intestine

SIR,—Having had two recent cases of intraperitoneal rupture of the intestine without an external wound under our care, both due to crushing injuries, we were interested to read your report (January 17, p. 166) of the case of *Payne v. St. Helier Group Hospital Management Committee and Another*. Few will have a wide personal experience of this condition, and a short report of these two cases may be of interest.

Case 1.—A child aged 2 years 6 months was seen two hours after he had pulled the top of a bird-bath weighing 1½ cwt. (50.4 kg.) on to him. He was shocked, pale, and cold, with a pulse of 140. There was no abrasion or contusion of the skin of the abdomen, but there was slight tenderness all over, with some resistance, but no rigidity, in the left flank. The latter was no more than might have been explained by bruising of the abdominal wall. There were no red blood cells in the urine. The patient was admitted and half an hour later his pulse was recorded as 170. In view of this a laparotomy was performed. A ragged hole 1 in. (2.5 cm.) in diameter was found in the jejunum 2 ft. (0.61 m.) from the duodeno-jejunal flexure. The tear was on the antimesenteric border, and mucous membrane was pouting through. Peritoneal soiling was slight, and apart from bruising in a small area and enlarged mesenteric glands there was no other abnormality. The hole was sutured and recovery was uneventful.

Case 2.—A man aged 17 was admitted six and a half hours after being struck in the abdomen by the starting-handle of a tractor which had backfired. He felt bruised at first, but continued for a while to work. Later he had to cease work, but the degree of pain did not start to increase until two hours after the accident, when it started steadily to increase. He vomited once and passed urine which did not contain obvious blood. On admission his general condition was very good and he was not shocked. His pulse was 80 per minute and his blood pressure 145/80. The site of the blow had been in the umbilical region and he was tender there and in the hypogastrium. There was some resistance to palpation in the lower abdomen, but there was no rigidity. Bowel sounds were absent. It was felt that the clinical signs might well be accounted for by bruising from injury to the abdominal wall, but the history of the case raised doubt and so laparotomy was performed. At operation there was a small quantity of serous fluid in the right iliac fossa. About 3 ft. (0.91 m.) of the lower ileum was bruised and oedematous, and there were petechial haemorrhages in the bowel wall and adjacent mesentery. In the lower part of this bowel, and about 2 ft. (0.61 m.) from the ileo-caecal valve, there was a perforation in the antimesenteric border, ½ in. (1.25 cm.) in diameter. It appeared already sealed by the omentum, but it was sutured. Recovery was uninterrupted.

The only features common to these two cases were the absence of obvious bruising of the abdominal wall and the absence of rigidity on examination. In neither case was

laparotomy performed on account of unequivocal abdominal signs, and Case 2 was not shocked. Early diagnosis of rupture of the intestine is always difficult, and it is quite possible for it to occur without producing shock or rigidity of the abdomen.—We are, etc.,

A Journal and its Readers

SIR,—Having, as a member of the Journal Committee, acquired some knowledge of the difficulties with which you are faced, may I mention some points which I think are relevant?

It may surprise your readers to learn that 50 years ago the *Journal*, like the *Lancet*, had about twice as much reading matter as it has to-day. Each issue had 64 pages compared with the present 52–56 (excluding the *Supplement*). Editorials were 1,240 words to the page compared with the present 900. Minor articles and many paragraphs in major articles were printed in a type which, if used now, would cause howls of protest, despite National Health Service spectacles. Soon we shall refuse to read any type smaller than that used for "The Owl and the Pussy-cat" or "The Tiny Toddler's First Story-book," and we shall demand pictures illustrating every object named.

The articles submitted can be divided into three groups: those accepted without question, those which would have been accepted if there were more space, and those which are below standard. The contents would be more varied and the appeal would be wider, without materially lowering the standard, if more of the second group could be published. This could be done if contributors were less prolix.

In scientific or philosophic arguments writers cannot expend too much trouble on composition. Most writers, even those of great experience, have to rewrite and rewrite in order to get the correct words and the correct order of words. The specimen proof-page of Mr. Churchill's *The Second World War* displayed by Messrs. Cassell & Co. Ltd. at the South Bank Exhibition shows how much travail is undergone by a Master, though to the casual reader the result seems effortless. In descriptions of clinical cases, however, rounded sentences (not to say turgid periods) are unnecessary. Technical facts need only to be brief and accurate, an aim which is best achieved by the telegraphic, or, as Professor D. M. Dunlop (*Journal*, February 21, p. 441) calls it, the Jingle style. If this were adopted the inordinate space now occupied by such descriptions could be cut to one-third.

Here are some examples. I hope the authors, if they recognize the passages as theirs, will not take offence.

"Examination revealed that the pulse was of poor volume but regular at 120 beats per minute." Only through examination could this revelation have come; 120 could only be beats per minute. *Pulse 120, regular; volume poor*—5 words instead of 16.

"Laparotomy was carried out through a lower right paramedian incision. There was no free fluid in the peritoneal cavity." Laparotomy cannot be carried out without an incision: it is, in fact, an incision. Where on earth was free fluid expected except in the peritoneal cavity? *Lower right paramedian laparotomy. No free fluid*—7 words instead of 19.

"There was slight distension of the upper jejunum." Here the noun is used instead of the verb. *Upper jejunum slightly distended*—4 words instead of 8.

"The spleen was enlarged three fingerbreadths below the left costal margin." Where else could it have been enlarged? *Spleen enlarged 3 fingers*—4 words instead of 11.

"Pathological Report. Microscopical examination of the tissue was performed by Dr. X, who reported: . . ." *Pathological Report (Dr. X): . . .*—4 words instead of 14.

It may be objected that literature is debased by such condensation. But, with all due respect to Professor Dunlop, I maintain that the Jingle style, when properly used, can be very effective: ". . . On the fifth [day], in the morning, deafness; all the symptoms exacerbated; spleen swollen; distension of the hypochondrium; alvine discharges scanty and black; he became delirious. On the sixth, delirious;

at night, sweating, coldness; the delirium continued. On the seventh, he became cold, thirsty, was disordered in mind; at night recovered his senses; slept. . . ." Thus Hippocrates, in Adams's translation. The case stands out with dramatic vividness.

As Dr. Stephen Taylor says (March 21, p. 673), readership varies inversely with verbosity. But his remedy, a ruthless subeditor, however appropriate for a daily newspaper, hardly meets the case of the *Journal*, where a subeditor has quite enough work in touching articles up. Anything more drastic should be done by writers themselves; they should not expect the editorial staff to revise their contributions.

Finally, with Sir Adolphe Abrahams (March 21, p. 673) I venture to question the need to publish the lengthy "Isotiazid in Treatment of Pulmonary Tuberculosis" (March 7, p. 521). This work, having been sponsored by the Medical Research Council, should surely have been published by Her Majesty's Stationery Office? Why should the Association bear the heavy cost? For readers of the *Journal* your admirable leading article was sufficient.—I am, etc.,

Histon, Cambridge.

FFRANGCON ROBERTS.

POINTS FROM LETTERS

Emphysema

Dr. J. TODD (Littlemore, Oxon) writes: I note with regret that Dr. W. N. Leak (February 21, p. 450) continues to argue in favour of using morphine in certain cases of status asthmaticus. To be sure, a few of the older textbooks continue to recommend this practice, but modern opinion is firmly set against it. The latest edition of Martindale's *Extra Pharmacopoeia* (1952, 1, 23rd ed., London) contains the following statement: "It (morphine) should never be given in the presence of bronchial asthma or of heart failure secondary to chronic lung disease." Dr. Leak does not give first importance to the cough reflex in "a man gasping for his life," but I respectfully suggest that areas of atelectatic lung (due to retained mucus) may *per se* contribute to this melancholy situation. Furthermore, he seems to ignore the habit-forming propensities of morphine. In those cases where the differential diagnosis between bronchial and cardiac asthma causes difficulty an intravenous injection of aminophylline has much to commend it.

Research into Relief of Pain

Dr. H. BROSTOFF (London, N.W.10) writes: I recently have had two cases of inoperable carcinoma with intractable pain in which attempts at relief were woefully inadequate. . . . All the drugs used, either in series or in combination (including, finally, morphine), failed to produce a satisfactory relief of pain for more than very short periods. Surely there is ample scope here for intensive investigation to relieve the large numbers of these unfortunates.

"Efocaine" and the Relief of Pain

Dr. T. H. HOWELL (London, S.W.11) writes: I have recently been seeking for a local anaesthetic with a long duration which could be used in the treatment of chronic rheumatic disease. I used "efocaine" (*Journal*, December 13, 1952, p. 1243) on a series of 15 patients suffering from fibrositis. In five of these there was a local reaction with pain and tenderness at the site of injection lasting two or three days; one patient also showed a rigor and a rash; five patients had relief for a period of three days, two for a period of a week, one for a period of two weeks, and two more for three weeks. Although this series is only a small one I feel it should be put on record so that others using the drug may have a chance to compare their results with those I have obtained.

Danger of Blood Injections

Dr. E. ROBERT REES (London, W.1) writes: It appears that the serious consequences that may follow the injection of even small quantities of whole blood into rhesus-negative female infants are still not universally realized. My attention was drawn last month to a case where a girl of 3 years was given a syringe of her mother's blood because her other sister had contracted measles. The mother was an Rh-positive, group O, and I can only conclude that the doctor thought that the daughter must also be Rh-positive. This, of course, is by no means necessarily the case, as is readily understood if we consider its mode of inheritance.

Obituary

S. S. WHILLIS, M.D.

Mr. S. S. Whillis, honorary consulting surgeon to the ear and throat department of the Newcastle-upon-Tyne Victoria Infirmary, died at his home in Gosforth on February 28. By his death Newcastle loses a personality and one of its colourful medical pioneers—a man known only as Sam to his contemporaries and as Sammy to generations of students and house-surgeons.

Born in the west end of the city in 1870, Samuel Short Whillis received his medical training at the old College of Medicine and the old Infirmary on the Forth Banks. He graduated M.B., B.S. in 1892, proceeding M.D. in 1896. While he was holding an appointment at the Ingham Infirmary, South Shields, in 1894, his work was noticed by Mr. Frederick Page, who invited him to become house-surgeon at the Newcastle Infirmary. At that early stage the gruff manner, which never changed throughout his life, had already developed: it was a characteristic which inspired the utmost devotion in many patients and something like terror in a few. About 1895 Whillis entered general practice and also became visiting surgeon to the Wingrove Hospital, where he supervised all the patients and did a good deal of general surgery. He held this post until 1911, and over the years he exercised a considerable influence with the board of guardians. Between the ages of 30 and 40 Whillis led a very busy life, for at the beginning of this century he took up ear and throat work in addition to general practice, beginning as a kind of unauthorized assistant to the late Mr. Walter Ridley, a general surgeon to the infirmary who held an out-patient clinic for ear, nose, and throat diseases. Before the new Royal Victoria Infirmary was established on the Leazes site the house committee decided to appoint official assistants in special departments, and in 1905 Whillis became the first honorary assistant ear, nose, and throat surgeon. On Mr. Ridley's death in 1911 Whillis was appointed honorary surgeon to the now separate department, of which, for almost 20 years, he was chief.

Despite a busy consulting practice Whillis served his hospital well, being a strict timekeeper in out-patients, in the theatre, and in the wards. His out-patients clinic began at 9 a.m., and he was very late if not there by 9.3 a.m. The operating list was timed for 10 a.m., and at 10 o'clock exactly he would turn the corner of the corridor to enter the theatre and ask always the same question, "Where's Mr. So and So?"—the anaesthetist was always "Mister" to Sam Whillis. Other appointments which Mr. Whillis held were those of honorary surgeon to the Fleming Memorial Hospital for Children and honorary otorhinologist to the Sanderson Orthopaedic Hospital for Children, and he was one-time lecturer in otorhinology in the University of Durham. He was a past-president of the Newcastle-upon-Tyne and Northern Counties Medical Society.

In many ways Whillis was a shrewd clinician. For example, he had made observations about the general picture of lateral sinus septicaemia which had escaped his contemporaries and which were not to be found in textbooks; and many years ago, long before there was any safety under drug "umbrellas," he had noted that there was a stage in cerebral abscess when the surgeon might interfere with hope of success, but woe betide the patient if the surgeon did not wait for that stage. Despite

a well-merited reputation, established more than 40 years ago, for a method of tonsil enucleation in children, he was strangely lacking in confidence when it came to tonsillectomy in adults. Seen against the background of his own time Whillis was an excellent temporal bone surgeon, for he performed a very pretty and efficient radical operation. Even in those days most of his radicals were done by hand-gouging, the mallet being used very little. His house-surgeons loved him, soon finding that once his confidence was established his gruffness was no more than a cloak. A little unbending, a little lowering of the barrier, was the equivalent of high praise from Sammy.

He retired from his hospital in September, 1930, and was elected honorary consulting surgeon in the same month. Within a very short time he had abandoned practice altogether and retired to the north of the city. Whillis was always an introspective type, at times tending to be almost morbid, and hence the bereavements of his later life fell very heavily upon him. His last few years of active work at the infirmary were clouded by the sudden loss of an only daughter, and in November, 1943, he was shattered by the untimely death of his only son, Robert, who had but recently succeeded as chief in the department which his father had virtually founded. Mrs. Whillis died some years ago, and so the last days of the old pioneer were lonely indeed.—F. MCG.

JOHAN M. HOLST, M.D., Hon.L.L.D., Hon.F.R.C.S.
Hon.F.R.C.S.Ed.

Professor LAMBERT ROGERS writes:

Professor Johan Holst, whose death and professional career were referred to in the *British Medical Journal* of March 21 (p. 680), was a charming host whom visitors to his clinic in Oslo will remember for his courtesy, enthusiasm, and the high standards which he himself practised and so obviously induced in his staff. Those who have been to his island home and seen him in his family surroundings will have happy memories of the lovely island in the fiord where they were so lavishly entertained and where he spent such leisure moments as his busy practice and many activities allowed him. His frequent visits to this country, and the pleasure which he appeared to find both in visiting us and being visited by friends from here, have done much to make a happy bond of association between members of our profession in our two countries. His death is not only a loss to surgery, but it also takes from us a most charming and very courteous colleague whom we shall sadly miss but remember with admiration and affection. Our sincere sympathy must be with Madame Holst and the members of his family.

Dr. F. ARNOT BEARN writes: The news of Professor Holst's death will cause grief to many R.A.M.C. officers who served with him during the last war. I saw a great deal of him during my service in Iceland and later with the 52nd Division, to which the Norwegian medical services were attached, and like many others was most impressed by his very brilliant and charming personality. He came out regularly on our winter exercises under rather grim conditions in Scotland, and was most helpful to me with his wide knowledge of winter warfare and the evacuation of casualties under these conditions. During purely medical "exercises" he most readily acceded to my request to lecture to us on some of the aspects of military surgery, and I well remember the applause that greeted my thanks for "a masterly address by a master." Apart from surgery, he was widely read in the literature of many countries and many subjects, but even so I was startled one evening when, sitting with him in my "two-man" tent discussing Kitchener's Nile campaign, he remarked that the railway from Wady Halfa to Abu Hamed was very vulnerable. My

wife and I were his guests in Norway three years ago, and again realized what an able and charming person he was.

Dr. V. F. USHER, who had a large practice in Auckland, died on October 26, 1952, as a result of a boating accident on Lake Rotoiti. He had many friends in Britain. Victor Field Usher was born at Nelson, New Zealand, in 1880, the son of Mr. Thomas Usher, and was educated at Nelson College, where he excelled at football and swimming. Having decided on the medical profession as a career, he enrolled as a student in 1902 at the University of Edinburgh, where he became a close friend of Dr. Douglas Guthrie and the late Sir John Fraser, and where he graduated M.B., Ch.B. in 1907. He obtained the F.R.C.S.Ed. in 1910, and proceeded to the M.D. two years later. After graduation he held a clinical assistantship at Edinburgh Royal Infirmary, and later was house-surgeon at the Seamen's Hospital, Greenwich, before returning to New Zealand in 1913 to settle in practice at Auckland. He served with the New Zealand Forces throughout the war of 1914-18 and returned to Auckland in 1920, and later was appointed honorary surgeon to the Auckland Hospital. Dr. Usher took an exceptional interest in the welfare of his patients and built up a large practice. He was a keen sportsman, and for many years nothing pleased him more than to entertain friends at his cottage at Rotoiti, where he would arrange fishing, shooting, riding, and boating expeditions for their pleasure. He married Miss Doris Salter, daughter of the Reverend Walter Salter, and had two daughters, one of whom is a member of the medical profession and the other a nurse.

Dr. J. E. H. SAWYER, who died at his home at Burwash, Sussex, on February 22 at the age of 78, was the elder son of the late Sir James Sawyer, formerly professor of medicine and a consulting physician at the Queen's Hospital in Birmingham. Born at Birmingham on September 8, 1874, James Edward Hill Sawyer was educated at Shrewsbury and at Christ Church, Oxford, going on from there to do his clinical work at St. Thomas's Hospital, where he gained the Solly and Bristowe medals and the Hadden prize. He graduated B.M., B.Ch. in 1900, and in 1903 he proceeded to the D.M. and obtained the M.R.C.P. After holding resident posts at St. Thomas's Hospital, Dr. Sawyer returned to his native city, and in 1906 he was appointed assistant casualty physician and in 1914 assistant physician to the General Hospital, Birmingham. He was also physician to out-patients at the Children's Hospital, and assistant to the professor of medicine in the University. For some years Dr. Sawyer was editor of the *Birmingham Medical Review*, and papers by him, notably one on the physical signs of disease in the thorax and abdomen, appeared in medical journals and in French's *Index of Differential Diagnosis*. When the British Medical Association held its Annual Meeting at Birmingham in 1911 he served as one of the secretaries of the Section of Diseases of Children. His career as a consulting physician ended with the onset of the 1914-18 war. He had been much interested in the Territorial Army since its inception, and he received the Coronation medal of 1911. When war broke out the First Southern General Hospital (T.A.) was mobilized, and the unit converted part of the Edgbaston buildings of Birmingham University into a military hospital. Dr. Sawyer, who had been registrar since 1908, was mobilized in that capacity and served with the unit throughout the war, becoming the administrator in 1917 and receiving the brevet of lieutenant-colonel. He was released from the Army in 1919, and he retired also from his civilian hospital appointments and from active practice. Dr. Sawyer then settled at Burwash, where he lived for the remainder of his life. From 1939 to 1943 he served as a captain in the 19th Battalion of the East Sussex Regiment, retiring from those duties in his 70th year. Although in younger days Dr. Sawyer was a physician of some promise, he ceased to practise as a consultant nearly 40 years ago, and his Birmingham colleagues remember

him chiefly as the conscientious administrator of the Birmingham military hospital at Bournbrook. In 1906 he married Miss Margaret Longstaff, who, with three sons and a daughter, survives him.

A shadow was cast over the village of Chipping Campden and the neighbouring countryside in Gloucestershire by the sudden death on March 1 of Dr. C. E. MOORHEAD at the early age of 46. Charles Edward Moorhead was born at Birmingham on August 15, 1906, the son of the late Dr. J. H. Moorhead and nephew of Professor T. Gillman Moorhead, Regius Professor of Physic at Trinity College, Dublin. He received his medical education at the University of Birmingham and graduated M.B., Ch.B. in 1930. After holding resident appointments at the Queen's Hospital he settled at Edgbaston, where he was in practice for six years until the outbreak of war in 1939. Immediately mobilized as a member of the Territorial Army, he went to France with the 268th Regiment of Artillery, and came through the evacuation of Dunkirk. Later he took part in the Burma campaign, being mentioned in dispatches for gallant and distinguished services and attaining the rank of lieutenant-colonel. He was appointed O.B.E. in 1946.

G. H. D. writes: Blessed with great charm, Charles Moorhead was nevertheless a forceful character who did not suffer fools gladly. He combined in his person the old type of country doctor with the more modern physician. A lover of the countryside and country ways, he truly enjoyed a day's shooting and was a keen fisherman, but work in the last few years had put a stop to hunting and golf. First and foremost, however, he was a doctor, and a very good one. Able and extremely conscientious, he lived up to his high standards. He was not one to be content with the second best, and the strain under which he must have worked without doubt contributed to his death. Campden Church was filled at his funeral service, and his epitaph might well be written in the words of one of his patients who wrote to me after his death: "A truly great gentleman and a friend to all." To his widow, formerly Miss Pandora Pollen, of Norton Hall, Mickleton, and to his two young children, will be given the sympathy of all who knew him.

Mr. FRANCIS BARTHOLOMEW, who died on March 2, received his medical education at St. Thomas's Hospital and qualified M.R.C.S., L.R.C.P. in 1930. After holding the appointment of house-surgeon at the Royal Victoria and West Hants Hospital, Bournemouth, where his rapidly growing surgical skill greatly impressed his seniors, he took the Fellowship of the Royal College of Surgeons of Edinburgh, and entered the Sudan Medical Service, in which he eventually became senior surgeon to the Sudan Government. He served in the R.A.M.C. from 1940 to 1944, attaining the rank of major and acting as surgeon-specialist to the Sudan Defence Force. He married Miss Joyce D. Hodgins, daughter of Mr. J. F. Hodgins, of Crowborough, in 1942, and she survives him, together with two daughters and a son. Bartholomew had an unobtrusive personality, but also a sturdy independence, a practical outlook, and a most kindly disposition. This last quality was invaluable to him as a doctor and made him many friends.

We are indebted to Dr. H. ABDALLA for the following appreciation: I was in close contact with Francis Bartholomew in 1935, when he was a medical inspector in the Northern province of the Sudan. It was while there that he began to make his great contribution to surgery. He toured in a river motor launch with a handful of instruments and would operate in village dispensaries or in a small cabin in the launch. Before his time major surgery was not attempted in outlying districts: he operated anywhere. The essence of his contribution was in the fact that he evolved a new routine in the theatre. This consisted essentially in limiting his surgical armamentarium to a few instruments and appliances, and in reducing the number of assistants and the time of operation. With his handful of instruments he was prepared to operate on any part of the

body with only one helper. He had no lotion bowls or saline packs or multitudinous swabs of different sizes. He employed a no-touch technique and made full use of spinal anaesthesia, hexobarbitone, and chloroform, and his results were an inspiration to all. He proved that with an intelligent variation of the theatre routine surgery could be undertaken anywhere with the minimum of instruments and assistance, yet without any deviation from the fundamentals of modern surgical practice. Apart from his own achievements and the benefits he gave to his patients, his example stimulated his contemporaries to carry the gospel of serious surgery to all parts of the Sudan. He was equally an exemplary character in other ways. His devotion to his patients, his quiet conduct of his duties, and his love and respect of all human beings won for him the friendship and esteem of all sections of the community. He has made his mark. His loss is a sad one.

Dr. A. C. WATKIN, who died at Shrewsbury on March 11 at the age of 70, after a short illness, was born at Llanfair-Caereinion, Montgomeryshire, in 1882, the second son of the late Alderman Thomas Watkin, J.P. Arthur Christopher Watkin studied medicine at University College Hospital, London, and qualified M.R.C.S., L.R.C.P. in 1906. He then held house appointments at the Brompton Hospital and elsewhere before going to Shrewsbury as a tuberculosis officer in 1914. He had taken the D.P.H. two years earlier. During the 1914-18 war he served with a field ambulance corps in France and was mentioned in dispatches in 1918. Released from the R.A.M.C. with the rank of major, he returned to Shrewsbury and eventually became senior tuberculosis officer for the county of Shropshire, holding the post until he retired in September, 1951. Dr. Watkin was a most conscientious worker and gave devoted service to his patients, by whom he was greatly liked. Always keenly interested in the administration of Shirlett Sanatorium, Broseley, he became a member of its committee of management. The presidency of the Shropshire and Mid-Wales Branch of the British Medical Association was an honour which came to him in 1936-7. Outside his professional work Dr. Watkin was particularly interested in Welsh literature and music, and he was a past-president of the Shrewsbury Cymrodorion Society. He was also an enthusiastic angler and bridge player. He is survived by his widow and one son and one daughter, to whom our sympathy is extended.—A. G. W.

The death of Dr. H. STEDMAN on March 9 at the age of 86 recalls the days when the countryside of Middlesex and Hertfordshire was much nearer to London than it is to-day. Herman Stedman was born at Islington, where his father, Dr. James Stedman, was in practice, on July 21, 1866, and was educated at Silverstone—now famous for its car-racing circuit—in Northamptonshire, and at Winterthur, in Switzerland. At the age of 16 he went to the United States with his father, and continued his education at the University of Cincinnati, where he studied medicine, graduating M.D. in 1887. In the following year, after a period of study in Glasgow, he took the Scottish triple qualification, and took over his father's practice at Towcester, in Northamptonshire. Later he went into practice in Poplar, and while there he took the F.R.C.S.Ed. His first wife, formerly matron of Halstead Hospital, where Dr. Stedman had been a house-surgeon, travelled on the first train on the Hampstead Tube—now part of the Northern Line—in search of a new home in more congenial surroundings, and so in 1906 they moved to Temple Fortune, and Dr. Stedman became the first medical practitioner at Golders Green. There he quickly built up a large practice and did a good deal of work as a gynaecological surgeon, both privately and at the Hendon Cottage Hospital, which he helped to found. Dr. Stedman had a long association with the old Volunteers and the Territorial Army, but on the outbreak of war in 1914 he was considered to be medically unfit for military service overseas, and in response to a request from the

British Red Cross Society he took charge of a special Belgian hospital at Calais, where he helped to combat an outbreak of typhoid fever among the civilian population. For his services he was awarded the Belgian Croix de Guerre, and he was also made a Chevalier de l'Ordre de Léopold. Later he joined the Royal Air Force and was appointed principal medical officer at York. After the war he returned to his practice at Golders Green, and on April 23, 1925, he presided at the inaugural meeting of the Hendon Division of the British Medical Association, and was its chairman until 1927. In the following year he retired from practice, though still continuing to treat a number of his old patients, and in 1934 he moved to Iwer Heath, joining the staff of the local hospital for service in the last war. From 1940 to 1952 he lived at Bushey Heath and elsewhere, until he finally settled at Farnham Common in January of this year. His second wife, formerly Mrs. L. J. Dipple, of Watford, died in hospital on March 7, only two days before the death of her husband. Dr. Stedman is survived by a son, his daughter having died a few years ago.

Dr. R. GALWAY MURRAY, who had been a general practitioner in Bayswater for nearly 50 years, died on March 9 at his home in London, at the age of 79. He was the eldest son of Dr. Thomas Murray and grandson of Dr. Thomas Murray, both of whom practised in Trinidad, British West Indies. His great-grandfather, Henry Murray, had fought against Napoleon in the Walcheren expedition of 1809, and later went with his regiment to the West Indies. At the termination of the war with France he married Mademoiselle de Rochard, daughter of the Marquis de Rochard and formerly lady-in-waiting to the Empress Josephine, and then settled in Trinidad, becoming Marshal of the island. Henry Murray's great-grandson, Richard Galway Murray, was born in Trinidad on September 15, 1873, and was educated in England at Epsom College and St. George's Hospital, where his father and grandfather had studied medicine before him. He was one of the first to join the Epsom College volunteer cadet corps on its inception. He won the Macfarlane challenge cup for athletics, and was one of the invincible Rugby team of 1891-2. He represented the United Hospitals against Cambridge University in the 100 yards in 1896. On coming to London, he joined the London Scottish and was one of the guard-of-honour at the celebration of Queen Victoria's diamond jubilee. He qualified M.R.C.S., L.R.C.P. in 1898, and when the South African war broke out enlisted in the 62nd Company of the Middlesex Imperial Yeomanry (The Duke of Cambridge's Own). He was promptly promoted sergeant, and after three months' training saw active service in South Africa. His battalion lost its medical officer, and Sergeant Murray was called upon to shoulder his duties as well as those of a combatant. This he did until after the battle of Wittebergen, when he was promoted surgeon-captain by the "forced orders" of Lieutenant-General Sir Hector Macdonald, which were later confirmed by Lord Kitchener. On his return to England, having taken the Cambridge D.P.H., he went into general practice in London near the Marble Arch. In the war of 1914-18 he first went to France on the staff of the Allied Forces Base Hospital, but later returned to England, joined the R.A.M.C. as a captain, and was put in charge of a hospital at Lydd. He returned to France in 1916 as medical officer to the 55th Heavy Artillery Group and was present at the Battle of the Somme. In 1917 he was invalided out of the R.A.M.C. and returned to his practice, taking the degree of M.D. at Durham three years later. Developing an interest in radiology, he took the D.M.R.E. of Cambridge in 1928 and was appointed radiologist to St. Charles's Hospital, North Kensington, and to the St. Mary's Hospital for Women and Children, Plaistow. In the last war he was medical officer in charge of mobile first-aid units in Paddington. Dr. Galway Murray married Florence Edith, eighth daughter of Paymaster T. B. M. Richards, of Mutley, Plymouth, and she survives him with two married daughters.

Medical Notes in Parliament

Pneumoconiosis in Miners

Mr. JOYNSON-HICKS, Parliamentary Secretary to the Ministry of Fuel and Power, stated in reply to Miss Jennie Lee on March 26 that about 80 coal-miners in 1950, and 101 and 112 in the two following years, were advised to leave the industry or were suspended on account of having pneumoconiosis with tuberculosis.

Home Equipment or Hospital Bed

Sir GUY LLOYD, on March 26, asked the Minister of Health whether a local authority or a hospital board was expected to pay for equipment which, if provided to a disabled person, could permit him to be discharged from hospital, thus freeing a bed for another patient.

Mr. IAIN MACLEOD replied that local health authorities had power under Section 28 of the National Health Service Act, 1946, to provide home-nursing equipment and to make such charges, if any, as they considered reasonable having regard to the person's means. Individually fitted surgical and medical appliances for permanent or semi-permanent use were provided through the hospital and specialist service, and hospitals might lend certain other equipment for domiciliary treatment under specialist direction.

Control of Cortisone

Mr. C. R. BENICE, on March 26, asked the President of the Board of Trade what limitations were placed on the importation of cortisone.

Mr. PETER THORNECROFT replied that licences permitting private commercial imports of finished cortisone were not at present being issued. Supplies were purchased by the Ministry of Health for continuing clinical research and for use in selected hospitals where treatment could be strictly supervised.

Mr. BENICE asked what was the use of using cortisone in hospital if it was to be denied to the patient after leaving hospital.

Mr. THORNECROFT said he understood that the Ministry of Health still considered it necessary to control the use of the drug very carefully, and it could be adequately supervised only if done in this way.

Pricing Prescriptions

Miss PAT HORNSBY-SMITH, Parliamentary Secretary, Ministry of Health, informed Mr. Hugh Linstead on March 26 that the total number of staff employed in prescription-pricing offices in January, 1952, was 1,089, and in January this year 1,302. The number of National Health Service prescriptions dispensed during the year 1952 and priced to date was approximately 139 million.

Registration Service Bill.—A Bill entitled the Registration Service Bill was introduced on March 24 in the House of Lords. It is a consolidating measure dealing with the central and local organization of the service which, under the Registrar-General, administers the law on registration of births, marriages, and deaths and many aspects of solemnization of marriages in England and Wales. This body of law has been contained in a large number of scattered enactments, some of them old and not easy to read together.

The Services

Colonel W. R. Ward, T.D., R.A.M.C., T.A., has been appointed Honorary Surgeon to the Queen, in succession to the late Major-General P. H. Mitchiner, C.B., C.B.E., T.D.

AUXILIARY R.A.M.C. FUNDS

The annual general meeting of the members of the Auxiliary Royal Army Medical Corps Funds will be held at 11, Chandos Street, London, W.1, on Monday, April 13, at 5 p.m., to receive the annual report and accounts for the year 1952 and to appoint officers and elect auditors for the year 1953.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending March 14 (No. 10) and corresponding week 1952.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenzal pneumonia.
§ Includes puerperal pyrexia.

Vital Statistics

Smallpox in the North Country

Up to noon of March 27 the following cases (with deaths in parentheses) had been reported: Todmorden M.B. 11 (1), Bacup M.B. 2 (1), Oldham C.B. 1 (0), Bury C.B. 2 (0); total 16 (2). 9 cases are in hospital at Oakwell, Yorkshire West Riding, and 5 in hospital at Ainsworth, Lanes.

Since last week's report (*Journal*, March 24, p. 738) further cases had occurred up to March 27 as follows:—Bacup M.B.: 1 case, wife of a Bacup patient with smallpox. Todmorden M.B.: 2 cases, both contacts of the new Bacup case. Bury C.B.: 2 cases in children at the Florence Nightingale Hospital, Bury, who are contacts of a previously reported case in the hospital. All recent cases have been direct contacts with previous cases.

The Minister of Health announced in Parliament on March 26 that he had asked the Medical Research Council to investigate the possibility of smallpox transmission by raw cotton, imported bales of which are suspected of being the source of infection in this outbreak. He was advised there was no danger of infection being spread by cotton yarn or finished materials made from it. All possible steps had been taken to isolate the suspected bales.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1944-52 are shown thus -----, the figures for 1953 thus ————. Except for the curves showing notifications in 1953, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

Rises in the number of notifications of infectious diseases in England and Wales during the week ending March 14 included 314 for whooping-cough, from 2,758 to 3,072; 141 for scarlet fever, from 1,534 to 1,675; and 73 for dysentery, from 289 to 362. The largest falls were 714 for measles, from 27,638 to 26,924; and 202 for acute pneumonia, from 1,301 to 1,099.

The largest decreases in the number of notifications of measles were 332 in Hertfordshire, from 1,190 to 858; 250 in London, from 1,621 to 1,371; 182 in Middlesex, from 1,613 to 1,431; and 178 in Buckinghamshire, from 494 to 316. The largest rises were 263 in Lancashire, from 1,455 to 1,718; 192 in Surrey, from 1,769 to 1,961; 169 in Staffordshire, from 1,119 to 1,288. Only small variations were recorded in the local trends of scarlet fever and whooping-cough. 31 cases of diphtheria were notified, 9 more than in the preceding week. The chief features of the returns for diphtheria were rises from 6 to 10 in Lancashire and from 1 to 4 in Warwickshire; all these cases were notified in three cities—Liverpool C.B. 7, Manchester C.B. 3, and Birmingham C.B. 4.

17 cases of acute poliomyelitis were notified during the week. They were 3 more for paralytic and 3 fewer for non-paralytic cases than in the preceding week. Sussex with 3 notifications (Chancetonbury R.D. 2) was the only county with more than one case.

The largest returns of dysentery were Lancashire 82 (Liverpool C.B. 43, Rainford U.D. 20; Manchester C.B. 11); Yorkshire West Riding 59 (Todmorden M.B. 19, Bradford C.B. 13, Barnsley C.B. 10); Leicestershire 36 (Leicester C.B. 35); London 28; Middlesex 21; Worcestershire 21 (Oldbury M.B. 20).

139 deaths were attributed to influenza, 54 fewer than in the previous week.

Quarterly Report for Scotland

The birth rate during the fourth quarter of 1952 was 17.0 per 1,000, being 0.9 above the rate for the December quarter of 1951 but 0.7 below the average of the five preceding fourth quarters. The infant mortality rate was 39 per 1,000 registered live births and was 3 above the rate for the preceding fourth quarter. The general death rate was 12.5

per 1,000 and was 1.0 above the rate for the corresponding quarter of 1951 and 0.3 above the five years' average. The death rate from all forms of tuberculosis was 28 per 100,000, and that from respiratory tuberculosis was 24. Both these rates were 9 below the rate for the fourth quarter of 1951, and they were respectively 33 and 30 below the average of the five preceding fourth quarters.

Deaths from the principal epidemic diseases numbered 422, or 710 fewer than in 1951. This decrease was mainly due to the fall in the number of influenza deaths, from 958 in 1951 to 316. 26 deaths were attributed to whooping-cough, 22 to measles, 8 to diphtheria, 12 to acute poliomyelitis and polioencephalitis. Other figures for 1952 were given in the *Journal* of March 14, (p. 628).

Week Ending March 21

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,625, whooping-cough 3,104, diphtheria 20, measles 27,226, acute poliomyelitis 26, dysentery 433, paratyphoid fever 2, typhoid fever 3.

Medical News

Human Factors in Industry.—The Department for Scientific and Industrial Research and the Medical Research Council announce that they have appointed two committees to work on human problems in industry. The object is to improve production. The first, under the chairmanship of Sir Frederic Bartlett, F.R.S., lately professor of experimental psychology at Cambridge, will deal with "human factors in individual efficiency." The work of this committee will fall under three main heads: fitting the job to the man, selection and training, and job assessment. This committee includes among its members Professor J. Drever (Department of Psychology, Edinburgh), Dr. C. B. Frisby (Director, National Institute of Industrial Psychology, London), Professor Esther Killick (Department of Physiology, Royal Free Hospital School of Medicine), Professor W. E. Le Gros Clark, F.R.S. (Department of Human Anatomy, Oxford), and Professor R. W. Russell (Department of Psychology, University College, London). The second committee, under the chairmanship of Mr. A. B. Waring, managing director of Joseph Lucas Industries, Ltd., will be concerned with human behaviour and human relations in industry. It will review joint consultation procedures, attitudes to work, and the structure of informal groups in the factory. Members of this committee include Professor T. Ferguson (Department of Public Health, Glasgow), Professor Aubrey Lewis (Institute of Psychiatry, London), Professor R. W. Russell, and Dr. A. T. M. Wilson (Director, Tavistock Institute of Human Relations). The committees will advise the D.S.I.R. and M.R.C. on research policy in their respective fields.

Society of Anaesthetists of South Wales.—The following officers have been elected: president, Dr. F. Pearson; vice-president, Dr. W. W. Mushin; honorary secretary, Dr. K. S. Thom, 41, Caerau Road, Newport, Mon.; honorary treasurer, Dr. D. S. Jones.

Princess Tsahai Memorial Hospital.—The hospital is still in need of further equipment and funds, and about £700 is required to complete payment for goods already installed. Help in meeting these expenses will be gratefully acknowledged by the honorary treasurer, Lord Horder. Cheques should be made payable to the Princess Tsahai Memorial Hospital, and sent to him, c/o Messrs. Gould and Prideaux, 88, Bishopsgate, London, E.C.2.

Scientific Films.—A supplement is planned to the catalogue of medical films published last May by the Scientific Film Association, and owners of films not listed in it are

invited to send details to Dr. M. Essex-Lopresti, at 164, Shaftesbury Avenue, London, W.C.2. They should state title, running time, summary of contents, date of production, gauge, sound or silent, colour or black-and-white, free loan or hire, and the name and address from which the film may be obtained.

Medical Photography.—The centenary programme of the Royal Photographic Society includes an item of special interest to the medical profession. It is an exhibition arranged by the Medical Group of the Society on "100 Years of Medical Photography" for display at 16, Princes Gate, London, S.W.7, on April 7-30.

Professor P. A. Buxton, F.R.S., professor of entomology at the London School of Hygiene and Tropical Medicine, is to receive the Linnean Medal for 1953. The award will be made at the anniversary meeting of the Linnean Society of London on May 28.

Sir Harold Himsworth, secretary of the Medical Research Council, is among those who are to receive the honorary degree of LL.D. at Glasgow University's Commemoration Day on June 17.

Dr. Albert Sharman, gynaecologist to the Royal Samaritan Hospital for Women, Glasgow, has been elected a vice-president of the International Fertility Association, representing the United Kingdom.

Sir Henry Dale, O.M., F.R.S., who toured Austria last month, had the honorary degree of M.D. conferred upon him by the University of Graz on March 23.

COMING EVENTS

Annual Dinner of Guild of St. Luke.—The annual dinner and ball sponsored by the Guild of St. Luke, SS. Cosmas and Damian (Westminster Branch) is to be held at the Dorchester Hotel on April 9 at 7 p.m. Tickets may be obtained, price 2 gns., from the Hon. Secretary of the Westminster Branch of the Guild, 5, Wimpole Street, W.1. (Tickets for the ball only are available price 25s. each.) Among those who have accepted invitations to be present at the dinner are Cardinal Griffin and the Spanish, Irish, and Portuguese Ambassadors.

World Health Day.—April 7 is World Health Day, and the World Health Organization has selected "Health is Wealth" as an appropriate theme for its observance this year. In London there is to be a meeting at the Caxton Hall at 5 p.m. on Tuesday, April 7, at which the speakers will be the Minister of Health and Dr. H. S. Gear, Assistant Director-General of the World Health Organization.

International College of Surgeons.—The International College of Surgeons will hold meetings as follows: University of Amsterdam, April 8 to 10; University of Rome, June 5 to 7; University of Vienna, June 11 to 13. The Bank of England has consented to grant a travelling allowance to delegates. Further information may be obtained from the secretary (British Chapter), International College of Surgeons, 20, Highfield Road, Edgbaston, Birmingham, 15.

Scottish Society of Anaesthetists.—The annual meeting of the Scottish Society of Anaesthetists will be held at Dunblane Hotel Hydro from April 24 to 26. The 1953-4 president of the Society is Dr. W. M. Shearer. Further details may be obtained from the hon. secretary of the Society, 7, Kinellan Road, Bearsden, Glasgow.

British Association of Plastic Surgeons.—The 1953 programme of meetings of the British Association of Plastic Surgeons is now available. There will be a meeting at the Royal College of Surgeons on April 24, at Salisbury from September 10 to 12, and at the Royal College of Surgeons (annual general meeting) on December 4. Those wishing for further information are asked to get in touch with the secretary, British Association of Plastic Surgeons, 45, Lincoln's Inn Fields, London, W.C.2.

Meeting on Vitamins.—The National Research Council of Italy is holding a meeting on vitamins at the National Museum for Science and Technology, Milan, from April 12 to 16. Applications to attend the meeting should be made to: Consiglio Nazionale delle Ricerche, Segreteria della Giornata della Scienza, Piazzale delle Scienze, 7, Rome, Italy.

British Medical Students' Association.—The annual conference of the British Medical Students' Association (Midland Region) will be held in Oxford from April 15 to 17, at the invitation of the Oxford University Medical Society. The inclusive fee for the conference is £5, and those wishing to attend are asked to communicate with the Conference Secretary, Oxford University Medical Society, c/o Medical School Office, University Museum, Oxford.

The Family.—The Second British National Conference on Social Work is to be held at Bedford College for Women, Regent's Park, London, N.W.1, from April 15 to 18. The subject of the Conference, which is under the chairmanship of Sir Wilson Jameson, will be "The Family." The fee for the Conference is two guineas. Further information and registration forms may be obtained from the Secretary, British National Conference on Social Work, 26, Bedford Square, London, W.C.1.

Congress of Oto-neuro-ophthalmology.—The Eighteenth International Congress of Oto-neuro-ophthalmology will be held in Bologna, Italy, from May 3 to 7. The chairman will be Professor Q. Di Marzio, and the two main subjects for discussion are "Dysgraphia in Oto-neuro-ophthalmology" and "Ménière's Disease." Those wishing to submit a paper or take part in the discussions are asked to apply to the Congress Secretary, Dr. Giuseppe Cristini, Clinica Oculistica-Polichinico, Bologna.

European Society of Haematology.—The Fourth Congress of the European Society of Haematology will be held in Amsterdam in September. Full particulars will be available later on, but those interested are asked to communicate with Dr. A. Piney, 152, Harley Street, London, W.C.1.

World Federation for Mental Health.—The Sixth Annual Meeting of the World Federation for Mental Health will take place at the University, Vienna, from August 16 to 22. The theme of the meeting will be "Social Provisions for Mental Health." Further information may be obtained from the secretary, National Association for Mental Health, 39, Queen Anne Street, London, W.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Wednesday, April 8

INSTITUTE OF UROLOGY.—At St. Paul's Hospital, W.C., 4.30 for 5 p.m., Dr. J. J. Stevenson: X-rays.
MIDLAND MEDICAL SOCIETY.—At Dudley Road Hospital, Birmingham, 8.15 p.m., clinical meeting.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—3.45 p.m., Arnold Demonstration by Professor Lambert Rogers: Tumours of the Central Nervous System.
ROYAL EYE HOSPITAL.—5.30 p.m., Dr. A. A. Guild: Mechanism and Appearances of Puffiness.
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Dr. Guy W. J. Bousfield: The Case for Combined Diphtheria-Pertussis Prophylaxis in Young Infants (Illustrated).

Thursday, April 9

ALFRED ADLER MEDICAL SOCIETY.—At 11, Chandos Street, W., 8 p.m., Dr. Walter Schindler: Group Psychology.
FACULTY OF HOMOEOPATHY.—5 p.m., Dr. Pierre Vannier: Humans and Homoeopathy.
ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Brigadier J. S. K. Boyd, F.R.S.: Some Aspects of Chemotherapy in Tropical Medicine.

Friday, April 10

ROYAL EYE HOSPITAL.—4.30 p.m., Mr. A. J. Cameron: Ophthalmic Aspects of Hypertension and its Treatment.
WHIPPS CROSS HOSPITAL MEDICAL SOCIETY.—8.30 p.m., Professor S. P. Bedson, F.R.S.: Recent Trends in Virus Research.

Saturday, April 11

SOUTH-EAST METROPOLITAN REGIONAL TUBERCULOSIS SOCIETY.—At Benenden Sanatorium, 10.30 for 11 a.m., clinical meeting.
SOUTH WEST LARYNGOLOGICAL ASSOCIATION.—At Portsmouth and Southern Counties Eye and Ear Hospital, Southsea, 2.30 p.m., meeting.

APPOINTMENTS

AIRD, PATRICK JOSEPH, M.B., B.Ch., D.P.H., D.P.M., Resident Medical Superintendent, District Mental Hospital, Ennis, Co. Clare.
BACKHOUSE, KENNETH MORLEY, M.B., B.S., Lecturer in Anatomy, St. Bartholomew's Hospital Medical College, London, E.C.
BARCLAY, R. F., M.B., B.S., D.P.H., Medical Officer of Health for Borough of Newbury and Rural Districts of Newbury, Hungerford, and Bradfield; Assistant Medical Officer, Berkshire County Council.
CASSELLS, NULCE, M.B., Ch.B., C.P.H., Assistant County Medical Officer and Schools Medical Officer in the County of the Isle of Ely.
COTTON, JOHN L., M.B., Ch.B., D.P.H., Deputy Medical Officer of Health and Deputy School Medical Officer, County Borough of Bury.
GRAHAM, ANDREW, N., M.B., B.S., D.P.M., Physician-Superintendent (Consultant), St. Crispin Hospital, Northampton, Oxford Regional Hospital Board.
HOSPITAL FOR SICK CHILDREN, Great Ormond Street, London, W.C.— Daphne S. A. Anderson, M.D., D.C.H., Part-time Clinical Assistant (Radiotherapy); Pauline I. M. Winn, M.B., Ch.B., House-physician to Neurological and Neurosurgical Unit; Dorothy F. M. Burnett, M.B., Ch.B., and S. G. F. Wilson, M.B., Ch.B., House-physicians; G. G. Wyllie, F.R.C.S., House-surgeon.
MCFARLAN, ALLAN M., M.B., Ch.B., Epidemiologist for Tuberculosis, Department of Public Health, City and County of Bristol.
MURPHY, PHILIP KEVIN, L.R.C.P.S.I., D.P.H., T.D.D., Assistant Medical Officer of Health in Guernsey, Channel Islands.
RUSSELL, ALAN PETER, M.B., Ch.B., D.P.M., Physician-Superintendent and Consultant Psychiatrist, Bellisdyke Mental Hospital, Larbert, Scotland.
SHEARER, CHARLES WILLIAM, M.B., Ch.B., D.P.H., Deputy Medical Officer of Health, Swindon.
SKONE, J. F., M.D., D.P.H., D.C.H., D.I.H., Deputy Medical Officer of Health and Deputy School Medical Officer, City of Oxford.
WELSH REGIONAL HOSPITAL BOARD.—J. M. Marchant, M.B., B.Chir., D.A., Consultant Anaesthetist, Wrexham, Powys and Mawddach H.M.C.; A. W. Fowler, M.B., F.R.C.S., Assistant Traumatic Surgeon (S.H.M.O.), Mid-Glamorgan H.M.C.; J. M. Lewis, M.B., B.Ch., D.A., Consultant Anaesthetist, Gwent H.M.C.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Matthews.—On March 16, 1953, at St. Helier Hospital, Carshalton, Surrey, to Diana, wife of Dr. Harold W. Matthews, a sister for Rohan—Fiona Elizabeth Marguerite.
Rafferty.—On March 7, 1953, at the Trevalyn Manor Nursing Home, Wrexham, Denbighshire, to Julia (formerly MacHale), wife of John Pearce Rafferty, M.B., B.Ch., a son—John Roger.
Summers.—On March 22, 1953, at Brixworth, Northants, to Mary, wife of Dr. H. A. Hamilton Summers, a son and a daughter.

DEATHS

Bartlett.—On March 13, 1953, Frank Whinfield Bartlett, M.R.C.S., L.R.C.P., of The Haven, Brixham, Devon, formerly of Romsey, Hants, aged 83.
Bennett.—On March 11, 1953, at his home, Chakrata, Werneth Road, Woodley, Cheshire, John George Bennett, M.C., M.D., aged 63.
Brennan.—On March 2, 1953, at his home, Anacloone, Oughterard, Galway, Eire, Joseph Roland Brennan, M.B., B.Ch., Surgeon Captain, R.N., retired.
Briscoe.—On March 13, 1953, at Axminster, Devon, Ralph Cay Briscoe, M.R.C.S., L.R.C.P.
Burt.—On March 18, 1953, at 5, Springfield Place, Bath, Joseph Barnes Burt, M.D., aged 72.
Crossley.—On March 13, 1953, at 12, Passmonds Crescent, Rochdale, Lancs., Harry Newbold Crossley, M.B., Ch.B., D.P.H.
Cunningham.—On March 8, 1953, at 41, Lyndhurst Road, Barnehurst, Kent, David Muir Cunningham, M.B., Ch.B., aged 50.
Eves.—On March 13, 1953, at 10, Stanford Avenue, Brighton, Sussex, Percy Stanhope Eves, M.D.
Johnson.—On March 8, 1953, in a London nursing-home, Marcus Beauchamp Johnson, M.R.C.S., L.R.C.P.
MacDougall.—On March 13, 1953, at his home, Dunollie House, Oban, Argyll, Alexander James MacDougall, C.M.G., M.B., C.M., J.P., Colonel, R.A.M.C., retired, aged 81.
McMillan.—On March 16, 1953, at St. John's, Melrose, Roxburgh, John James McMillan, M.D.
Mason.—On March 12, 1953, at his home, 79, Willes Road, Leamington Spa, Warwickshire, Harold Mason, M.B., J.P., aged 87.
Murray.—On March 9, 1953, at 225, Sussex Gardens, London, W., Richard Galway Murray, M.D., D.P.H., D.M.R.E.
Roberts.—On March 17, 1953, in the National Hospital, London, W.C., David Reid Eccles Roberts, Ch.M., of 107, Stanhope Road, Darlington, Co. Durham.
Roxburgh.—On March 17, 1953, at "Oaksleigh," Locks Heath, Hants, Alexander Bruce Roxburgh, M.B., F.R.C.S.
Ryrie.—On March 9, 1953, at Berford, Milton Terrace, Kirkcaldy, Fife, Gordon Alexander Ryrie, M.B., Ch.B., late of Sungai Buloh, Malaya.
Shields.—On March 17, 1953, at The Rectory, Lound, near Lowestoft, Charlotte Annie Shields, M.B., B.S., formerly of Westcliff-on-Sea, Essex, aged 81.
Spon.—On March 11, 1953, in St. George's Hospital, London, S.W., the result of an accident, Harry James Spon, M.R.C.S., L.R.C.P., D.P.H., of West Lodge, Leigh, Kent.
Stedman.—On March 9, 1953, at the West Hertfordshire Hospital, Hemel Hempstead, Herman Stedman, M.D., F.R.C.S.Ed., formerly of Temple Avenue, Bushy Heath, Herts.
Sutton.—On March 3, 1953, at 24, Northcourt Avenue, Reading, Berks, Henry Martyn Sutton, M.R.C.S., L.R.C.P., formerly of Bagdad and Truro, aged 93.
Vincent.—On March 15, 1953, at 37, Westbourne Road, Sheffield, William James Nathaniel Vincent, C.B.E., M.D.
Watkin.—On March 11, 1953, at Grassendale, Shrewsbury, Salop, Arthur Christopher Watkin, M.R.C.S., L.R.C.P., D.P.H.
Wheelodon.—On March 3, 1953, at Woodlands Cottage, Ashford, Ludlow, Salop, Frederick John Wheelodon, M.R.C.S., F.S.A., aged 60.

Any Questions?

Correspondents should give their names and addresses (not or publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

A Quick Eye

Q.—What is the physiological basis of a "quick eye"? How may it be acquired or improved?

A.—There does not appear to be any precise or definite knowledge directly bearing on this problem. Knowledge of the eye is based more on static than on dynamic tests, and is difficult to obtain direct information on the interrelationship of the eye and the brain. It is practically certain that the possession of a "quick eye" has very little to do with the retina or refraction, and a person who wears spectacles can have a quick eye, provided that the vision is well corrected. The ability to keep in sight a rapidly moving object like a tennis or cricket ball is undoubtedly closely associated with the control and rapid adjustment of the musculature of the head and neck, and particularly of the intrinsic ocular muscles.

People who wear glasses usually have some restriction of the peripheral field of vision, due to obstruction by the rim of the spectacles. Flat lenses also restrict vision in the periphery of the field and are less satisfactory than toric lenses in this respect. Thus people who wear glasses might be expected to use the head and neck muscles more than a person without glasses, who might use mainly the intrinsic ocular muscles. Contact lenses are an advantage in this respect, since they give a full unobstructed field of vision and permit the more "normal" movement patterns of the head, neck, and eyes for the visual processes. There is also a "central" factor concerned with co-ordination of and action upon visual information. The distance receptors are used with a certain measure of anticipation of action, as was pointed out by Sherrington in his *Integrative Action of the Nervous System*. Little known about this.

Poisonous Snakes

Q.—What treatment is advised for snake bites? I live in Australia, and a veterinary surgeon tells me that the mortality of cattle from snake bites has been vastly reduced since the use of antihistamine drugs. Is this true, and would these substances be useful in humans?

A.—Most bites occur on the limbs. The limb should be immobilized and a tourniquet applied where possible about 1 in. (5 cm.) proximal to the bite. Tourniquets may be tight enough to stop all circulation if rapid neurotoxic effects are expected; usually it is sufficient to stop venous and lymphatic flow. They should be loosened for half a minute after the first 20 to 30 minutes, and subsequently at intervals of 10 minutes; they should be moved proximally as oedema spreads.

Vash the wound before incising, as many snakes dribble venom when they bite. Incisions should be about half an inch (1 to 2 cm.) long and through the fang puncture. Avoid large vessels, and in the case of viperine bites keep the wound on subsequent bleeding, which may be very severe. Tension may be applied to the wound; if the mouth is closed it must be protected with thin rubber such as that used in condoms.

Specific antivenin should be given intravenously as soon as possible, provided there is no serum sensitivity. Identification of the offending snakes is very important, since antivenins are highly specific. Local knowledge and the snake's history are helpful if the snake is not available.

Polyvalent serum should be given only in cases where there is doubt about the identity of the snake. Antivenin may also be injected into the tissues proximal to the bite. After the intravenous dose has been given and local treatment has been instituted for an hour or more remove the tourniquet if the local reaction has become stationary; if the latter is increasing, the tourniquet should be retained, with frequent release and reapplication.

When the bite is in a suitable place on the leg or arm, a double tourniquet may be applied to wash out the venom from the region of the bite. A proximal tourniquet is placed above the knee or elbow tight enough to obstruct all circulation. A second tourniquet tight enough to obstruct only venous flow is placed above it, and a vein in the limb is cut. The lower tourniquet is loosened for a minute or two, during which bleeding takes place from the incised vessel. The tourniquet is then tightened and the procedure repeated at intervals.

Haemotoxic venoms may lead to severe shock and bleeding so that intravenous infusion of plasma or blood transfusion may be necessary. Artificial respiration may be necessary where the venom is neurotoxic.

Bites from non-poisonous snakes should be treated with respect because of the danger of infection. Severe bites—for example, from pythons—present the risk of anaerobic infections, and injection of tetanus antitoxin may be an intelligent precaution.

There is no reputable evidence that antihistamine drugs reduce the mortality of cattle bitten by snakes, in Australia or elsewhere. The action of these drugs in snake bite in man has also not yet been established.

Pregnancy after Subarachnoid Haemorrhage

Q.—A woman of 27 had a baby six years ago, and nine months later had a subarachnoid haemorrhage. She then had recurrent subarachnoid haemorrhages one and two years later. She is now six months pregnant, and apart from an anxiety state—due to her being warned that she should not become pregnant again—is perfectly well. (a) Is there any indication for caesarean section at term? (b) What should be done if she shows signs of toxæmia? (c) If she had been seen earlier, would there have been any indication for therapeutic abortion?

A.—Cases of pregnancy occurring in women who have previously suffered from subarachnoid haemorrhage are not common; most obstetricians come across only one or two in a lifetime, and each case has to be treated on its merits. Within the writer's experience previous subarachnoid haemorrhage with residual paralysis has been regarded by physician, neurosurgeon, and obstetrician as an indication for therapeutic abortion. If the pregnancy is allowed to continue many believe that caesarean section involves less risk of a recurrence of the haemorrhage than does vaginal delivery. This view, however, is based on theoretical considerations and expectations rather than controlled observations. If it is decided to deliver vaginally, no straining in the second stage should be allowed, and forceps delivery should be carried out as soon as the cervix is fully dilated.

Whatever method of delivery is effected, one important consideration is anaesthesia, because the straining associated with post-anaesthetic vomiting might in itself carry a risk of recurrence of haemorrhage.

Since the patient in question had a normal first pregnancy she is unlikely to develop toxæmia this time. If she does become hypertensive, however, termination of pregnancy, possibly by caesarean section, should not be long delayed.

Spontaneous Combustion of Alcoholics

Q.—Is there any foundation for the belief in the spontaneous combustion of chronic alcoholics?

A.—There is no scientific foundation for the theory that hell-fire is anticipated by spontaneous combustion of the living body in chronic alcoholics. The body contains

approximately 72% water, which renders it highly combustible: a temperature of 1,500° C. is required for the destruction of the body at cremation.

It is probable that the greatest publicity to the theory of spontaneous combustion was given by Charles Dickens in *Bleak House*, but in the preface to that volume, dated August, 1853, he admits that "the possibility of what is called spontaneous combustion has been denied since the death of Mr. Krook." Dickens stated at that time that there were about thirty cases on record, and cited several instances occurring in the eighteenth century. There is some support for the theory that bodies which have undergone extreme fatty degeneration are possibly unusually combustible and may act as the tallow of a candle, the wick being provided by clothing.

Death as a result of a conflagration is undoubtedly commoner in chronic alcoholics than in the general public, but this is owing to the fact that the alcoholic does not take ordinary precautions against fire, such as extinguishing cigarette ends, guarding the fire, etc., and he is of course more liable than ordinary persons to fall into a fire. But the detailed investigations carried out by fire brigades into the cause of individual fires have not confirmed the belief that the chronic alcoholic has, of himself, been the site of origin. Spontaneous combustion has been put forward as a defence in murder cases, and on one occasion at least in the eighteenth century it succeeded, but the theory is now quite contrary to all scientific knowledge.

Gases may be formed within the intestinal tract which can be ignited on the application of a flame, but there is no evidence that such gases are spontaneously combustible.

Mepacrine for Rheumatoid Arthritis

Q.—Is mepacrine of value in the treatment of rheumatoid arthritis?

A.—Mepacrine has been reported to be of value in rheumatoid arthritis in several papers which have appeared in the United States. No controlled series has yet been reported, but preliminary observations which have been carried out in this country have not proved to be encouraging. Such improvement as has sometimes been reported by patients has, on examination, seemed to be subjective rather than objective.

Percussion for a Painful Stump

Q.—What treatment is advised for constant pain and pins-and-needles in a forearm amputation stump? On inspection the stump appears healthy. Local injection of the cervical sympathetic (with the production of a Horner's syndrome) has failed to benefit the patient, and he is now weary of hospital treatment. Would tapping the stump with a rubber hammer do any good, and, if so, could you please give details?

A.—Many of the paraesthesiae and pains experienced in amputation stumps or phantom limbs undoubtedly originate in neuromata in the stump. This is demonstrated by the temporary disappearance of such sensations when the nerves to the stump are blocked by local analgesia. Percussion treatment to the end of the stump is often effective in relieving these pains (see *British Medical Journal*, 1950, 2, 68). It seems to render the neuromata insensitive and gradually converts them into painless scars. The patient must at first treat himself several times a day. For the lower limb a short length of broom handle (15 cm.) is fitted with a metal applicator at one end which is then pressed firmly against the tender neuromata and hammered with a heavy wooden mallet, gently at first, for 10 to 15 minutes. The relief experienced is often quite startling to both patient and doctor. For the upper limb the patient may slap the end of the stump repeatedly on a smooth wooden table, but the better way is to use an electric vibrator, and these have become so popular that the Ministry of Pensions now issues them on loan to certain patients.

This causes the neuromata to become insensitive—a traumatic local analgesia—and the effects of such repeated percussion or vibration seem to be very effective in most cases. Incidentally the local analgesic effect of a vibrator used in this way makes it useful for a variety of other conditions in which local tenderness or even pruritus are prominent.

NOTES AND COMMENTS

Spinach.—OUR EXPERT writes: Your correspondents Dr. J. E. and Mr. N. S. Bamji (March 21, p. 674) must be thanked for their useful review. Spinach is certainly rich in oxalic acid, and it is clear that it may adversely affect the absorption of calcium in rats when it is given in large amounts after concentration into the dry form. Indications that it is harmful to humans when consumed in reasonable quantities after cooking, however, are much less definite. The oxalic acid is largely soluble, and some may be discarded in the cooking water or exuded juice. Bonner *et al.*¹ have reported that a daily intake of 700 mg. of the acid has no ill effects on children receiving adequate amounts of calcium in their food, and less than this amount should be contained in a normal helping of the vegetable. From experiments with rats, Gortner *et al.*² have even suggested that oxalic acid may protect the teeth from etching caused by other acids, such as citric and phosphoric, which may be included in soft drinks. The teeth of Hawaiian natives are said to have deteriorated since they stopped eating taro, which is rich in oxalic acid. Iron is less well absorbed from spinach than from wheat, but the same finding appears to apply to kale and other green vegetables.

The progress of nutritional research has revealed objectionable features in many common foodstuffs. Wholemeal flour depresses calcium absorption on account of its high content of phytic acid. Cod-liver oil opposes vitamin E and can cause serious lesions of the muscles and brain in experimental animals. Cabbage contains a factor which opposes the action of thyroxine. Maize is associated with the incidence of pellagra. When eating a good mixed diet, however, we may include all these foods without ill effects, and the same immunity probably applies with spinach.

Perhaps the most alarming point raised by your correspondents is the tendency in some children for spinach to cause soreness round the mouth and anal region. It should certainly neither be given to young children in unreasonable quantities nor be forced upon them at all if not wanted. A watch should be kept for signs suggesting that it is poorly tolerated.

Allergic Rhinitis.—Mr. C. HAMBLIN-THOMAS (London, W.1) writes: I am sorry to see the proposal ("Notes and Comments," March 7, p. 576) to revive the use of the long-discarded method of electric ionization in the treatment of hay fever. Apart from the suggestive effect with an electric method in this age of "electrotonics" I consider the treatment disappointing as well as harmful to the mucous membrane of the nose and likely to destroy the delicate hair cells which are so important; there is also often considerable pain. If an empirical treatment is to be used, simple cauterization with the electric point applied to a minimal area is preferable and considerably more effective. The area touched is not more than 1-1 mm. in diameter and rapidly heals with normal tissue. But in all cases of hay fever a careful investigation of all factors is necessary and a correspondingly well-planned treatment carried out if the patient is to receive lasting benefit.

Correction.—Dr. S. D. MITCHELL has written to point out that he made no claims for the "curative" value of music at the recent conference on "Pictures, Books, and Music in Hospitals" (March 21, p. 683), but only gave examples of its value as an "ancillary in treatment."

THE NATURE AND PLACE OF THINKING IN MEDICINE*

BY

Sir FREDERIC BARTLETT, C.B.E., F.R.S.

1. The Nature of Thinking

At a first encounter there may seem to be something peculiar about the title of this lecture. Surely it could be said the nature of thinking is the same under all circumstances, and in no way dependent upon its subject matter. This view has, indeed, been held by a great many people, and among them are some excellent psychologists. But it is not to be taken for granted. Even a swift survey, whether of contemporary medical activities or of the history of medicine, is enough to suggest strongly that the fact of the very great diversity of the persons to whom medical discovery and practice offer an overwhelming attraction cannot possibly be accounted for simply in terms of difference of interest in particular medical topics. It would seem that there must be some radical differences between strongly preferred methods of investigation, and that these, in their turn, may be traced to equally radical differences in the process of thinking. Doubtless the differences which I am going to try to discuss can be illustrated in other branches of knowledge as well. But their wide range, as well as the rapidity of change of fashion, of method, and of emphasis to which they have been subjected throughout the whole of their history, makes medical science and practice an outstandingly interesting and fruitful field within which to study the nature and the place of thinking.

Both in ordinary conversation and in technical definition "thinking" is a term which is almost always given an inconveniently wide application. When a man says "I didn't think of that," all that he means is that he failed to give attention to something which was not, in fact, there for him to see or hear, or otherwise to perceive. And most formal definitions which have been framed amount also precisely to this: that there is thinking whenever sensory or perceptual signs or stimuli are supplemented in the course of their observation or discussion in any way whatsoever. Now, there is no known human observation or discussion in which supplementation of this kind does not take place. And so the common view means not only that thinking is present in perceiving—which nobody need doubt—but also that remembering is thinking, and the whole sweep of imagination and fancy is thinking, and believing is thinking. Thinking, in fact, becomes so multiform that it is quite impossible to say anything definite about it at all,

except the one formal statement that it is the use of information not immediately sensorially or perceptually present.

If we are to get anywhere effectively we must have more definite starting-points than this, although in a single lecture these will have to be stated in a rather dogmatic manner, and without that experimental justification which is available.

Everybody agrees that thinking is one of the ways that animals have developed for dealing with evidence. Broadly, all human evidence is of two sources—either it comes from direct observation or else it is in some form of record, sometimes descriptive, but more often in the mode of an achieved generalization presented for acceptance or criticism. The first is the only original source, and it requires sensorial perception. When evidence of this sort is fairly examined the striking thing about it is its partial and fragmentary character. At no stage is animal observation a literal and complete reduplication of the external environment upon which it works. The character of the sensory and perceptual mechanisms through which it is made renders such reduplication impossible. Moreover, every great step in advance of animal observation has been less in the service of the accurate and complete reduplication of the external signs and stimuli and more in the service of extending the range and increasing the amount of available evidence, and especially of the building up of information on evidence. It is exceedingly likely, for example, that human observation is less accurate and less complete, relative to its possible range, than that of more primitive and restricted forms, where the sensory mechanisms are fewer and much less specialized. However this may be, all the evidence that is directly accessible comes to us fragmentary and scrappy to a degree. It is full of gaps, and we must try to fill up the gaps. Sometimes—there are innumerable cases in clinical diagnosis and in all kinds of experiments—we have evidence, and then a gap, and then more evidence. We must interpolate. Sometimes, as in clinical prognosis, there is evidence and the evidence stops short and we must extrapolate. We can interpolate or extrapolate, if we like, in the interests of what is often called aesthetic satisfaction, or we can do either or both under the dominance of objectivity—that is, in such a way that the issue we reach can be identified by observation, or proved in accordance with the nature of the system within which we are working. Thinking chooses the second, the objectivity-dominated way.

*A lecture given to the British Postgraduate Medical Federation at the London School of Hygiene and Tropical Medicine on January 27.

Thinking also usually, though not invariably, requires a number of steps or links, and when it does each step must be such that it reduces the number of possible next steps, until eventually, sometimes quickly, sometimes after a protracted process, a stage is reached beyond which all thinking persons will proceed uniformly.

That the kind of process which I have just described briefly does take place when people are given fragmentary evidence and required to bring it to an objective issue can be experimentally demonstrated. That it is the kind of process which all people who have used the term "thinking" rigorously have intended to indicate seems at least to be extremely likely.

This, however, is a lecture on thinking in medical science, and so without any more discussion I propose to try to see what direction this somewhat general lead can give to a study of *the Nature and Place of Thinking in Medicine*.

2. Everyday Thinking in Medicine

First I want to consider the psychological processes involved in certain relatively simple cases of thinking, very common and necessary as I understand them, in medical practice. I shall call this "everyday thinking."

When a "man in the street" is confronted with fragmentary evidence, say about current events, and is required to bring it to an issue, more often than not he will do it by accepting or adopting some generalization, because somebody that he trusts has said so or because it has prestige within his social group, and immediately identifying the evidence as an instance. The issue is then little or nothing more than a restatement of the generalization in terms of the particular evidence.

There seems no good reason to refuse to call this "thinking." At any rate, it certainly is what passes for thinking in most of us most of the time. It does consist in filling a gap between the generalization which is accepted and some concrete evidence which has to be directly examined. It is, basically, the process of at least some of those doctrines of "physical signs" which have received much support in medical practice from time to time.

Or perhaps an instance is the recorded statement of Ambroise Paré when he was asked if the wound of the King of Navarre was mortal. "Yes," he said, "because all wounds of great joints, and especially contused wounds, are mortal according to all those who have written about them."

From our present point of view we need not be much concerned with the generalization or formulated principle which is involved. It is sufficient to notice that this is simply accepted and may be believed. The critical part of the process lies in the treatment of the concrete evidence. For in a great many instances this evidence will lack some of the characters that are required to put it into a general class, and in practically all instances it will possess other or, in many cases, assuming points of similarity and ignoring differences. The interesting thing is that for anybody who relies solely on direct observation differences stick out much more prominently than similarities, and are much easier to observe. But once we have accepted a principle the situation is radically changed, and it becomes increasingly easy to slur over differences. Consequently the integrity of thinking in this simple kind of case depends almost entirely upon a determined, and usually conscious, effort to observe and weigh differences, and it is this quality in observation, to give due weight to differences, which needs above all else to be stressed in relatively routine diagnosis. No doubt extreme instances of what can happen when it is ignored are the eighteenth-century theories of "large and small" doses associated with the names of John Brown and Samuel Hahnemann.

Or, again, though maybe it is unfair to treat this as an instance of medical diagnosis, there was the driver of an ambulance wagon in the American Civil War. He was asked if he knew how to treat wounded men. "Oh, yes," he said; "if they are hit here"—pointing to his abdomen—"knock 'em on the head; they can't get well." Any pre-occupied medical practitioner who is forced to make rapid routine diagnosis is always up against this difficulty, the psychological source of which is the power of principle to obscure differences, and there seems to be only one real remedy, the development of an experimental approach. We must therefore go on to consider and attempt some analysis of

3. Experimental Thinking in Medicine

Experiment is still often regarded as a kind of abrogation of thinking. Every medical student must have been told of John Hunter's advice to Jenner, "Don't think, but try; be patient, be accurate," or, in an alternative version: "Why think? Why not try the experiment?" But Hunter's own practice, and Jenner's, too, show clearly that the warning was simply against the pitfalls of the kind of thinking that we have just been considering. I believe it can be shown that experimental thinking is different in important respects from the kind which I have called "everyday."

Perhaps there are two sorts of scientific experiment. One, usually the earliest kind to occur, is when some large topic or field of knowledge is well known to be inadequately mapped out, and somebody decides to try to improve ordinary unassisted processes of observation by special methods of recording which will make the detection and interpretation of likenesses and differences in arranged cases that come within this topic more exact and certain. The other, more limited and directed, usually begins when somebody decides to take seriously certain differences revealed by direct observation between specific instances and accepted principle. The kind of thinking required is pretty well the same in both, but the first tends to grow into the second, which becomes both more common and more fruitful as specialization advances. I propose, therefore, to take a fairly simple case of the second kind—probably simplifying it more than is right for the purposes of rapid discussion—and to try to bring out its leading characters as an illustration of experimental thinking.

When Sir James Mackenzie was a young medical practitioner he wrote, "I set myself the task of finding out the nature of the symptoms and signs I met with in the course of my practice. This placed before me two definite objects at which to aim—(1) the understanding of the mechanism of symptoms, and (2) the understanding of their prognostic significance." In this general statement there are two points of importance: the first a resolve to take direct observation seriously, and the second that observations of medical significance must inevitably fall into time-related sequences with gaps that must be filled in. The general resolve, however, had to become more specific. A few years later the death of a patient from heart failure directed Mackenzie's attention to the disorders of circulation, and especially to irregularities of the pulse. At that time any form of pulse irregularity tended to be regarded as serious.

The story of Mackenzie's investigations is already well known. First came the improvement of direct observation by the systematic use of instrument tracings. Then came the first critical step: the comparison of two sources of direct information, sphygmographic and jugular tracings which so far had not been combined for practical purposes, leading to the separation into a special group of those forms of irregularity alleged to be due to a premature beat of the ventricle. There followed the recognition that these also must not be lightly placed all into one class, leading eventually, after about ten years of observation and thinking, to the separation of that form of arrhythmia in which the absence of the auricular wave in jugular tracings was associated with the disappearance of the presystolic murmur, to the reinstatement of a sensible form of digitalis therapy,

and finally to a radical revision of the significance of heart murmurs which had already been studied and described over and over again, and to the view that in the end the only thing that matters is the reserve power of the heart muscle.

It is already an old story, and of course much of it has been rewritten since, but the course of Mackenzie's investigations does bring out very well some of the leading characteristics of experimental thinking in medicine.

First comes the firm resolve not to be swept away by the slumping power of established generalizations, but to give the direct evidence a fair chance. This means almost always that unaided observation must be supplemented by instrumental records. As soon as this is done differences between cases will at once, and, so to speak, by their own inherent capacity to attract attention, spring into prominence. This is only a first step. Differences of themselves lead nowhere, but hidden within them may be some significant similarities which have to be searched for, for they are inherently as difficult to identify as differences are easy. Almost always, perhaps always, they are found only when two or more sources of evidence or of information which so far have never been effectively combined are brought together. This identification of significant likeness or agreement, coupled with an appreciation of differences but a determination not to be controlled by them, is really the crux of the whole thinking activity in the case of the experimental investigation. There is, however, a third characteristic, important in all biological experimentation, but probably more vital in medicine than anywhere else, and this is that the direct sources of information which are used must all be treated as related in a sequence in time and proceeding towards some point which can be treated as terminal. This consideration leads us at once to the third kind of thinking, different in its nature from the other two, far more difficult to understand, and more fascinating to study; namely, to

4. Prognostic Thinking

Perhaps it is not too much to say that all really characteristic or specific medical thinking started in a recognition of the importance of prognosis. "I hold," said Hippocrates, "that it is an excellent thing for the physician to practise forecasting." All the great clinicians have said much the same, though it is less fully recognized that prognosis is equally a part of medical experiment, and that when general biological experiments turn out to have a medical significance it is because their conclusions are viewed in the light of some prognostic approach.

On the whole there seems to have been very little direct and sustained attempt to discover and understand the processes which are internal to medical prognosis. They are perhaps most frequently supposed to depend upon continuous faithful observation and accumulated experience. "No doctor," said James Mackenzie, "lives long enough to write a reliable book on prognosis." He was himself no doubt a fine clinician, but the idea behind this assertion seems wrong. Prognosis is often, at the least, a swift process, though its confirmation may be slow enough. On the whole I think that the great prognostic physicians have shown their special facility early, just as they have also been far more successful with the particular case than with their generalizations from many cases.

There seems to be something about medical prognosis not unlike expertness in games. At some stage the games expert seems pretty well sure to attempt an analysis of his expertness, and then he will write things like the tortuous books on golf, or cricket, or lawn tennis. The elaborate post-mortem examination gets cluttered up with detail which has minor importance, if any at all, at the living moment of performance. And this may be more than an analogy, for there is something about prognosis identical with the technique of the surgeon. Sir James Paget, speaking of William Fergusson, referred to his hands, "which were so strong and yet so sensitive, so swift and light," so apt to "clear and prompt invention." There is something execu-

tive about prognosis that seizes, so to speak, the chance of the moment. It is observation of direction, and what that is still remains a psychological puzzle as yet unravelled.

There are great differences between extrapolative thinking in mathematics and the physical sciences and extrapolative thinking, of which prognosis is obviously an example, in biology and medicine. In the former the elements which have to be used are known; their properties are known, too, and the relations of those properties can be defined at the beginning and do not change. But in the latter the elements which are to be used must be picked out of a lot of others, all of which may at first seem to have an equal status. We cannot enumerate the properties of the elements completely, and especially we do not know at the beginning what are their relations. We have to inspect instances, and, basing ourselves always upon agreements and differences, reach an issue through an appropriate use of these.

However, prolonged extrapolative thinking does, of course, take place in mathematics, the main difference perhaps being that in the mathematical case the issue is more or less defined to begin with, whereas in medical prognosis it has to be extracted from the direct evidence just as much as the items of evidence which are going to lead up to it. As is well known, Poincaré and Jacques Hadamard, in particular, have made penetrating studies of mathematical extrapolation. There is one suggestion of Hadamard's which seems to me to be particularly interesting. He is discussing Barnard's statement that "those who have an excessive faith in their own ideas are not well fitted to make discoveries." He says that this is not very important in mathematics, because good mathematicians when they make errors soon perceive and correct them. "As for me, I make many more of them than my students do; only I always correct them so that no trace remains in the final result. The reason for this is that, whenever an error has been made, insight—that scientific sensibility . . . —warns me that my calculations do not look as they ought to."

Can this suggestion be taken over directly into the biological field of medical prognosis? If we do this we have to suppose that the directional character which is always present in vital evidence can be known, or perceived, only, or mainly, through a greatly enhanced sensitivity to wrongly assigned directions. I see no reason to doubt that this does happen, but that it is the whole story, or even a main part of it, seems exceedingly unlikely. I know of no outstanding recorded instance of medical prognosis in which the final verdict was reached through the progressive rejection of all possible, or even of a large number of possible, errors. What, then? Are we reduced to the view that the directional character of evidence gathered from the examination of a patient is immediately perceived, or known, by some process of immediate insight or intuition about which nothing more can be said?

I believe that the whole of this matter could be brought to the test of reasonably controlled psychological experiment. But the experiments have not been carried out, and all that I can do now is to make certain suggestions in an extremely tentative manner.

No medical prognosis is achieved on the basis of a single examination. When this appears to be done it is only because the physician has already a fund of information, based upon other examinations, about the signs and symptoms which his direct observation has identified. Moreover, the symptoms and signs are never seen in isolation, never merely enumerated; they are seen as carrying trails which run off into the contemporary life setting, and in most cases also into the course of individual history. This being so, it seems to me very likely that prognostic thinking has fundamentally the same character as the thinking involved in scientific discovery. This is a refusal to accept apparent differences at their face value, and a capacity to probe beneath them in order to find out whether there are significant likenesses. In the case of the prognosis, the observation and information made or used are sections of

an individual life stream; in the case of scientific discovery they are more commonly fields of fact or of knowledge that are to a more superficial examination separate. In the first the resemblances are essentially of changing phenomena in temporal process. In the second this is less often the case. The essence of both is a persistent search for uniformities and likenesses where differences abound. Success in both is difficult and somewhat rare, principally because our human apparatus for building up factual observation and knowledge makes the appreciation of differences among similarities relatively easy, but of similarities among differences relatively hard.

If this is even broadly along the right lines the main reason for one thing which will impress itself upon everybody who studies the history of medicine will become more clear. All the great doctors, especially the clinical physicians, have been men of wide and varied interests and have used them all. They have put their need for this in different ways according to the different times in which they have lived, but it is a theme that crops up again and again. "The doctor," said Paracelsus, "must be a traveller because he must inquire of the world." Osler was for the peripatetic professorship, the quinquennial rejuvenation by return to hospital and laboratory, the bedside library by no means to be restricted to medical writing. Only the man of many and related interests is likely to find those uniformities in nature and in human life which he must use to fill up the gaps of observed and recorded evidence, in ways that pass unnoticed by the mass. This process of bringing together fields or items of knowledge and observation which hitherto have been unrelated is almost always the first step of discovery, especially in biology. Since in a sense every exercise in medical practice is a voyage of discovery, the vital value of varied interests is never to be overlooked.

5. The Conclusion

I have said that thinking is the expansion of evidence in accord with the evidence, to fill up the inevitable gaps in evidence. The gaps are so filled that either at once, or through a series of steps, a stage is reached beyond which all persons who accept and remain loyal to the evidence must reach the same objective issue. Since all medical science and all medical practice claim a direct evidential basis, and since our human mechanisms for dealing with evidence cannot avoid fragmentariness, thinking has its essential place in absolutely every medical exercise, whatever its level, and whatever its generality or individuality. There are some activities required in everyday life, especially probably in much current industrial practice, where all that is required is simply to treat each particular case as it comes along as nothing but a fresh instance of an already defined class of cases. Then the decision, and the resulting action, if there is any, can fairly be called automatic or mechanical. If there is any genuinely routine diagnosis it has this same character, but it is doubtful whether there ever can be, and so the physician can never get away from the challenge to think.

But the nature of medical thinking does differ in different instances. In so far as routine diagnosis is approached the success of the whole thing depends upon the identification of similarities combined with a resolute refusal to neglect differences. And it is the latter that is apt to be difficult.

Once the function of the observed differences becomes clear, either for the purpose of individual diagnosis or for the general development of medical science, the first step is usually to supplement the deficiencies of direct unaided observation by the invention and use of instrumental recording. Experiment comes upon the scene, and must play a greater and greater part as time goes on. But in first-hand observation the difficult thing is the identification of likenesses. So inherently difficult is this that once experiment starts it inevitably develops in the direction of limited range and specializations which separate one branch of knowledge

or topic of exploration from another. Practically all biological discovery, however, whether it concerns the individual instance or the establishment of general principles of treatment and explanation, rests upon the combination of different specialized fields of evidence. Thinking then is apt to be effective only when the thinker has many interests and is able to combine them. Always the watchword or slogan is "Search for likenesses, especially in unexpected places."

All medical phenomena have a future as well as a past, and their significance at any stage is as much determined by what lies ahead as by what has already happened. When this becomes dominant we have prognostic thinking, the mechanism of which is still hardly at all understood. Perhaps it depends upon some unusual sensitivity to those lines of exploration which are not likely to be very fruitful, or perhaps there is something more positive about it: the direct identification of lines of interpretation which will reach an issue. We call this insight. But it may be a capacity to use memory and stored experience, and at the same time to stay loyal to direct observation; so that likenesses which are embedded in a mass of differences and very likely to escape attention are given fair weight. If so, insight, intuition, wisdom, good judgment, are as analytical in their nature as any other thinking processes.

The doctor, like any other thinker, is all the time using "signs." The items, and the established principles, of evidence are used to carry him into the gaps in evidence. If we could know what these signs are we should be in a better position to understand the internal mechanism of thinking. And if it turned out that there are signs which the doctor must use, and which are not used much or at all anywhere else, we could perhaps say whether his thinking is peculiar in its internal mechanism. This seems very unlikely. It is certain that the signs need not be words at any level of medical thinking. It seems likely that the medical scientist and the physician can use effectively any, or all, of the signs open to any other person: words, or images, or perhaps immediately apprehended "directions." Until we know a lot more about this the attempt, not uncommon nowadays, to be dogmatic about the internal, particularly the central nervous, mechanisms of thinking, whether for medicine or for any other field, seems to be premature.

A recent account published by the National Joint Industrial Council for the Rubber Manufacturing Industry summarizes the accident experience of a considerable part of the British rubber industry from January, 1950, to June, 1952. In this period more than 26,000 reports of accidents were received; they varied from those causing trivial injuries to those with disastrous results. The authors of this enterprising study have not only shown how accidents arise in the rubber industry but indicate how wide and useful may be the application of similar methods of investigation elsewhere. They emphasize need for accuracy in classification: far too many accidents, many of them severe, come under the general heading "Other Cause." A high proportion of the accidents were found to be not specific to the conditions of the industry and its machinery but to be in two groups—"Persons Falling" and "Falling Material"; these account for 40% of the serious accidents. Some of the figures, however, are of questionable value. For instance, the fact that more men than women were injured in certain types of accident is of no interest unless the numbers of each at risk are known. One practical result of the survey has been a substantial drop in the frequency of accidents in the industry. The important role of the foreman in keeping workers alert and careful is emphasized. The authors state that "goggles can give positive protection, and the men who need their protection really must accept them." Unfortunately, they do not. Perhaps only legal sanctions and fear of dismissal can make rules observed, though much can be achieved by education, competition, and good morale.

A RELATIONSHIP BETWEEN CANCER OF STOMACH AND THE ABO BLOOD GROUPS

BY

IAN AIRD, Ch.M., F.R.C.S.*

Professor of Surgery, University of London

AND

H. H. BENTALL, M.B., F.R.C.S.

Senior Surgical Registrar, Postgraduate Medical School of London

With statistical analysis by J. A. FRASER ROBERTS, M.D., D.Sc., F.R.C.P.†

Lecturer in Medical Genetics, London School of Hygiene and Tropical Medicine

It was shown by Stocks (1950) that the standardized mortality of cancer of the stomach tended to be greater in northern than in southern towns in England. Stocks considered this to be consistent with the hypothesis that gastric cancer depends on an irritant. The only environmental factor which appeared to correlate in any way with the varying incidence of cancer of the stomach was hardness of water, towns with a water supply of moderate hardness tending to have lower rates than towns with soft or very hard water. This correlation was not a very close one. He showed also that the standardized mortality of cancer of the stomach was greater in towns with a low proportion of people of advanced age and in towns with a high proportion of men in unskilled and partly skilled occupations. Stocks did not explore, and apparently did not take into account, any possible genetic difference in the populations which he examined, nor was this possibility mentioned by Legon (1951, 1952) in attempts to correlate the geographical variations in the mortality from gastric cancer with variations in the organic content of the soil.

It occurred to one of us that there might be a correlation between the high northern incidence of cancer of the stomach and the genetic differences which are reflected in the ABO blood groups, the frequency of blood group O being greater, that of A less, in northern than in southern populations, B and AB being similar in all geographical areas in England and Scotland.

Previous published work on the association of the ABO blood groups with cancer has been on very small series of cases without adequate controls. The results have been diverse and without statistical significance (Alexander, 1921; Johannsen, 1925; Goldfeder and Fershing, 1937).

Method

A collection was made of cases of cancer of the stomach from a number of hospitals in England and Scotland, and the distribution of the ABO blood groups in patients with stomach cancer from each hospital was compared with the distribution of ABO blood groups in an equal number of patients chosen at random from the same hospital. The criterion of diagnosis has in most cases been a histological

report on material obtained at operation or post-mortem examination, but in a few cases we have been dependent upon "a cast-iron clinical diagnosis based on radiological findings, operative findings, and clinical follow-up." Our survey concerns only cases treated in the past five years, for in most hospitals blood grouping has been dependable and accurately recorded only during this period. In most cases the blood groups have been determined by hospital laboratories, though in a very few cases the determinations have been made in the laboratory facilities of a clinical unit. Wherever possible, cross-checks against the case records were obtained from the hospital transfusion service.

For controls we have selected, where possible, a cross-section of the patients of the hospital concerned rather than data from the regional transfusion organization, since the hinterland of a hospital has not necessarily the same population as that served by the transfusion service. This type of control has been used in all the provincial and Scottish hospitals which we have approached, with two exceptions. In these two exceptions controls were not easily obtainable from the hospital population, and in the case of these, affecting 566 of our controls, the blood groups of an equal control number were estimated from their frequencies in very large numbers of the local population obtained from the local transfusion centre. In the London area we have used as controls the blood-group frequencies in a series of 10,000 from North-west London collected and published by Discombe and Meyer (1952). These frequencies are very close to those given by Fisher and Taylor (1940) for Southern England.

Results

Our results are presented in simple form in Table I, and are analysed statistically by Dr. Fraser Roberts in Table II. It is clear that throughout England the distribution of blood groups in cancer of the stomach is different from their

TABLE I.—Percentage Distribution of Blood Groups in Cases of Stomach Cancer Compared with that in Equal Numbers of Controls

	Cancer Cases				Controls			
	O	A	B	AB	O	A	B	AB
Newcastle (101 cases)	43.6	43.6	11.9	1.0	52.5	37.4	7.6	2.5
Leeds (217 cases)	42.4	47.9	7.4	2.3	46.5	40.3	7.1	6.2

†Calculated from nomograms published by Boyd (1937-8).

distribution in the general population in England, and this difference is highly significant. Blood group A is more frequent, blood group O less frequent in patients suffering from cancer of the stomach than in the general population of the same locality. In every hospital from which data were obtained this same difference was observed. There thus seems to be a direct or indirect correlation between the A and O groups and susceptibility to cancer of the stomach in this country.

Discussion

Since cancer of the stomach is commoner in the North of England than in the South, while group A is less common in the North of England than in the South, it follows that this correlation with the blood groups is not responsible for the geographical differences in the incidence of cancer of the stomach demonstrated by Stocks. We must postulate that there are at least two influences operating in the cause of cancer of the stomach in England. One is an inherited influence with a relation to the A and O blood groups. The other, presumably environmental, must be assumed to be responsible for the high northern frequency of carcinoma of the stomach which Stocks showed. Since group A is commoner in the South of England than in the North and is more frequent in the cancer of stomach patients, it follows that the inherited factor operates in a direction opposite to the environmental factor of Stocks with regard to the geographical distribution of cancer of the stomach in England. Because of the low frequency of group A in the North of England, cancer of the stomach should be less common there than it is in the South, while Stocks has shown that it is in fact more common. Our figures thus add weight to the importance of the environmental factor which Stocks has postulated.

Any explanation of the apparent susceptibility to cancer of the stomach with which blood group A is invested, or protection against cancer of the stomach which is afforded by the possession of blood group O, is exceedingly difficult. It is clear that the susceptibility to cancer of the stomach or the protection against cancer of the stomach which our figures suggest must be inherited, since blood groups A and O are inherited. Our preliminary interpretation of the data was that they revealed high-incidence and low-incidence strains in the population of England with respect to cancer of the stomach. Such a hypothesis, however, would be difficult to substantiate in the light of the known facts of Britain's genetic history. The essential difference between patients with cancer of the stomach and controls affects blood groups O and A in a reciprocal fashion, B and AB retaining an equal level in both groups throughout. This reciprocity between O and A, and the constancy of B and AB, which are characteristic of the ethnological pattern of the population in this country, do perhaps strengthen an anthropological (i.e., ethnological) hypothesis. It would still be difficult, however, to devise a genetic explanation for the correlation of the blood groups with cancer of the stomach based on the known ethnological origins of the population of this country.

The alternative explanation would in its turn offer difficulty to the pathologist. It is hard to conceive any mechanism whereby the antigen A could offer a slight but definite susceptibility to, or the antigen O offer a slight but definite protection against, such a disease as cancer of the stomach. Further speculation would appear to be unprofitable at this stage. Extension of the data to cover other forms of malignant disease and other populations ethnologically alien to ours might make it clear whether an ethnological or a serological hypothesis is more tenable.

Some other conclusions may be drawn from our figures. It is generally assumed that the ABO blood groups have no selective value, at least in adults, the possession of any one of the groups conferring neither advantage nor disadvantage on its possessor with respect of survival. Our figures would seem to show that blood group A has in England at least a negative selective value, blood group O a positive selective value because of the greater and lesser

risk of cancer of the stomach which they respectively offer. Admittedly cancer of the stomach most often affects individuals after their most active reproductive period, and the transmission of the gene for group A is in most cases not prevented. Nevertheless, cancer of the stomach does affect younger people on occasion, and blood group A must therefore be regarded as having some negative, and blood group O some positive, selective value, however slight.

It is possible that there is some intermediate influence affording an indirect rather than a direct correlation between these blood groups and cancer of the stomach. Achlorhydria and pernicious anaemia, for example, come to mind as possible links.

Cancer of the stomach is commoner among the unskilled and semi-skilled than among the professional and clerical orders. We have attempted, but failed, to find a method to correlate blood groups with social class. It seems unlikely that in this country there should be differences of blood-group distribution in the various social orders, and Fraser Roberts (1953) has informed us that no such class difference appears to exist in at least one English locality.

The inheritance of cancer of the stomach has been previously suspected. One need only mention the Bonaparte family in this connexion.

Further evidence could be obtained from studies on the incidence of cancer of the stomach in twins. Gorer (1937-8) reviewed the literature on cases of cancer of all sites occurring in twins. He recorded four pairs of monozygotic twins and one pair of dizygotic twins of which each pair developed cancers of the stomach either simultaneously or within a year of each other. He concluded: (1) that heredity and environment should not be regarded as alternative causes of cancer, and that genetic factors must be regarded as influencing the sensitivity of individuals to stimuli capable of giving rise to malignancy; (2) that evidence obtained from studies with pure lines of mice shows that such genetic factors can be of great importance but do not fix the time at which the tumour will appear; (3) the likelihood of obtaining simultaneous development of identical tumours in man is probably much lower; and (4) that tumours of the alimentary canal, and especially the stomach, appear to be influenced by genetic factors.

Our findings would seem to substantiate that inheritance plays some part in the susceptibility to or protection against cancer of the stomach. The data respecting twins suggest that susceptibility is more important in this connexion than resistance.

We have explored a little the geographical and ethnological aspects of the correlation between blood groups and cancer of the stomach beyond the British Isles, but the collection of data is difficult. We have, however, obtained with the help of Dr. Holländer and his Swiss colleagues the most striking figures from Basle, where the incidence of blood groups in 704 cases of cancer of the stomach is O 36.22%, A 53.12%, B 7.53%, AB 3.13%, while in 4,518 controls from the general population the frequencies are O 41.65%, A 45.06%, B 9.03%, AB 4.26%. These differences are highly significant.

Certain North American Indian tribes have a very high incidence of group A indeed. If it could have been shown that they had also a high incidence of cancer of the stomach the hypothesis that predisposition to or protection against cancer of the stomach depended directly on an antigenic or a serological factor would be greatly strengthened. The American Bureau of Indian Affairs has assisted us in this matter, but the Indian tribes with high incidence of group A are so small, and their expectation of life is so low, that figures about cancer of the stomach are not available.

This technique of examining the distribution of blood groups in a disease is capable of further extension. It could be applied most conveniently to those diseases which require blood grouping for their treatment by transfusion, or which are commonly submitted to an operation which requires transfusion. We propose to examine cancer of the rectum, cancer of the colon, cancer of the lung, brain

tumours, and the blood dyscrasias with particular reference to pernicious anaemia, and peptic ulceration for other possible relationships with the blood groups. In view of the virus work of Bittner it would be desirable to apply the method also to cancer of the breast, though transfusion is seldom required for a patient submitted to radical amputation of the breast, and a large enough series might be difficult to collect.

Statistical Analysis

It is clear that there is practically no difference in the proportions of those with gene B for England and Scotland: $\frac{(B + AB)}{(O + A + B + AB)} = 11.08\%$ and 11.57% respectively.

The Swiss data do show a difference—10.65% and 13.28%—but this is not significant: χ^2 (with Yates's correction) = 3.504. What the British data do show is a reciprocal difference in the relative proportions of O and A. Hence the simplest and most straightforward analysis is to examine the ratio $\frac{A}{(A + O)}$. This is done in Table II. The conclusions are clear. The total χ^2 for the difference in $A/(A + O)$ between cancer patients and controls is enormously significant, $P < 1/10,000$, and the seven separate areas are perfectly homogeneous in this respect.

TABLE II.—Analysis of Differences in Relative Proportions of Groups O and A in Cancer Patients and Controls

Groups														
1	2	3	4	5	6	7	8	9						
	Cancer Cases		Controls		A/(A+O)%			χ^2						
	O	A	O	A	Cancer	Control	Diff. Cancer-Control							
Manchester ..	343	349	402	295	50.43	42.32	+8.11	9.183						
Liverpool ..	85	97	108	86	53.30	44.33	+8.97	3.022						
Leeds ..	92	104	102	87	53.06	46.03	+7.03	1.902						
Birmingham ..	37	57	50	44	60.64	46.81	+13.83	3.616						
Newcastle ..	44	44	53	37	50.00	41.11	+8.89	1.418						
London ..	578	617	614	565	51.63	47.92	+3.71	3.267						
Scotland ..	245	174	252	155	41.53	38.08	+3.45	1.022						
Total ..	1,424	1,442	1,581	1,269	50.31	44.53	+5.78	19.198						

Col. 9: χ^2 separately from the eight 2×2 tables.

Analysts		D. of F.		χ^2	
Sums of χ^2 for seven areas separately	7	7	23.430		
Total for England and Scotland	1	1	19.198		
Difference attributable to heterogeneity	6	6	4.232		

As might be expected, weighting makes practically no difference. The mean difference becomes +5.80 instead of +5.78, and the χ^2 for heterogeneity 4.121 instead of 4.232.

The frequencies in the controls correspond reasonably with what would be expected in the regions concerned.

Fisher and Taylor's (1940) figure for $\frac{A}{(A + O)}$ for the South-east of England is 48.8, against that given for London in the present paper of 47.9. A figure of 45.5 would very fairly represent England east of the Pennines over an area stretching from Leeds, Bradford, and Hull to Newcastle-upon-Tyne. The northern area controls give 43.4. Thus the ratios for controls are lower than expectation, though only slightly so; in any event the ratios for the cancer series are far higher than those for the corresponding general populations.

Conclusions

The frequency of blood group A is greater and the frequency of blood group O less in patients suffering from cancer of the stomach than in the general population of the locality in which they live.

From this correlation of blood groups and cancer of the stomach it follows that there is an inherited element in the susceptibility to or protection against cancer of the stomach.

This inherited element is not responsible for the known geographical differences in the incidence of cancer of the stomach in England.

The environmental element which Stocks has postulated in the aetiology of cancer of the stomach is more potent than would appear from the geographical incidence of the disease in England.

It is not possible from our present data to deduce whether the relationship between blood groups A and O and cancer of the stomach is dependent upon high- and low-incidence strains of cancer of the stomach in the general population of Great Britain or upon some specific effect of the antigens A and O.

In view of the relationship with cancer of the stomach in Great Britain it is no longer possible to regard blood groups A and O (in adults) as being devoid of selective value.

We gratefully acknowledge the help and advice received from Dr. A. E. Mourant, Mr. J. W. Boag, Professor Sir Ernest Kennaway, Mr. M. P. Curwen, Professor D. F. Cappel, and Dr. John Wallace.

It will be apparent that an investigation of this kind would have been impossible without the co-operation and labours of the clinicians and records officers of all the participating hospitals. Our indebtedness is very great to the staff of the following institutions:

Ciba Laboratories have recently presented a film on senile obliterative arteritis of the legs to the B.M.A. Film Library. The course, diagnosis, and management of the condition are demonstrated by members of the university surgical unit, Manchester Royal Infirmary. The film is a 16-mm. colour film with commentary, and it runs for about 55 minutes. It is divided into three parts: the first deals with the pathological anatomy, the second with clinical examination, and the last with the general and local management of intermittent claudication and severe ischaemia. The producer was Dr. Brian Stanford.

SYMPTOMATIC DISTURBANCE AFTER SINGLE THERAPEUTIC DOSE OF X RAYS

ITS RELATIONSHIP TO THE GENERAL RADIATION SYNDROME

BY

W. M. COURT BROWN, M.B., Ch.B., B.Sc., F.F.R.*

Department of Medicine, Postgraduate Medical School of
London, W.12

The development of atomic power and the consequent dangers, both in war and in peace, of exposure to the radiations produced by nuclear fission have instigated extensive research into the effects of whole-body irradiation on many animal species. This research, together with the observations made on the populations of Hiroshima and Nagasaki following their exposure to the radiations of the atomic bombs, has shown that such irradiation produces a fairly well defined pattern of signs and symptoms, collectively known as the general radiation syndrome (Fig. 1). This syndrome has been reproduced following whole-body irradiation given to a wide range of mammals such as rats, mice, monkeys, dogs, swine, etc., and, although there are certain species differences, particularly concerning the critical dose of x rays required to produce the full syndrome in each instance, the overall picture of the syndrome is sur-

FIG. 1.—Diagrammatic representation of the general radiation syndrome in man. (Adapted from Liebow, Warren, and De Coursey, 1949.)

prisingly comparable throughout the range of mammals investigated. The fact that such a reproducible syndrome exists is of great value and importance in furthering basic research work into physiological disturbances produced by x rays.

Walsh (1897) first described acute constitutional symptoms in an x-ray worker, and since that time many reports have appeared concerning the production of such symptoms as nausea and vomiting in patients undergoing radium and x-ray therapy. Early workers held several factors to be responsible for these symptoms, among which may be mentioned poor ventilation of the treatment rooms, electrical charging of the patient's body, psychological disturbances, and the release into the circulation of the toxic products of protein breakdown.

*Working for the Medical Research Council

The position to-day regarding the aetiology of these symptoms is only a little less confused. Progress has been hampered by the lack of any clear-cut definition in the medical literature of what has come to be known to radiotherapists as radiation sickness, and the apparent absence of any correlation with the disturbances found after the experimental whole-body irradiation of animals.

It is the object of this communication to describe the pattern of symptoms which occurs in human beings shortly after a single exposure to a dose of x rays within therapeutic limits, and to demonstrate the place of this pattern within the general radiation syndrome.

Clinical Material

Concurrently with the supervision of the x-ray therapy of certain patients referred to the Radiotherapy Department of Hammersmith Hospital, detailed clinical observations were made before and after a single dose of x rays. Fifty such patients have now been observed, and they were selected for these studies because their general health was good and the nature of their disease necessitated the irradiation of a large volume of tissue. The primary diseases of these patients are as follows:

Ankylosing spondylitis	20
Reticulosis	20
Carcinoma of ovary (post-operative)	5
" " testis "	2
" " thyroid "	1
Malignant melanoma (recurrent)	2

It will be seen that the majority suffered either from ankylosing spondylitis or from various forms of reticulosis. In the latter group all patients except one have been early or moderately early cases of Hodgkin's disease, follicular reticulosis, and reticulum-cell sarcoma, the single exception being a case of multiple myeloma. The patients suffering from carcinoma of the ovary, testis, and thyroid had been referred for radiotherapy following surgical excision of the primary tumour. Both cases of melanoma demonstrated metastases after surgical treatment of the primary tumour at an earlier date, the recurrences being widespread.

To provide a control series of observations, sham irradiations were also given to 34 of the 50 patients. The conditions of the sham irradiation exactly resembled those of the actual irradiation in respect of the positioning of the patient under the x-ray tube, the number of fields apparently irradiated, and the delineation of the fields of irradiation on the skin. The patient believed that irradiation was being carried out, and was in position under the tube for the correct period of time. The x-ray tube, however, was not energized.

Irradiation

Sites.—The main sites of irradiation are shown in the Table. The sacro-iliac joints and whole length of the spine were irradiated in patients suffering from ankylosing spondylitis and also in the one patient with multiple myeloma. In the patients with reticulosis, irradiation was given either to the upper half of the trunk or to the abdomen, depending upon the main sites of distribution of the lesions, the only exceptions being one individual with reticulum-cell sarcoma in whom radiation was directed to the lower part of the left half of the pelvis and upper half of the left thigh, and three

Incidence of Symptoms After a Single Dose of X Rays to Various Sites

Radiation Given	Mean Integral Dose	No. of Patients		
		Irradiated	Developing Symptoms of Any Type	Developing Vomiting
Whole spine and sacro-iliac joints	4.0	21	20 (97%)	12 (57%)
Whole abdomen ..	3.4	10	9 (90%)	6 (60%)
Upper half of trunk	3.9	13	11 (84.5%)	4 (31%)
Whole body ..	2.9	4	2 (50%)	1 (25%)
Lower abdomen and thigh ..	4.2	1	0	—
Both thighs ..	3.8	1	0	—

patients to whom whole-body irradiation was given. Whole-abdominal irradiation was employed in those patients who had had testicular and ovarian tumours excised. One patient with an undifferentiated carcinoma of the thyroid was given wide-field irradiation of the upper half of the trunk; and of the two patients with melanoma metastases one was given whole-body irradiation and the other had both thighs irradiated.

Dosimetry.—All patients were irradiated with x-ray tubes operating at 250 kV, the tube current being 18 mA. In each instance dosage has not been expressed in terms of the number of conventional r units received on the skin or at some defined point deep to the skin, but in terms of the total amount of energy absorbed within the body, calculated in megagram-roentgens. The estimate of total energy absorption is known as the "integral" dose, and from the biological standpoint it carries greater significance than an estimate of dose in r units, allowing, with certain reservations, comparisons to be made between results obtained following irradiation in differing sites of the body. In the calculation of integral doses, valuable help has been given by Mr. J. W. Boag, of the M.R.C. Radiotherapeutic Research Unit, and the figures for whole-body irradiation have been derived from the observations of Mayneord and Clarkson (1944). The Table demonstrates the mean integral dose given in the various sites irradiated.

Results

The General Symptom Pattern

Symptoms developed in 42 out of 50 patients irradiated (84%), and the chief symptoms were found to be fatigue, anorexia, nausea, and vomiting. The pattern of symptoms in each instance was found to be very similar (Fig. 2), and

FIG. 2.—Diagrammatic representation of symptom pattern after a single therapeutic dose of x rays.

differed in degree only from one patient to another. The time interval which elapses from the beginning of irradiation until the disappearance of all symptoms can be divided into three main periods: the latent period, the period of acute disturbance, and the period of recovery.

Control Sham Irradiation

Information was obtained from the control sham irradiations concerning the part played by psychological and emotional disturbances in determining the incidence of symptoms. Eight out of the 34 patients developed symptoms from their sham irradiations (23.5%), but in no instance did the pattern of symptoms resemble that following the actual irradiation. It was characteristic that in these circumstances the patient complained of symptoms, chiefly headache and fatigue, either during the period of apparent irradiation or immediately after leaving the treatment room. The emotionally or psychologically disturbed patient failed to demonstrate any latent period—in complete contrast to the symptom pattern following actual irradiation. In the great majority of instances the sham irradiation was given some days before the actual irradiation, and it was noticeable that those who developed symptoms after their sham exposures did not develop any symptoms at comparable times after their actual irradiation.

Detailed Analysis of Symptom Pattern:

1. Latent Period

The mean time lapse from the beginning of irradiation to the development of symptoms was 2.7 hours. It appeared that the latent period was shorter in those patients who were generally more severely upset and who developed vomiting. A comparison made between these two groups showed that there was a difference of nearly three-quarters of an hour between the mean values of the latent periods, a difference which was found to be statistically significant (see appendix). The lengths of these two latent periods have been examined for possible influences upon them of sex distribution, dosage, disease, and site of irradiation, but no evidence has been found that these factors were responsible for the significant difference observed. It seems fair to conclude that, following a given dose of x rays, the more sensitive an individual is to the effects of irradiation the earlier are the symptoms likely to appear.

It will be realized that the latent period as calculated includes the period of time occupied by the positioning of the patient under the x-ray tube and in most instances by the irradiation of several fields. On an average this period is approximately half an hour, so that the absolute value of the latent period, assuming irradiation to have been given in an instantaneous period of time, is approximately 2.25 hours for all the patients in the series.

2. Period of Acute Disturbance

The usual complaints are of a sudden bout of nausea or of a sudden feeling of severe fatigue. Less frequent initial symptoms are headache of no particularly characteristic distribution, a feeling of dizziness or "muzziness" in the head, and an emotional disturbance taking the form of acute mental depression, in a few instances accompanied by actual weeping. Whatever the initial symptoms may be, the predominant symptoms which establish themselves in the early part of this period are fatigue, anorexia, and nausea. Objective assessment of these symptoms is practically impossible, but it appears that, after being present for a time interval varying approximately from half an hour to an hour and a half, three developments may occur, depending on the severity of the patient's upset. In the mild case the symptoms gradually subside; in the moderately severe case either the fatigue element or the feeling of nausea, or both, become accentuated for a further period of about one hour before subsiding; and in the severe case vomiting and retching supervene. Only one bout of vomiting may occur, but in the more severe cases there may be vomiting at intervals for a period of two to three hours. After the cessation of vomiting the recovery period ensues.

In studying the incidence of the various symptoms in this period of acute disturbance it is clear, both from

impressions of the observer and from the descriptions given by the patients, that fatigue appears to be dissociated from nausea and vomiting. Thus in some individuals the outstanding complaint is one of fatigue, nausea being a mild transitory symptom and vomiting not occurring at all. In rare instances the patient has never complained of nausea but solely of fatigue. On the other hand, at least four patients were encountered whose presenting symptom was nausea, which was rapidly followed by vomiting, but in whom fatigue, apart from slight tiredness apparently consequent upon the act of vomiting, did not occur at all. It was a striking observation that these latter patients remained perfectly well between their bouts of vomiting, and as soon as their vomiting ceased had no further symptoms. This suggests that two aetiological disorders may underlie the development of these symptoms—one associated with fatigue and the other with nausea and vomiting.

A detailed analysis of the incidence of symptoms for each site irradiated, and in particular for the incidence of vomiting, is shown in the Table. The incidence of vomiting when irradiation was confined to the upper half of the trunk was 31%, as opposed to an incidence of 60% when the abdomen alone was irradiated. However, the total numbers in each group are small, and, by considering all instances in which radiation was not directed to the abdomen in contrast to all those in which the abdomen was irradiated, irrespective of whether radiation was directed to other sites as well, the relevant figures are 29% and 53%. Statistically these two sets of figures are not significant, but in the larger group the difference approaches much nearer to a significant level than in the smaller group. It is possible that with an even larger series of patients a significant difference may be found in the incidence of vomiting, depending on whether the abdomen is irradiated or not.

During this period of acute disturbance no consistent changes have been noted in the pulse rate, blood pressure, body temperature, and respiration rate up to the act of vomiting.

3. Recovery Period

An accurate estimation of the recovery period is difficult, but it is possible to make an approximate estimate to the nearest day. With the subsidence of the period of acute disturbance the patient is left with a feeling of mild fatigue, nausea, and anorexia. Depending on the degree of acute disturbance, these symptoms either persist for one day or less, or extend in the most severe instances over a period of up to five days. In the most severely upset patients nausea may persist for two to three days, but of the three outstanding symptoms it is the first to disappear. Its disappearance is followed by the gradual subsidence of fatigue and anorexia, in that order.

The General Radiation Syndrome

The pattern of symptoms following a single dose of x rays within therapeutic limits having been demonstrated, the basic pattern of the general radiation syndrome, observed after the exposure of both animals and man to high levels of radiation, must now be considered.

The main features of the general radiation syndrome are depicted in Fig. 1. This diagram was derived from the observations made upon Japanese necropsy material and from the histories and clinical features of the survivors (Liebow, Warren, and De Coursey, 1949). It will be seen that there are four main periods in which clinical disturbances and death may or do occur, which may be designated: the period of initial reaction, the period of acute reaction, the period of subacute reaction, and the period of chronic reaction.

Period of Initial Reaction.—This supervenes after a brief latent period following exposure, and is characterized by nausea, vomiting, and fatigue. It is probable that the mean length of this latent period is approximately two hours, although species differences and the level of dosage received

may well determine its actual length. In the Japanese cases the latent period is said to have been in some instances as short as half an hour. On the other hand, Painter and Brues (1949) state that the initial signs and symptoms occur within the first six hours in man, the dog, rat, mouse, guinea-pig, and goat. Theoretically it is possible for a human being to die during this stage, as it has been shown that animals subjected to radiation of very high intensity may die either during the period of irradiation or within a few hours of its cessation (Henshaw, 1944). It is generally stated that in most instances the duration of the initial reaction is approximately two to three days and that following its disappearance a period of comparative well-being ensues before the next stage of the general radiation syndrome supervenes. It appears likely, however, that in some of the Japanese casualties and also in some rats and dogs (Painter and Brues, 1949) this period of initial reaction is prolonged towards the end of the first week after exposure and terminates in death. The human beings showing this developed high fever, thirst, diarrhoea, and delirium before they died. At the time of death clinical evidence of bone-marrow damage was not prominent, and it seems likely that death at this stage is the outcome of an extremely severe form of damage inflicted during the original irradiation.

Period of Acute Reaction.—This stage becomes apparent towards the end of the second week, and is characterized by the clinical features of acute marrow failure, of ulceration of the mucous membrane of the gastro-intestinal tract of acute secondary infections, and also by epilation.

Period of Subacute Reaction.—This stage occurs at about the end of the sixth week, at which time the marrow damage clinically obvious in the preceding phase, is becoming less marked. At this stage death may result from lung or brain abscess, persistent ulceration of the large bowel, an exacerbation of a pre-existing focus of infection, and malnutrition.

Period of Chronic Reaction.—The preceding period of subacute reaction probably merges insensibly into the period of chronic reaction, where the presenting features and causes of death are malnutrition, chronic anaemia, chronic infections, premature senility, and possibly leukaemia.

It will be realized that in the majority of patients the complete syndrome will not be shown. In these patients depending on the amount of radiation received during the original exposure and the inherent radiosensitivity of the individual, one or more of the acute manifestations may develop, resulting in some instances in death. On the other hand, there may only be evidence of mild upset, probably in the form of a minor degree of suppression of marrow function and some epilation. Finally, a proportion of individuals will show no clinical features of the syndrome, but haematological investigation will demonstrate an abnormally low total white-cell count.

Conclusion

It has been shown that, following a single dose of x rays within therapeutic limits and of the order of 3-4 megagram roentgens, there is a well-defined latent period which terminates in the sudden onset of symptoms, and that the period of acute disturbance, after lasting for a variable number of hours, passes into a recovery phase. The total duration of the symptomatic disturbances has been shown to vary from one to five days, depending on the radiosensitivity of the individual and the actual dose given. The similarity of the symptom pattern following the therapeutic dose of x rays to the period of initial reaction, the first manifestation of the general radiation syndrome, is evident. The close agreement in the length of the latent periods and the similarity of the symptoms justifies the conclusion that after therapeutic x-ray doses the symptom pattern is a milder version of the symptom pattern of the period of initial reaction seen in animals after mid-lethal doses. This conclusion indicates that it is justifiable to utilize observations made

after a single therapeutic dose of x rays in the interpretation of the consequences of exposure to irradiation of greater and possibly lethal proportions.

Summary

The pattern of symptoms following a single therapeutic dose of x rays has been described, based on the findings in a group of 50 patients. The pattern was found to consist of three well-defined phases: a latent period extending from the administration of the x rays to the onset of symptoms; a period of acute disturbance which persisted for approximately between one and a half and four hours after the onset of symptoms, depending on the degree of upset; and a recovery period which in the most acutely disturbed patients extended over four to five days. In those patients in whom the period of acute disturbance was not associated with vomiting the latent period was found to be significantly longer than in those who vomited.

A brief description has been given of the general radiation syndrome produced in man and in many types of mammals following a single mid-lethal dose of x rays, in which four general periods of reaction can be discerned: the periods of initial reaction, acute reaction, subacute reaction, and chronic reaction.

The similarity between the pattern of symptoms following therapeutic doses of x rays and the symptoms of the period of initial reaction of the general radiation syndrome has been stressed, and attention has been drawn to the possible value of using clinical studies based on single therapeutic doses of x rays to interpret what may occur when, either accidentally or under conditions of war, much higher doses are received.

No account has been given of the physiological disturbances produced by therapeutic doses of x rays, which will form the subject of a later communication.

I wish to thank Professor J. McMichael and Dr. Russell Fraser, of the Department of Medicine, Dr. J. F. Loutit, of the M.R.C. Radiobiological Research Unit, A.E.R.E., and Dr. C. A. P. Wood, Director of the M.R.C. Radiotherapeutic Research Unit, for their advice and criticism.

APPENDIX

The mean length of the latent period in the less severely upset group of patients (Group A) has been compared with that in the more severely upset group (Group B). The distribution of the different lengths of the latent periods within each group, the value of the mean and t and P values of the difference of the means are shown below.

	Length of Latent Period (Hours)							
	1-1.49	1.50-1.99	2.0-2.49	2.5-2.99	3.0-3.49	3.5-3.99	4.0-4.49	4.5-4.99
Group A (19 patients)	0	1	2	7	0	7	2	0
Group B (23 patients)	5	4	4	4	1	2	1	2

Mean length of Group A = 3.06 hours } Difference of mean
Mean length of Group B = 2.44 hours } lengths = 0.62 hr.
The t value of the difference is 2.10, indicating that P<0.05 and that the difference is significant.

ORAL N,N'-DIBENZYLETHYLENE-DIAMINE PENICILLIN IN CHILDREN

BY

I. A. B. CATHIE, M.D., M.R.C.P.

AND

J. C. W. MacFARLANE, M.D., B.Sc.

(From the Department of Clinical Pathology, The Hospital for Sick Children, Great Ormond Street, London)

The greatest drawback to the use of oral penicillin has been, in our experience, the variability with which it is absorbed into the blood stream. Several penicillin derivatives have been tried in different dosages, with and without antacids, before and after meals, and scaling the dosage according to body weight. While in a good proportion of cases therapeutic blood levels have been obtained by the oral route, with no preparation have consistent levels been observed; this has meant that, when any case has been treated with oral penicillin, blood-level estimations have been essential to confirm that the antibiotic was being absorbed.

Recently a new salt N,N'-dibenzylethylenediamine penicillin has been available (Szabo, Edwards, and Bruce, 1951); this is referred to here as "penidural." It has been the subject of a recent report by Fletcher and Knappett (1953) as a long-acting repository penicillin following intramuscular injection; we have investigated it from the point of view of reliability of absorption following oral administration.

Side-effects.—Several adults have complained of borborygmi and urgency at stool during the first 24 hours of treatment but not subsequently. No children of any age have been disturbed, and the palatability of the product has made its administration easy.

Material and Methods

Penicillin blood levels were estimated, using a dilution technique with a strain of *Staphylococcus aureus* of sensitivity to 0.03 µg. of penicillin per ml. A total of 101 children of all ages were given 300,000 units of penidural and their blood levels were estimated three to four hours after administration for reliability of absorption. In addition a small series of 17 adult volunteers were investigated with the same preparation.

The penidural was given irrespective of the times of meals and whether the stomach might be full or not.

Results

Fig. 1 shows that the antibiotic was reliably absorbed in all of the 118 cases in which it was administered, and Table I shows the levels obtained in the 101 children. In several

FIG. 1

FIG. 2

cases hourly penicillin levels were estimated and a cumulative effect was seen following a second oral dose. Fig. 2 shows one such typical example, in which there were satisfactory blood levels for six hours, but no residual level at 12 hours after a single dose. When a second dose was given at six hours, not only were the levels for the succeeding six hours higher than in the first period but there was also a residual level at 12 hours.

In Table II are shown the blood levels at 24-hour intervals in four consecutive patients of differing weights and ages to whom six-hourly penicillin was being given. Blood samples were taken at the same time each afternoon, three hours after the last dose of the drug. Each shows the same increase in blood levels as is depicted in Fig. 2. There was some indication in the figures shown in Table I that better blood levels were obtained when penicillin was given before meals.

Discussion

Penicillin is the first oral preparation of penicillin which has in our experience been reliably absorbed in 100% of patients, irrespective of size and weight and using a standard dosage of 300,000 units. No attempt has been made to work out a graded system of dosage according to body weight, but it is possible that in the smaller children ther-

apeutic blood levels might be obtained with lesser amounts of penicillin. The emergence of a reliable oral penicillin seems to bring this drug into line with the newer antibiotics where penicillin-sensitive organisms are being dealt with.

In the treatment of acute infections blood levels during the first six hours with this oral penicillin alone cannot be regarded as adequate, and in five cases of acute illness in which penicillin has been used therapeutically a single intramuscular injection of a large amount of crystalline penicillin has been used to augment the blood level during this period. In these cases—two of osteomyelitis and three of pneumonia—the results obtained have been as good as those which would have been anticipated had intramuscular penicillin been chosen for treatment.

A rational scheme of treatment of acute infection appears to be an initial intramuscular injection of 600,000 units of penicillin (Fletcher and Knappett, 1953) and 100,000 units of crystalline penicillin, with 300,000 units of penicillin orally, the treatment continuing thereafter only with oral penicillin. Such a scheme will produce reliable therapeutic penicillin levels and should be adequate to treat infection by penicillin-susceptible organisms. Abuse of this new penicillin preparation is likely to enhance the growing number of strains of penicillin-resistant bacteria, and it is hoped that the growing menace of penicillin-resistant staphylococci will not be unnecessarily increased by improper dosage or dose-spacing.

We are indebted to Messrs. John Wyeth, Ltd., London, for a plentiful supply of penicillin.

COMBINED ORAL PENICILLIN AND SULPHADIMIDINE IN ACUTE MIDDLE-EAR INFECTIONS

BY

DAVID WHEATLEY, M.D.

Modern antibacterial drugs have revolutionized the treatment of acute otitis media, and the role of surgery in this condition is of rapidly diminishing importance. Before the discovery of antibiotics, sulphonamide administration was an established part of the therapy of this condition (Hall, 1948). Owing to the limitations imposed by toxicity upon the attainable blood sulphonamide level, and the diversity of the invading organisms, it is not surprising that sulphonamides alone are often unable to quell the infection.

The Literature

The commonest causal agents are *Staph. aureus* and *Str. haemolyticus*; consequently much better results follow the use of penicillin as the antibacterial agent (György *et al.*, 1946; Lierle and Paul, 1946; Robinson *et al.*, 1948; Jersild and Kiørboe, 1950). However, this still leaves the dangerous residue of insensitive Gram-negative bacilli, notably *Bact. coli* and *Proteus* strains, which are often present in varying numbers in a mixed infection. Elimination of the main infecting bacteria allows, and even stimulates, these fellow-travellers to multiply rapidly and restore the severity of the original disease condition.

Of the newer antibiotics, streptomycin carries with it a danger of vestibular damage and is unlikely to commend itself for the treatment of infections in the aural cavities. Chloramphenicol and aureomycin, with a wider antibacterial range, approach more closely to the ideal.

treatment of this condition. The cost of these antibiotics, however, is prohibitive; and, if used with penicillin, the superior bactericidal power of the latter might be prejudiced by their antagonistic action (Armstrong and Lerner, 1951). My personal impression of a very limited trial of chloramphenicol is that it is not quite so effective in a mixed infection as penicillin and a sulphonamide combined.

That such a combination results in a pronounced synergism between the two drugs has been repeatedly demonstrated in the laboratory (Bigger, 1944; Chain and Duthie, 1945; Kolmer, 1948). Further, this synergistic action extends to Gram-negative organisms such as *Bact. coli* and *Bact. typhosum* (Stewart, 1947; Thomas and Hayes, 1947; Bigger, 1950; El Borolossy and Buttle, 1950). The action of the sulphonamides in preventing destruction of penicillin by penicillinase (Cronheim and King, 1951) may be of importance when dealing with these latter organisms. On the clinical side there are very few reports of combined therapy with the two drugs, although Johnson *et al.* (1951) have described a synergistic action between oral penicillin, sulphadiazine, and sulphamerazine in the treatment of gonorrhoea. On the other hand, Nielsen and Sørtrup (1951) found no difference between combined therapy and therapy with either drug alone in the treatment of pneumonia. I can trace no records of similar treatment in acute otitis media, although Moffett and Dalton (1949) have successfully treated acute mastoiditis with penicillin and sulphadiazine. It is the purpose of this paper to describe a number of cases treated with sulphadimidine and penicillin, with particular emphasis on the oral route for the latter drug.

There can be no doubt that, when administered on an empty stomach, penicillin is well absorbed from the first part of the duodenum in a dosage some five times in excess of that by injection (Little and Lumb, 1945; Buchanan, 1946; Husson, 1947; Markowitz and Kuttner, 1947; Reisman *et al.*, 1947; Stewart and May, 1947; Cohlan *et al.*, 1948). Hypochlorhydria, occurring as a result of severe illness, contributes to this (Buchanan, 1946; Anderson and Landsman, 1947; Bicknell, 1951). The adequate clinical effect of oral therapy in serious illnesses such as pneumonia has been amply demonstrated (Bunn *et al.*, 1945; Finland *et al.*, 1945; Suchett-Kaye and Latter, 1947; Anderson and Landsman, 1947; Eadie *et al.*, 1951). Good results have also been claimed in ear, nose, and throat infections (Robinson *et al.*, 1948; Wheatley, 1951). Oral administration is of greater convenience in general practice, where most cases of acute otitis media are likely to be seen. As this infection most commonly occurs in children, the oral route is again particularly desirable. For combination with sulphonamides, too, it is convenient to administer both drugs together by mouth, at the same dosage intervals. After some trial I adopted an eight-hourly interval for the treatment of these cases. This is a schedule which others have found to be highly effective with oral penicillin in pneumonia and scarlet fever (Bunn *et al.*, 1950; Weinstein and Perrin, 1950). Bunn and his co-workers also treated some of their cases with 12-hourly dosage, as did Austrian *et al.* (1951). Results were comparable with those following parenteral therapy.

In treating the acute middle-ear infection, the ideal procedure is to institute chemotherapy before perforation of the tympanic membrane can occur; thereby spontaneous perforation or the need for paracentesis may be avoided. The latter procedure is a difficult one to perform in general practice, and I am not convinced of its absolute necessity. Simpson (Fleming, 1950), considering this question in relation to penicillin therapy, advises paracentesis after 24 hours if there is no improvement. He rightly stresses that the object of treatment is the preservation of the function of hearing, and points out that even a sterile collection of fluid in the middle-ear may lead to resultant adhesions, and a possible recurrence later. I personally feel that such a collection of fluid will naturally drain away via the Eustachian tube, without the need for paracentesis. However, in order to prevent the possibility of serious permanent disability chemotherapy must be prompt and adequate.

Results

The cases have been divided into two groups, classified as mild and severe. Mild cases were those in which there was little constitutional disturbance but inflammation and bulging of the tympanic membrane were present. Severe cases were those in which there was much pyrexia and pain, or in which perforation of the ear-drum had already occurred before they were seen. Most of the mild cases were treated with penicillin alone, sulphadimidine being held in reserve in case there was not a prompt response to treatment. The severe cases were treated mainly with combined penicillin and sulphadimidine from the onset. Chloramphenicol was substituted in three cases when the results of bacteriological examination showed an organism highly sensitive to this antibiotic. In these cases the response to combined therapy had not been as immediate as in the other cases in the series. The results are tabulated and compared with some earlier results obtained with sulphonamides alone and with parenteral penicillin. These cases do not include acute exacerbations occurring in chronic otitis media. The standard dose for adults was 0.375 g. (600,000 units) of penicillin plus 1 g. of sulphadimidine, eight-hourly by mouth; there was a proportionate reduction in amounts for children.

Comparison of Results

Treatment	Cases			Perforated Before Treatment	Perforated After Treatment	Recurrence in 3 Months	Chloramphenicol Substituted
	Mild	Severe	Total				
S.	3	4	7	3	Nil	3	Nil
Inj. P. . . .	8	9	17	8	2	1	"
Inj. P. and S. .	3	5	8	3	Nil	1	"
Oral P. . . .	23	6	29	6	Nil	Nil	1
Oral P. and S. .	4	28	32	13	"	1	2
Total	41	52	93*	33	2	6	3

S.=Sulphonamide. P.=Penicillin. * There were 2 separate attacks in 4 cases.

Bacteriology.—Swabs were taken from one-third of the 33 cases in which perforation had occurred before treatment was begun. The cultures gave the following results:

<i>Staph. aureus</i>	3 cases
" " and diphtheroids	1 case
" " " <i>Proteus</i>	"
" " " <i>Bact. coli</i>	"
<i>Bact. coli</i> , pneumococci, and <i>Staph. albus</i>	1 "
<i>Staph. albus</i> (48 hours after treatment)	1 "
<i>β Str. haemolyticus</i>	1 "
" " <i>Staph. albus</i> , and diphtheroids	1 "
Sterile	1 "

Late Results.—General practice offers some unique opportunities for follow-up of these cases, with particular reference to late effect on hearing. This is so because over the course of years many of these patients are seen from time to time for other ailments. About three-quarters of the cases described here have been thus observed for periods of one to three years. In none of these was there any residual hearing defect, as measured by their ability to hear the whispered voice at 15 feet (4.6 metres) with the affected ear alone. Where perforation had occurred healing took place in every instance. Sometimes a minute scar could be seen at the site of the perforation; but in many it was impossible to detect any evidence of the previous rupture of the membrane or of the original infection. The six cases in which there was a recurrence in three months resolved with further treatment. In four cases there were repeated but separate infections (often in the opposite ear). These also resolved with repeated treatment, and further attacks were prevented when infected tonsils and adenoids were removed.

Conclusions

The small numbers of cases treated with sulphonamides alone and with parenteral penicillin offer no basis for accurate comparison. However, they are useful in that they indicate that oral penicillin is no less effective than penicillin by injection. Of the seven cases treated with sulphonamides

alone there was a recurrence within three months in three. This was regarded as an unsatisfactory result. Although one case out of 32 treated with oral penicillin and sulphadimidine suffered a recurrence in three months, it must be borne in mind that this group included by far the greatest number of severe cases. The satisfactory end-results in 93 cases of acute otitis media treated with chemotherapy alone are held to obviate the necessity for surgical intervention. The results of bacteriological examination in 11 cases indicate that the majority of cases are probably due to infection with penicillin-sensitive organisms, but that non-sensitive bacteria, particularly *Bact. coli*, form an important minority. It is held that the co-administration of sulphonamides with penicillin will effectively deal with most of these infections. This is particularly important in those cases (the majority) in which perforation of the ear-drum has not occurred and, as a result, the nature of the invading micro-organism cannot be ascertained. In the occasional instance in which a more specific antibiotic is required, combined therapy will stay the infection until the result of bacteriological examination is known.

Summary

The role of chemotherapy in acute otitis media is discussed and the advantages of combining penicillin and a sulphonamide are outlined. The synergistic action of these two drugs and the desirability of co-administration in mixed infections is stressed. The literature on oral penicillin administration is surveyed, and it is concluded that this is an effective and convenient method of administering the antibiotic.

The results in 93 cases of acute middle-ear infection are described. Of these, 61 were treated with either oral penicillin alone or oral penicillin and sulphadimidine, according to severity. Out of 34 severe cases treated in this manner, perforation of the tympanic membrane had already occurred in 19 before treatment was begun. The results were uniformly good, with no permanent sequelae or after-impairment of hearing. Healing of the ear-drum occurred in all cases in which perforation had occurred. The bacteriology in 11 cases showed a preponderance of infection with *Staph. aureus* and *Str. haemolyticus*. However, the infection was usually a mixed one, with *Bact. coli* and *Proteus* as the usual co-invaders.

I wish to express my thanks to Dr. L. W. Cann, of Ashford County Hospital, for undertaking the bacteriological examinations.

THE Q-T INTERVAL IN MYOCARDIAL INFARCTION

BY

ROEINTON B. KHAMBATTA, M.B., M.R.C.P.
M.R.C.P.Ed.

(From the Department of Cardiology, University of Manchester, and the Cardiac Department, Royal Infirmary, Manchester)

The Q-T interval of the electrocardiogram is measured from the beginning of the Q wave to the point where the T wave ends at the isoelectric line. It is an indication of the total time occupied by ventricular excitation and recovery. Recently, great interest has been evinced in this hitherto neglected feature of the electrocardiogram, and its variations have been reported in a variety of conditions.

A statement in a leading textbook of electrocardiology (Wolff, 1950) that "abnormal Q-T occurs regularly as a result of myocardial injury. If QRS is normal, the prolonged Q-T must signify a profound disturbance in the recovery process" aroused interest in this question, and, as a search of the literature of the subject was barren in its results, this particular study was embarked on.

Clinical Material and Methods

As this study was undertaken to evaluate the significance of the Q-T interval in myocardial infarction particularly, it was decided to rule out all possible variables. For this purpose all the normals which serve as controls were selected from the ages of 40 and above. It was also made absolutely certain that all the normals had no electrocardiographic abnormality. The group of cases of myocardial infarction selected was also carefully scrutinized to exclude any which showed any changes of rhythm, of ventricular hypertrophy, of bundle-branch block, or of hypertensive heart disease, or which demonstrated either erect or inverted U waves. Also, any patient who had had digitalis (Berliner, 1931) or who had been on a regime of mercurial diuretics was discarded.

A total of 600 normal tracings (400 males and 200 females) and 800 tracings of myocardial infarction were studied. All the tracings had been taken on the standard Cambridge string-galvanometer electrocardiogram, by the same individual, with the same standardization (1 mV=1 cm.). In the examination of each tracing a strict routine was adhered to, the tracings being examined under a powerful magnifying-glass. Any tracing which showed any abnormality in the shape or the duration of the QRS complex was discarded, as were also all tracings in which the end of the T wave was not clearly definable. Each Q-T interval was measured from the point at which the Q wave (in the absence of the Q wave, the R wave) left the isoelectric line to the point where the T wave after its excursion returned to the isoelectric line. Each R-R interval was measured from the peak of the R wave of one complex to the peak of the R wave of the next complex.

To calculate the Q-T and R-R intervals the following procedures were followed: (1) Any two Q-T and R-R intervals were measured in each of Leads II, aVF, V₂, and V₄, giving a total of eight separate values for both the Q-T and the R-R intervals. (2) The Q-T₀—Q-T interval corrected to the rate (Taran and Szilagyi, 1947) of each corresponding Q-T and R-R interval—was worked out as explained below. (3) The average of these eight Q-T₀'s was taken as the final Q-T₀ figure. This procedure was followed in each tracing throughout the 1,400 tracings studied.

Methods of Calculation of Q-T₀

Various formulae have been recommended from time to time for the correlation of the Q-T interval to the cardiac cycle. The one that is simplest and has stood the test in most studies on the Q-T interval is that formulated by Bazett (1920):

$$S = K \sqrt{C}, \text{ where } S = \text{systole} = (Q-T) \\ C = \text{cycle-length} = (R-R) \\ K = 0.37 \text{ second for males and } 0.40 \text{ second for females}$$

Taran and Szilagyi (1947) introduced a very important new conception—the Q-T₀—namely, the duration of the Q-T interval corrected for the cycle-length. By the use of this modification, Bazett's formula standardizes the Q-T interval to a heart rate of 60 a minute, or, in other words, to a cycle-length (R-R interval) of 1 second. Now, the formula can be expressed as:

$$Q-T_0 = \frac{Q-T}{\sqrt{R-R}}$$

To obviate tedious calculations involved by this formula, use was made of the slide-rule method (Fox *et al.*, 1950), based on Taran and Szilagyi's modification of Bazett's formula. After the first few calculations on the slide-rule, Kissin's nomogram (Kissin *et al.*, 1948) was used in conjunction with the slide-rule. This nomogram is based on Taran and Szilagyi's modification of Bazett's formula, and employs exactly the same principle as the slide-rule method. Since no differences were recorded in the use of either of these methods, after the first 200 readings, Kissin's nomogram was employed in all cases.

All figures obtained were statistically analysed by the formula $\sigma = \sqrt{\frac{\sum(x-\bar{x})^2}{n}}$ and found to be admissible.

Results

The results of the normal electrocardiographic tracings of the 400 males and 200 females, divided into age groups, are shown in Table I. In both the normal males and females

TABLE I.—Q-T₀ Plotted Against Age for Normal Males and Females (Aged 40 and Over)

Age Group	No. of Cases		Mean Q-T ₀ in Seconds		Q-T ₀ Range in Seconds	
	Male	Female	Male	Female	Male	Female
40-49 ..	124	97	0.398	0.415	0.392-0.404	0.409-0.421
50-59 ..	163	54	0.397	0.404	0.392-0.402	0.399-0.409
60+ ..	113	49	0.388	0.400	0.379-0.397	0.391-0.409
Total ..	400	200	0.394	0.406	0.387-0.401	0.399-0.413

there seems to be an inverse relationship between age and the duration of Q-T₀, but when the χ^2 test was applied no significant difference was found. Sex, however, definitely

TABLE II.—Comparison of Q-T₀ in Seconds in Normal Subjects Obtained by Various Authors

Author	Males	Females	Average Q-T ₀
(1) Bazett (1920) ..	0.370	0.400	0.385
(2) Dock (1931) ..	0.3841	0.3890	0.3885
(3) Cheer (1930) ..	0.3743	0.3877	0.3810
(4) Taran and Szilagyi (1947)			0.3924
(5) Alimurung <i>et al.</i> (1950)	0.403	0.400	0.4015
(6) Krasnoff (1950) ..	0.392	0.406	0.399
(7) Present study ..	0.394	0.406	0.400

In studies (1), (2), (3), and (5) "K" is used instead of "Q-T₀."

seems to play a part, the average Q-T₀ for normal males being 0.394 second, with a range of 0.387 to 0.401 second; and the average for females 0.406 second, with a range of 0.399 to 0.413 second.

These "control" readings are compared with those obtained by other authors (Table II). It will be noticed that almost all the figures approximate one another closely. Moreover, if it is appreciated that the studies of Taran and Szilagyi and of Alimurung *et al.* contained only children, further proof is added to the statistical contention already stated that Q-T₀ has no correlation with age.

Q-T₀ in Cases of Myocardial Infarction

Eight hundred electrocardiographic tracings following myocardial infarction were studied (496 of males, 304 of females). The procedure used in measuring the Q-T₀ was exactly as already outlined. The Q-T₀'s in males and females were plotted against the localization of the infarct, and this is shown at various stages of the infarct—on the first day, at the end of the first week, at the end of the first month, at the end of the sixth month, at the end of a year, and at varying periods after a year. Tables III and IV demonstrate the changes taking place in males and females respectively.

TABLE III.—Average Q-T₀ at Various Periods After Myocardial Infarction in Males, Plotted Against Localization of Infarct

Localization of Infarct	No.	Average Q-T ₀ in Seconds					
		1st Day	1st Week	1st Month	6th Month	1st Year	1 Year+
Antero-lateral	238	0.425 (39)	0.485 (35)	0.475 (60)	0.460 (64)	0.443 (13)	0.413 (27)
Posterior	192	0.430 (32)	0.430 (36)	0.417 (52)	0.416 (33)	0.443 (20)	0.413 (19)
Antero-septal	66	0.431 (19)	0.427 (16)	0.415 (20)	0.411 (11)	—	—

The figures in parentheses show the total number of tracings in each group.

TABLE IV.—Average Q-T₀ at Various Periods After Myocardial Infarction in Females, Plotted Against Localization of Infarct

Localization of Infarct	No.	Average Q-T ₀ in Seconds					
		1st Day	1st Week	1st Month	6th Month	1st Year	1 Year+
Antero-lateral	112	0.414 (30)	0.460 (34)	0.434 (35)	0.430 (6)	0.421 (7)	—
Posterior	108	0.470 (32)	0.465 (24)	0.450 (24)	0.435 (9)	0.418 (11)	—
Antero-septal	84	0.474 (17)	0.466 (21)	0.431 (25)	0.424 (8)	0.414 (13)	—

The figures in parentheses show the total number of tracings in each group.

It will be noticed that exactly the same pattern is followed in both the sexes. In antero-lateral infarctions, after a preliminary rise of the Q-T₀ interval on the first day, there is a further maximal rise at the end of the first week, after which it gradually regresses, but fails to reach normal levels. In the posterior and antero-septal infarctions the maximal rise is seen on the first day, and then the Q-T₀ interval regresses, until after a year it is nearing normal limits. Hence it is evident that the localization of the infarct has no direct bearing on the Q-T₀, this particular interval being always prolonged in the acute stages and gradually tending to return to normality with the healing of the infarct.

TABLE V.—Average Q-T₀ in Males and Females at Various Periods After Infarction

Period of Time Elapsed After Infarction	Average Q-T ₀ in Seconds			
	Males		Females	
	No.	Q-T ₀	No.	Q-T ₀
1 day ..	90	0.425	79	0.423
1 week ..	87	0.438	87	0.482
1 month ..	132	0.450	84	0.470
6 months ..	108	0.440	23	0.454
1 year ..	33	0.424	31	0.423
1 year+ ..	46	0.474	—	—

Chart showing average Q-T_c in males and females at various periods after infarction.

Since the localization of the infarct does not play a significant part, but the stage of the infarct does, it was decided to tabulate the Q-T_c's against the period of time elapsed after infarction, irrespective of the localization. This is shown in Table V and the Chart.

Discussion

The Q-T interval of the electrocardiogram represents the period of electrical systole of the heart. Katz (1921) suggested that measuring the duration of systole in diseased hearts compared with normal hearts would give a method of determining the functional integrity of the myocardium. White and Mudd (1929) pointed out that the Q-T interval is prolonged in paroxysmal tachycardia or disorders causing a marked widening of the QRS complex, but not in conditions associated with structural defects. Dock (1931) did not regard the Q-T interval as a satisfactory index of cardiac function, since only one-third of patients with failing hearts have electrical systoles longer than the maximum in normal subjects of the same sex and age. Moreover, he found that the duration of the Q-T interval in hypertensives with left ventricular enlargement without failure is the same as in those who are badly decompensated.

In 1939 Ashman disagreed with the above authors, and showed that measurement of the electrical systole gives valuable information regarding the degree to which the myocardium is affected in cases of diphtheria or acute rheumatic carditis. Taran and Szilagyi (1947) confirmed this in cases of acute rheumatic carditis, though their results are vigorously contested (Alimurung *et al.*, 1950). Similar prolongation of the Q-T interval has been noted in cases of hypotassaemia (Bellet and Dyer, 1937; Stewart *et al.*, 1940; Brown *et al.*, 1944; Currens and Crawford, 1950); and in cases of hypocalcaemia (Carter and Andrus, 1922; Kellogg and Kerr, 1936; Barker *et al.*, 1937).

Katz (1921), Robb and Turman (1947), and Horwitz and Graybiel (1948) have shown that many physiological factors such as cellular metabolism, sex, and position may influence the Q-T interval. Berliner (1931), Bayley (1942),

Savilahti (1945), and Krasnoff (1950) have shown that prolongation of the Q-T interval occurs in hypertension, bundle-branch block, ventricular hypertrophy, etc. (pathological cardiac states). Hence it may be taken as fairly certain that ischaemia and injury of the myocardium have a bearing on the duration of the Q-T interval.

As all these various factors may be playing a part, it is difficult to estimate the effects of one or many of these possible factors on the prolongation of the Q-T interval. However, this study definitely supports previous work of Krasnoff (1950) that the Q-T interval is prolonged in the early stages of myocardial infarction, and gradually diminishes until, after about one year, average normal levels are approached. There are good grounds for believing that the prolongation of the Q-T interval is directly related to the myocardial damage, though the immediate mechanism remains unknown.

A good correlation exists between these results and the findings of Mallory *et al.* (1939), which demonstrated the changes in the cardiac musculature following acute myocardial infarction. These results are summarized in Table VI. It will be seen that necrosis of the musculature starts on the first day, and reaches a maximum at one week, when there is maximum dead and dying muscle. At the end of a month granulation tissue is present, and clearance of the dead muscle is being effected, and collagen has started to be laid down—the earliest signs of repair. At the end of six months repair is fairly well advanced, and at the end of a year there is maximum deposition of collagen.

The Chart shows that the changes in the Q-T_c interval closely follow this pattern. Thus the Q-T_c interval increases on the first day, reaches its maximum at the end of a week, when cardiac damage is at a maximum, and then gradually recedes as the process of repair sets in.

Hence the Q-T_c interval may prove to be of use in estimating the duration of rest in bed, so that activity is indulged in only when a firm process of repair has set in.

Summary

The Q-T interval is dependent on the cardiac rate. The average normal Q-T_c was found to be 0.394 second, with a range of 0.387–0.401 second for males, and 0.406 second, with a range of 0.399–0.413 second for females. The Q-T interval has no relation to age. It was found to be prolonged in cases of acute myocardial infarction reaching a maximum at the end of the week, gradually approaching normal limits again after about one year. A definite correlation is shown between the length of the Q-T_c and pathological changes in cardiac musculature of cases of acute myocardial infarction. The Q-T_c bears no relation to the localization of the infarct.

The methods of selection of cases, the choice of the formula used, and the methods of measurement are described in detail.

TABLE VI.—Pathological Changes in Cardiac Muscle Following Myocardial Infarction in Relation to Time-interval (Modified from Mallory *et al.*, 1939)

Time Interval	Necrotic Muscle	Polymorphs	Blood Vessels and Connective Tissue	Removal of Fibres	Pigmented Macrophages	Eosinophils	Plasma Cells and Lymph	Collagen
1 day	++	+	0	0	0	0	0	0
1 week	++++	+++	++	+	+	+	+	+
1 month	+	0	++++	++	+++	+	++	+
6 months	0	0	++++	?	+	0	++	++
1 year+	0	0	++++	0	+	0	+	+++

The relation of the Q-T interval to various physical, chemical, and pathological states is discussed.

I am grateful to Professor Crichton Bramwell for permission to review the cases on the files of the cardiographic department of the Manchester Royal Infirmary. I also acknowledge with gratitude the help and advice of Dr. A. Morgan Jones and of Dr. Donald Makinson.

CHLOROQUINE IN THE TREATMENT OF AMOEBIC LIVER ABSCESS

BY

J. C. PATEL, M.D., Ph.D., M.R.C.P.

Honorary Assistant Physician, King Edward Memorial Hospital, Bombay, and P.G. Singhanee Hindu Hospital, Bombay, India

The antimalarial action of the derivatives of the 4-aminoquinoline series was thoroughly established during the last war, and from among the series chloroquine (7-chloro-4-(4-diethylamino-1-methylbutylamino)-quinoline diphosphate) was found to be one of the most effective compounds, and to be of low toxicity. Observations revealed that the drug had a peculiar depot action, being stored in the liver in concentrations as high as 500 to 600 times the plasma level (Conan, 1948). This property of the drug, as well as its pronounced anti-plasmodial activity, led to the testing of its possible efficacy in protozoan infections other than those caused by malaria plasmodia. Tests carried out in England and America immediately after the war showed that it had a pronounced action in *Entamoeba histolytica* infections of the liver that were responsible for hepatic amoebiasis and liver abscesses. These experimental findings now seem to be generally confirmed by clinical trials.

Conan (1949) used chloroquine successfully in seven cases of amoebic hepatitis and found that it was an effective chemotherapeutic agent for the treatment of amoebic infections of the liver, being at least as effective as emetine but apparently without the latter's toxicity. In the same year Manson-Bahr (1949) reported his experience with chloroquine in a case of *E. histolytica* liver abscess in a very advanced stage, which could not

be influenced either by emetine or by streptomycin and penicillin. Fever and other symptoms persisted in spite of the latter. He then resorted to treatment with chloroquine and observed a prompt recession of the symptoms. The temperature was soon brought down to normal, and healing of the abscess was claimed after a fortnight's treatment. Similar results were reported by Murgatroyd and Kent (1948) in their case of liver abscess, which had proved very resistant to emetine, di-iodohydroxy quinoline, streptomycin, penicillin, and local emetine lavages. More comprehensive work on the subject has been reported by Harinasuta (1950, 1951), working in Siam, where hepatic amoebiasis is of frequent occurrence. In his first paper he reported nine cases of amoebic liver abscess (two with pulmonary complications) successfully treated with chloroquine. Later he made a comparative study of the action of chloroquine and emetine in amoebic liver abscesses, putting 45 cases on chloroquine treatment exclusively and an equal number of cases on emetine. In conclusion, Harinasuta remarked: "In comparison with emetine, chloroquine appeared to possess as much curative value in the treatment of amoebic liver abscess. It might be somewhat inferior on the point of relapse rate; but in other respects it had its own advantages—e.g., peroral administration, tolerability, and low toxicity in general—so that it might be employed even in cases in which emetine was contra-indicated." Among the side-effects of chloroquine Harinasuta listed nausea, vomiting, mild diarrhoea, transient pruritus, disturbance of ocular accommodation, and also a slight fall in the blood pressure. He noted, however, that these side-effects were usually mild and insignificant and only transitory in nature.

Among the publications by Indian research workers reference may be made to those of Sharma *et al.* (1951) and of Subramaniam (1951). The former reported on two cases of amoebic liver abscess from Bangalore which proved resistant to treatment with emetine, vitamin B-complex preparations, sulphonamides, and penicillin. At the time of chloroquine therapy the patients appeared to be so gravely ill that their chances of recovery seemed to be extremely small. The authors concluded: "Our impression was that the administration of chloroquine marked a turning-point in an otherwise downward course. Our cases are in line with the striking results by chloroquine reported by others, and the drug marks a definite advance in the treatment of amoebic hepatitis, especially cases with abscess formation." Subramaniam used chloroquine diphosphate only in four cases of amoebic hepatitis, but claimed good results with this exclusive treatment. He stated that in all cases the temperature subsided within 24 to 48 hours, there was a marked lessening of the pain, and the patient felt better.

Present Series

I have used chloroquine diphosphate ("resochin") in a series of 11 cases of amoebic liver abscess, and the results obtained seem to confirm the observations of others that this drug has advantages in the treatment of extra-intestinal infections with *E. histolytica*.

The patients were admitted to the King Edward Memorial Hospital or to the P.G. Singhanee Hindu Hospital, and were kept there throughout the course of treatment. They were asked to return if there were any symptoms suggesting relapse, and each was given a postcard to be filled in by a doctor treating him for the complaint. Each patient also received another card with particulars of the previous history and treatment given.

The diagnosis of amoebic liver abscess was based upon the history of the clinical signs and characters of the pus aspirated by liver puncture. One patient with enlarged tender liver, raised temperature, and leucocytosis was negative on aspiration; he was treated with chloroquine without success. Fluoroscopy was carried out to show the movement and elevation of the dome of the diaphragm and the condition of the lungs and pleura. In every case the blood was examined for evidence of leucocytosis and was repeated in some cases during the course of treatment. It was only after the diagnosis was established by aspiration of pus that treatment with chloroquine was instituted. Emetine was not given in any case. The dosage of chloroquine was one tablet (0.25-0.15 g. of base) twice a day, preferably after food, for a period of 10 to 12 days in the first six cases. After two of these cases had relapsed the length of treatment was increased to 30 days. The initial higher dosage advocated by Conan (1949) and used by most workers was not adopted because of the untoward reaction noticed in a case of amoebic hepatitis not included in the series. As Indians are of small size, the lower dosage was more likely to be tolerated, with fewer untoward reactions. The drug was given for a period of 30 days in a case of relapse. It was not administered by the parenteral route.

Eleven cases (nine male, two female) of amoebic liver abscess were treated during a period of two years. As there were rigid criteria for diagnosis, not all the cases of liver abscess were taken for study, particularly if there was any doubt about whether emetine had been given before or during hospital treatment. In some cases sulphadiazine and antibiotics were given for the lung and abdominal conditions. Details of the cases are shown in the Table.

Details of 11 Cases of Amoebic Liver Abscess

Case No.	Age	Sex	Result of Liver Aspiration	Stool Exam. for <i>E. histolytica</i>	Treatment Schedule		Day of Normal Temp.
					Daily Dose	Length of Treatment	
1	32	M	400 ml.	Neg.	0.5 g.	10 days	5th
2	45	M	200 "	"	0.5 "	12 "	2nd
3	29	M	50 "	"	0.5 "	12 "	3rd
4	46	F	50 "	Pos.	0.5 "	10 "	Died 3rd day
			50 "		0.5 "	2 "	
5	40	M	600 "	"	0.5 "	11 "	2nd
6	30	M	100 "	"	0.5 "	30 "	3rd
7	32	M	250 "	"	0.5 "	10 "	4th
8	37	M	200 "	Pos.	0.5 "	30 "	3rd
9	29	M	400 "	Neg.	0.5 "	30 "	2nd
10	36	F	50 "	"	0.5 "	30 "	3rd
11	44	M	300 "	"	0.5 "	30 "	3rd
			200 "	"	0.5 "	21 "	2nd

E. histolytica was found in the stools in two cases. The temperature subsided within 72 hours in most cases, and within 48 hours in five. In some cases in which the temperature was normal after aspiration of the abscess it did not rise after the drug was given. The patient felt better by the fourth day, and had an improved appetite. All patients gained weight—as much as 20 lb. (9 kg.) in a month in one case. A lessening of liver tenderness was the first sign of improvement, and the lower margin of the liver soon disappeared from below the costal margin. The leucocytosis subsided in about a week in those cases in which examinations were made. No attempt was made to measure any changes in blood pressure, as observed by Harinasuta (1950, 1951), but no overt effects of a lowered blood pressure were noticed. Apart from mild nausea in two cases and dimness of vision in one, toxic symptoms of the drug were not recorded. Nausea, gastro-intestinal irritation, itching, and changes in accommodation in the eyes were noted in one case (not included here) when the initial dose was double that used in this series.

Relapses

Two patients were readmitted with recrudescence of the disease, one of them three months and the other four

months after treatment with chloroquine for 10 days. In both cases pus was again aspirated. One of them (Case 4) died two days after the second admission, before chloroquine had any chance of action. This patient had a pulmonary complication. Case 5 was again treated with chloroquine, 0.5 g. a day for four weeks, with complete success.

Harinasuta (1951) had 10 relapses in a series of 45 cases which responded to further chloroquine treatment—a relapse rate of 22.2%. They occurred after a two-weeks or a three-weeks course of treatment. In the present small series the relapse rate was two in six (33.3%) after 10 to 12 days' treatment at a lower initial dosage. Harinasuta observed a definite refractoriness to a single course of chloroquine in two patients, both of whom died. Similar drug-resistance has been recorded with emetine.

Discussion

Conan (1949) advocated a three-weeks course of treatment, and subsequent workers have more or less followed the same course with satisfactory results. More than one-fifth of Harinasuta's (1951) cases required a second course of treatment, as did two of the first six cases in the present series. Relapses occur also with emetine and require further treatment. In order to avoid relapse the period of treatment in the remaining cases was increased to 30 days—longer than that advocated by Conan. From published work it seems obvious that the drug has a definite curative action on amoebic liver abscess, and it is the impression of most workers, including myself, that it acts more quickly than emetine and without the latter's harmful effects. It can be given when the general condition of the patient is poor and when emetine would be contraindicated and even harmful. Unlike emetine, it has no general toxic action and can be given orally. The dosage and the length of treatment so far used by most workers, even though satisfactory in most cases, needs evaluation by further clinical trials.

Relapses occur more often with smaller doses of shorter duration. They occurred even with the dosage advocated by Conan. Harinasuta (1951) had to use as many as five three-weeks courses in one case. From this it is obvious that the dosage advocated by Conan should be increased in length to four or even six weeks, as the drug can be taken by mouth and has no major untoward effects on the body. Conan's three-weeks course may be adequate for amoebic hepatitis, but not in all cases of abscess. In the present series cases of abscess and not of hepatitis were treated, as the value of the drug in the treatment of undoubted cases of liver complication of amoebiasis had to be established.

Extended clinical trials with a good follow-up should be undertaken in order to evaluate the length of treatment with chloroquine in cases of abscess. At present the drug is not readily obtainable, but when it is freely available and cheaper such a trial would be possible. Harinasuta (1951) advocated a combined treatment with emetine. I consider, in the light of present available knowledge, that a prolonged course of treatment is all that is necessary. A therapeutic trial with chloroquine can safely be carried out in cases of liver enlargement in which diagnosis is doubtful, and liver abscess can be easily excluded by such a trial, without any of the harmful toxic actions which accompany emetine therapy.

Summary

Eleven cases of amoebic liver abscess, three with pulmonary complications, were treated with chloroquine diphosphate with very good results. The dosage was 0.5 g. a day. It was found that treatment for 10 to 12 days was adequate in four out of six cases: two relapsed, but responded to further treatment. In the remaining cases the drug was given for 30 days. One patient died during a relapse. It is suggested that further work

should be carried out in order to determine the dosage of the drug required and the length of its administration in the treatment of the abscess. Minor toxic symptoms were observed. The drug can be safely used as a therapeutic test if diagnosis is doubtful.

My grateful thanks are due to the Dean of the King Edward Memorial Hospital and to the Honorary Director of the P.G. Singhanee Hindu Hospital for facilities, and to Dr. A. G. Brooke, of Chowgule and Co. (Hind) Ltd., for a free supply of the drug.

“DANGEROUS RECIPIENTS” OF TRANSFUSION INCOMPATIBLE REACTIONS AFTER TRANSFUSION OF GROUP O Rh-NEGATIVE BLOOD

BY

GEOFFREY H. TOVEY, M.D.

Director South-west Regional Blood Transfusion Service

C. P. WARREN, M.B., B.S., D.C.P.

Consultant Pathologist and Area Transfusion Officer,
Torquay Sub-Area

AND

EILEEN E. WOOD, M.R.C.S.

Haematologist and Area Transfusion Officer, West Cornwall
Clinical Area

The following case reports are placed on record to re-emphasize that Group O Rh-negative blood is not free of potentially dangerous blood-group factors, and that inexperienced medical staff are not suitable persons to undertake the matching of blood for transfusion.

Case 1

A multiparous woman aged 26, known to be Group O Rh-positive, was delivered of her third baby by elective caesarean section. Because of haemorrhage during the operation a transfusion of 2 pints (1,140 ml.) of blood became necessary, and the house-surgeon “matched” two bottles of Group O Rh-positive blood against the patient's serum by a saline slide technique. No incompatibility was detected, but on the day after the transfusion the patient was noticed to be “slightly jaundiced.” The baby also had developed a definite jaundice within a few hours of birth, but since the mother was Rh-positive and the baby's haemoglobin was 140% (20.7 g. per 100 ml.) the possibility that the mother's serum contained irregular blood-group antibodies was not considered.

Seven days later the mother's general condition was unsatisfactory and her haemoglobin 35% (5.2 g. per 100 ml.). Transfusion of a further 2 pints (1,140 ml.) of blood was therefore prescribed, and on this occasion the house-surgeon selected and matched 2 pints (1,140 ml.) of Group O Rh-negative blood, presumably as a safeguard against a haemolytic transfusion reaction. No incompatibility was detected, but the transfusion was discontinued after 1½ pints (850 ml.)

had been transfused because the patient had developed a severe rigor. During the next 48 hours she had jaundice and oliguria. Although her haemoglobin remained at 35% (5.2 g. per 100 ml.) she refused any further transfusion and made a gradual recovery to normal health during the next six to eight weeks.

Laboratory investigations showed the patient's blood to be Group O Rh-positive, Rh genotype cDe/cDe, and that the transfused Rh-negative cells had undergone haemolysis. Immune antibodies, type anti-e + anti-C, were demonstrable in the patient's serum to a titre of 256 with homozygous e-positive red cells (Rh-negative cells, cde/cde) suspended in saline and in albumin. The titre against heterozygous cells (R₁R₂cDe/cDe) was 64.

Inquiry into the patient's previous history revealed that she had been transfused with 4 pints (2,270 ml.) of blood (Rh group unknown) at her first pregnancy seven years before, because of a severe accidental haemorrhage, and was subsequently delivered of a stillborn macerated foetus. Her second pregnancy, three years later, had resulted in the delivery of a healthy female child who had shown “a slight jaundice” shortly after birth, but whose subsequent progress was uneventful. The third baby, the outcome of the pregnancy under discussion, was subsequently found to be Group A, R₁R₂ (cDe/cDe); a direct antiglobulin (Coombs) test on its red cells was positive, and by the twenty-ninth day of life its haemoglobin had dropped to 42% (6.2 g. per 100 ml.). After a transfusion of Group O blood of genotype cDe/cDe it made a satisfactory recovery.

Case 2

A woman who had had two normal children received an emergency blood transfusion (group unknown) during an air raid in 1941. Later she had one normal full-term child and then two miscarriages, each being a six-months foetus. At the age of 42 she was admitted to hospital because of menorrhagia. After a few days in hospital she had a sudden haemorrhage at night, and a resident house-surgeon transfused a pint (570 ml.) of Group O Rh-negative blood in emergency and without previous direct matching. At the same time another member of the resident medical staff “matched” a further bottle of Group O Rh-negative blood for her by a slide technique, but transfusion of this blood was found not to be necessary. Nine days later it was decided to transfuse this “matched” blood so that the patient might be made fit for curettage. She developed a rigor at the conclusion of this transfusion, followed by jaundice, haemoglobinuria, and oliguria for the next seven days.

Serological investigations demonstrated the patient to be Group O Rh-positive, Rh genotype cDe/cDe. Immune antibodies of the type anti-c + anti-E were demonstrable in the post-transfusion sample of her blood to a titre of 32 in saline and 256 in albumin against homozygous c-positive cells (Rh-negative cells, cde/cde), and 2-4 in saline and 16-32 in albumin against heterozygous c-positive cells (R₁R₂cDe/cDe). The patient's post-transfusion sample contained no Rh-negative cells, thus confirming that the blood transfused was incompatible.

Comments

Both these patients nearly lost their lives, and both suffered severe renal damage, because of the transfusion of Group O Rh-negative blood. Fortunately, although Rh-negative corpuscles contain the Rh antigens c, d, and e, and may contain other antigens such as Kell, Fya, and S, which are known to have been the cause of similar haemolytic transfusion reactions, few patients requiring transfusion possess the corresponding antibodies, anti-c, anti-e, anti-Kell, etc., in their plasma. In consequence incompatible transfusions from this cause remain a rarity. The fact, however, that immune antibodies of this type may be present in the circulation of certain patients, even on rare occasions, constitutes a challenge, and, by a more thorough applica-

tion of knowledge already well established regarding the hazards of transfusion therapy, accidents from this cause need not arise.

In neither of these instances was the transfusion of whole blood so pressing that advantage could not have been taken of existing laboratory facilities for blood-matching by trained laboratory staff. These cases serve as a reminder that this must be done whenever circumstances permit if the best service is to be given to the patient. As soon as plasma prepared during the war years was found to carry a risk approaching 10% of inducing hepatitis in the recipient, preliminary plasma transfusion whilst the matching of blood was being undertaken, or as the sole emergency transfusion for cases of moderate haemorrhage, wisely fell into disrepute. Now that the transfusion of "small-pool" plasma carries little greater risk of transferring the hepatitis virus than does a transfusion of whole blood, and, alternatively, satisfactory plasma substitutes, dextran and polyvinylpyrrolidone, are available, we believe with Discombe (1952) that greater use should be made of such fluids for the avoidance of incompatible transfusions.

Immune antibodies active against transfused corpuscles of the patient's own ABO group are particularly likely to be present in the circulation of recipients who have had jaundiced or stillborn babies, or who have reacted adversely with a rigor, jaundice, or haemoglobinuria to a previous blood transfusion. Even in a dire emergency, where the transfusion of unmatched whole blood may seem entirely warranted, strenuous efforts should be made to have blood specially matched against the patient's serum when there is a history suggesting the presence of immune antibodies. It is such patients that one of us (Tovey, 1950) has proposed should be termed "dangerous recipients," and in each of the above cases the patient's history would have placed her in this category.

Dangerous recipients run a particular risk in that if they are Rh-positive the immune antibodies they have developed may well be of the type anti-c or anti-e, and thus active against Rh-negative corpuscles (cde/cde). Or, should the recipient be Rh-negative with Rh antibodies (anti-D) in her serum, an Rh D-positive bottle of blood which has been misgrouped or mislabelled "Rh-negative" may give rise to a serious haemolytic transfusion reaction. Moreover, in some instances incompatibility from immune antibodies can be detected *in vitro* only by methods of direct matching which are too complicated to employ as a routine, such as an indirect antiglobulin technique or a titration procedure using bovine albumin. It is important, therefore, that clinicians obtain a history of the outcome of previous pregnancies or transfusions from any patient about to be transfused. Should the history indicate the patient to be a dangerous recipient, blood should not be transfused until it has been matched by the special procedures mentioned. Whenever possible, the danger in the event of an emergency transfusion should be anticipated, and as soon as it is known that a patient has given birth to a jaundiced or stillborn baby or has suffered a serious reaction to transfusion a full serological examination should be carried out to determine whether immune antibodies are present, and, if so, their exact type.

In neither of the above patients, although their histories indicated the need, had such serological investigations been made before the transfusion accidents. Although Gunz (1946) drew attention to the need for a standard history sheet to accompany every request for transfusion, and such a sheet has been employed by regional transfusion centres for the past six years, many hospitals are still not taking this precaution as a routine for their cases for transfusion.

Case 2 further illustrates that, although a patient may be transfused without serious reaction with blood of a certain ABO and Rh group, this does not mean that a later transfusion of blood of the same ABO and Rh group will be similarly unaccompanied by reaction. It is important to bear in mind that the transfusion of blood can result in

the stimulation of dangerous antibodies, and any further blood for transfusion should invariably be matched on a freshly taken sample of the recipient's serum if more than 48 hours have elapsed since a previous transfusion.

We are grateful to Dr. M. Gillespie and Dr. J. S. Campbell, of the South-west Regional Transfusion Service, and to Dr. A. E. Mourant and Dr. D. Parkin, of the M.R.C. Blood Group Reference Laboratory, for help with the serological investigations.

SENSITIVITY OF AUTONOMIC GANGLIA TO HEXAMETHONIUM IN HYPERTENSION

BY

JAMES CONWAY, M.B.

Senior Lecturer in Physiology, Charing Cross Hospital
Medical School

The introduction of hexamethonium bromide (H.M.B.) by Paton and Zaimis (1949, 1951) as a substance which blocks the transmission of nervous impulses across the synapses of autonomic ganglia presented a potentially valuable therapeutic means of controlling hypertension. The specificity of its action on autonomic ganglia makes it also a most valuable tool in the study of the autonomic nervous system, and this property is used here to study the underlying mechanisms producing hypertension. Repeated doses of hexamethonium bromide or bitartrate* are given intravenously, and the following points are observed:

- (1) the sensitivity of the blood pressure to depression by autonomic blockade;
- (2) the level to which the diastolic blood pressure may be depressed; and
- (3) the dose required to affect the pupillary light reflex.

The first indicates the state of activity of the autonomic ganglia controlling blood vessels, and incidentally the suitability of patients for treatment. The second gives the minimal diastolic pressure which is used to differentiate various types of hypertension. This term is used in the sense defined by Frew and Rosenheim (1949), as the pressure maintained by the inherent tone of the blood vessels and circulating pressor substances, and corresponds to the term blood pressure "floor" of Ferris *et al.* (1948). Both of these authors used tetraethylammonium bromide (T.E.A.B.) to block autonomic ganglia.

Material

Tests were performed on patients who had been in hospital for at least seven days, and in one-third of the cases repeated tests were performed to establish the reliability of the method. The admission of patients to hospital was made for the investigation and treatment of hypertension or renal disease, and was quite independent of the present study. Cases with heart failure, extreme renal failure, or a history of recent thromboses were excluded.

The clinical diagnosis of essential hypertension was made after exclusion of other causes. Renal hypertension was assumed to be present if evidence could be obtained of

*All doses are expressed as those of the dibromide salt. Messrs. May and Baker kindly gave supplies of the bitartrate used in this investigation.

previous renal disease or associated toxæmia of pregnancy. In all cases a standard amylobarbitone sedation test (White, 1944) was performed, and in a quarter of the cases a test using T.E.A.B. was performed.

Methods

After a single injection of H.M.B. the effect on the blood pressure is found to be maximal within five minutes; repeated injections give a progressively diminishing effect. To minimize the effect of the biological variation in sensitivity to drugs a number of repeated doses were given in preference to a single standard dose. After a single injection it is also found that there is a transient overswing in the fall of pressure which exaggerates the fall in blood pressure particularly when larger doses are used. All blood-pressure readings are taken by the same person, using the auscultatory method and the diastolic pressure taken at the fifth phase—that is, as all sound disappears. This is necessary because the fourth phase often disappears when the blood pressure falls. Attention is paid to the diastolic pressure, as this gives more constant responses and the end-point can easily be defined, whereas the systolic pressure is more variable and sometimes shows a progressive fall in pressure.

The Test.—The procedure outlined gives reliable results and is free from complications. The patients, after being told precisely what is going to be done, are placed in quiet surroundings lying *absolutely flat* except for one pillow under the head for comfort. Blood pressures are taken every ten minutes until a resting level is established, when the first injection of 10 mg. of H.M.B. is given intravenously and pressures are read at three-minute intervals for 15 minutes. Thereafter injections of 25 mg. are made at 15-minute intervals until the maintained reduction in diastolic pressure does not exceed that of the previous dose by more than 8 mm. Hg. This is usually achieved by doses of 35–60 mg.—that is, second or third injections. The dose producing 75% of the fall in diastolic pressure is recorded as the *effective hypotensive dose*. If the blood pressure does not respond to a dose of 35 mg. it will not do so to larger doses. This was demonstrated by the additional doses it was necessary to give in order to block the ciliary ganglion. The dose at which the response of the pupils to light is slight and unsustained is recorded as the *effective pupillary dose*. When large doses (exceeding 85 mg.) are given there is sometimes a secondary slight fall in blood pressure. This is not closely related to the injections, and is partly accounted for by the onset of somnolence and the prolonged immobilization of the patient. For this reason, blood-pressure readings are taken at half-hourly intervals after the completion of the test until an upward trend of pressure is established. The results of some earlier tests in which there were minor variations in procedure have been used.

Precautions.—Mild fainting sometimes occurs when the first, and rarely the second, dose produces a profound and

rapid fall in pressure. This is readily overcome by raising the foot of the bed. No patient has lost consciousness, and it has not been necessary to give pressor drugs. On three occasions when the blood pressure fell considerably after both the first and the second injection it was thought prudent to stop the test, although the patients did not complain of ill effects. Postural hypotension persists for a variable time after the test, and patients are not allowed out of bed or to sit upright in bed until the following morning.

In spite of a considerable reduction in blood pressure in some patients there has been no evidence of thrombosis occurring during the period of hypotension or afterwards. No symptoms due to the paralysis of other organs under the control of the autonomic nervous system were encountered.

Results

A total of 69 tests have been performed on 46 patients with hypertension, and in addition tests were carried out on a control series of 12 patients suffering from minor surgical disorders. According to the responses of the diastolic pressure to the test, the hypertensives can be divided into three groups (see Table).

Group A.—Eighteen patients in whom there was an appreciable fall of diastolic pressure (exceeding 14 mm. Hg.) to 90 mm. Hg or below. The mean fall in diastolic pressure was 28 mm. Hg (range 16–58) and the mean minimal diastolic pressure was 82 mm. Hg with a mean effective hypotensive dose of 25.8 mg. of H.M.B.

Group B.—Nine patients in whom the fall in diastolic pressure was at least 14 mm. Hg but remained above 90 mm. Hg. The mean fall was 28 mm. Hg (range 16–48) and the mean minimal diastolic pressure 104 mm. Hg with a mean effective dose of 37.7 mg. of H.M.B.

Group C.—Nineteen patients in whom the pressure remained within 14 mm. Hg of the initial level. To exclude the possibility that variations in sensitivity might account for the absence of response, repeated doses were continued in this group until an average dose of 110 mg. had been given. At these doses there was sometimes the slight fall in pressure already described, and this has been disregarded.

Throughout the entire series the reduction in the blood pressure was not related to the initial systolic, diastolic, or pulse pressures (Fig. 1). The initial resting blood pressures recorded show that the pulse pressure is related to the diastolic pressure and not to the age of the patient. The degree of response to the test was not determined by the clinical severity, as is illustrated by Fig. 2, in which the results of two similar cases are recorded. Group A contained the greatest proportion of cases of uncomplicated essential hypertension, while the nine cases of Group B appear to be more severe.

The average age in Group A was 53.1 years (only four being below 50 years) and in Group C it was 35.6 years.

Data of Controls and of Hypertensive Patients Divided into Three Groups According to Responses to Tests with Hexamethonium Bromide

	No. of Cases	Mean Age	Sex	Clinical Type of Hypertension	Mean Initial Blood Pressure	Mean Minimal Diastolic Pressure	Mean Fall in Diastolic Pressure	Mean Effective Dose	
								B.P.	Pupils
Controls	12	46.1 yrs. (s.d. 14.0)	M 4 F 8	None	118/64 mm. Hg	60 mm. Hg	4 mm. Hg		77 mg.
Group A	18	53.1 yrs. (s.d. 7.2)	M 5 F 13	Essential 13 Malignant essential 1 Renal 3 Malignant renal 1	186/110 " "	82 " "	28 " " (s.d. 11.1)	25.8 mg	76.7 "
Group B	9	43.6 yrs. (s.d. 10.3)	M 6 F 3	Essential 2 Malignant essential 5 Renal 1 Malignant renal 1	206/132 " "	104 " "	28 " " (s.d. 8.2)	37.7 "	83 " "
Group C	19	35.6 yrs. (s.d. 11.6)	M 9 F 10	Essential 10 Malignant essential 3 Renal 2 Malignant renal 3 Coarct. aorta 1	188/112 " "	107 " "	5 " "		82.6 "

Fig. 1.—Initial status of 46 patients with hypertension, divided according to their responses to tests with hexamethonium. Group A—fall in diastolic pressure exceeds 14 mm. Hg and reduces it to 90 mm. Hg or below. Group B—fall in diastolic pressure at least 14 mm. Hg but remains above 90 mm. Hg. Group C—fall in diastolic pressure is less than 14 mm. Hg.

This difference was highly significant ($P < 0.001$), and was still valid when all cases of renal hypertension were excluded and essential hypertension was considered alone. The sensitivity of the blood pressure was not associated with that of the pupils. The effective pupillary dose in all groups was approximately the same (76.7–83 mg.).

Controls.—The control series of 12 patients showed an insignificant fall in diastolic pressure. There were no differences in the response of older and younger subjects. The average age of the group was 46.1 years. The effective pupillary dose was approximately the same as that of the hypertensive patients.

Repeatability.—To establish the value of the test 15 patients were given two or more tests, and in these the minimal diastolic pressure remained within 10 mm. Hg. Five patients had repeated tests over a period exceeding 12 months, the minimal diastolic pressure remaining at the same level in all except one, in whom it rose as the clinical state deteriorated. The effect of treatment with H.M.B. is found in general to follow that of the tests, a response being obtained in the blood pressure of patients in Groups A and B, but not in Group C. Prolonged treatment, however, with hexamethonium, or by sympathectomy, has not been found to affect the minimal diastolic pressure. In one patient, however, a strict rice diet which had been maintained for

Fig. 2.—Response to hexamethonium test of two clinically similar patients, EV and PK, with malignant hypertension.

two months had a considerable effect on the minimal diastolic pressure, reducing it from 88 to 64 mm. Hg. A similar effect has been reported by Stead *et al.* (1948) using T.E.A.B.

Discussion

Hypertension is a single physical sign of what is known to be a large group of diseases. The separation of these from one another is sometimes difficult because the raised blood pressure itself in time produces changes, particularly in the arteries, and treatment is usually required for these effects of the raised pressure and not for the cause. The test described offers a method of identification of those cases of hypertension in which the nervous system plays an important part. It is only by the separation of types that order can be introduced into this bewildering subject.

The appreciation of the part played by nervous factors in elevation of the blood pressure has been maintained in spite of evidence to the contrary (Pickering, 1936; Prinzmetal and Wilson, 1936), from the study of the variability of the blood pressure (Ayman, 1931; Alam and Smirk, 1943) and its response to rest in bed (Watkin *et al.*, 1950) and sedatives (Cady *et al.*, 1936). More recently this has been reinforced by the markedly depressor response sometimes obtained to drugs which block the activity of the autonomic nervous system—T.E.A.B. (Lyons *et al.*, 1948; Frisk *et al.*, 1948) and more recently hexamethonium. This drug, like T.E.A.B., reduces the blood pressure by causing arteriolar dilatation and has little effect on the cardiac output in the recumbent subject (Gilmore *et al.*, 1952). Evidence of the overactivity of sympathetic ganglia controlling the blood vessels is demonstrated by their marked sensitivity to blockade in contrast with the ciliary ganglion. The main effect on the blood pressure is achieved by a small dose (10–35 mg.) before transmission through the sympathetic ganglia is completely blocked, and at approximately one-third of the dose required to paralyse the pupils. Response to hexamethonium is therefore similar to experimental neurogenic hypertension, which is the only type of experimental hypertension responding to autonomic blockade by T.E.A.B. (Page, 1949; Page and McCubbin, 1951).

As the degree of vasoconstriction is represented by the fall in blood pressure it is inevitably somewhat exaggerated in these tests, since the neurogenic component is always removed at the highest initial pressure. The same degree of vasodilatation at a lower initial pressure would give a smaller reduction in pressure. Nevertheless a great fall in pressure, particularly if it then comes within the normal range, must indicate that the nervous system is the dominant though not necessarily the only aetiological factor.

The responses in clinically similar cases were found to be quite unpredictable, as there was no correlation with the signs by which the severity is assessed, and each group contained both mild and severe cases. The depression of blood pressure was compared with that of amylobarbitone sedation, and in 12 patients it was also compared with the response to T.E.A.B. Although the trend of the three tests was often the same, there were considerable quantitative differences between them, and each test would have resulted in a somewhat different classification in this series. There is likewise a broad correlation between results of the H.M.B. test and those of Frew and Rosenheim (1949) using T.E.A.B., and also of Frisk *et al.* (1948) and Lyons *et al.* (1948), with the difference that Frisk *et al.* and Lyons *et al.* both report a correlation between the response and the initial level of diastolic blood pressure.

The variability of the minimal pressure in a particular patient reported by Levinson *et al.* (1948) and Ferris *et al.*

(1948) using T.E.A.B. was not found. Stability of the minimal diastolic pressure suggests the relative independence of the nervous and humoral factors in hypertension. The striking difference in the ages of Groups A and C is the only factor with which the response to H.M.B. could be correlated, and it suggests the separation of elderly hypertensives into a distinct aetiological group.

Collateral evidence for this is found in the well-known differences in mortality of hypertension below and above 50 years (Bechgaard, 1946; Burgess, 1948), particularly as the incidence of hypertension increases so strikingly with age, rising from 5% in young adults to 30–40% after the age of 40, and thereafter increasing progressively with age (Master *et al.*, 1943). In contrast to the severity and frequency of changes in the renal arteries of young hypertensives, in elderly hypertensives the lesions have been shown to be mild, and only a little more severe than those seen in subjects of the same age without hypertension (Perera and Krane, 1951).

In the group which failed to respond to hexamethonium it is clear that the autonomic nervous system can play little part in the elevation of the blood pressure at rest, and in this they behave in the same way as experimental renal hypertension. It is concluded that the absence of a response in the case of coarctation of the aorta is evidence that a humoral mechanism is present in this condition.

The evolution of early labile hypertension into a sustained humoral one is not supported by the present findings, but the reverse seems possible. Subjects in the intermediate Group B and those with renal hypertension in Group A may tentatively be said to have had a nervous mechanism superimposed upon a humoral one.

Summary

Hexamethonium was used to investigate a group of 46 cases of hypertension. It was given in repeated doses to produce the maximal fall in diastolic pressure. The results show that the neurogenic component is present in elderly hypertensives and is very uncommon below the age of 50 years.

I acknowledge the co-operation of the staff of Charing Cross Hospital, Drs. R. A. Hickling, K. Shirley Smith, and E. C. Warner, who allowed me access to their cases of hypertension, and to Mr. E. A. Crook and Mr. L. A. Broster for allowing certain of their cases to act as controls. I also thank Dr. A. A. Osman for facilities to investigate cases of hypertension at the Renal Unit, Pembury Hospital, Kent, and Mr. K. Browne for checking the statistical material.

TERRAMYCIN IN THE TREATMENT OF ACUTE OTITIS MEDIA IN CHILDREN

BY

STUART MAWSON, F.R.C.S.

Surgeon to the Ear, Nose, and Throat Department, King's College Hospital and the Belgrave Hospital for Children

J. D. GRAY, M.D.

Pathologist, the Belgrave Hospital for Children

AND

A. B. HEWLETT, M.R.C.S., L.R.C.P.

Clinical Assistant, the Ear, Nose, and Throat Department, King's College Hospital and the Belgrave Hospital for Children

It is generally agreed that procaine penicillin, in single daily injections of not less than 300,000 units, is the most reliable means of controlling acute otitis media in children with a minimum degree of supervision. Larger doses of crystalline penicillin at more frequent intervals increase the margin of certainty. Oral penicillin and sulphonamides are less reliable, but they offer advantages of administration which favour their use in certain cases. Lewis *et al.* (1952) assessed the value of chloramphenicol and aureomycin in this disease, but concluded that they were unsuitable for domiciliary treatment because, although as effective as penicillin against the organisms commonly found in acute otitis media, some children took such a strong aversion to them that it was impossible to maintain an adequate dosage.

With the advent of terramycin it was decided to review the position, as this compound appeared to offer certain advantages that might answer the need for an oral antibiotic effective in this disease. Terramycin has a wide range of antibacterial activity, and so far has been reported free from toxicity. It is reasonably stable in flavoured solutions, not unduly bitter to the taste, and can also be given in the form of sugar-coated tablets or capsules. In the absence of any published studies of the action of terramycin in otitis media and of an exact precedent for dosage, a clinical trial was made using 50 mg. of terramycin per kg. of body weight per twenty-four hours, against a control series of cases receiving penicillin.

Method

A two-page form was prepared, the first page containing the history, results of examination, type of treatment, and notes on the bacteriological investigation. The second page showed the patient's name only and a summary of daily progress. When a case of acute otitis media was accepted the necessary parts of the form were completed and the pages separated; the first was retained in the laboratory and the second in the out-patient folder. This was to ensure that the clinical observers (S. M. and A. B. H.), who saw each case from the second day onwards, had no knowledge of which antibiotic was being used for treatment and could therefore rely on the impartiality of their judgment.

All cases were first seen by the same casualty officer, well experienced in the recognition of the disease, who allocated the cases to their respective antibiotic in strict alternation. Myringotomy was performed, regardless of

antibiotic, if it was considered necessary to relieve tension. Penicillin was given in the form of "distaquaine," 1.2 ml. daily for five days; this contains 100,000 units of crystalline penicillin and 300,000 units of procaine penicillin. Terramycin was administered orally for five days in the form of a flavoured elixir, tablet, or capsule—the mode depending on the age of the patient. The daily dose was 50 mg. per kg. body weight split into three portions, one being given after each main meal. Five days was regarded as the minimum safe period of administration, for each antibiotic, to be reasonably certain of avoiding an unextinguished disease due to bacterial "persisters."

Results

Clinical.—The Table shows the effect of the terramycin treatment of acute otitis media in children in comparison with treatment with procaine penicillin. It will be seen

The Effect of Terramycin Compared with that of Procaine Penicillin in the Treatment of Acute Otitis Media in Children

Treatment Groups	Distaquaine (F)	Terramycin
No. of cases	33	35
" ears affected	42	44
" unilateral cases	24	26
" bilateral cases	9	9
Average days' duration before seen	2.6	4.0
Drums intact	34	30
" perforated	8	14
Myringotomy required	16	9
Average days for:		
Relief of—		
Pain	1.4	1.4
Discharge	2.2	3.5
Ear to return to normal—		
Ear discharge, surgical or spontaneous	8.6	8.6
Ear never discharged	7.0	5.7
Failures	4	4
Mastoidectomies	0	0

that the results are comparable, the apparent failure rate—four cases in each series—being the same. On analysing the incidence of acute otitis media in childhood in relation to age in the 68 cases it was found that it was highest in the 6-year-old group. The Chart demonstrates the age/incidence relationship. It suggests that during the first school

Chart showing incidence of acute otitis media in relation to age.

year exposure of the child to an alteration in its usual bacterial environment plays a part in the causation of this disease. The cases were equally divided between the sexes.

Bacteriological.

Two media were used, blood-agar and blood-crystal-violet agar plates, the second to suppress *Staphylococcus aureus* in order that any underlying haemolytic streptococci could be isolated. Meatal swabs taken as close as possible to the drum were inoculated on each medium.

No. of sterile swabs in presence of an intact inflamed drum	21
No. of swabs giving growth in presence of an intact inflamed drum	9
Coagulase-negative <i>Staph. albus</i>	4
Diphtheroids	1
Coagulase-positive <i>Staph. aureus</i> (1 penicillin-resistant)	4
No. of swabs giving growth in presence of a perforated drum or after myringotomy	29
Haem. strep. in pure culture	14
Coagulase-positive <i>Staph. aureus</i>	7
Haem. strep. and <i>Staph. aureus</i> mixed	5
<i>H. influenzae</i>	2
<i>Str. pneumoniae</i>	1
(1 strain of <i>H. influenzae</i> isolated was insensitive to penicillin)	

All organisms isolated were tested for sensitivity to both antibiotics using the A.C.P. (1952) disk method. With the exceptions given above, all pathogens were sensitive to terramycin and penicillin.

Penicillin Failures

Case 1.—On the third day of treatment for otitis media of the left ear, acute disease set in on the other, healthy, side, and bilateral myringotomy became necessary. The course of penicillin therapy had to be extended to 10 days before the infection was brought under control.

Case 2.—This case was one of unilateral otitis, for which myringotomy was required. Haemolytic streptococci in pure culture were isolated from the exudate. Two days after the completion of treatment there was a recurrence in both ears, followed by perforation of the drums. A five-day course of terramycin was given, with return of the middle ear to normal.

Case 3.—This was a case of right otitis media with an intact drum. Five days after apparent satisfactory response to penicillin, otitis media recurred; this responded well to a course of terramycin.

Case 4.—Bilateral otitis media with perforated drums and a discharge from which haemolytic streptococci were isolated in pure culture. After five days' treatment there was still a copious discharge from the left ear (no growth obtained on culture). Terramycin therapy was then started, and led to a dry left middle ear with a small healing perforation.

Terramycin Failures

Failure in Cases A and B was due to refusal of the patient to take the antibiotic in any form, the refusals being apparently based on childish antipathy to "medicine."

Case C.—A case of unilateral otitis media requiring myringotomy. Three days after completing the terramycin course bilateral relapse occurred. *Staph. aureus* was recovered from the primary and relapse exudates. This organism was only moderately sensitive to terramycin, but was highly sensitive to penicillin. Substitution of the latter antibiotic gave satisfactory clinical response.

Case D.—A case of unilateral otitis media with a perforated drum and copious discharge from which haemolytic streptococci in pure culture were isolated, equally sensitive to terramycin and penicillin. After two days' terramycin treatment the discharge was sterile and showed signs of abatement. Fourteen days after completion of the antibiotic course there was a recurrence of exudate through the unhealed perforation. A course of penicillin then resulted in cessation of discharge in six days.

Discussion

Of the four failures in the penicillin-treated cases, three responded to terramycin. In the terramycin series, if the two which refused medicine are discounted, the balance of favour indicated by an assessment of the failures rests with terramycin. In all other respects there is little to choose between the antibiotics. We have experienced no real difficulty in administration, nor have we encountered unwelcome side-effects. Terramycin should thus prove a satisfactory antibiotic for domiciliary use, particularly in treating nervous, frightened children whose reaction to a hypodermic needle leaves one exhausted and dismayed at the future prospects, and in those cases in which daily attendance by a doctor or nurse is difficult or impracticable.

Summary

A clinical trial of terramycin in the treatment of acute otitis media in children is reported.

The results indicate that this antibiotic, at a dose of 50 mg. per kg. daily for five days, compares favourably with intramuscular procaine penicillin daily for the same period.

No real difficulty was encountered in the administration of terramycin. Toxic effects were not observed.

We are indebted to Dr. Ivor Marsh, late casualty officer, Belgrave Hospital for Children, for his interest and enthusiasm; to the Medical Research Council Antibiotic Clinical Trials (Non-tuberculous Conditions) Committee; and to Dr. R. K. Phillips, of Pfizer, Ltd., for supplies of terramycin.

Medical Memoranda

Familial Cystinuria

Cystinuria is an inborn error of metabolism in which the amino-acid cystine, together with lysine and arginine, is excreted in greatly increased quantity in the urine. There is also evidence that some cystine is excreted as a labile precursor of unknown composition which liberates cystine on standing. (In the absence of calculi, cystinuria is a symptomless condition.) The output of cystine is not increased by feeding this amino-acid, as it is excreted as a sulphate. However, if cysteine or methionine is fed there is an increased output of cystine. High-protein diets would therefore seem inadvisable. The factors responsible for keeping cystine in solution in the urine are not yet known, but calculus formation does not seem to be directly related to the concentration of cystine in the urine. It has been reported that solution of stones will take place if the urine is kept at a pH of 7.5 by administration of sodium citrate.

The occurrence of cystinuria in families has recently been reviewed by Dent and Harris (1951). In addition to the 11 families reported in the literature they have collected a further 11. As a result of their study they have put forward the view that cystinuria occurs in three types of case: (1) in the Fanconi syndrome, associated with many other amino-acids; (2) in Wilson's disease (hepato-lenticular degeneration); and (3) "classical" cystinuria, the type considered here, in which there is also an increased excretion of lysine and arginine: several of the cases of this type in the literature were, in their opinion, examples of the Fanconi syndrome.

In the past the detection of cystinuria depended mainly on the recognition of the typical hexagonal crystals of cystine in the urine or on the qualitative cyanide nitroprusside test. Lewis (1932) examined the urine of 10,534 students by the cyanide-nitroprusside test and found an increased quantity of cystine to be present in 1 in 600. It seems likely that the use of the newer and more sensitive methods of chromatography and polarography will bring more cases to light.

FAMILY HISTORY

The family reported here was discovered initially through the finding of cystine crystals in the urine of one member. Subsequent examination of the urine of all available members of the family by the cyanide-nitroprusside test and the methods of paper chromatography and polarography brought one further case to light.

The family tree, showing ages of members and presence or absence of cystine in the urine.

Case 1.—A retired coach-driver aged 51 was operated on for removal of bladder stones at the ages of 6, 14, and 25 years. He had a right nephrectomy for "staghorn" calculus in 1943. He was admitted to St. Mary's Hospital in January, 1951, for treatment of cardiac failure following myocardial infarction in May, 1948. On routine treatment he complained of a burning pain on micturition. Microscopical examination of the urine revealed cystine crystals. The cyanide-nitroprusside test was positive and paper chromatography showed an increased excretion of cystine, lysine, and arginine. An x-ray picture of the bladder showed two stones.

Case 2.—A younger brother (aged 42) of Case 1. There is no history of renal or cystic calculus. His only symptoms are those due to a peptic ulcer. Paper chromatography showed the same abnormal pattern of amino-acid excretion as in Case 1.

In both these cases polarographic studies (Reed, 1942) suggested that the output of cystine was about 0.5 g. a day. The range of output in normal persons is 40–80 mg. in 24 hours. In cystinurics the range has been given as 0.4–1.8 g. in 24 hours.

The investigations of Dent and Harris tend to show that classical cystinuria is inherited through a simple recessive factor or is a heterozygous condition with irregular manifestation. The family history reported here would fall into either of these forms of inheritance.

I am indebted to Dr. J. W. Litchfield for permission to publish this case report, and to Dr. H. Harris and Professor F. L. Warren for examining the urine by chromatography and polarography at University College, London.

Blackwater Fever Treated with Cortisone

CASE REPORT

A Yoruba boy aged 19 months suddenly became ill at 11 a.m. on August 25, with a high fever, and was given an injection of quinine before admission to hospital the same day. He had been quite well, apart from having attacks of fever at varying intervals since birth, for which he had always received quinine. This treatment had apparently terminated the fever rapidly on each occasion.

On admission he was in a collapsed condition; his temperature was 104° F. (40° C.), his pulse 140 and of a poor volume, but he appeared to be well nourished. The mucous membranes were very pale and no icterus was noticed at the time. The heart was apparently normal. In the lungs scattered sibilant wheezes were audible. The spleen was palpable three fingerbreadths below the costal margin, and the edge of the liver was just palpable. At 11.30 a.m. he passed 10 ml. of almost jet-black viscid urine, and methaemoglobin was demonstrated spectroscopically. The haemoglobin was 4.8 g.%, and a blood film showed large numbers of *Plasmodium falciparum* trophozoites. On August 26 he appeared to be moribund. The conjunctivae were icteric, and his general condition had deteriorated. By 3.45 p.m. only 1 oz. (28 ml.) of black urine had been passed since the last specimen was collected at 11.30 a.m. on the previous day.

Cortisone, 100 mg., was given intramuscularly, and at 8 a.m. on August 27 there was a noticeable clinical improvement: the child sat up and ate; his temperature was 97.2° F. (36.2° C.), and his pulse 94. He had taken 70 oz. (2 litres) of fluid in the past 24 hours and was known to have excreted 8½ oz. (240 ml.) although he had been incontinent since 3.45 p.m. on August 26. The first three specimens following the injection of cortisone were dark, but were lighter than previous specimens, and the next three

specimens appeared normal in colour. Cortisone, 100 mg., was again given intramuscularly. This was followed by a dose of 50 mg. on August 28 and 29. On the 30th he was sitting up; the conjunctivae were icteric, and there was slight oedema of the feet and face. No further cortisone was given.

The urinary output on August 28, 29, and 30 was about 20 oz. (570 ml.) a day, and some urine was voided into the bed; it contained no methaemoglobin. The anaemia was treated with iron, and the malaria from the outset with mepacrine. The child made an uneventful recovery and was discharged.

COMMENT

It is suspected that blackwater fever is a haemolytic disease occurring in those infected with *P. falciparum* and whose cells have been sensitized by quinine. As cortisone lowers the sensitivity of body tissues in certain allergic states (Carey *et al.*, 1950), it was given in the hope that it might reduce the sensitivity of the cells to the circulating haemolysin and relieve the renal cortical ischaemia responsible for the anuria.

Although the clinical state of cases of blackwater fever is known to alter rapidly, it was felt that the condition of this child on the second day was such that a fatal outcome was inevitable. Cortisone seemed to have had an effect in this case.

Advantages of a Perineal Curve Applied to Midwifery Forceps

The first patterns of midwifery forceps—those of Chamberlen in the seventeenth century and of Edmund Chapman (1733) and William Giffard (1734)—were short and straight. William Smellie (1752) recommended the short straight forceps for general use, and he it was who discovered, to his great delight, how this instrument could be used for rotating the head in occipito-posterior presentations. Nevertheless, it was Smellie, too, who lengthened the forceps and added the pelvic curve in order to reach the head higher up in the pelvis—an invention also claimed for André Levret (1751) and Benjamin Pugh (1754). The pelvic curve was also an outstanding feature of the *mains de fer* designed by Palfyn in 1720. In the course of time the long curved forceps has supplanted the straight forceps for general use.

It was soon discovered that there were several disadvantages in the pelvic curve, notably the fact that traction on the handles is inefficient, as the direction of force is not in the axis of the birth canal. Many attempts to overcome this difficulty were made, and it was finally solved by Tarnier in 1877 with the axis-traction forceps. By the time axis traction became definitely established the necessity for the high forceps operation had vanished with the introduction of the relatively safe forms of caesarean operation in use to-day. The principle of axis traction still holds, but the patterns of forceps in general use are unnecessarily heavy and powerful for the low forceps operation, and many obstetricians have abandoned their use. Furthermore, with the long forceps with the pelvic curve, whether with axis-traction rods or without, it is not possible to obtain a good cephalic application when the head, in mid-pelvis or higher, lies in the transverse position. Severe lacerations of the birth canal have followed attempts to use the long curved forceps to rotate the head in this position, and most obstetricians in this country condemn the practice.

As long ago as 1769 R. Wallace Johnson, realizing some of the disadvantages of the long curved forceps, endeavoured

to overcome them by bending back the shanks in a perineal curve, thus bringing the handles more into line with the axis of the blades. This was the first of many attempts to obtain axis traction without the use of additional apparatus. The well-known forceps designed by Kielland (1916) also has a perineal curve for the same purpose, and solves most of the problems of applying forceps to cases of deep transverse arrest, but it has not yet become very popular, probably because of certain other features which require a special technique to be practised if this instrument is to be used as Kielland intended.

During the winter of 1949–50 I had an old forceps of the Ramsbottom type replated, and took the opportunity of getting the shanks bent back at an angle of about 30 degrees, close to the lock (see Diagram). I have used this instrument now for nearly three years, and have found that the alteration exceeded my expectations in making the forceps more efficient and handy. A line drawn through the ends of the handles and passing through the centre of the fenestrae almost exactly corresponds in direction with a line drawn in the same way but passing through the traction crossbar of the Barnes–Neville axis-traction forceps I used formerly. The curve of the instrument as seen from the side very closely corresponds with the curve of the Kielland forceps.

I claim that the addition of a perineal curve in this way gives the following advantages over the ordinary long forceps: (1) It provides axis traction for all low forceps deliveries without the addition of any traction rods, and nearly as efficiently as that provided by the Barnes–Neville forceps. (2) It can be more easily applied to the foetal head in transverse positions, giving a proper cephalic grip. It could be used for rotating the head in much the same way as the Kielland forceps is used, though I have not yet tried it. (3) It is more convenient than the normal type for use on the aftercoming head in breech presentations, as the handles are bent away from the body of the child in the same way as those of Piper's forceps (Piper and Bachman, 1929). (4) It is an ideal instrument for the general practitioner, as it is more versatile and more convenient to carry.

I claim no originality in this instrument, the idea being nearly two centuries old. Peterson (1952) has described a very similar forceps, which he has used for over 100 deliveries with complete satisfaction, and claims much the same advantages for it. It is my view that a special instrument is not necessary, and that it will suffice to give a perineal curve to any standard instrument, such as Simpson's or Anderson's.

Reviews

A REFUGEE DOCTOR IN ELIZABETHAN LONDON

Hamey the Stranger. By John J. Keevil. (Pp. 192. 21s.) Geoffrey Bles, London. 1952.

There were two Baldwin Hameys: the father—the “stranger”—that is, the alien (1568–1640)—and the son, the “Englishman” (1600–1676). Dr. Keevil has devoted a second volume to the son, who is remembered as a very successful practitioner and particularly as a generous benefactor of the Royal College of Physicians of London. The “stranger” attained no eminence and made little or no impact on the medicine of his day. He would hardly obtain mention in even the most detailed history of medicine, and was, professionally, no more than a reasonably successful and rather unreasonably conservative London practitioner.

And yet Hamey the stranger was well worthy of this memorial. It has been said that the true inner history of any life, however drab and ordinary it may seem, if properly told can be a topic of the most absorbing interest. But the life of Hamey the stranger, though outwardly undistinguished, was very far from being drab or ordinary. Dr. Keevil has told it with allusive charm. He has discovered many documents by or referring to the Hameys at the library of the Royal College of Physicians and, more unexpectedly, in the library of the University of Leyden. Nearly all of these papers are in Latin or Dutch, and their reading and translation was itself no mean task. But the secret of Dr. Keevil's power to arrest the reader's attention lies especially in his skilful use of the contemporary background as the setting of biography.

Hamey was born in Bruges of a family with Protestant sympathies. They suffered much from the acts of that monster of cruelty, the Duke of Alva (1508–83), in command of the Spanish forces that for years ravaged the Low Countries. In the terror which followed the year of Hamey's birth tens of thousands of innocent people were wantonly slaughtered by Alva's troops. Hamey's parents became refugees. They settled in Leyden, and Baldwin became a student in 1584 at its newly founded university. He was admirably taught by the eminent anatomist Pieter Paaw (1564–1617), himself a pupil of Geronimo Fabrizio, Harvey's master, and by Jan Heurnius (1543–1601), an excellent and learned physician who stood for the simpler Hippocratic medicine against the pretentious Galenism fashionable at the time. Hamey was a devoted correspondent of Heurnius and of his son after him. Much of Dr. Keevil's material is drawn from Hamey's letters to these two.

In 1594, being now 26 and having failed to obtain a suitable post in Holland, Hamey accepted, on the urging of Heurnius, the position of personal physician to the Tsar of Russia. He set out for Moscow by the only practicable route, that via Archangel. Much of the interest of Dr. Keevil's book is the description, largely from the Hamey papers, of the conditions in Moscow in the years 1594–7, the domestic and foreign relationships of the reigning house, and the palace intrigues within the Kremlin. He detested the ignorance and bigotry, the suspicion and treachery, the squalor and cruelty and filth that were daily before his eyes. It was not long before he sought a way of escape, but that was by no means easy. Ultimately he obtained permission to go to Archangel to meet his affianced bride, who had ventured to follow him across the sea. The two escaped and sailed for London, where they settled in a house in the Tower ward of the City, from which Hamey practised.

The rest of the life of Hamey the stranger is the story of a refugee slowly and surely adapting himself to the conditions of the country of his adoption, but not without

humiliation and opposition. At that time the Royal College of Physicians had the exclusive right of licensing any practitioner of medicine in and around London. Hamey had much difficulty in obtaining the licence, and was several times rejected by that body on grounds which seem now trivial, unfair, and quite unrelated to his professional competence. His ultimate success was substantial but in no way remarkable. The things that were remarkable about the man are, first, his firm and honest character, admirably backed by an able and devoted wife; secondly, the picture that he has left of the life of a refugee in Elizabethan and Jacobean London; thirdly, his Russian experiences; and, last and by no means least, the picture that he presents of the actual conditions of day-to-day practice. Very few practitioners have left such a record, and the history of medicine would be the richer for more. It is a moving story excellently told.

CHARLES SINGER.

RADIOTHERAPY FOR STUDENTS

X-ray and Radium Therapy for Students. By Basil A. Stoll, F.F.R., D.M.R.(Lond.), D.M.R.T.&D.(Eng.). Foreword by Frank Ellis, M.D., M.Sc., F.F.R. (Pp. 206. 17s. 6d.) London: H. K. Lewis and Co. 1952.

In his preface the author states that this book is intended as a guide to the place of x rays and radium in medical and surgical practice and that its concise format should make it of value to a wide field of students, postgraduate and undergraduate. It is certainly concise in that the diagnosis, pathology, and treatment—surgical and medical—of almost the whole field of malignant disease as well as of some other pathological conditions are discussed in a book of pocket size of 206 pages. But it seems doubtful if the book will serve as a useful guide to the place of radiotherapy in practice, and it may be misleading to students. Its conciseness does not allow of discrimination between the numerous facts and opinions set down. A useful list of references is appended.

B. W. WINDEYER.

DETECTING LIES

The Instrumental Detection of Deception: The Lie Test. By Clarence D. Lee. (Pp. 249. £2 7s. 6d.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1953.

This book, written by an American police detective, shows again how the spirit of man can be attacked by mechanistic approaches. The lie detector depends on the fact that alterations of blood pressure, respiration, and pulse rate are greater in most normal persons when questions involving personal guilt are put to them. Psychiatrists and psychologists know there are many exceptions to this generalization: one false positive response quoted in this book was due to a suspect under examination seeing a girl start to undress and sunbathe through the police station window. And the author realizes that such tests alone would hardly stand up to critical examination in a court of law, although important information can be obtained.

The purpose of these methods becomes clearer, however, when it is frankly admitted that their real value in the hands of the American police who use them is to enable more confessions to be extracted from frightened and guilty people. If a suspect can only be convinced of the supposed infallibility of the test he can be more easily broken down. In 80% of cases giving positive results confessions were, in fact, extracted afterwards, and a description is given of how these confessions are best obtained from the victims. Even if the test is negative, the police may sometimes pretend it is positive in order to get a confession.

The history of “scientific” examination of religious or criminal suspects throughout the ages shows many general fallacies inherent in such methods. In the olden days examiners, and even the accused, came to believe in skin tests for witches, which we now know were merely the

physical stigma of hysteria often brought on by the tension of the examination itself. One would like to know more about experiments made in those wrongly persuaded of their guilt in a preliminary "grilling" and whether subsequent tests might not become positive by suggestion. Behind the Iron Curtain it is as wrong for the examiner to accept knowingly a false confession as it is in the U.S.A. But fear-provoking methods can also affect the judgment of all concerned in such work, and absurd confessions may come to be genuinely believed. There is no conclusive evidence that the lie detector eliminates this risk in an atmosphere so emotionally charged that the electric chair is often the issue at stake.

A chapter is devoted to the suggested use of the method as a deterrent in department stores, banks, industry, and the investigation of insurance claims. The author rightly points out that most people would be more careful if they knew the test was to be given as a routine. The reviewer was just beginning to think the whole question was hardly "cricket" by British standards, when a London insurance firm was stated in an American magazine article to be willing to reduce premiums for American banks where the entire staff was tested for dishonesty in the first year, and at least one-third of them each succeeding year. We hope this is not really true, or we shall soon find it happening here as we increasingly copy American business methods. Streamlined models might even be provided for hospital gate porters under the N.H.S. to stop the staff from pilfering.

WILLIAM SARGANT.

OPHTHALMIC PATHOLOGY

Ophthalmic Pathology: An Atlas and Textbook. By Jonas S. Friedenwald et al.; with the editorial assistance of Helen Knight Steward. (Pp. 489; 240 illustrations. £4 10s.) Published under the joint sponsorship of the American Academy of Ophthalmology and Otolaryngology and the Armed Forces Institute of Pathology. Philadelphia and London: W. B. Saunders Company. 1952.

A book on ophthalmic pathology running to 477 pages larger than quarto is an event in ophthalmic literature. Sponsored as it is by the American Academy of Ophthalmology and Otolaryngology and the Institute of Pathology of the U.S. Forces, expectation runs high. It carries, in fact, not only the authority of the two sponsoring organizations, but also that of two previous publications, for it is based on the *Atlas of Ophthalmic Pathology*, first published in 1938 by the Ophthalmic Registry of the American Forces, and the *Pathology of the Eye* brought out by Friedenwald in 1930. The dual origin of the present volume is also apparent in the format in which it now appears, for half the book is taken up by plates—contributed by Helenor C. Wilder (who was also responsible for the illustrations in Friedenwald's book)—while the text is devoted to general discussions rather than to histological descriptions. The preface by Dr. W. L. Benedict indicates that, though many authors have contributed to the book, Friedenwald and Maumenee are mainly responsible, and it would appear that its preparation began in 1945.

The text itself follows the usual mixed anatomical and aetiological classifications, but contains in addition lucid chapters on anatomy, physiology, histology, and senescence of the eye in relation to pathological lesions. Clinical discussions are introduced here and there, and these are not always relevant or illuminating. While the text is generally competent, the bulk of the chapters on congenital and developmental anomalies, and the heredo-familial and degenerative diseases, are disappointing; they even include such monstrosities as "atavism." The illustrations—some 1,000 figures on 240 plates—are well chosen and beautifully reproduced. In themselves they fully justify publication of the book, but the legends are open to criticism. In the original atlas full case reports were given; here they have been replaced by more useful short descriptions, but occasionally there is little more than a heading without any explanation

of the details shown. It is also unfortunate that the text appears to have been written without any relevance to these excellent illustrations, so that the volume is in fact two books bound under one cover. It is to be hoped that the next edition will be a happier synthesis, even if drastic revision of the text is necessary with more emphasis on histopathology, for the book could be a landmark in ophthalmic literature.

ARNOLD SORSBY.

CONSTRUCTIVE MEDICINE

Man and Epidemics. By C.-E. A. Winslow. (Pp. 246. £1 5s.) Princeton, New Jersey: Princeton University Press. London: Geoffrey Cumberlege. 1952.

Do you have a son of years enough to be lured towards medicine? Be you student health worker, family doctor, consultant, or of epidemiological persuasion, this book will stir the mind and warm the heart. Some readers, finding pleasure in half-forgotten fact, will pause to wonder that works written for the non-expert can be so much more expertly informative than erudite expositions. Others, perhaps for the first time, will evaluate their contribution to past events and to those events which are in the making. All will be led towards a reasoned perfecting of medical principle and practice. Be warned that, once begun, this book will not be laid aside.

For 50 years Dr. Winslow has been engaged in preventive medicine, or, as he prefers to call it, constructive medicine. Now he is professor emeritus of public health at Yale, and one is grateful not only for his long and continuing contribution to medicine but also for his years of receptiveness in humility and with humanity. His chapters are on such things as the history of disease concepts, water supply, milk, sewage, food hygiene, and insects in relation to disease. To the cynic these may be the subjects of old-time public health, subjects made strangely less worthy by their passing into common acceptance and usage. It is from the past, however, and from these subjects, that Dr. Winslow, with drama, logic, and perfect lucidity, develops and poses a concept for the future. The reader is informed in the preface that Dr. Winslow may follow this volume with other works on preventive medicine. May they be indeed forthcoming.

J. M. MACKINTOSH.

STUDY OF TWINS

Studio dei Gemelli (The Study of Twins). By Luigi Gedda. Preface by Professor Cesare Frugoni. (Pp. 1,381; 548 figures. 15,000 lire.) Rome: Edizioni Orizzonte Medico. 1951.

A monograph covering the biological and other aspects of twinning in creatures ranging from plants to man is something for which there is an unquestionable demand. This book is an attempt to satisfy it. Two chapters are on twins in art, legend, history, and science. The excellent reproductions of paintings and sculpture, from Etruscan times to the present, and quotations from Plautus to Aldous Huxley enrich these most illuminating chapters. A chapter on comparative "gemellology" gives the layman a broad outlook on how complex is the problem of twinning and how useful twins may be as a tool in research. The bulk of the text is on twinning in man—incidence, causation, genetics, and embryology, twin pregnancy, and the anatomy, physiology, pathology, and psychology of twins. A full chapter summarizes the original work of the author on the similarity of glutathione levels in the blood of twins and their rhythmical variation. The significance of this contribution is not easy to assess on the basis of the data supplied.

The book is illustrated by a wealth of photographs and excellent colour plates, which accounts for its price. It is a pity that shortcomings of presentation and of critical selection, together with a lack of conciseness, reduce the value of the book considerably, the compilation of which must have required a large amount of work.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY APRIL 11 1953

ORAL PENICILLIN

When penicillin is given by the mouth only a proportion of the dose, varying from about one-quarter to one-tenth, is absorbed, and various antacids, capsules, tablets, oils, and other devices to protect it against destruction by gastric acid increase this proportion little if at all. Moreover, the amount absorbed varies inexplicably from one person to another, and even in the same person at different times. It is thus not surprising that oral administration is often condemned—except in young children, for whom it has obvious special advantages—as both extravagant and unreliable. It nevertheless has its advocates. Binns,¹ reviewing the literature of the subject, concludes that oral penicillin in four-hourly doses of 400,000 units before meals should be satisfactory for fully sensitive coccal infections. Like all others who have reached such a conclusion, he qualifies it by recommending an initial intramuscular dose for seriously ill patients and by restricting such treatment to patients whose life is not in danger. Oral administration is also considered inadvisable for syphilis, deep-seated suppuration and osteomyelitis, bacterial endocarditis, and any infection due to an organism less sensitive than a pneumococcus, haemolytic streptococcus, or gonococcus. Elsewhere in this issue (p. 806) Dr. David Wheatley reports encouraging results in acute infections of the middle ear with combined oral penicillin and sulphadimidine.

The only insuperable objection to oral penicillin is the inconstancy of its effect, and according to Boger and his colleagues² much more consistent and sustained blood concentrations can be secured by giving probenidol ("benemid") at the same time to delay renal excretion. According to these authors' findings 300,000 units of potassium penicillin with 0.75 g. probenidol given every eight hours has an effect equivalent or superior to that of 300,000 units of procaine penicillin injected intramuscularly once daily.

It also seems that more consistent effects can be obtained from a different form of penicillin, although this was first introduced for quite another type of use. We referred recently³ to the introduction of a penicillin compound of low solubility, N,N'-dibenzylethylene-diamine dipenicillin (known also as "penidural" and benzethacil), after a single intramuscular dose of which penicillin may be detected in the blood for as long as one month. This compound is also available in a form for oral administration, and the results of administering this to 101 children at the Great Ormond Street Children's Hospital are reported on page 805 by Drs. I. A. B. Cathie and J. C. W. MacFarlane. A standard dose of 300,000 units was given, and after a single dose a therapeutic blood concentration was invariably found after three hours. When the dose was repeated at six-hour intervals a cumulative effect was observed, with continuous maintenance of a therapeutic concentration. These authors remark that this is "the first oral preparation which has in our experience been reliably absorbed in 100% of patients." The effects of this preparation have also been tested in normal adults by Bayne, Gylfe, Carfagno, and Boger,⁴ who controlled their observations by "cross-over" tests with the same dose of potassium penicillin. The effect of giving probenidol at the same time was to increase the concentration of penicillin in the blood at two hours and sustain it for some hours thereafter. These findings show that what is now known in the U.S.A. as an adequate "penicillaemia" can regularly be maintained by this combination of drugs. But it is a little puzzling that a penicillin compound of such low solubility—with consequently a slow rate of absorption when injected—should be absorbed quite rapidly and regularly when swallowed. Neither of these papers discusses the mechanism of absorption, and it would be interesting to know something about this. Nothing yet published shows whether this compound acts as such or only, as with penicillin esters, after breakdown.

Ideas about oral penicillin evidently need revision, and in this process ease of administration and diminished risk from sensitivity reactions will be given due weight. On the other side of the scale must be weighed the greater risk of indiscriminate use and of inadequate treatment when an infection is due to a less sensitive organism. The possibilities of self-medication when bottles of such preparations find their way into households also need to be considered, particularly if it should become known that a mouthful at the right time is a preventive of most forms of venereal disease.

THE ACCUSED RUSSIAN DOCTORS

We print in this week's *Supplement* a statement issued by the council of the World Medical Association on March 27 in Lisbon on the case of the nine Russian doctors recently accused of grave malpractice—indeed of the murder of some of their patients—and of acting as spies for the U.S.A. and Britain. The statement is restrained in tone, and no attempt is made to prejudge the issue. The last paragraph implies that the W.M.A. Council doubts whether the judicial procedure employed in the case of the nine doctors was such as to establish the truth, or at least in a way to convince those outside the U.S.S.R. On April 4 an astonished world learnt that the new regime in Russia declared that the accusations were false and arrived at "through the use of methods of investigation which are inadmissible and most strictly forbidden by the Soviet law," according to the statement published in *Pravda*.¹ The nine doctors, and six others unnamed, have been released. The W.M.A. Council made its protest on behalf of the 700,000 doctors throughout the world belonging to its constituent member associations. Whether or not it had any effect in Moscow, the W.M.A. has done well to voice its anxiety about the fate of doctors in a country which has no medical organization affiliated with it.

What are the facts? On January 13 of this year the Tass Press Agency in Moscow released a press statement which began thus: "Some time ago the security organs of the State discovered the existence of a terrorist group of doctors who had set themselves the goal of shortening through medical sabotage the lives of active functionaries in the Soviet Union." Nine medical specialists were named as belonging to the group, the majority of them apparently being Jews. Through allegedly wrong diagnosis and treatment they were accused of causing the death of Zhdanov and Shcherbakov, and of attempts against the health and life of five highly placed officers in the Russian armed forces. These accusations were arrived at on the basis of "documentary evidence, of investigations and conclusions arrived at by medical specialists, as well as on the basis of the confessions of those arrested." *Pravda* of January 13 elaborated the accusations in terms meant to leave the reader in no doubt of the guilt of the nine doctors, the majority of them allegedly "recruited by a branch of the American intelligence service—the international, Jewish, bourgeois-national organization 'Joint'." Three of the doctors were accused of being agents of the English secret service. "In front of the whole world," stated *Pravda*, "the true face of the slave-owners and man-eaters from the U.S.A. and England has been revealed."

¹ *The Times*, April 6, 1953.

From January 13 to April 4 these were the facts presented to the world in the Russian press and broadcast widely over the air. As doctors we felt disturbed by this assault upon the professional integrity of our Russian colleagues, and especially by the probable effect of the accusations on the trust patients universally have in the sanctity of the doctor-patient relationship. As members of one of the learned and liberal professions we were alarmed at this renewed threat to civilized values in the anti-Semitism implicit in the charges and echoing the anti-Semitism of the Prague trial at the end of last year. But now the tables have been turned with a vengeance. The accused are released with a clean bill of legal health. The accusers are now accused. The unhappy Dr. L. F. Timashuk, the woman doctor who informed against her colleagues, has had taken from her the Order of Lenin bestowed on her on January 20 for this act. Such a *bouleversement* creates a feeling of both relief and bewilderment. As *The Times* puts it: "Surely there is no precedent in Soviet history for this public admission of fraudulent and evil methods in the State police and judicial system." If this violent loosening of tension between Russia and the non-Communist world is to be more than a nine-days' wonder, we may hope to renew those contacts with Russian doctors that began during the war. The B.M.A.'s invitation of hospitality to individual Russian doctors still stands. The World Health Organization refused to look upon Russia's withdrawal from it as permanent. The World Medical Association, we understand, has informed the Russian medical profession of the First World Conference on Medical Education to be held in London this year in August. If their delegates come to it they will be welcomed. Their colleagues from all over the world want to meet them, to exchange views, to share experiences, to get rid of mutual suspicions in mutual and friendly intercourse. Is it too much to hope that this may yet be possible?

A HAPPY EVENT

Women in labour owe much to the events of April 7 one hundred years ago. The *Court Circular* of that date contained the following announcement:

"Buckingham Palace, April 7.
"At ten minutes past one o'clock this day the Queen was safely delivered of a prince."

This referred to the birth of Prince Leopold, Duke of Albany, Queen Victoria's eighth child. And it was the administration of chloroform to the Queen during her son's birth that did so much to dispel the

¹ *Association Medical Journal*, April 15, 1853, p. 318.² *Lancet*, May 14, 1853, p. 453.³ *Association Medical Journal*, May 27, 1853, p. 450.

prevailing religious and professional objections that made childbirth a needless misery to many women.

In reporting the happy event, this *Journal* (then called the *Association Medical Journal*)¹ remarked that "there are circumstances connected with the event which have likewise imparted to it no small degree of medical importance. We refer to the employment of chloroform having been sanctioned by Her Majesty's Physician in Ordinary, Sir James Clark, Her Majesty's First Physician Accoucheur, Dr. Locock, and Her Majesty's other Physician Accoucheur, Dr. Ferguson; to its having been administered by Dr. Snow; and to the fact of the Queen and the infant prince having gone on favourably from the first." After recording that "the Queen expressed herself as grateful for the discovery of this means of alleviating and preventing pain," the account went on:

"The responsible position, and the acknowledged skill of the physicians who sanctioned the inhalation of the chloroform, the Royal Majesty of the patient, and the excellence of her recovery, are circumstances which will probably remove much of the lingering professional and popular prejudice against the use of anaesthesia in midwifery, even when sanctioned by competent authority, and induced with requisite precaution. It is for this reason that we chronicle the recent accouchement of Her Majesty as an event of unquestionable medical importance."

The mention of professional prejudice comes as a surprise to the reader to-day, but it found forceful expression in the editorial columns of the *Lancet*²—uncharacteristically behind the times. "Intense astonishment," wrote our contemporary, "has been excited throughout the profession by the rumour that Her Majesty during her last labour was placed under the influence of chloroform, an agent which has unquestionably caused instantaneous death in a considerable number of cases. Doubts on this subject cannot exist." The article was concerned to draw a distinction between the necessary use of chloroform as an anaesthetic during surgical operations and what it considered to be its unnecessary use to ease the pangs of normal labour. The *Journal* report, it seemed, was hardly to be believed:

"Probably some officious meddlers about the Court so far overruled Her Majesty's responsible professional advisers as to lead to the pretence of administering chloroform, but we believe the obstetric physicians to whose ability the safety of our illustrious Queen is confided do not sanction the use of chloroform in natural labour."

A fortnight later³ the *Journal* fired a parting shot at the *Lancet* for casting doubt on the accuracy of its original report and expressed its "own humble opinion" that

"the cautious inhalation of the vapour of chloroform during labour is entirely free from danger, and calcu-

lated to afford merciful relief from pain, in one of the most agonizing trials of humanity."

John Snow lived to see this "humble opinion" gain wide acceptance—more emphatically than it would to-day—and attended Queen Victoria again, for the birth of Princess Beatrice in 1857. He died aged only 45 the following year, when appeared his classical monograph *On Chloroform and Other Anaesthetics*.

HEALTH SERVICE INQUIRY

Noisy protests broke out on the Opposition benches last week when the Minister of Health announced that a committee was being set up to inquire into Health Service costs. But obscured in the rancour clothing Mr. Bevan's observations was one of special interest to the medical profession. He complained that the issue of Health Service economies was a matter primarily for the House of Commons and for political decisions, and criticized sending to a committee of inquiry "a matter which is at the centre of British politics." Most doctors agree that one of the most unfortunate features of the Health Service is that it started—under Mr. Bevan's aegis—at the centre of British politics and that it has never gravitated far enough away from that thoroughly unsuitable point. Mr. Bevan's successors, whether Labour or Conservative, have done something to remove the Health Service from the political arena. Clearly it can never be wholly withdrawn from it while it remains a State service. But there are many details in its finance and administration that should be free of political dispute and subject only in the most formal way to political decision. If the new committee is to be seen as a further endeavour to treat the issues non-politically, then it is to be welcomed for that alone. The Government would surely not be so inept as to appoint a committee of this sort merely to prepare the ground for destructive economies.

Given enough powers the committee should discover some much-needed information. It is asked to review the present and prospective cost of the Health Service, and to advise how a rising charge on the Exchequer can be avoided while providing for the maintenance of an adequate service. Dr. Ffrangcon Roberts has done much to show, both in this *Journal*¹ and in a book published last year,² how the cost of medical care has risen, goes on rising, and will continue without limit if allowed to do so. Various checks have been put on it, and the most effective may prove to be the dental charges. This is not to say that precisely similar charges can or should be imposed elsewhere. But, if it is agreed that stability

¹ *British Medical Journal*, 1949, 1, 293.² *Ibid.*, 1952, 1, 321.³ *The Cost of Health*, 1952, London.

is best achieved by proper design of the Service rather than by panic cuts and arbitrary limits, then a committee of inquiry is a move in the right direction. And if the committee is a non-political one only Mr. Bevan and his associates are likely to complain.

The question of block grants to hospitals is apparently to be inquired into—belatedly, the medical profession would add. The present financial methods, quite apart from the irksome restrictions the Treasury imposes when employing them, defeat their object in actually encouraging waste. In withholding that greater measure of independence that block grants would confer on hospital boards, the existing methods impair the sense of responsibility that surely ought to accompany public administration. Yet, when Mr. Macleod said that many people had for a long time considered that block grants were a matter which should be inquired into, there were cries of “No” from the Opposition benches. It is not clear whether they were denying the undoubted fact that many people thought the subject should be investigated or whether they were denying that such an inquiry ought to be held. In any case these dissentients will find no support for their views anywhere in the Health Service.

Whatever the nature of the committee (its chairman is a distinguished economist with experience of arbitration disputes), we may hope that it will fully consult the medical profession in the course of its inquiry. In the past too many Government actions have been decided—at times plotted seemed a better word—behind closed doors in Whitehall. An impartial committee can now do much to dispel the mistrust that is noticeable in the Service, and may help to give a better sense of direction and unity of purpose to all concerned with the nation's health.

ATTACK ON POLIOMYELITIS

An experimental vaccine against poliomyelitis has been prepared in the U.S.A. and its effects studied in human beings. According to Dr. J. E. Salk and his colleagues, who report¹ this important advance, the results are encouraging, but “should not be interpreted to indicate that a practical vaccine is now at hand.” It seems that antibody against all three immunological types has been induced by inoculation of the vaccine.

Behind the preparation of this vaccine lies a multitude of experiments on the recognition, isolation, and culture of poliomyelitis virus strains. Ever since Landsteiner² transmitted poliomyelitis to monkeys the search has gone on for a more convenient laboratory animal for poliomyelitis research. However, strains of the virus, with the exception of a few capable of causing disease in rodents (Lansing, Type II), are pathogenic only to the primates. Attempts to adapt poliomyelitis virus to tissue culture in the past were

largely unsuccessful in that no conclusive evidence was obtained of *in vitro* virus multiplication, except where primate tissue was used. A report by Sabin and Oliitsky³ in 1936 on the cultivation of the virus in human embryonic brain (later confirmed⁴) suggested that the choice of tissue would be limited. Many of the original disadvantages of tissue culture, often technical in nature, have now been overcome. The use of antibiotics has virtually eliminated bacterial contamination, a major obstacle to success before the last war. And the idea of using human tissue for culture, as suggested by Goodpasture and Anderson⁵ for the growth of zoster virus, offered new lines of approach to the study of viruses affecting man.

Although the essential lesion in poliomyelitis is neuronal, primary multiplication of virus probably occurs in extraneural tissues. In 1949 Enders, Weller, and Robbins⁴ at the Children's Hospital, Boston, using tissue culture of human embryonic material, demonstrated that poliomyelitis virus would multiply in neural and non-neural tissues and also in completely differentiated infantile skin.⁶ In a series of recent communications Enders and his colleagues⁷⁻⁹ have shown with abundant clarity that tissue culture is no mere technical exercise but a method of great practicability and even greater possibilities.

Two well-known methods have been found successful in growing all three immunological types of virus. The one is flask culture, when tissue fragments are suspended in a balanced salt solution; the other is roller-tube culture, when tissue fragments are embedded in a plasma clot and covered by salt solution. Opinion is hardening in favour of roller-tube culture as the method of choice.⁹ The selection of tissue for cultures presents certain difficulties. Human embryonic, uterine, and renal tissues among others have given good results but have obvious limitations. Material removed at necropsy is not satisfactory, and growth in species other than man and monkeys has not been observed.⁸ Monkey testicular tissue supports growth well and in many laboratories will be found more practicable.¹⁰⁻¹² A recent observation by Ledinko and Melnick¹³ that testicular tissue from immune and non-immune monkeys is equally satisfactory suggests that serum antibody plays little part in determining *in vitro* susceptibility. Similar observations have been made on other viruses,¹⁴⁻¹⁵ and it will mean that adult human tissue need not necessarily be obtained only from subjects whose immune state is known. Protein-containing cell stimulants are invariably incorporated into the fluid phase in the roller-tube method to ensure good cellular outgrowths. A move

towards simplifying the nutrient medium—and this is indeed welcome—is suggested in a report by Melnick and Riordan¹⁶ that such protein stimulants can be replaced by an enzymatic protein hydrolysate. Furthermore they obtained excellent yields of virus when the roller-tubes were kept stationary. Reports on the use of synthetic media have also been made.¹⁷ Evidence of multiplication of poliomyelitis virus in tissue culture can be shown by recognized methods of animal inoculation.⁸ Simpler and equally reliable evidence can be obtained from the degenerative changes seen in cellular outgrowths (cytopathogenic effect) and by alteration in cellular metabolism with decreasing acid production (pH differential test).⁸

Tissue culture offers tremendous possibilities in research not only into poliomyelitis but into other virus diseases primarily infecting man, such as the acute exanthems. With the antibiotic era in full swing, direct isolations can be made from human material (faeces and brain) and the method extended for epidemiological surveys. How to treat or control disease is the ultimate aim of investigation, and the adaptation of poliomyelitis to tissue culture is a signal advance in this direction. Repeated passage of virus in tissue culture reduces its virulence to monkeys with no loss in tissue culture infectivity.¹⁸ Inactivated vaccines have been found antigenic in experimental animals¹⁹ and now in man.

WORLD HEALTH

The publication of the annual report¹ of the Director-General of the World Health Organization closely coincides with World Health Day—April 7—which many of the member States now officially celebrate, some by proclaiming it a public holiday, others by holding meetings and exhibitions designed to increase local interest in preventive medicine and in the advantages that accrue from international co-operation. The practical benefits of such co-operation are plainly set out in the report. W.H.O. is the great co-ordinator of public health work. Not only are backward countries helped to combat malnutrition and such endemic diseases as malaria and yaws, but the Western nations also gain from W.H.O.'s work on the biological standardization of drugs and other therapeutic substances, from its thorough investigation of B.C.G., and from the information being gathered by the World Influenza Centre in London—to mention only a few of the projects in which W.H.O. is interested. The amount of money available last year to finance all its activities came to between 7 and 8 million dollars—not a vast sum in these days of astronomical spending. Lack of trained workers has led to difficulties all over the world, but during 1952 more awards of training fellowships were made than in any previous year—1,147 as against 662 in 1951.

In his foreword to the report Dr. Brock Chisholm states that “the whole organization has now passed through its formative period. Its general policies and procedures and its relationships, both internal and external, have been established.” That they should have been so soundly established is largely due to

Dr. Chisholm himself. Five years ago he was appointed the first Director-General of W.H.O., and he retires in a few months' time. The report for 1952 is the last he will make to the World Health Assembly, and he has taken the opportunity to comment on one of the difficulties which faces any organization whose purpose is to help all the peoples in the world and not just some of them. To do its job properly the World Health Assembly must have unprejudiced advice, and members of its executive board ought to feel themselves responsible to the Assembly alone, and not to Governments or other bodies. Any Government unwilling to allow independence to the members it designates to the executive board should refrain from making designations, and members of the executive board who find themselves unable to act independently should resign. “Nothing short of complete world-mindedness is acceptable in any member of the executive board,” writes Dr. Chisholm. In all the fields of international endeavour perhaps only in that of health could such an idealistic conception be stated with such confidence in its practicability.

BETTER FACTORIES

Sitting between two fat men to keep warm on his journey to work 50 years ago, the man who recalls¹ this experience found strikingly different conditions on arrival at his factory from what is afforded to-day. Then dirty, rat-ridden, cold, and ill-lit, many factories provided neither a healthy climate to work in nor safe machines to tend. The great and beneficial changes wrought by legislation and changing opinion during these years are reviewed at length by the Chief Inspector of Factories in his latest annual report, and if better plumbing, brighter illumination, and purer air were sufficient to man's working needs his contentment at work could never have been deeper than it is now. But there have been other changes too, though they barely come within the report's scope. “A good example of British, and especially Birmingham, methods of production during the years” is the bicycle industry. Formerly one skilled man assembled one bicycle or made a complete handlebar. Now he “adds one screw as the article passes on a conveyor belt.”

All the same, such improvements as the report recounts are exceedingly welcome, though a special cause of concern is the accident rate. Unfortunately, statistics are inadequate for comparisons back to 1901, nor are the numbers exposed to risk clearly known in any year. There were 828 fatal accidents in 1951, which was 29 more than in 1950. But the number of non-fatal accidents fell by 5% to 182,616, which was the lowest total recorded since 1938. The number of accidents connected with transport continued to rise, and the report comments: “While it is not to be expected that the widespread introduction of mechanical methods of handling and transportation would be unaccompanied by an increase of accidents of this kind, a rise of the order of 250% over 1939 is extremely serious.” No

¹ *The Work of W.H.O.*, 1952. Published by the World Health Organization, Geneva.

² *Annual Report of the Chief Inspector of Factories for the Year 1951*. 1953. H.M.S.O.

doubt the use of these new machines has averted many accidents—and more serious accidents—that would have resulted from the contact they often prevent between workmen and other machines that chop, press, saw, and so on. The stricter discipline among users of the new machines that the report calls for would reduce the accident rate, but that is only one of several ways in which the problem is being attacked. Clearly the design of machines as nearly foolproof as possible is desirable, and much work has been done on that in recent years. Again, industrial psychologists are aware that employment too far below a man's intellectual capacity is detrimental to him. Lack of interest will lead to lack of attention; to attribute the resulting accident to lack of discipline is only part of the story.

Perhaps the greatest change noticeable in the last 50 years—certainly to the workpeople themselves—is the reduction of working hours in a week. The Factory and Workshop Act of 1901 allowed a working week of 60 hours for women and young persons in non-textile factories (in textile factories 55½ hours). It was during the first world war that the effects of fatigue on production were first scientifically studied, and partly because of these studies, partly because of changed social attitudes, the 48-hour week came to be recognized as normal in 1918. During the 'thirties the five-day week became popular; since the second world war it has been worked almost everywhere, and with it the mid-morning tea break has come to stay. But how best to enjoy his leisure may be hard to learn for a man who at his work spends every minute, hour, day, and year adding screw after screw.

CANCER OF STOMACH AND BLOOD GROUPING

The search for relationships between blood groups and susceptibility to disease has not as yet proved very fruitful, and attempts to find an association with cancer have been inconclusive. In 1942, for example, Schinz¹ showed the frequencies of ABO groups among 1,000 patients with malignant neoplasms from the Röntgeninstitut at Zurich to be 430 of group O and 456 of group A, compared with 402 and 480 respectively among 1,000 patients with non-malignant conditions, the differences being not quite statistically significant. Now the findings of Professor Aird and his colleagues in cancer of the stomach, reported at page 799 of this issue of the *Journal*, are likely to provide fresh stimulus to such studies. The ABO blood-group distributions of 3,632 patients with cancer of the stomach in a number of hospitals in England and Scotland were compared with those of control groups of people in the same hospitals or localities. In respect of all but two of the Birmingham, Leeds, Liverpool, Manchester, Newcastle, and Scottish hospitals equal numbers of controls were taken at random from cross-sections of patients in the same hospital, and for the other two hospitals estimates were made from the data of the local blood-transfusion centres. In London 1,340 patients with stomach cancer were compared with the

blood-group frequencies in Discombe and Meyer's series of 10,000 from north-west London.

Comparison of the distributions in Scotland, the northern towns of England, and London showed no important differences for the B and AB groups, but group A was more frequent and group O less frequent in patients suffering from cancer of the stomach than in the general population of the same locality, and this difference was present in every hospital from which data were obtained. In Scotland the percentages of group A were 36.4 for patients with cancer and 32.5 for controls; in the northern towns they were 46.4 and 39.3 respectively; and in London they were 46.0 and 42.2. Statistical tests showed the differences to be highly significant. In agreement with this, some hitherto unpublished figures for 704 patients with stomach cancer in Basle reported to the authors by Dr. Holländer showed 53.1% of group A compared with 45.1% among 4,518 controls. It may be noted that this relation is in the reverse direction to that reported from Zurich for cancer of all sites as quoted above, and this suggests that similar studies for other varieties of cancer would probably give very different results.

Interesting as these findings are, their effect on cancer rates for whole populations can be only slight. And a little calculation shows that, even if two populations existed having such unlikely extremes as 25% of group A in one and 65% in the other, the cancer rates would not differ by as much as 10% because of this genetic difference. The authors are at pains to point out that the association with blood grouping, far from accounting for the observed excess of stomach cancer mortality in English northern towns, tends to increase the divergence, which has to be explained, it would seem, by environmental factors not yet identified. The northern town populations have a smaller proportion of group A and would therefore be expected to have slightly less cancer of the stomach. Neither could racial blood-group differences, whatever they may be, go any distance towards accounting for the excess of stomach cancer mortality in North Wales compared with neighbouring English rural areas, which over the last 30 years has been of the order of 70% after allowing for all the local factors capable of assessment at the present time, such as differences in the verification of diagnosis.

The relationship between blood groups and cancer of the stomach shown by the statistics of Aird and his colleagues leads them to conclude that "it is no longer possible to regard blood groups A and O (in adults) as entirely devoid of selective value." The validity of this conclusion depends on the validity of an assumption, tacitly made, that a blood group can never be changed by cancer or by extrinsic factors causing cancer. This cannot be regarded as certainly true until it has been properly tested; and, if it should prove to be incorrect, an explanation of the statistical relationship might be found in a common cause.

Sir Russell Brain was re-elected President of the Royal College of Physicians of London on March 30. He was first elected President in 1947.

REFRESHER COURSE FOR GENERAL PRACTITIONERS THE MANAGEMENT OF LATE AND LATENT SYPHILIS*

BY

G. L. M. McELLIGOTT, M.A., M.R.C.S.

Senior Physician, Department for Venereal Diseases, St. Mary's Hospital, Paddington

The rapid and sustained decline in early infectious syphilis that has taken place in most parts of the civilized world since the end of the war has not been accompanied by a similar fall in the incidence of latent and late infection. In England and Wales the number of these patients attending the treatment centres was higher in 1950 than it was in 1946. With the growing awareness among medical practitioners of the possibility of late and latent infection, and the rapidly growing practice of routine antenatal blood testing, it is likely that still larger numbers of these patients will be discovered in the future, and that we will be increasingly concerned in their management and treatment.

Dangers of Latent Syphilis

The ultimate importance of a disease depends upon its power to shorten life, and syphilis, especially when untreated in its early or asymptomatic stages, is well known as a not uncommon cause of premature death. I have always believed, however, in common with many colleagues both at home and abroad, that the lethal hazards of untreated syphilis, considerable as they may be, are not so great as is popularly supposed, and that in the patient who receives reasonable and fairly prompt treatment they are usually minimal.

The legacy of undetected syphilis, especially in women, that follows a war is bound to be considerable, though we now know that most of the gloomy prophecies about the fate of the untreated thousands during the first world war have not been fulfilled. To-day the growing practice of routine antenatal blood testing is doubtless averting many tragedies, and it seems a pity that these tests do not yet form part of the routine medical examinations of hospital out-patients and in-patients, candidates for life assurance, soldiers and sailors on discharge from National Service, and that these are not performed on those contemplating marriage. Though prompt treatment of the comparatively few cases of early syphilis that we now see, and, of course, of their consorts, is important, the death rate from syphilis during the next 30 years will depend largely on the discovery and treatment of the thousands who must still be at large in the as yet asymptomatic stage of late syphilis, and it is sometimes the doctor's duty to risk personal unpopularity by insisting on the examination and testing of spouses, children, and sometimes of parents.

Obvious late activity in syphilis is almost always preceded by a period of apparent latency, and it is during this time that we can do so much to arrest permanently, and in many cases cure, the still hidden chronic inflammatory process.

Diagnosis

The diagnosis of latent syphilis is one of exclusion, and is always difficult, and sometimes impossible, to make with accuracy. It will depend upon the skill and experience of the physician, on negative results of radiological examinations of heart and great vessels, on examination of the cerebrospinal fluid, and upon the verification by repetition of unexpected positive blood findings. Clerical or technical errors are still the commonest causes of so-called "false positive" serum reactions. Latent syphilis is never an emergency, and, once neurosyphilis and established cardiovascular

disease have been excluded, the danger of delaying treatment for weeks or months is negligible. The notion of treating in order to "play for safety" is nearly always, except in pregnancy, bad medicine and will inevitably confuse the ultimate diagnosis. It is sometimes difficult to persuade the patient that more or less prolonged observation without treatment is necessary if his case is to be properly assessed, but it can be done, and he will appreciate it in the end.

In many cases of late or latent syphilis—possibly in the majority—one cannot even guess at the duration of infection. We are, perhaps, too much inclined to date it to the years of early adult life, or to the period spent in the armed Forces. Occasionally we are deceived; the middle-aged, or even the elderly, do contract syphilis, and primary and secondary signs frequently pass unnoticed in women. Also, the possibility of congenital infection can never be overlooked, and classical stigmata are often absent.

Telling the Patient

When a diagnosis has been reached, the question arises—What is the patient to be told? The answer is, the truth. All, except the very old, or some rare cases of mental instability, must have the facts, as the doctor sees them, carefully explained. The word "syphilis" must not be avoided and vague allusions to a "blood condition" or some such indefinite euphemism must not be substituted in its place. If this frank truth-telling is not done, the necessity for prolonged observation after treatment will be difficult to justify. I have been impressed by the bitterness with which patients have spoken of doctors who had failed to tell them the truth in a mistaken attempt to spare their feelings.

The significance of sero-resistance, and, indeed, of its probability, in spite of adequate treatment, should be explained as soon as possible to all patients who are in any way capable of understanding. If this is not done at an early stage the patient will inevitably associate a persisting positive blood reaction with a lack of response to treatment, and will consequently become either dissatisfied with his physician or apprehensive about or even despairing of his condition. In latent syphilis, perhaps more than in any other chronic condition, the doctor can afford to be optimistic, and it is surely his duty to be so. The findings of the United States Co-operative Clinical Group, which are in line with the experience of many of us, suggest that even without treatment only 20% to 30% of latent syphilitics would develop later manifestations of disease, and that treatment, even of the most moderate nature, would reduce this chance to one of from 2% to 5%. Such a risk is surely minimal when one considers the everyday hazards of life.

Late syphilis, especially when asymptomatic, must not be allowed to spoil lives, but only too often it does so. The medical curse descends upon the unfortunate patient in no uncertain manner, so that much of his outlook and many of his ambitions are conditioned by the knowledge that he is a syphilitic, and a man apart. Victims of far more serious conditions are more optimistic and less depressed by their diseases than are many adequately treated latent syphilitics. This is largely because a venereal infection is so essentially a secret between patient and doctor, and because secrets weigh heavily on many minds.

* *Erbarzt*, 1942, 10, 209.

factory. Many physicians, often obsessed by the bog of persistently positive blood reactions, have traditionally insisted on years of treatment with arsenicals and bismuth, which was only terminated by the collapse of the patient's health from the toxic effects of the treatment, of his morale from anxiety, and not infrequently of his bank balance. Though at least another decade must pass before the results of penicillin in late syphilis begin to be known with certainty, an encouraging indication of its probable effect is already provided by the results in neurosyphilis. In the great majority of patients treated, sustained improvement in the spinal fluid occurs, and, provided that irreversible structural damage to brain or spinal cord has not yet taken place, clinical results are much more impressive than after malaria and arseno-bismuth treatment and are, moreover, more rapidly attained. It is perhaps significant that certified deaths in England and Wales from dementia paralytica declined from 585 in 1943 to 167 in 1950, and those from tabes dorsalis from 313 in 1943 to 123 in 1950—a far more rapid fall than has ever before been recorded in so short a time.

Penicillin and Cardiovascular Syphilis

In this country there has been until recently a certain reluctance to use penicillin in cardiovascular syphilis, mainly because of exaggerated fears of the Jarisch-Herxheimer reaction. Cardiovascular syphilis is often not diagnosed until irreparable harm has been done, and, though even then quite a modest amount of treatment will probably heal the chronic inflammatory process, the resulting structural damage to the aortic wall or valves may inevitably shorten life. I am, however, becoming increasingly convinced that prompt intensive treatment with penicillin will in most cases, by halting the inflammatory process, improve the prognosis and help to prolong life. Earlier diagnosis, rather than better treatment, would seem to be what is wanted for the successful management of this condition. These views are supported by the work of Dr. J. H. Stokes and his colleagues in Philadelphia, who have recently reported the results of treating over 100 cases of various types of cardiovascular syphilis with penicillin alone during the last five years, and it is interesting to note that in this series no evidence of significant therapeutic shock or vasculo-toxic effect was forthcoming, neither were any certain cases of therapeutic paradox encountered. The penicillin was well tolerated even by the decompensated heart, and clinical improvement, particularly of anginal pain, was noted in a high proportion of cases. In the autumn of 1947 I decided to abandon the arsenicals in the treatment of syphilis in all its stages, and up to the present I have had no cause to regret my decision. Bismuth I retained in a modest total dosage of 2-4 g. until two years ago, not so much because I was attracted by the idea of consolidation treatment with a drug whose treponemacidal power fell so far behind that of penicillin, but because I believed that many patients would default from subsequent observation if the treatment time was so short as to bring it into contempt.

Dosage of Penicillin

At this stage it is hard to say how much treatment is necessary in the late or latent stages of syphilis. My present opinion is that, though it certainly should not be less than that recommended for early infections, it may one day be found to be not much more. Careful post-treatment observation with retreatment of considered failures or relapses is, in my view, far more important than the blind, continuous, so-called "insurance" therapy so popular in the past. I would commend without prejudice the idea of following an initial intensive course of six to twelve million units of penicillin, lasting from ten to fourteen days, with not more than two courses each of ten twice-weekly injections of 900,000 units of procaine penicillin in oil with aluminium monostearate (P.A.M.). I am convinced that each one of these injections will be far more therapeutically active than

the fullest dose of any arsenical or bismuth preparation, and, which is perhaps more important, that it can do no harm.

It is perhaps as a preventive of congenital syphilis that penicillin has had its greatest success, and it is now established that as little as eight to ten days' intensive treatment of a syphilitic pregnant woman will almost always ensure that her infant is born free from disease. The expectant mother whose blood tests have proved positive on routine examination can thus be assured of her baby's safety, and every effort should be made to allay her anxiety.

Conclusion

In conclusion, I would restate my belief that in penicillin we have the most powerful, as well as the safest, treponemacidal agent yet known; that the progress of the disease can in most cases be rapidly and effectively halted by its intelligent use; and that its true value in late and latent syphilis will be certainly known only when careful clinical, cardiographic, and pathological observations (to include always examination of the cerebrospinal fluid) become general practice and when post-mortem study of treated cases becomes the rule rather than, as at present, the comparatively rare exception.

Next Refresher Course Article.—"Injuries to the Back," by Mr. E. A. Nicoll.

THE HEALTH OF SCOTLAND SOME ENCOURAGING FIGURES

The 1952 reports of the Department of Health for Scotland and of the Scottish Health Services Council were published last week in one volume. The most striking improvement in the country's health was the decline in mortality from respiratory tuberculosis. The provisional rate of 27 per 100,000 (1,404 deaths) is the lowest figure yet reached for Scotland, and compares with rates of 37 in 1951, 47 in 1950, and 60 in 1949. The reduction was apparent in all age groups of both sexes, except males at the extremes of life. The highest mortality was still among young women, but even here there has been a remarkable fall: for women aged 20-24 the rate fell from 122 in 1950 to 45 in 1952, while for those aged 25-30 it was reduced from 124 to 46. The death rate from non-respiratory tuberculosis, at 4 per 100,000, was also lower than ever before. These encouraging figures were due to "improved medical and surgical treatment, together with the fact that the disease is now being brought under treatment at a much less advanced stage." By the end of 1952 the number of hospital beds in Scotland for respiratory tuberculosis had risen to 6,098, and the waiting-list had fallen to 1,711. To help ease the waiting-list over 400 tuberculous patients have been sent to sanatoria in Switzerland.

The provisional infant mortality rate fell to the record low figure of 35.2 per 1,000 births. A disturbing feature of the mortality in the pre-school years (1.5 per 1,000) is the high place taken by accidents. The principal causes of death among children aged 1 to 4 years, in order of frequency, were accidents, tuberculosis, pneumonia, and infectious diseases. Of the accidents, roughly one-half were caused by motor vehicles.

The Hospitals and General Practitioners

In 1951 the Department of Health published the Scottish Health Services Council's report on "The General Practitioner and the Hospital Service," and this has been studied by both the department itself and hospital boards. The Department of Health has this to say about the integration of the work of general practitioners with the hospitals:

"Some progress has been reported as regards direct access by general practitioners to hospital ancillary departments—for example, laboratory and radiology. There are signs that difficulties may arise in recruiting sufficient full-time hospital staff in some of the intermediate grades, and this factor may encourage the

wider use of general practitioners (especially former registrars) as part-time members of hospital staffs. Generally it seems true to say that the hospital boards are alive to the importance of establishing the closest possible link between the family doctor and the hospital service."

Size and Cost of the Health Service

About 64,000 persons are wholly or partly engaged in the Health Service in Scotland. Nurses and midwives (25,000) and hospital domestics (22,500) form the largest groups, then come doctors (5,300), administrators and clerical staff (4,000), and pharmacists (2,800). There are 1,400 dentists and about the same number of medical auxiliaries, and lastly 900 opticians. Last year about half the doctors were in general practice, there being 2,439 principals (of whom 1,280 were in partnerships) and 306 assistants. In the hospitals there were 750 consultants (372 of whom were whole-time) and 330 S.H.M.O.s (219 whole-time).

The general-practitioner services cost £5.37m. (excluding a back payment under the Danckwerts award of about another million pounds). Of this sum, £83,000 was paid in grants under the trainee assistants scheme and £20,000 as inducement payments. There was a small fall in the number of prescriptions compared with the previous year (from 20,787,000 to 20,371,000), but the average cost of each prescription rose from 5s. 1d. to 5s. 4d. during the year. The slight fall in the number of prescriptions is ascribed partly to the absence of any major epidemic, such as influenza, and partly to the 1s. charge. In all, the pharmaceutical services cost just over £5m. The supplementary ophthalmic service accounted for a little over half a million pounds.

Public Health Matters

Vaccination of children under 1 year against smallpox declined a little during the year, and is still far short of the desirable minimum. "Figures of the order of those shown in recent years (under 30% of the children of that age) do not afford adequate protection of the community." Immunization against diphtheria continued at a high level, although the 1952 figure for primary inoculations showed a decrease. There were eight deaths from diphtheria during the year, all in children who had not been immunized.

Another sign of the times was the continued decline in the number of domiciliary births, both absolutely and in relation to the total number of births. Steps now being taken to adjust maternity benefit rates in favour of the mother who is confined at home may perhaps alter this.

Apart from the subjects mentioned above, the Department of Health's report also deals with welfare services, food hygiene, water supplies and sanitation, housing, and town and country planning.

Scottish Health Services Council

Among the matters inquired into by the Scottish Health Services Council were the future duties, responsibilities, and status of medical superintendents in Scottish hospitals and the serious shortage of almoners in Scotland. At present, out of an estimated 500 almoners required for a complete service, there are only 75 employed. The council's recommendations for relieving the shortage are to reduce the cost of training by making it possible for a complete training to be had in Scotland, and secondly to create a new category of worker intermediate between the almoner and her clerical assistant. The position of these "almoner assistants" would be analogous to that of the assistant nurse. This proposal runs counter to the recommendation of the Cope Committee on Almoners.

The council also initiated an inquiry on co-ordination in the field of child health. While it proved possible to make some specific recommendations, such as that more hospital beds should be provided for children, the general feeling was that it was too soon after the appointed day for a full review of the subject.

Nova et Vetera

FRANCOIS RABELAIS, M.D.

Born about 1495, Rabelais died 400 years ago on April 9. He spent his youth in a Franciscan monastery until, renouncing holy orders, he entered the faculty of medicine at Montpellier. Here he gained the distinction of being the only person to lecture on Hippocrates and Galen from the original texts, for Rabelais was an enthusiastic humanist who studied the classics avidly.

Some say he was the first to dissect the human body. If not the first, he was certainly one of the first, using criminals who had been hanged. As a result of his demonstrations, it is recorded in the archives at Montpellier, the medical school was allowed two criminals a year for dissection instead of one every sixteen years or so.

Rabelais could never stay in one place for long. He left Montpellier and went to Lyons, then the centre of the printing industry in France, where he was employed as a proof-reader, putting to good use his knowledge of Greek. It was here he published his first medical work—*Epistolae Medicinales Manardi*—an annotated translation. Manardi was a doctor at Ferrara, and Rabelais translated his treatises, pointing out at the same time that the doctrine of *magister dixit* should not be followed too faithfully. In direct opposition to most medical men of the time, he thought the advancement of medicine and science should be viewed with an open mind. Later he published the lectures he had given at Montpellier.

In November, 1532, Rabelais was appointed physician-in-chief to the Hôtel Dieu at Lyons. Here he was in charge of 200 beds—some of them accommodating two or three people—and he saw all the patients daily. The hospital was the only one which admitted all types of case, from fevers to maternity, and he must have been kept busy. It is recorded that during his stay the mortality rate was reduced by 3%. Although Rabelais journeyed a good deal, and rarely settled anywhere for long, he practised medicine almost all his life.

Gargantua and *Pantagruel*, the books which won him immortality, are uninhibited—some critics have said coarse, though in the context of their times they do not seem to be unusually so. He advocated liberal doses of good food and drink, plenty of exercise, and adequate sleep. Nor was he concerned only with man's bodily welfare, for he believed laughter and the mental wellbeing it denotes to be his birthright and salvation. Many of Rabelais's descriptions overflow with physiological information—his picture, for instance, of the birth of Gargantua, miraculous and imaginative though it is. Gargantua's mother was given a drug which caused the child to leap from the womb "and entering the vena cava climb by the diaphragm above her shoulders (where that vein divides in two) and then taking the left branch issue from her left ear." If Rabelais contributed nothing of lasting value to the advancement of medicine—nothing to be compared with the achievements of his contemporaries Vesalius and Leonardo da Vinci—his legacy of laughter may rank as a great contribution to the wellbeing of man.

"An understanding of the scientific basis of good feeding should be part of the everyday knowledge of an educated community" according to the Ministry of Food's *Manual of Nutrition* (3rd edition, H.M.S.O., price 2s.). The book sets out to supply the necessary information. Much of it is elementary, but medical men called upon to advise on diets for varying age and occupational groups may find some useful tips in the sections on nutritional requirements and the composition of food (especially the valuable appendix A).

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Chlorophyll as a Deodorant

SIR,—From the letters written by Dr. W. Mitchell and Mr. L. Deadman (March 14, p. 621) it would appear that the alleged potency of chlorophyll and the chlorophyllins as deodorants varies so much that the experimentalist would be wise to use only preparations offered to the public by reputable firms. This is precisely what Dr. J. C. Brocklehurst did. He obtained his sodium copper chlorophyllin (so highly valued by Dr. Mitchell) from a chlorophyll manufacturer, and solution "C" was "a true sample of this substance as it is sold to the public" (March 21, p. 674). I have followed Dr. Brocklehurst's example by using a proprietary preparation of chlorophyll in tablet form called "amplex" for an "asparagus test" carried out on myself.

Critics of Dr. Brocklehurst's paper (*Journal*, March 7, p. 541) emphasized the need to allow chlorophyll an adequate period of time for deodorizing offensive gases and to ensure that there is an abundance of chlorophyll available. These exacting requirements are not mentioned on the label of the "amplex" containers, which merely says: "One tablet swallowed or dissolved in the mouth every morning for basic freshness all day." I decided, however, to leave nothing to chance, and took 100 tablets of "amplex" an hour after breakfast; and three and a half hours later I ate 40 more, making 140 in all. The tablets in the first batch were powdered and then washed down with sips of water; the second lot were chewed thoroughly and swallowed. After two and a half hours I ate a dozen asparagus tips (which also contained a considerable quantity of chlorophyll). In less than two hours my urine had the unmistakable and rather offensive smell which is a characteristic effect of eating asparagus. After six hours the odour was intense, and it persisted even in specimens voided on the following day. The timing of the dose of chlorophyll tablets makes no obvious difference. On one occasion I swallowed 100 tablets (powdered), and after seven hours I took another dose of 100 tablets, followed at once by a serving of asparagus. In less than two and a half hours the asparagus smell was apparent in the urine.

Such a test should not be regarded as a single instance of failure of chlorophyll as a deodorant. So long as there is a substantial quantity of chlorophyll in the alimentary canal, every occasion when an offensive urine is voided (say four or five times in 24 hours) must be considered as a separate test and as a separate instance of failure. I may add that during this particular experiment I noticed the taste and odour of asparagus in the occasional eructations that occurred. I have personal knowledge of ten such failures to add to the observations made by Dr. Brocklehurst on himself.

Dr. Brocklehurst says that "it would be helpful if a large number of doctors would themselves repeat this simple experiment." I agree, but we must not forget that the value of physiological and pharmacological experiments carried out on a solitary human subject may be of a very high order—as, for example, in the classic case of the observations on Alexis St. Martin and, more recently, in the studies on pain made by Kellgren and others. It is certainly not unreasonable to suggest that if chlorophyll is offered to the public as a deodorant its reputation must stand or fall by clinical trials on man—a subject which Dr. Mitchell "does not feel competent to discuss." It should be noted that there are special advantages in the asparagus test: it is simple to carry out, and the necessarily intermittent observations eliminate the fallacy of olfactory fatigue. Experimentalists will also take into account the fact that the malodorous substances are rapidly removed *in vitro* by treatment with a small quantity of activated carbon.

Dr. Mitchell speaks as an expert of the deodorant effect of sodium copper chlorophyllin in a chemical plant used for the distillation of garlic oil. This is interesting and doubtless important in the pharmaceutical industry, but it does not follow that the observations must necessarily have any clinical application. A description of the technical procedure which Dr. Mitchell mentions might enable clinicians to determine whether the process could be applied to the practice of medicine. Dr. Mitchell has suggested that chlorophyll "may catalyse oxidation of

odorous material, perhaps by forming a loose combination with oxygen and parting with the latter at the sites of action." But this hypothesis was destroyed by Kohler *et al.*,² who reported that chlorophyll is not absorbed from the gastro-intestinal tract. This disposes of any suggestion that oral medication with chlorophyll can abolish the fetor of, say, bronchiectasis or sinusitis.

Dr. Mitchell promises to produce evidence of the effectiveness of chlorophyll preparations in deodorizing benzyl mercaptan. This will be awaited with interest; but his experiments will be much more significant to clinicians if he will perform his tests with methyl mercaptan, which is known to occur in the human bowel. I therefore suggest that he should use methyl mercaptan. This will make it possible to compare his results with those of Dr. Brocklehurst and other workers. Further, there are fallacies attending the use of benzyl mercaptan for this purpose which do not apply to methyl mercaptan.

Mr. B. E. Chanell (March 14, p. 622) gives the names of two substances not contained in "airwick." Would he care to tell the medical profession the names of the constituents for which a deodorant action is claimed? Is chlorophyll one of them? Even more important, will he be good enough to explain how this preparation acts—if it acts at all? Is it seriously suggested that chlorophyll is dispersed through the atmosphere of a room, or does the air obligingly gravitate to the tiny impregnated wick and filter itself so rapidly that a few thousand cubic feet of air are dealt with in as many minutes?—I am, etc.,

Glasgow.

SIR,—Your *Journal* is to be congratulated upon the article by Dr. J. C. Brocklehurst (March 7, p. 541) and upon its stand in connexion with it. I have read with interest the reactions to the article as conveyed by the *New York Times*.

I agree with Dr. Brocklehurst that the responsibility for demonstrating the effectiveness of chlorophyll or of its derivatives lies with the proponents of its use. In this connexion, the manufacturers of chlorophyll derivatives have themselves repeatedly failed to define their materials adequately. Most of the commercial materials now on the market consist of 50–75% alfalfa extractives other than the green pigments derived from chlorophyll. The demonstration that such an impure material has any given property has nothing whatsoever to do with the proposition that this property is inherent in the green pigment fraction of the material used. Since alfalfa oils are commonly left in the extracts used, it is incumbent upon the manufacturers to prove that any "deodorant" properties which the nose may detect are not, in fact, due to a masking of the undesired odour with alfalfa oil.—I am, etc.,

Baltimore, Maryland, U.S.A.

ALSOPH H. CORWIN.

SIR,—Taking note of your evidence that chlorophyll preparations have no, or very little, deodorant action (March 7, p. 554), I would like to state that we have used the water-soluble, copper-treated chlorophyll "J. J." in low concentration, soaked into one layer of gauze in between dressings for foul-smelling carcinomas and ulcerated legs, etc., and the result was quite remarkable. One demonstration was given to the nursing staff on a septic, gangrenous leg which through its intense foul smell was of annoyance to other patients. A piece of such gauze soaked with chlorophyll solution was dropped over the leg, and the smell quite dramatically disappeared. As long as treated in this way, no smell was present in the ward. A daily, relatively short medical inspection which confirmed this could hardly be long enough to render the olfactory nerve endings less capable of detection. Moreover, no crotonaldehyde or other substance than above was used. After many experiments this was the first time we were able to combat satisfactorily smells which arise only too frequently in large wards with chronic sick and at times create a problem. It should be said that chlorophyll does not diminish all smells, and not all chlorophyll preparations, pure or otherwise, have this

effect. Its action is undoubtedly selective, and I feel that in view of the results obtained here, not only as described but also in other forms, the experience of other users may be of interest.—I am, etc.,

Birmingham, 18.

R. S. HOLZER.

SIR,—With reference to the annotation (March 7, p. 554) on the subject of chlorophyll, what most of us want to know is not whether an experiment conducted with elaborate apparatus on purified chemical substances yields a positive result, but whether ordinary people, using their noses in an ordinary way, can detect a deodorizing action in naturally occurring evil-smelling mixtures. It is quite untrue to suppose that such experiments cannot give conclusive results, for nowadays statistical design and experimental methods have been developed for just this kind of case. Attempts to eliminate the subjective element are apt to result in pointless experiments, but it is also true that many other experiments have been reported in which the proper precautions have been ignored and are therefore also nearly valueless.

We have carried out experiments reported more fully elsewhere (*Pharm. J.*, 1953, 170, 209) in which 139 people were used as testers with precautions in design and analysis of results which we think exclude bias. We conclude that chlorophyll on cotton pads does reduce the odour of decomposing blood, the probability of our results arising by chance being less than one in 2,000 million.—We are, etc.,

Psychosomatic Medicine

SIR,—Most of your readers will have read with profound interest Dr. R. R. Bomford's paper on this subject (*Journal*, March 21, p. 633) and been grateful for the refreshing lucidity with which it was phrased. Most of them would surely agree, too, that in every consultation it is a body-mind something with which doctors have to deal—Dr. Bomford calls it a unity. But there are some of us, like Henry Head, who have never been able to persuade ourselves that there are any "diseases" of mind *qua* mind. The "diseases" are all of tissue, though mind can deeply affect them and is in turn—in its individual terrestrial expression (behaviour)—deeply affected by them. But the things that happen, or can be made to happen, to the individual mind itself, such as the development of tissue-influencing courage and equanimity, must occur, it would seem to us, in some non-material dimension. St. Paul's Cathedral, for example, was once a thought. The thought was as real as the cathedral. But where exactly was it after the moment of its birth? Was it occupying space inside the skull of Christopher Wren? When, as part of his mind, it accompanied him through the years on his daily journeys, was it indeed geographically occupying space anywhere? If mind is only just another aspect of matter, can matter—always occupying space—have an integral part or aspect *not* occupying space? It is because we find it so hard to believe this that we should have preferred, I think, to use the word tenancy rather than unity—though always prepared, I hope, to be shattered by our philosophical superiors.—I am, etc.,

Easton Royal, Wilts.

H. H. BASHFORD.

Blackwater Fever

SIR,—The study reported by Lieutenant-Colonel Inder Singh (*Journal*, March 14, p. 598) is of considerable interest. We consider it unfortunate, however, that the term blackwater fever should have been used in the title of this paper as there is no incontrovertible evidence that this was the correct diagnosis.

An essential characteristic of blackwater fever is intravascular haemolysis, an occurrence which may be recognized by the presence of methaemalbumin in the circulating plasma, an increase in the serum bilirubin, and clinically

by jaundice. In the cases reported there is no mention of jaundice, while no estimates were made of plasma methaemalbumin. Serum bilirubin was estimated in one case and was within the normal range. In that case, tests carried out on serum and urine for haemoglobin and methaemoglobin were negative; in the other oxyhaemoglobin and methaemoglobin were found in the serum, and haemoglobin—presumably oxyhaemoglobin—in the urine. Blackwater fever is not the sole possible cause of the findings in the latter case, and is contraindicated by those in the former. Without further information the diagnosis must be regarded as unproved.—We are, etc.,

A. W. WOODRUFF.

Smoking and Lung Cancer

SIR,—If one may descend for a moment from the clouds of speculation and somatomorphology to the more pedestrian subject of tobacco smoke, I should like to point out an aspect of aetiology which I have not so far seen mentioned.

Theories of carcinogenesis have had to be revised in the light of recent work by Berenblum and Shubik.¹ These workers have presented evidence that the process of carcinogenesis may be divided into two distinct stages. There is an initial phase when a carcinogen, and only a carcinogen, causes a specific cell change which may remain latent. Actual tumour formation can only be brought about by further application of either a carcinogen or a non-specific irritant which acts as a co-carcinogen. Many such irritants are now known which, though incapable of causing carcinoma by themselves, are able to do so when applied to a tissue previously exposed—even only on a single occasion—to a carcinogen. In experimental work the total tumour incidence is found to depend on the strength of the carcinogenic "initiator," and the latent period before the appearance of a tumour depends on the time and intensity of subsequent applications of a co-carcinogenic "promoter."

We know that the atmosphere of cities, and road dust, contain benzpyrene and probably other carcinogens derived, no doubt, from tarred roads, coal smoke, and soot, etc. Here are known sources of an initiating carcinogen which must often be inhaled. Continued exposure to these carcinogens can by itself lead to tumour development, as they also possess a promoting action. But it may well be that other irritant substances not carcinogenic in themselves could, if inhaled regularly over long periods, have a powerful co-carcinogenic promoting action on cells already transformed by the carcinogen into latent tumour cells.

It would seem worth investigating whether tobacco smoke contains any such co-carcinogenic irritants. If it were found to do so, it would explain the apparent "carcinogenic" significance of cigarette smoking in the absence of any recognized carcinogen (of the initiating type) in tobacco smoke. It might then even be possible to remove by suitable filters the noxious agent from tobacco smoke, to the relief and joy of nicotinephils.—I am, etc.,

Swansea.

CONSTANCE M. OTTLEY.

Cancer Education

SIR,—The circular sent to general practitioners by the British Empire Cancer Campaign has just been brought to our notice.

It might interest your readers to know that the Central Council for Health Education has also been considering for some time the desirability of cancer education, and has conducted experimental educational campaigns in about a dozen areas, both rural and urban. In each case the mayor

or chairman of the health committee invited all interested parties from the medical side and representatives of local lay organizations to a meeting at which there was a talk by a cancer authority on the present position of cancer and its treatment. Discussion then ensued, and the audience were asked whether they considered it a suitable subject on which to call meetings of the organizations they represented. In nearly all cases it was resolved to set up a cancer education committee, and these are now functioning under varying constitutions in many areas. The reaction of the representatives of general practitioners varied from area to area, but with one or two exceptions was favourable, mainly because they were able to see the interest of the public in the subject and their level-headed appreciation of the issues, and were able to satisfy themselves that the type of education proposed was not such as to cause alarm or hold out extravagant promises.

Reading the British Empire Cancer Campaign questionnaire, it seems to us that many practitioners may answer "No," mainly because they have frequent experience of cancer-phobes, and have not had the opportunity of taking part in such a conference. We hope very much that this questionnaire, which seems prejudiced in favour of the answer "No," will only be interpreted as a very slender piece of evidence.—We are, etc.,

JOHN BURTON.

Intravenous Iron

SIR,—I have read with considerable interest the article on "Toxic Reactions due to Intravenous Iron" (January 3, p. 21) just received. We work in an area where there is a 95% infestation with hookworm, and patients with haemoglobin levels of 15–20% (Sahli) are admitted almost daily. There is no blood available for transfusion, and it is a matter of some urgency to raise the haemoglobin level in the blood, particularly in cases of advanced pregnancy, where this degree of anaemia is usually associated with gross oedema and a dilated heart. Although we are only a 50-bed hospital, we give literally hundreds of intravenous-iron injections a year. The preparation available out here is "iviron," and we usually give 5 ml. (100 mg. of iron) on admission and 10 ml. (200 mg. of iron) on alternate days for three doses, which usually brings the haemoglobin to 50% or so.

It would be interesting to know the percentage incidence of toxic reactions in England. We have never encountered any here except a rise of temperature up to 102° F. (38.9° C.) on the day of injection. I only hope these are not "famous last words."—I am, etc.,

Narsapur, India.

BETTY D. HOLT.

Frustration in the Hospitals

SIR,—Some may be indignant and surprised at the interference of the Minister of Health with the details of management of the great teaching hospitals of London. May I express my opinion that they need be neither surprised nor indignant? The "frustration" that has happened is strictly in sequence and conformity with the previous actions of the Minister, whatever his political colour. In my presidential address to the Surrey Branch of the British Medical Association last June, I drew attention to the vast progress made in medicine by the initiative of the individual doctor since the times of Hippocrates of Kos over 2,000 years ago. It was exemplified in the last 300 years in England by Harvey's discovery of the circulation of the blood, Jenner's discovery of vaccination for the prevention of smallpox, Lister's discovery of antiseptics, Ross's discovery of the transmission of malaria by the mosquito, and Bruce's discovery of the transmission of Malta fever by the goat and of sleeping sickness and allied diseases by the tsetse fly, to mention but a few. When medicine became the "plaything of politics" under the so-called National Health Scheme, it was, as Bertrand Russell pointed out, to invite interference with the general practitioner and also,

as admitted by the late medical adviser to the Ministry of Health,¹ to make his work more difficult. The confiscation of the Kingston Hospital, in spite of the strongest local protest supported by the medical profession throughout the country, shows that public opinion counts for less than nothing in the mind of the case-hardened official. What happened in Kingston is only a forerunner of what is happening in the London hospitals to-day. Only by removing all medical services from politicians and Civil Servants, the former of whom just catch votes, and the latter work by rule, can a satisfactory medical service become possible.

What are now required are English, Welsh, and Scots corporations elected by the medical profession, not nominated by the Minister. They should be charged with organizing and operating the best possible medical services with the money available. The Minister of Health would then be free to study the cost, with the Government co-operating, of removing the unhealthy influences, which I set out in my address and copied from the statement of the British Medical Association, affecting good food, good houses, clean air, etc., which the medical profession is not competent to carry out. Guided by the medical profession, the Minister would have abundant work to do and he would provide the global sum required.—I am, etc.,

Peaslake, Surrey.

MALCOLM WATSON.

Handwriting and Personality

SIR,—The medical profession should be grateful to you that you have given so objective and lively an account of "Handwriting and Personality" (*Journal*, March 14, p. 607). As I have been a student of handwriting for over 30 years (and a psychiatrist), I hope you will allow me to write about some points regarding graphology.

First, there are many more than two camps of graphologists. In my opinion, and according to my experience, the schools following Dr. Ludwig Klages (Germany), and especially Robert Saudek (Czechoslovakia), are the only ones which should be taken very seriously. Any serious graphologist considers not only single signs, such as peculiar characters, t-bars, i-dots, etc., but the handwriting as an entity. There is the size of the characters, the spacing both vertical and horizontal, margins, pressure, speed, signature, and some more projected features of personality. The one and only difficulty lies in that the interpretation of these signs is not uniform, although many graphologists have arrived at identical interpretation and evaluation of the main features. After all, science is based, in general, on observation, comparison, and relevant conclusion. These principles are applied in serious graphology, and I am convinced that the fundamentals of personality can be assessed by means of graphological analysis.—I am, etc.,

Prudhoe-on-Tyne.

A. D. HELLER.

Lung Resection for Pulmonary Tuberculosis

SIR,—Mr. F. Ronald Edwards claims (March 7, p. 561) that "resection is not carried out through an area of active tuberculous endobronchitis." I wonder what evidence Mr. Edwards may have to support this claim. In an investigation carried out on behalf of the British Tuberculosis Association¹ I found active tuberculous bronchitis at the site of amputation in no less than 91 of 95 specimens. These specimens were limited to those cases in which the proposed site of amputation was within range of bronchoscopic vision, and in all cases the bronchus was reported upon before operation. In 56 cases no abnormality was detected. In the remaining 39 cases in which some abnormality was reported this usually took the form of slight redness or slight oedema. Clearly the value of a negative report by the bronchoscopist in suspected cases of tuberculous bronchitis is of very limited value. This is largely due to the fact, well known to pathologists though often ignored by clinicians, that quite serious bronchial disease is often covered by intact and normal epithelium. These figures go a long way towards solving the question posed

by Dr. F. H. Young (*Journal*, February 7, p. 287): "Are we paying too little attention to minor bronchoscopic findings?" It should also be mentioned that the material for the British Tuberculosis Association's investigation came from six different hospitals.

Mr. Edwards asks for a fuller explanation of the statement that "pulmonary tuberculosis is a generalized disease." The following points may assist him: (1) In the majority of resected specimens there is evidence of tuberculous endobronchitis at the site of surgical amputation. Similar lesions may be found very frequently in the normal parts of resected lobes and lungs. These lesions are frequently separated from frank, obvious tuberculous lesions by quite wide areas of lung and bronchus which are normal both to the naked eye and on histological examination. The exact significance of these lesions is still unknown, but nevertheless they are clear evidence of a generalized disease. (2) In the vast majority of a very large number of surgical specimens from cases of pulmonary tuberculosis the pathological areas have been found to be more extensive than was expected from the critical study of a long series of radiographs. (3) Where a limited resection had been intended but has, at operation, been found impossible and the "sacrifice of healthy lung tissue resorted to," the healthy lung tissue has almost without exception been found to contain macroscopic foci of either pneumonic or bronchial tuberculosis.

The fact that these lesions may be impossible to visualize in radiographs, and difficult to find in the specimen unless adequately searched for, does not constitute a licence to ignore them. On the contrary, they provide a challenge to the clinician, the radiologist, and the pathologist to co-operate in solving the problem of their significance.—I am, etc.,

London, S.W.3.

J. W. CLEGG.

Tuberculosis Case-finding

SIR,—My colleagues and I are grateful to Dr. H. G. Calwell (February 14, p. 404) for drawing attention to the omission in our article (January 10, p. 64) of any reference to the examination of the teachers in the infant schools where the children were tuberculin-tested. No sort of attempt was made to examine the teachers. We entirely agree with Dr. Calwell that schoolteachers are a most important group who should be routinely examined, but such a project raises a number of various issues which we rather sought to avoid in the present investigation. We decided before the investigation began that if in any one school or class an unusually high proportion of tuberculin-positive reactors appeared our first measure would be to x-ray all the teachers concerned. However, that did not arise. Analysis of our material showed very little difference in the proportion of positive reactors in each age group from school to school in the different parts of the town. There was a slight, but not significant, suggestion that schools serving new housing estates in particular had a lower proportion of positive reactors.

We entirely agree with Dr. Calwell that the regular x-ray examination of schoolteachers is a most desirable, and reasonable, measure for an education authority to adopt.—I am, etc.,

Bournemouth.

W. H. TATTERSALL.

Compressive Lesions of the External Popliteal Nerve

SIR,—I read with interest the article by Drs. Hugh Garland and Doreen Moorhouse on "Compressive Lesions of the External Popliteal Nerve" (*Journal*, December 27, 1952, p. 1373). About the time this article appeared I was consulted by a European male, aged 54, who had been suffering from foot-drop on the left side for one week. There were no paraesthesiae. He was a heavy drinker and had suffered at one time from delirium tremens. He attributed the paralysis to the wearing of puttees.

On examination there was a complete paralysis of the muscles supplied by the anterior tibial nerve; the peronei were normal

and there was no anaesthesia. Palpation of the leg revealed a softish sausage-shaped swelling 3 in. (7.5 cm.) long, the upper border of which was 1½ in. (3.7 cm.) below the neck of the fibula. It was not easily palpable, as it was beneath the deep fascia and his legs were rather fat. The swelling was transilluminated and evidently contained clear fluid. There was nothing abnormal palpable at the neck of the fibula. Ten days later the nerve was explored. Beneath it, as it crossed the neck of the fibula, was a small ganglion about the size of a pea, and this was removed. The swelling lower down consisted of a chain of similar cysts arising in the septum between the peronei and the soleus. These were also excised. The day after the operation there was substantial recovery in the affected muscles and their power was normal in two weeks.

The interest in this case lies in the nature of the compressing agent, which was not palpable clinically; the fact that, though the nerve was involved before its bifurcation, the muscles of the anterior compartment only were affected—one would, of course, expect motor nerves to be more susceptible than sensory; and the rapid recovery after operation. Had the other ganglia not been palpable one would presumably have treated the case conservatively.—I am, etc.,

Nairobi.

J. A. S. GREEN.

Fatal Anaphylactic and Anaphylactic-like Reactions

SIR,—With reference to the report by Mr. G. S. Ramsay (*Journal*, February 21, p. 439) of a death following intravenous administration of iodoxyl, and the letter of Dr. H. J. Barnes (March 14, p. 618), I wish to add the following comments on the pathogenesis of fatal anaphylactic and anaphylactic-like reactions. Solutions or suspensions of any substance whose molecules possess a highly active surface-acting force are liable to precipitate an anaphylactic-like response if given intravenously. These molecules initiate a rapid and chaotic proteolysis by a physico-chemical mechanism, resulting in the liberation of toxins identical with those acting in anaphylactic shock (Godlowski¹). The activated tryptic enzymes can be again inactivated by heparin, which, if given in high dosage, forms a heparin-tryptic enzyme compound deprived of hydrolytic potency (Rocha a Silva²). Adrenaline, a potent agent in combating the hypotension in the anaphylactic reaction, cannot avert the fatal issue of these reactions, because it does not influence the basic pathogenetic phenomenon of toxic proteolysis. The rational treatment of anaphylactic and anaphylactic-like reactions in men is intravenous infusion of adrenaline (Godlowski³), with the addition of heparin in high dosage (Godlowski⁴) and any potent antihistaminic compound, all in glucose saline solution. Problems of anaphylactic and anaphylactic-like responses are dealt with at length elsewhere (Godlowski⁵).—I am, etc.,

Edinburgh.

Modern Treatment

SIR,—Sir Robert Hutchison's letter on modern treatment (March 21, p. 671) brings back the memory of another great teacher and colleague of Sir Robert's at the London Hospital—the late Mr. Russell Howard.

Russell Howard, like Sir Robert, did not approve of the "prevailing fashion of obscuring things by calling them by their initial letters." In fact, he abhorred this type of abbreviation, and when a student asked him: "What about N.A.B. in this case, Sir?" he replied with a characteristic smile: "I will answer you in your own coinage, N.B.G."—I am, etc.,

London, W.1.

MICHAEL SMYTH.

SIR,—I read Sir Robert Hutchison's letter (March 21, p. 671) with interest and no little comfort. I am one of those to whom the majority of articles in the *Journal* of

to-day mean little or nothing, and it is a comfort to know that I am, in this, in such good company. Many of the titles to such articles do little for me beyond recalling the lines of Goldsmith describing the village schoolmaster:

"While words of learned length, and thundering sound,
"Amazed the gaping rustics ranged around."

In the last line put in the words "general medical practitioner," or, to be in the fashion, G.M.P., and so add to the long list of letters in place of words, and thus still further confuse and exasperate the reader.—I am, etc.,

Watford.

THOMAS FENTEM.

SIR,—I am reassured to learn that such a distinguished physician as Sir Robert Hutchison (March 21, p. 671) often finds, as I do, that many of the articles in the *Journal* mean nothing to him. I suppose these articles and the work that goes into them may be expected to contribute to medicine in the future, though it is sometimes difficult to see just how and why.

The ultra-scientific spirit in medicine seems now to have got out of control and is perhaps a reflection of our time. Younger members of the rank and file cannot escape these influences. Perhaps it represents a *trahison des clercs* in the medical profession—as doctors are taught so they will approach clinical medicine.

Dr. R. R. Bomford's Bradshaw Lecture (March 21, p. 633) on "Changing Concepts of Health and Disease" exemplifies the critical and thoughtful leavening and corrective we need to counteract mere "scientism." A welcome addition to the otherwise disheartening mountain of textbooks on the scientific aspects of medicine would be a textbook on such features of the art of medicine as these. It would benefit those of us suffering from an excess of mechanics and super-science and could well be written by a man of the experience of Sir Robert Hutchison.—I am, etc.,

Bridgend, Glam.

H. M. FLANAGAN.

An Unusual Case of Chickenpox

SIR,—A 6-year-old schoolboy received a boosting dose (0.2 ml.) of A.P.T. by deep intramuscular injection into the left arm, above the insertion of the deltoid. Next day he complained of stiffness and pain in the arm, which was red and slightly swollen around the site of injection. On the fourth day the arm was red, hot, and swollen from the shoulder to the elbow, yet there was little constitutional disturbance. Each day thereafter a steady improvement was noted. On the ninth day, however, a crop of vesicles appeared on the left arm concentrated around the site of inoculation. Examination of the rest of the body surface, and of the mouth, proved negative. Next day (the tenth day) the lateral surface of the arm was heavily studded with vesicles, so numerous as to be almost coalescent, while a few vesicles were found on the scalp, chest, abdomen, and in the groins, justifying a diagnosis of chickenpox. There had been numerous cases of chickenpox among pupils of the school which this boy attended.

It is presumed that this boy received his booster dose of A.P.T. while actually incubating chickenpox. The selective action of the virus for an area where slight tissue damage and hyperaemia were present is well demonstrated.

My thanks are due to the general practitioner, Dr. E. R. L. Gregson, for his co-operation.—I am, etc.,

Kirkcaldy.

JAMES A. PETRIE.

Advertising

SIR,—The recent flood disaster has given to all men of good will a great opportunity of eliminating waste in every department of expenditure. It seems that the world in general is going to go short of food in some five years' time, and we are all encouraged to take such steps as we can to increase our productivity against this imminent disaster. It has been stated officially that our share of the earth's surface is adequate, whereas the manpower to match it is deficient. Some of us are aware of serious waste in

the use of valuable manpower in advertising to, and by, the medical profession. I presume my case can be multiplied by thousands. In a fortnight I received 18 circulars, two of them 7 in. by 9½ in. Most of them are printed on expensive paper, nearly all of them are illustrated, and some of the illustrations appear to reflect in the mind of the advertiser some symbolical significance which does not readily jump to the eye. The amount spent in postage, once a valuable item in the Postmaster's returns, is now a source of understandable dissatisfaction on the part of the Post Office staff. This spate of advertising comes down to the competitive element in free distribution. I will be told by the professional advertisers that I do not understand the importance of building up and maintaining goodwill and good name. Perhaps this is so, but no one can get away from the fact that manpower is being wasted in producing and circularizing on a scale so vast.

I suggest that medical men should approach, in a conciliatory spirit, the Chancellor of the Exchequer, in the hope that he will put a stop to the overflowing waste-paper baskets of a profession which has already too much paper with which to cope.—I am, etc.,

Harrow.

H. CRICHTON-MILLER.

Intravenous Barbiturates for Drunkenness

SIR,—I feel that certain points from Dr. A. H. Bartley's letter (January 17, p. 163) require further comment, since this method of treatment as described therein is potentially dangerous, the more so as it is a method which by its very simplicity may well appeal to the harassed casualty officer or other hospital resident, particularly if newly qualified, when confronted with patients who are violent and disorientated in their drunkenness.

The quelling of a drunken patient by intravenous thiopentone, unless preceded by thorough stomach wash-out, contravenes one of the most important rules regarding the administration of an intravenous anaesthetic—namely, that thiopentone must never be given to a patient where a full stomach is suspected. The well-recognized phenomenon of "silent regurgitation" of gastric contents up the oesophagus and their inhalation into the trachea constitutes a very real risk if thiopentone is used in such cases. Even if no inhalation of gastric contents occurs, the risk of severe glottic spasm is a grave hazard to some patients, particularly the elderly hypertensives, where the subsequent strain imposed upon the myocardium is badly tolerated.

Apart from the increased likelihood of local venous thrombosis following the use of a 10% solution, as Dr. Bartley suggests, the risks mentioned are in no way diminished, for it is then more difficult to inject a given dose of the drug as slowly as if the customary 5% solution were used. Assuming that the stomach is empty, and even though the injection of a mere "sleep dose" is contemplated, some means of positive-pressure oxygen administration should be immediately at hand. For those interested, the excellent article by Drs. H. J. V. Morton and W. D. Wylie (*Anaesthesia*, 1951, 6, 190) on anaesthetic deaths due to regurgitation or vomiting should be read.

In view of the points mentioned, the writer feels that a far safer, if less dramatic, method of calming the obstreperous drunk is the intramuscular injection of 10 to 20 ml. of paraldehyde. Alternatively, subemetic doses of apomorphine have been found effective by some clinicians.—I am, etc.,

London, W.2.

PETER NOBES.

Polypharmacy

SIR,—It is with regret that I note in your columns an advertisement for a new haematinic which recalls the palmy days of polypharmacy; it is said that each capsule of this preparation contains 192 mg. ferrous sulphate, 10 micrograms vitamin B₁₂, 0.85 mg. folic acid, 50 mg. ascorbic acid, 100 mg. powdered hogs' stomach, and 350 mg. of an insoluble liver fraction; and it is recommended as "the greatest step forward yet made in the treatment of the

common anaemia," and "invaluable in the treatment of nutritional hypochromic anaemia, post-infectious anaemia, the megaloblastic anaemias of pregnancy, infancy, pellagra and sprue and allied dyscrasias."

Whatever may be the situation in the United States, this polypharmacy is not needed in Britain. The megaloblastic anaemias of pregnancy, infancy, pellagra, and sprue are so rare that a full-scale investigation is needed before any such diagnosis can be accepted; treatment may then be with folic acid, vitamin B₁₂, and ascorbic acid, nicotinic acid, etc., whichever is indicated. Nutritional hypochromic anaemia—an elegant term for iron deficiency—can be treated quite efficiently by simple iron salts or by injection of saccharated iron hydroxide.

Further, such blunderbuss preparations are dangerous, because they prevent accurate diagnosis. I was asked recently to study an anaemic patient who had received iron salts, folic acid, liver extract (parenteral and oral), vitamin B₁₂, and a mixture of other B vitamins. This treatment had effectually destroyed the clues on which I depend, and I could not help the patient. Another patient, referred to a colleague for diagnosis of a suspected pernicious anaemia, received oral and parenteral liver extract only 24 hours before reference to hospital for investigation—making the diagnosis unnecessarily difficult. No one can exaggerate the importance of diagnosis in anaemia, or the difficulty of establishing it after treatment has started. In more than nine cases out of ten a simple history and simple laboratory tests suffice to establish the diagnosis—and laboratory tests are becoming available to more and more practitioners.

One must conclude that the manufacturers of this new concoction are hoping to divert a larger proportion of the nation's drug bill into their own pockets. This is a lawful—and perhaps even a commendable—aim: but the money available for the Health Service is limited, and the cost of curing a patient with the new remedy is likely to exceed that of curing him with some simpler and less elegant preparation. It is difficult to escape the conclusion that to order so elegant a preparation is against the best interests of patients and of the country.

Such sentiments are spreading among the younger consultants and their registrars. Our task to-day is to restore to health (and work) as many patients as possible, and to do this with the minimum of expense. Recently it was pointed out that about £240,000 has been wasted by ordering a proprietary preparation in place of its official equivalent. When public moneys are wasted on this scale those who encourage such expenditure are challenging the Government of the day, one of whose chief tasks is to secure value for money. The introduction of unnecessary, high-priced polypharmaceutical mixtures encourages waste of public money and must bring forward the day when practitioners are allowed to prescribe only from a standard formulary and manufacturers will have to secure a licence to use a proprietary name for their preparations. The introduction of such mixtures is against the best interests of the medical profession and of the pharmaceutical industry.—I am, etc.,

London, N.W.10.

GEORGE DISCOMBE.

Treatment of Impetigo

SIR,—In the reply to the question on the treatment of impetigo ("Any Questions?" March 14, p. 631) your expert wisely stresses the undesirability of interference with lesions. But it is surely impossible to avoid interference if pastes or creams are used, as recommended. It is my experience that a foolproof method of treatment is that of eau d'Alibour (lot. cupri et zinci sulph. N.F.) with 50% spirit, applied every three or four hours in the form of a spray. Exudation ceases after 24–48 hours, and within a few days the crusts will have separated and will drop off spontaneously. The de Vilbiss spray or similar apparatus could presumably be loaned to the patient on the payment of a returnable deposit.—I am, etc.,

Portsmouth.

RONALD SCUTT.

Operative Treatment of Hallux Valgus and Rigidus

SIR,—I would like to support Mr. N. Ross Smith (January 31, p. 274) in his contention that arthrodesis of the metatarso-phalangeal joint is the operation of choice for hallux rigidus and valgus. Whilst agreeing with Professor

Bryan McFarland (p. 275) and Mr. J. M. P. Clark (January 17, p. 162) that Keller's operation and Mayo's operation are both capable of producing good results in a high proportion of cases, there is no doubt that occasionally they may both produce a very bad result. The bad results are invariably due to interference with the head of the metatarsal, weakening the transverse arch and aggravating still further the well-known disabilities produced by a short metatarsal.

I have not yet seen a single bad result following arthrodesis of the metatarso-phalangeal joint, but would like to suggest the following variation in technique, which was suggested and introduced to me by Mr. J. B. Leather and is what he appropriately called a "two-stage Girdlestone." First, the metatarso-phalangeal joint is arthrodesed in the straight position, by simply denuding the articular surfaces of cartilage, leaving a smooth concave base of proximal phalanx and a smooth convex head of metatarsal. The foot and great toe are then immobilized in a plaster case, the metatarsal arch being well moulded. One month later, the plaster is removed, and the distal half of the proximal phalanx is excised extra-osteally in order to restore dorsiflexion of the toe. Two to three weeks later the patient has a good strong foot and no physiotherapy is usually needed. In elderly patients not wishing to engage in strenuous activities, I modify the technique in leaving out the second stage, but anticipating this by arthrodesing the metatarso-phalangeal joint in 30 degrees dorsiflexion.

Finally, I would make a plea for careful selection of patients. If the symptoms are essentially due to the bunion and exostosis, provided the joint shows no evidence of arthritis, then simple removal of the exostosis is all that is necessary; the valgus deformity in itself is not an indication for interference with the joint, but arthritis is.—I am, etc.,

Wolverhampton.

J. H. KIRKHAM.

Treatment of Threadworms

SIR,—Dr. W. Ivon Hayes's inquiry (February 28, p. 510) about the relation of the incidence of threadworm infection to the consumption of meat is a stimulating one, but it is probably unanswerable. Unless surveys are made by National Institute of Health (N.I.H.) swab, pestle, adhesive cellulose tape, or one of the other reliable methods (Watson and Mac Keith¹) they are of little value. Most infected people have no symptoms, and clinical impressions of incidence cannot be trusted. Unfortunately the only surveys in this country are of 1941 and 1946 (Young² and Mac Keith and Watson,³ and a fuller report to be published). Furthermore, is it not true that with rationing the consumption of protein has changed more in its distribution than in its total, the present consumption being 90% of pre-war?

The suggestion made by Dr. Hayes may well be correct, but I doubt whether it is true that children with oxyuriasis are more often "hungry, especially for sweets and sugar." It was evident from asking the mothers of a large number of children that the incidence of bulimia, of nail-biting, and of nose-picking was not higher in the infected ones. The only symptoms attributable to oxyuriasis were perianal itchiness and consequent disturbed sleep and fatigue.

Although the generally better hygienic habits of adults may account for their relative freedom, there is evidence (Schüffner and Swellengrebel⁴) that infection may occur per anum, vitiating the benefits of hand-washing before meals. A chemical difference in bowel contents is perhaps the reason. What is the incidence of oxyuriasis in the well (protein) fed children and adults of Melbourne?—I am, etc.,

London, S.E.1.

Intercourse after Syphilis

SIR,—When asked in the first place to answer this question I realized that the period advised for resumption of intercourse after treatment would arouse some critical comment.

Colonel L. W. Harrison (February 28, p. 510) quotes in full the statement made by Klauder in the discussion following the

Obituary

IRWIN MOORE, M.B., C.M.

Dr. Irwin Moore, who died at his home in Wimpole Street on March 23 at the age of 86, was almost the last of the older generation of British laryngologists, and was a link with the golden age of consulting practice in London, which ended in 1914. In earlier years he had made many important contributions to laryngology.

Dr. Irwin Moore's father, Dr. George Moore, of Hertford Street, London, had been a young assistant in Staffordshire until he was called, in the absence of his principal, to attend at Trentham the famous Duchess of Sutherland, who in her day ruled London society—Queen Victoria, attending some function at Stafford House, is reputed to have said, "I have come from my home to your palace." Dr. Moore was a handsome young man, to whom the Duchess took a fancy, telling him that if he would come to London she and her friends would support him, and he quickly built up an aristocratic practice in Mayfair.

Dr. George Moore's son, James Lennox Irwin Moore, was born in 1866, and was educated at Westminster School and Edinburgh University, where he graduated M.B., C.M. in 1893. After the usual house appointments at Edinburgh, he spent five years in general practice at Market Harborough, but in 1900 came to London to devote himself to laryngology. He became chief assistant in the throat department at King's College Hospital, and for a number of years was private assistant to Sir StClair Thomson. He was appointed honorary surgeon to the old London Throat Hospital in Great Portland Street, which amalgamated with the Throat Hospital, Golden Square, in 1914. Irwin Moore was never particularly happy about this amalgamation, and it was without regret that he left Golden Square, where he was honorary surgeon, to join the staff of the Metropolitan Ear, Nose and Throat Hospital in 1922 as senior assistant surgeon. He had been promised promotion to full surgeon after a short probation, but when after two or three years this did not eventuate he resigned. The committee of management were happy to assuage an old grievance in 1946, when he was appointed consulting surgeon to the hospital.

He was an energetic honorary secretary of the Section of Laryngology of the Royal Society of Medicine in 1919, and in the nineteen-twenties there was hardly a meeting of the Section where he did not show cases and never a volume of the *Journal of Laryngology* without one or more important articles from his pen. In 1925 he was vice-president of the Section of Laryngology and Otology of the B.M.A. at the Annual Meeting at Bath, where he showed an important collection of early endoscopic instruments. His contributions to the literature included articles on "Achalasia of the Oesophagus" (1918), "Angeiomata of the Larynx" (1921 and 1923), "Prolapse of the Laryngeal Ventricle" (1922), "Stenosis of the Larynx" (1923), "Cartilaginous Tumours of the Larynx" (1925), "An Historical Survey of Peroral Endoscopy" (1926), and "Oesophagectasia" (1927), all of them well illustrated and with copious bibliographies. He was one of the leading British pioneers of endoscopy, and invented ingenious instruments for use in bronchoscopy and oesophagoscopy, perhaps the most notable being his large-diameter

paper by Pariser,¹ but the dermatologists and syphilologists of Philadelphia who followed this work very closely testify to the fact that no spirochaetes were found in the semen unless there were active lesions in the genital tract. Stokes and his collaborators in the standard textbook on syphilis² state: "The source of spirochaetes in the semen seems to be the real question at issue. . . . This [the work of Pariser] would seem to set at rest, if confirmed, the belief that there is a rest form of *Spirochaeta pallida* capable of being carried in the sperm or semen and capable of transmitting the disease to the ovum instead of to the foetus through the mother. Kemp has established for late syphilis the same principle which Pariser established for early syphilis."

None of the correspondents has presented any new evidence to support his point of view, and a great deal of their thinking is based on the pre-penicillin therapy of syphilis when the time required to effect a cure was much longer than it is now. Penicillin has revolutionized the treatment of syphilis, and the writer has used it in a large number of cases with no relapses and only two reinfections. It may also be noted that the incidence of the disease, especially in this country, is now extremely low, and before many years have elapsed it may well be as rare as rickets or chlorosis.

The available scientific evidence supports the overwhelming evidence of practical experience that intercourse without protection is permissible six months after completion of treatment.—I am, etc.,

"YOUR EXPERT."

² *Modern Clinical Syphilology*, 1944. Philadelphia.

SIR,—The correspondence recently published in the *Journal* suggests that this is a difficult question. I think the answer depends on whether we consider the problem from a theoretical point of view or in the light of ordinary practice.

Theoretically, as long as we have no test of cure that is 100% reliable, any intercourse between married or unmarried people is to be forbidden. In ordinary practice, this sort of prohibition would not be complied with, and it seems to me that it cannot be enforced, for the following reasons: (a) Experience has shown us that after using "modern" treatment (9 or 15 mega units penicillin, in France) no contaminated partner and no syphilitic newborn children have been seen, even if the patients do not wait for six months' negativity before resuming intercourse; (b) with such treatment we have not seen true relapse (reinfections and minute modifications of serological tests being disregarded, after a period of six months of negativity. We know one case only, a muscular gumma (?) in a tabetic patient (which is a rather uncommon case), the diagnosis of which could not be made from a biopsy. Rationally the contamination of partners or of babies remains still more unlikely than the occurrence of some late manifestation in the treated patient; and (c) disclosure of syphilis means a severe psychological shock to the patient and for a married couple. To forbid intercourse for years, because of a very slight risk, creates an obsession that syphilis is incurable and may wreck the marriage. Indeed, this possibility seems more dangerous to me than a contamination which could be treated very easily, and this social aspect deserves consideration.

The fact that a treponema can be present in a spermatozoon head (or rather stick to its surface) is a very interesting one, for it will support the hypothesis of foetus contamination by the father, without contamination of the mother. In any case, this is not relevant, for Finger and Landsteiner, Uhlenhuth, Bessemans, Levaditi, and Vaisman's experiences were drawn from non-treated people or animals with active syphilis.

I consider that we must be satisfied with your expert's answer, and allow intercourse after a six months' period of serological and C.S.F. negativity, especially when the usual serological tests are controlled by a treponemal immobilization test. However, in pregnancy, in order to prevent any possibility of trouble, I suggest that the mother be treated as follows: 9 mega units of procaine penicillin at the very beginning and 9 mega units near the end of pregnancy, when she has no more intercourse. When the husband's syphilis cannot be disclosed to his wife, a gynaecological excuse is easy to find.—I am, etc.,

L'Hôpital St. Lazare,
Paris

P. DUREL.

oesophagoscope and his useful cutting-shears. In 1921 he published a book entitled *Intrinsic Cancer of the Larynx and the Operation of Laryngo-fissure*, based on his experience "in performing or co-operating in over 50 cases of laryngo-fissure," and he was perhaps a little naïve in being surprised that Sir StClair Thomson was annoyed at the appearance of the book, of which he knew nothing until its publication, for most of the recorded cases were those at which Irwin Moore had assisted StClair Thomson, though Irwin Moore had designed a useful set of instruments for the operation. In 1928 he published a large volume entitled *Tonsils and Adenoids and their Diseases*, fully illustrated and with numerous references; in this he laid much emphasis on the value of treating chronic tonsillitis with an escharotic paste, "London paste," the formula of which he had found in Morell Mackenzie's classical textbook on diseases of the throat, and with which he treated many patients who wished to avoid operation.

He was an outstanding advocate in favour of the rehabilitation of the professional reputation of Morell Mackenzie, and wrote many letters to newspapers and journals on this theme. In 1919 he became the tenant for a decade of Mackenzie's old country house at Wargrave, on the Thames, and in 1921 arranged a memorial service in the churchyard there in connexion with the summer meeting of the Section of Laryngology. He had been given a portrait of Mackenzie by his elder daughter, and when he wished to present this to the Royal Society of Medicine the then president refused to accept it. Irwin Moore, in high dudgeon, did not attend a meeting of the Section of Laryngology again for over 20 years. It is pleasant to relate that a year or two ago the portrait was accepted and hangs in the council room of the Royal Society of Medicine, and Irwin Moore, then in his eighties, became again a welcome attendee at the Section of Laryngology.

Irwin Moore had a large and fashionable practice, including royalty from home and abroad. He was distinguished by the courtly manners of the old school, and had a kindly, hospitable, and indeed lovable nature, though his righteous indignation was easily aroused and he could be irascible as well as generous. He had a fishing-lodge down in Radnorshire, and used to dash off there for a week-end's fishing even at an advanced age. He was one of the oldest members of the Savage Club, was happy to be a leading member of the famous old London dining club, the Knights of the Round Table, and for many years was honorary treasurer of the Hunterian Society, in which he took a great interest. His only son died in 1916, his first wife died in 1919, and his second wife and his brother both died last year. Nevertheless he was in active practice and attending patients right up to his last illness, and his ardent spirit was full of vitality to the end.—R. S. S.

W. J. N. VINCENT, C.B.E., M.D.

We record with regret the death of Dr. W. J. N. Vincent at his home at Sheffield on March 15 at the age of 85. He was medical superintendent of the South Yorkshire Asylum from 1911 to 1933. William James Nathaniel Vincent was born on August 24, 1867, the second son of the late Mr. H. J. Vincent, and was educated at the University of Durham and at the London Hospital, graduating M.B., B.S. in 1892 and taking the diplomas of M.R.C.S., L.R.C.P. in the same year. He proceeded to the degree of M.D. in 1914. After acting as assistant medical officer at the Durham County

Asylum and at the Borough Asylum, Mapperley Hill, Nottingham, he was appointed assistant medical officer at the South Yorkshire Asylum, Wadsley, Sheffield (now the Middlewood Hospital) in 1898. He succeeded the late Dr. W. S. Kay as medical superintendent in 1911, the same year in which he was appointed to the lectureship in mental diseases in the University of Sheffield. His services in that connexion were officially recognized by the University in 1934, when the honorary degree of M.A. was conferred upon him.

Dr. Vincent, who was accorded the rank of lieutenant-colonel in the R.A.M.C., was in charge of the Wharncliffe War Hospital at Sheffield from 1915 to 1920 and of the Ministry of Pensions Hospital at Wadsley. For his services during the first world war he was appointed C.B.E. in 1919. He took a lively interest in clinical psychiatry and in 1924 was enthusiastic in the use of malarial therapy for general paresis, a method of treatment which might be regarded as a forerunner of more recent physical methods. Among the distinctions which came his way was the presidency of the Sheffield Medico-Chirurgical Society. His keenness on hospital administration and design was exercised during his last years of office by the planning and building of the new admission block at Middlewood, which was opened in 1935. Kind and gentle in manner, and disliking formality, Dr. Vincent was highly esteemed by his colleagues and well loved by his patients. He resigned from the superintendency of his hospital in 1933 and enjoyed many years of retirement. His favourite hobby was painting, and his portrait of Dr. Kay still hangs in the medical superintendent's office at Middlewood Hospital, together with a useful pen drawing of the hospital buildings. Astronomy and alpine climbing were among his other recreations. He married Miss Kate Helen Barker, of Sheffield, in 1917, and she survives him, together with two sons, one of whom is a member of the medical profession, and two daughters.—F. T. T.

J. BARNES BURT, M.D.

Dr. J. Barnes Burt, well known as a rheumatologist on the Continent as well as in this country, died at his home at Bath on March 18 at the age of 72. His death was unexpected, for he had been in active practice until a fortnight before his fatal illness began.

Joseph Barnes Burt was born at Kendal, in Westmorland, in 1880, the son of Dr. J. K. Burt, and was educated at Epsom College and at University College Hospital, qualifying M.R.C.S., L.R.C.P. in 1902, and taking the London M.B. in the same year. He proceeded to the M.D. in 1904. After qualification he held the appointment of house-surgeon at University College Hospital, and then went to Cambridge as a research scholar in special diseases. Deciding to specialize in the treatment of gout, rheumatism, and allied diseases, he set up in practice at Buxton, where he was on the staff of the Devonshire Royal Hospital for many years. During the war of 1914-18 he served as a temporary captain in the R.A.M.C., and was in Mesopotamia from 1917 to 1919. It was relatively late in life, in the year 1935, that Dr. Barnes Burt moved from Buxton to Bath. He was immediately elected to the staff of the Royal Mineral Water Hospital—now the Royal National Hospital for Rheumatic Diseases—and remained an active member from 1935 to 1946, when he retired and was appointed consulting physician. Shortly before the beginning of the last war he was very actively engaged with the plans to rebuild the hospital, and was in fact

chairman and organizer of the medical appeal committee. It was a sad blow to him when the outbreak of war in 1939 put a summary end to the rebuilding, for which the plans had been proposed and most of the money collected.

Barnes Burt was the first president of the Section of Physical Medicine of the Royal Society of Medicine and a past chairman of the International Society of Medical Hydrology. On the death in 1940 of Dr. Fortescue Fox, who was the creator and father of the society, Barnes Burt took over the chairmanship, and largely through his efforts the society was revived at the end of the last war. When the British Medical Association held its Annual Meeting at Plymouth in 1938 he served as a vice-president of the Section of Physical Medicine and Physical Education. He had interested himself in the work of the Association some years before the Plymouth meeting, however, and was a member of the Spa Practitioners Group Committee from 1927 to 1946. He also served on the Physical Medicine Group Committee from 1945 to 1950, and was chairman of the Bath Division in 1932-3. A fine physician and a cultivated and a forthright colleague, he will be deeply missed. His kindness and consideration inspired a real affection in both his patients and his colleagues. During his long association with the treatment of the rheumatic diseases he wrote extensively, particularly on gout and neuritis.

Among his other activities Barnes Burt was a city councillor in Bath from 1939 to 1946, representing the Bathwick ward. He was an authority on etchings and water colours, and among his collection were some fine examples by Rembrandt and John Cotman. His own efforts in this field were of a high standard. At one time he was a governor of the Whitworth Art Gallery.

He married Miss Dorothy Armitage, and she survives him, together with the two sons and one daughter of the marriage. His eldest son has followed his father not only into the medical profession but also as president of the Section of Physical Medicine of the Royal Society of Medicine.—L. C. H.

Medico-Legal

MEDICAL EVIDENCE ON INSANITY

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

The vexed question of the respective functions of the jury and of medical expert witnesses was once again ventilated in the Court of Criminal Appeal on March 30.¹

The appellant, Joseph Holmes, had been convicted at Nottingham Assizes of the savage and frenzied murder of his landlady and duly sentenced to death. His defence was that of insanity, and it was conceded by the prosecution that he suffered from paranoid schizophrenia. After the murder he had gone to the police station, had told the police that he had killed his landlady, and had made a full statement about it. Under the M'Naghten rules the issue for the jury on which criminal responsibility for his act depended was the state of his mind at the time the act was done—that is, did he know what he was doing, and, if so, did he know that what he was doing was wrong?

The principal ground of the appeal was that one of the medical witnesses called on this issue had been asked whether in his opinion the appellant's conduct in going to the police immediately after the murder and making a full statement would indicate that the appellant had known that what he was doing was wrong in law. This, argued counsel, was an improper question, in that a medical man, however

eminent, should not be asked his opinion on the very question which it was for the jury, not for the expert witness, to decide. He submitted that a doctor, having first proved that the accused was suffering from a disease of the mind, might then be asked whether in his experience such a disease would affect his judgment of right and wrong, but that he must not be asked what was in the man's mind when the act was done.

During the argument the Lord Chief Justice, Lord Goddard, interjected to ask what was the point of the appeal, since everyone was now agreed that the appellant was certifiably insane. Whatever the result of the appeal the appellant would become a patient in Broadmoor. Counsel replied that, though the matter in respect of this appellant might be academic, it was one of general importance, and, if the judge at the trial had been wrong in allowing the question to be put to the doctor and answered, this ought to be plainly laid down by the court.

The judgment of the court dismissing the appeal was given by the Lord Chief Justice. He said that the doctor called for the defence was asked in cross-examination whether in his view the appellant's behaviour when he went to the police indicated that he knew that what he was doing was wrong in law. No member of the court had ever heard of objection being taken to such a question. If the answer the doctor had given to the question had been "No," to exclude the question might have placed an insuperable difficulty in the way of the defence. The court considered the question to be a perfectly proper one, and one which if held inadmissible could possibly produce injustice in the case of an innocent prisoner.

The court might well have gone further and asked how in the world a jury of twelve laymen could draw a conclusion about what was in the mind of a paranoid schizophrenic without the assistance of the opinion of a doctor with professional experience of that condition being given upon that very question. On the opinion being given, it is of course the responsibility of the jury to make up their minds whether it is an opinion on which they ought in conscience to act.

Medical Notes in Parliament

INQUIRY INTO HEALTH SERVICE COSTS

THE MINISTER OF HEALTH announced on April 1 his decision, taken in conjunction with the Secretary of State for Scotland, to refer the costs of the National Health Service to an independent committee for investigation. The chairman of this committee will be Mr. C. W. Guillebaud, a Cambridge don and economist, who has served on a number of trade wages councils and industrial arbitrations. The names of the other members are to be made known as soon as possible.

Mr. Iain Macleod, in his statement, said that he and the Secretary of State for Scotland had had under close review the whole problem of the present and future cost of maintaining a proper and adequate National Health Service. They had already initiated a number of administrative and other measures designed to alleviate, so far as possible, the considerable cost to the taxpayer without impairing the quality of the service provided. But these were inevitably measures of detail and the general long-term problem remained essentially unsolved. After a great deal of thought the Secretary of State and he both felt that the many issues involved in this problem were so complex that the wisest course would be to refer the whole matter for an independent and objective inquiry by a committee. They therefore proposed to appoint a small committee with the following terms of reference:

To review the present and prospective cost of the National Health Service; to suggest means, whether by modification in organization or otherwise, of ensuring the most effective control and efficient use of such Exchequer funds as may be made available; to advise how, in view of the burdens on the Exchequer, a

rising charge upon it can be avoided, while providing for the maintenance of an adequate Service; and to make recommendations.

Opposition Protests

The announcement provoked an immediate storm of protest among Opposition Members. Mr. ANEURIN BEVAN assailed it as an abuse of Parliamentary procedure, because immediately after the Easter recess there was to be the Budget, which naturally bore on the cost of the Health Service. That was the appropriate time for this kind of statement. Had the Cabinet seriously decided that this was an issue to be remitted to a committee of inquiry? It was primarily a matter for the House of Commons and for political decisions. This was an act of the most unprecedented political cowardice—to send to a committee of inquiry a matter which was at the centre of British politics. Why had the Minister not asked the Central Health Services Advisory Council for its advice about modifications in the organization of the Service? It had been set up for that purpose. What the Minister was doing as a consequence of struggles between himself and the Treasury was seeking another instrument by which he might mutilate the Service. Everyone knew the Minister was an avowed enemy of the National Health Service. He had publicly declared it, and in his own hands it had received many grievous blows. The best service he could render to it would be to resign.

Long-term Problem

Mr. MACLEOD said that he had seen Mr. Guillebaud the previous afternoon, and thought it was his duty to inform the House as soon as he could. The matter had been considered at the highest level by the Government, who thought that it was essentially a departmental matter and that the announcement should be made by him and not by the Chancellor of the Exchequer as part of the Budget, because it was the long-term problem which remained essentially unsolved. It was because the Central Health Services Advisory Council was representative of wide interests within the Service that he did not consider it to be the appropriate body for an inquiry of this nature. In his view what was needed was an entirely independent inquiry—not a political one, nor one linked in any way to membership of a committee or tied to any of the professions in the Health Service. He would never have agreed to the committee, nor would Mr. Guillebaud have accepted the chairmanship, if it had been designed to mutilate the Health Service. On a matter that so deeply concerned the finances of the Service the House would give the fullest value to the view of a Minister of Health who never got his estimates to within £100m. of the right figure.

Mr. BEVAN retorted to the last observation that on his last estimate expenditure was £14m. less. Was expenditure equal to £400m. of the National budget, and concerning the welfare of all the citizens of Great Britain, a fit subject to be remitted to a committee of inquiry? Why did not the Chancellor of the Exchequer remit to such a committee the question whether taxes should be higher or not? Why did he not hand over the whole of his Budget to such a committee? What the Minister was doing was to seek the most respectable auspices under which to destroy the Health Service.

In the considerable uproar Mr. C. J. M. ALPORT protested that a vicious personal attack was being made on the Minister; and Mr. S. SILVERMAN said the Minister had taken a large chunk of public expenditure and proposed a revolutionary and unconstitutional method of dealing with it. Mr. BEVAN repeated that an essential feature of the Budget would be expenditure on the Health Service, and the purpose of this statement by Mr. MACLEOD, made so shortly in advance of the Budget, was to nullify a great deal of the discussions on the Budget.

Mr. R. FORT, on the other side, said that many, inside and outside the House, would welcome the Minister's statement. It would enable a great deal of information about the cost and expenditure on the Service to be brought together in a form which could be appreciated. In putting

the matter before the committee, he asked, would the Minister ask its opinion about the effect of making block grants to hospitals to give regional boards greater independence than they had enjoyed under the organization set up by Mr. Bevan? Mr. MACLEOD said that it was true that many people had for a long time considered that this was a matter which should be inquired into. The question of block grants came within the terms of reference.

Mr. A. WOODBURN suggested that as an economist was being put in charge of the inquiry the purpose of the committee was to find out, as the Organization and Methods Division of the Treasury could, whether the existing Service could be more economically run. Mr. MACLEOD said that this was a general inquiry into the financing of the Service. It was not an economy cuts committee. He thought a committee not tied to the professions nor to any political party was the best way of dealing with a long-term matter, which might take months and perhaps a year.

Free Drugs for Private Patients

SIR EDWARD KEELING asked the Minister of Health on April 2 how much it would cost the taxpayer to give drugs, dressings, and appliances to private doctors' patients after deducting the 1s. prescription charge, but without allowing for the transfer of many National Health Service patients to private doctors which would follow such gift. Miss PAT HORNSBY-SMITH informed him that if the net cost per person were the same as for patients under the National Health Service (which assumed that private doctors would be bound to observe the same conditions as National Health Service doctors) the total cost to the taxpayer might be nearly £1½m. per annum.

Untreated Flour

VISCOUNT HINCHINGBROOKE asked the Minister of Food on April 1 whether he was aware of fresh evidence that consumption of wheat-flour treated with nitrogen trichloride (agene) or chlorine dioxide produced eczema and mental disturbance in allergically responsive persons and what steps he was taking to make chemically untreated flour or bread available to such persons and to those who preferred it. Major G. LLOYD GEORGE said he assumed that Lord Hinchingbrooke was referring to a recently published article in a medical journal (*Lancet*, 1953, 1, 577) reporting a single case of allergic response to flour treated with agene or chlorine dioxide. He was assured that flour which had not been treated with either of these improvers, and bread made from such flour, would, as hitherto, be available on special request.

Industrial Noise

Dr. BARNET STROSS questioned the Minister of Labour on March 31 about the effect of noise in metal-working industries on hearing, and the steps being taken to protect the workers from deafness of this type.

Mr. HAROLD WATKINSON, the Parliamentary Secretary, replied that the department was aware of the recent report of a committee of the Medical Research Council on the medical and surgical problems of deafness and that exposure over many years to noise above certain intensities might cause deterioration in hearing. Much research was being carried out into this question, and a committee had been set up jointly by the Department of Scientific and Industrial Research and the Medical Research Council which would consider, among other things, the effect of noise in relation to human efficiency. The harmful effects of noise on the individual could be reduced to some extent by the wearing of protective ear coverings and by eliminating injurious noise at its source by improved designs of machines and their mountings and the sound insulation of walls and ceilings; but the subject had been found to bristle with practical difficulties. He added that there was to be specific research into finding the right type of protective ear covering.

Hospital Staff Wage Awards.—The estimated cost in 1953-4 of wage and salary awards made to all full- and part-time hospital staff during the last 12 months was approximately £6½m.

¹ *The Times*, March 31.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending March 21 (No. 11) and corresponding week 1952.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Vital Statistics

Smallpox in the North Country

Up to noon, April 7, 21 cases of smallpox, including 4 deaths, had been reported from Yorkshire and Lancashire. Cases (deaths in parentheses) were distributed as follows:—*Todmorden M.B.*: 11 (3); *Bacup M.B.*: 2 (1); *Oldham C.B.*: 2; *Bury C.B.*: 2; *Halifax C.B.*: 4. Five cases have been notified since last week's report (which made the erroneous statement that 2 cases in *Todmorden M.B.* were both contacts of a new *Bacup* case). The new cases were as follows:—*Halifax C.B.*: 4 cases, which were contacts of one of the original cases at *Halifax General Hospital*; *Oldham C.B.*: 1 case, which was a contact of a previous case. Cases continue to be in the direct lines of contact with previous cases, and the outbreak appears to be well contained.

In reply to a question in Parliament, the Minister of Health stated on April 2 that of the 19 cases confirmed up to the previous day 10 had had no original vaccination, 7 had not been vaccinated since infancy, and 2 had been vaccinated in infancy and again in the 1914-18 war. After the outbreak had started 14 were vaccinated or revaccinated.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1944-52 are shown thus -----, the figures for 1953 thus ————. Except for the curves showing notifications in 1953, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

OPHTHALMIA NEONATORUM

Infectious Diseases

The largest fluctuations in the returns of infectious diseases during the week ending March 21 in England and Wales were a rise of 302 in the number of notifications of measles, from 26,924 to 27,226, 71 for dysentery, from 362 to 433, and a fall of 50 for scarlet fever, from 1,675 to 1,625.

The largest rises in the number of notifications of measles were 251 in Hertfordshire, from 858 to 1,109; 127 in Worcestershire, from 346 to 473; and 106 in Cornwall, from 263 to 369; and the largest falls were 250 in Essex, from 1,615 to 1,365; 156 in Surrey, from 1,961 to 1,805; 107 in Kent, from 1,415 to 1,308; and 103 in Oxfordshire, from 434 to 331. Only small fluctuations occurred in the local trends of scarlet fever. The notifications of whooping-cough rose from 3,072 to 3,104; the largest fluctuation was an increase of 67 in Lancashire, from 528 to 595. 20 cases of diphtheria were notified, 11 fewer than in the preceding week. A decrease in Lancashire from 10 to 5 was the chief feature of the returns of diphtheria.

26 cases of acute poliomyelitis were notified; these were 5 more for paralytic and 4 more for non-paralytic cases than the preceding week. The largest return was 3 in Sussex.

The largest centres of dysentery were Lancashire 80 (Liverpool C.B. 40), Leicestershire 64 (Leicester C.B. 63), London 41, Middlesex 43 (Edmonton M.B. 31), Yorkshire West Riding 37 (Leeds C.B. 12), and Cheshire 17.

133 deaths were attributed to influenza in the great towns, 6 fewer than in the preceding week.

Industrial Accidents and Disease

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in February was 121, compared with 101 in the previous month and 114 (revised figures) in February, 1952. The number of cases of industrial disease reported was 41, including 3 from lead poisoning, 4 from anthrax, 14 from epitheliomatous ulceration, and 20 from chrome ulceration. There were no deaths.—*Ministry of Labour Gazette*, March, 1953.

The Services

A Supplement to the *London Gazette* has announced the following awards:

First Clasp to the Territorial Efficiency Decoration.—Major A. M. Rennie, R.A.M.C.

Territorial Efficiency Decoration.—Major A. M. Rennie, Captain (Honorary Major) D. R. Beaton, and Captain H. J. Minford, M.C., R.A.M.C.

Medical News

Association of the Royal College of Surgeons in Ireland.

The annual general meeting of the association was held in the Royal College of Surgeons in Ireland on March 21 with the president, Dr. Paul Murray, in the chair. Professor A. K. Henry, professor of anatomy at the R.C.S.I. and emeritus professor of clinical surgery of Cairo University, was elected president for 1953-4. Dr. J. D. H. Widdess was elected vice-president, Dr. Catherine A. Quinn hon. treasurer, Dr. P. D. J. Holland hon. record secretary, and Mr. W. A. L. MacGowan hon. corresponding secretary.

Medical Aspects of Civil Aviation.—The standing medical committee of the International Air Transport Association held its third annual meeting at Estoril, Portugal, during the week March 21 to 28. The members represented 18 international airlines, and Sir Harold Whittingham was in the chair. The committee discussed the practical application of the W.H.O. International Sanitary Regulations, medical requirements for aircrew, medications contraindicated for use by aircrew when on duty, methods of disinfection of aircraft, and the maintenance of wholesome water supplies on aircraft. It was considered that aircraft could be kept virtually free of insects if fabric and paint were impregnated with a synthetic resin containing an effective insecticide. This would save time in transit and the personal annoyance caused by aerosol spraying.

Bravery in Kenya.—The award of the M.B.E. (Civil Division) to Mrs. Dorothy Meiklejohn, M.R.C.S., L.R.C.P., of Aberdare District, Kenya, was gazetted in London on March 27. The citation was as follows:

On an isolated farm Mrs. Meiklejohn and her husband were in their sitting-room when, suddenly, four Africans burst into the room and immediately launched a savage attack on them. At least one of the Africans was armed with a pistol, while the others were in possession of native knives. Mrs. Meiklejohn shouted to her husband and tried to reach for a firearm which was in her handbag, but was slashed on the wrist. Both Mrs. Meiklejohn and her husband were attacked again and again until the Africans thought they were dead; they then left. Mrs. Meiklejohn's husband climbed the stairs to his bedroom and collapsed there. Mrs. Meiklejohn was suffering from multiple and very serious wounds. Her face and arms were slashed and she was fast losing blood, but, determined to obtain help for her injured husband and raise the alarm, she staggered to her car and drove to the police station, at Thomson's Falls, a distance of nine miles, over a rough and lonely road. On arrival she was only able to identify herself before she collapsed. She was taken to hospital and recovered, but her husband succumbed to his injuries.

Mrs. Meiklejohn showed outstanding fortitude in the face of grave danger.

Award of Manson and Chalmers Memorial Medals.—The council of the Royal Society of Tropical Medicine and Hygiene has awarded the Manson Medal, 1953, to Professor Jérôme Rodhain, director of the Institute of Tropical Medicine, Antwerp. The medal is awarded triennially to the living author of original work in any branch of tropical medicine or hygiene. The Chalmers Memorial Medal, 1953, has been awarded by the council to Mr. D. J. Lewis, medical entomologist in the Sudan Government Service. This medal is awarded biennially for research of outstanding merit on tropical medicine or hygiene. Only those under 45 years of age are eligible.

Dangerous Drugs.—Two new Statutory Instruments affecting dangerous drugs came into force on March 31. The first, the Dangerous Drugs Regulations, 1953, consolidates and amends certain earlier Regulations and, apart from a few scheduled exceptions, applies to all substances covered by the Dangerous Drugs Act, 1951. The second, the Dangerous Drugs Act (Relaxation) Order, 1953, frees morpholinylethylmorphine from control by Subsection (1) of Section 11 of the Dangerous Drugs Act, 1951. This drug, which is obtained from one of the phenanthrene alkaloids of opium, is now controlled by Part III of the new Regulations.

Sir Howard Florey, F.R.S., is on a three months' visit to Canberra in his capacity as adviser to the Australian National University on the John Curtin Memorial School of Medical Research.

Dr. William Storrar, formerly assistant administrative medical officer of the South-western Regional Hospital Board, has been appointed medical director of the Montreal General Hospital. He graduated from Edinburgh in 1939, and went to Canada in 1951.

Professor R. M. Titmuss, formerly a member of the Medical Research Council's Social Medicine Research Unit and now professor of social administration at the London School of Economics, has been appointed a member of the National Insurance Advisory Committee.

The Rev. A. C. Irvine, M.D., senior missionary of the Church of Scotland Mission in Kenya, is to receive the honorary degree of D.D. at the summer graduation at Aberdeen University.

COMING EVENTS

National Association for the Prevention of Tuberculosis.—A meeting for members of all sections of the N.A.P.T. is to be held in the Great Hall, B.M.A. House, Tavistock Square, London, W.C.1, on Saturday, April 18, at 2.30 p.m. The subject to be discussed is "The Modern Management of Tuberculosis by Chemotherapy and Otherwise." Application for tickets should be made as early as possible to the National Association for the Prevention of Tuberculosis, Tavistock House North, Tavistock Square, London, W.C.1.

Seminar on World Health.—During the World Health Assembly at Geneva the World Federation of United Nations Associations is organizing a Seminar to be held at the Palais des Nations in Geneva from May 4 to 15. The Seminar will be opened by Dr. Brock Chisholm, and there will be lectures on world health problems. Applications may be sent through a United Nations Association or directly to the World Federation of United Nations Associations, 1, Avenue de la Paix, Geneva, or 19, Avenue Kléber, Paris, 16.

NEW ISSUES

British Journal of Industrial Medicine.—The next issue (Vol. 10, No. 2) will be available in a week's time. The contents include:

RESPIRATORS FOR PROTECTION AGAINST MERCURY VAPOUR. V. B. Vouk, Z. Topolnik, and M. Furgas.
THE ACTION OF FLINT OF VARIABLE SIZE INJECTED AT CONSTANT WEIGHT AND CONSTANT SURFACE INTO THE LUNGS OF RATS. E. J. King, G. P. Mohanty, and C. V. Harrison.
DUST SAMPLING TO SIMULATE THE HUMAN LUNG. H. H. Watson.
PNEUMOCONIOSIS OF COAL-MINERS IN SCOTLAND. John Black.
A PILOT INVESTIGATION INTO THE OCCURRENCE OF PNEUMOCONIOSIS IN LARGE POWER STATIONS IN SOUTH WALES. Idris Davies.
EXPECTED FREQUENCY OF BLADDER TUMOUR IN WORKS POPULATION. R. A. M. Case.
METHYLOCTYLBENZENE SULPHATE: A NEW INDUSTRIAL SENSITIZING AGENT. C. N. D. Cruickshank and H. Howard-Swaffield.
PSYCHOLOGICAL HANDICAP IN RELATION TO PRODUCTIVITY AND OCCUPATIONAL ADJUSTMENT. M. Markowe and L. E. D. Barber.

Issued quarterly; annual subscription £2 2s., single copy 12s. 6d.

Abstracts of World Medicine.—The April issue (Vol. 13, No. 4), which is now available, contains abstracts of important papers on both medical and surgical subjects drawn from the medical literature of some 20 different countries and of all five continents. In addition to clinical medicine and surgery, the subjects covered include pathology, bacteriology, pharmacology, and chemotherapy, and there are also sections dealing with public health, industrial medicine, forensic medicine and toxicology, aviation medicine, anaesthetics, radiology, and the history of medicine.

Issued monthly; annual subscription £4 4s., single copy 8s. 6d.; a specimen will be sent free on request.

These journals are obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, April 13

MEDICAL SOCIETY OF LONDON.—8.30 p.m., meeting of Fellows. Discussion to be introduced by Dr. K. Harris and Dr. S. Oram: Early Manifestations of Coronary Disease.

● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. F. Masina: Surgical Approach to Tumours of the Bladder; 6.30 p.m., Mr. V. H. Riddell: Thyroid Tumours.

ROYAL EYE HOSPITAL.—5.15 p.m., Dr. T. H. Whittington: Astigmatism and its Treatment. Factors Affecting Binocular Vision.

Tuesday, April 14

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Lumsden Lecture by Dr. E. A. Carmichael: Hemiplegia of Early Onset and the Results of Hemispherectomy.

● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. R. Furlong: Pseudocoxalgia; 6.30 p.m., Mr. P. Clarkson: Injuries of the Hand.

Wednesday, April 15

INSTITUTE OF UROLOGY.—At St. Paul's Hospital, W.C., 4.30 for 5 p.m., Dr. E. G. B. Calvert: Surgery and the Diabetic.

● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Professor Lambert Rogers: Costoclavicular Syndrome; 6.30 p.m., Mr. Harold Edwards: Treatment of Inguinal Hernia.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Dr. B. E. Schlesinger: Tuberculosis in Childhood (Illustrated).

Thursday, April 16

BRITISH INSTITUTE OF RADIOLOGY.—8 p.m., Dr. A. E. Jones: Clinical Aspects of Carcinogenesis; Dr. A. Glucksmann: Histological Aspects of Carcinogenesis.

EPSOM AND SUTTON INTER-HOSPITAL PSYCHIATRIC ASSOCIATION.—At Horton Hospital, Epsom, 5.30 p.m. Films: (1) Dr. T. F. Main: Grief; (2) Dr. H. R. Rollin: three short films illustrating manic and depressive psychoses.

FARNBOROUGH HOSPITAL, Kent.—5.30 p.m., Dr. C. J. Gavey: Physician's Evaluation of Surgical Risks.

LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—At 11, Chandos Street, W., 8.30 p.m., Dr. Michael Kremer: Modern Views on Epilepsy and its Treatment.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Lumsden Lecture by Dr. E. A. Carmichael: Hemiplegia of Early Onset and the Results of Hemispherectomy.

● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Dr. Kenneth Perry: Tuberculous Glands of Neck; 6.30 p.m., Mr. Cecil Flemming: Fractures of the Foot.

ROYAL EYE HOSPITAL.—5.30 p.m., Miss J. M. Dollar: Problem of Iridocyclitis and its Investigation.

ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Professor W. C. W. Nixon: Physiological and Clinical Aspects of Uterine Action.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. A. S. Paterson: postgraduate demonstration in neurology.

SOCIETY OF CHEMICAL INDUSTRY: MICROBIOLOGY GROUP.—At Medical Society of London, 6.15 p.m., Dr. Lois Dickinson: Use of the Bacteriophage in the Study of Viruses; Mr. L. J. Meanwell: Bacteriophages of the Lactic Streptococci.

Friday, April 17

BRITISH INSTITUTE OF RADIOLOGY.—5 p.m., meeting of medical members; 6.30 p.m., Professor J. Rotblat: Study of the Distribution of Thorotrast in the Body by Autoradiography.

FACULTY OF RADIOLOGISTS.—At Royal College of Surgeons of England, 4 p.m., Professor R. J. V. Pulvertaft: Study of Radiosensitivity in Vitro; Dr. Edith Paterson: Factors Influencing Recovery after Whole Body Radiation; Dr. W. M. Court Brown: Some Aspects of Water and Electrolyte Metabolism in Radiation Sickness.

KENT AND CANTERBURY HOSPITAL.—8 p.m., clinical meeting.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.—At Royal Free Hospital School of Medicine, 8.30 p.m., Mr. C. E. Shattock: Lumps in the Breast.

● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—6.30 p.m., Mr. Roland Jones: Surgery of Peripheral Vascular Disease.

ROYAL EYE HOSPITAL.—4.30 p.m., Mr. A. J. Cameron: Problem of Retinitis Pigmentosa.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Brittain.—On March 21, 1953, at the Christopher Nursing Home, Wigan, Lancs. to Dr. Ina (formerly Eakins), wife of Dr. George Brittain, a daughter.

Eason.—On April 2, 1953, at the Lambeth Hospital, London, S.E., to Ruth (formerly Towler), wife of Thomas John Eason, F.R.C.S.Ed., a brother for Robert and Charles.

Griffiths.—On March 26, 1953, at Overton Lea Maternity Home, Cheltenham, Glos. to Elizabeth, wife of Dr. Eric Griffiths, a daughter—Lynn Elizabeth.

Johnston.—On March 26, 1953, at the Varborough Nursing Home, Southsea, Hants. to Kay, wife of Dr. C. L. Johnston, a brother for Heather and Moya.

Levien.—On March 26, 1953, at Hamilton, New Zealand, to Norah Margaret (formerly Mathers), wife of G. H. Levien, F.R.C.S., a daughter.

MARRIAGES

Owen—Griffith.—On March 28, 1953, at Moriah Chapel, Caernarvon, Kelyth Lloyd Owen, M.R.C.S., L.R.C.P., to Jean Griffith.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Sound-proofing the Surgery

Q.—What are the best ways of sound-proofing a doctor's surgery? Often attempts seem to fail because of leakage at the door.

A.—As a general rule the insulation of the partitions themselves will be adequate if they are of brick or breeze, and plastered. Even a timber stud partition has moderate insulation if constructed with heavy lath and plaster, and it is only likely to give trouble when it is a light or temporary structure such as fibreboard or plain plasterboard on a light framing. Weight is the main requirement. For new work, therefore, I would suggest 4½ in. (11.5 cm.) brick if possible, but 3 in. (7.6 cm.) clinker concrete plastered ½ in. (1.3 cm.) thick on both sides would be reasonable.

Any weakness in a sound-insulating barrier has a marked influence on the overall insulation. In the case of surgery partitions the weakest part of the insulation is almost invariably the doorway, the leakage of sound being due to a double cause: (a) the air gaps round edges of the door, especially at the bottom; and (b) the door itself (or the door panels) being lighter than the main partition structure—the lighter the weight the poorer the insulation.

In taking remedial action the first step is to aim at sealing the air gaps all round the door. This can be done fairly well by means of metal draught-strip, in conjunction with a splayed or rebated threshold. An alternative method is to put rubber strip all round the door stop, but the door must be made to close tightly against it. The door itself must be reasonably heavy—either solid wood throughout or with thick panels, or covered with a heavy sheet material. Nevertheless, however heavy the door or however well sealed the edge gaps, the doorway will nearly always remain the weak point in the partition unless double doors are provided, separated either by an air space of not less than 6 to 8 in. (15 to 20 cm.), or better still by a lobby. The airspace or lobby should contain as much absorbent-lined surface as possible—say "acousti-celotex" or similar tiles fixed to the reveals, to the wall and ceiling, or to the door face. Double doors are certainly recommended whenever possible, both for new work and for adaptations. Single doors, even if heavy and with very tight closure all round, do not give real privacy.

If the surgery is sparsely furnished it may also be useful (in addition to the measures for sound insulation) to provide a reasonable area of absorbent treatment (acoustic tiling) on the ceiling and/or wall surfaces; but this is not worth while if the room already has a carpet and curtains and some upholstered furniture.

Best Antibiotic in Meningitis

Q.—What is the best antibiotic to use initially in meningitis due to the following organisms: (a) *Haemophilus influenzae*, (b) *Pseudomonas pyocyanea*, (c) *Bact. coli*, (d) *Proteus vulgaris*, and (e) *Strep. faecalis*? Please indicate dosage and route of administration.

A.—(a) *H. influenzae* is at least moderately sensitive to all the main antibiotics as well as to sulphonamides, and succeeding years have witnessed the use of sulphadiazine, penicillin, and streptomycin individually and in combination, and with or without antiserum. Still better results have more recently been obtained with both aureomycin and chloramphenicol. The organism is highly sensitive to both:

chloramphenicol is probably to be preferred because it attains higher concentrations in the cerebrospinal fluid (one-third to one-half of those in the blood, a level unapproached by any other antibiotic). The dose should be 200 mg. per kg. body weight per day in divided doses by the mouth.

(b) *Ps. pyocyanea*.—The antibiotic to which this species is most sensitive, and regularly so, is polymyxin. It must be injected intrathecally in daily doses of 20 mg. If systemic as well as meningeal infection exists, it may also be given intramuscularly (an average dose is 2.5 mg. per kg. body weight daily), but prolonged systemic treatment involves a risk of renal damage. The second choice is streptomycin, provided that the strain is sensitive (this must be tested: some are totally resistant). This also must be given intrathecally, the initial dose being 100 mg. daily. The newer antibiotics are less useful and penicillin useless. Failing anything else, full doses of sulphadiazine may help.

(c) *Bact. coli* meningitis is probably best treated with streptomycin if the strain is sensitive: chloramphenicol would be the second choice.

(d) *Proteus vulgaris*.—This form of meningitis is fortunately so rare that there are no adequate data on which to base any dogmatic statement about treatment. The organism is relatively insensitive to the three newer antibiotics, and streptomycin again offers the best hope of success, but with the same proviso as before.

(e) *Strep. faecalis*.—The rarity of this infection again precludes confident judgment, but the antibiotic to which this species is most sensitive by far is aureomycin: the dosage (exclusively oral) should be as for chloramphenicol (see (a)). In view of the synergic action of penicillin and streptomycin in endocarditis due to *Strep. faecalis*, it is possible that this combination might also be effective in meningitis due to it.

All the suggestions made are based on normal bacterial sensitivities, and should serve for initial treatment, but this may have to be varied in some cases following laboratory studies. There is no condition in which accurate assessment of the susceptibility of the organism to all appropriate and available chemotherapeutic agents is more important or more urgent than meningitis due to such awkward bacteria as those named here. The doses stated are those for adults: about one-quarter of these is usually given to infants.

Infectious Diseases and Public Laundries

Q.—I have recently seen a leaflet which states: "Since May, 1952, tuberculosis has been a notifiable infectious disease, and the 1936 Public Health Act requires that all materials contaminated by the organisms of notifiable infectious diseases must be sterilized before being sent to a public laundry." Is it therefore illegal for a tuberculous person in an infectious state to send his washing to a public laundry?

A.—The statement is incorrect. It was probably inspired by a misinterpretation of the Public Health (Tuberculosis) Regulations, 1952 (Statutory Instrument No. 904 of 1952), which came into force on May 1, 1952.

The nomenclature in respect of the notification of infectious disease tends to be confusing and may be briefly summarized thus:

S.144 of the Public Health Act, 1936, requires the notification of a "notifiable disease" to the local medical officer of health. "Notifiable disease" is defined in s.343, and the provisions of the Act apply only to the diseases thus defined. A local authority may add to the list of notifiable diseases so far as its own area is concerned in accordance with the provisions of s.147. It will be seen, therefore, that there are two types of "notifiable disease," (a) those specifically mentioned in s.343, which applies to all local authorities in England and Wales, and (b) those added by the local authority with the Minister's approval and having a territorial limitation. Both types are "notifiable diseases" and the sections of the Public Health Act (s.144-153, s.155-160) dealing with the notification and prevention of "notifiable diseases" apply to them.

By s.143 of the Public Health Act, 1936, the Minister of Health may make Regulations regarding the treatment and prevention of spread of infectious, epidemic, or endemic disease. The Minister

has exercised this power so as to require the notification of a number of diseases not notifiable under the Public Health Act, 1936—e.g., plague, malaria, measles, tuberculosis, etc. Diseases thus declared notifiable by the Minister are not "notifiable diseases" within the meaning of that term defined in the Public Health Act, 1936, and the provisions of that Act do not apply to them.

The Public Health (Tuberculosis) Regulations of 1952 merely revoke and re-enact the Public Health (Tuberculosis) Regulations, 1930, with minor administrative changes rendered necessary by the National Health Service Acts.

I do not know of any statutory prohibition on a tuberculous person in an infectious state sending his washing to a public laundry, but he might well incur a common law liability if damage resulted from his action. It is general practice in the laundry trade for the terms of the contract between laundry and customer to contain a clause excluding "infected articles" until they have been disinfected. In any event there is a moral duty not to spread infection, and the public should be thus advised.

"Cortisone Fractures"

Q.—What is the mechanism of fracture of the spine during cortisone therapy?

A.—Fracture-collapse of the vertebrae during cortisone therapy is due to osteoporosis and increased functional activity. Osteoporosis is in most cases the result of prolonged inactivity, usually bed-rest in cases of rheumatoid arthritis; occasionally it is of the senile type. If cortisone has been given for prolonged periods, it may have some slight additional effect, since it tends to produce osteoporosis. (This is well seen in Cushing's syndrome, essentially a hyper-corticoid state.) However, collapse is sometimes seen in rheumatoid patients being enthusiastically "rehabilitated" without any cortisone treatment. The increased mobility following the loss of pain and stiffness on cortisone is probably the major factor in the production of these "cortisone fractures."

Premature Orgasm in the Female

Q.—A woman of 38 years and married 15 years says that her marriage has been marred by the fact that she experiences a sudden premature orgasm after which she cannot bear her husband to touch her. What are the possible causes of this condition? She states that she is very anxious to have a child and the only time that she remembers being at all happy in her married life was once when, her period being late, she thought that she might be pregnant. What treatment is advised?

A.—Once a woman has reached orgasm it is usual for coitus to become difficult because the secretions dry up and the pelvic muscles contract to close the vagina. However, such strong aversion to continued attempts by the husband is abnormal. Premature orgasm in the female is also exceptional. Indeed, the account of the case suggests that the main symptom is only a cloak to a more important background, and sympathetic probing of the problem by the family doctor or by a psychologist might well help to elucidate the picture. The most obvious possible basis for the trouble is the sterility, and the best approach might well be to investigate both husband and wife from this standpoint. If sterility is the real problem, and if investigation shows that there is no absolute bar to conception in either partner, artificial insemination using the husband's semen might well circumvent the immediate problem of coitus and result in pregnancy. If the wife achieved a pregnancy by this or other means, her emotional upset might settle and this lead to spontaneous cure of her other symptoms.

Other questions which arise are: How long does the husband take to achieve orgasm? Does he in fact have an emission, or is he suffering from partial impotence?

If it be decided to treat the case symptomatically, orgasm in the wife might be deferred if preliminary love play is omitted entirely and by coitus *a tergo*.

NOTES AND COMMENTS

Alcohol and Barbiturates.—Dr. D. R. WOOD (Sheffield) writes: I was interested in the reply under "Any Questions?" (January 24, p. 232) to a query about alcohol and barbiturates. I wonder in what sense your expert is using the words "potentiated" and "synergistic"? In the papers to which the reader is referred the question is dealt with from the point of view of the LD50 of each substance. From the point of view of "drunk in charge" it would be important and interesting to know whether the substances reinforce each other's action in producing ataxia, euphoria, etc.

OUR EXPERT writes: Despite an exhaustive search I have found no reports on the effect of alcohol and barbiturates when used together on ataxia, euphoria, etc. I think in my original answer I might have been wiser to have used the word "synergism" rather than to have talked about "potentiation." The synergistic effect between ethyl alcohol and phenobarbitone has been well demonstrated experimentally by Jetter and Maclean.¹ When the maximum sublethal dose of one drug plus half that of the other was used, death was produced regularly. Similar fatal synergism is suggested by observation on three poisoning cases in human beings. Nevertheless Sandberg² has demonstrated a potentiative type of synergism between ethyl alcohol and six short-acting barbiturates—the degree of potentiation varying with the dose and the derivative.

Recurrent Parotid Enlargement.—Dr. M. SECKBACH (London, N.W.11) writes: Your correspondent ("Any Questions?" February 7, p. 348) asks whether there is any known relationship between menstruation and recurrent parotid enlargement. I am reminded of a case I saw 20 years ago which had previously been labelled "recurrent parotid enlargement." When I saw the patient she told me she had noticed a swelling, associated with tenderness, in the region of the parotid gland shortly after an abortion six years previously. This swelling subsided after a few days, but recurred at every menstruation. She had never noticed anything like that before the abortion. On examination I was able to feel a small soft nodule constantly present. There was no other pathological finding. Any lung or blood disease had been excluded and there was no evidence of calculus in the parotid duct. The fact that the swelling started after an abortion and had recurred with each menstruation for six years raised my suspicion of an accessory thyroid gland. Portions of this gland may be displaced during the course of development. The existence of a lingual thyroid and of small pieces of thyroid tissue at some distance from the normal thyroid gland between the tongue and the arch of the aorta is known. Puberty and pregnancy are among the predisposing factors of goitre. A minor swelling of the thyroid gland during or just before onset of menstruation, particularly in young girls, has often been observed. The thyroid gland was in its normal position in my particular case. An exploratory operation confirmed the diagnosis of an accessory thyroid. The small tumour consisted of thyroid tissue and had a fibrous capsule. The possibility of aberrant thyroid tissue has therefore to be borne in mind in the case mentioned by your correspondent.

"Any Questions?" Book: Second Series.—This is now available, price 7s. 6d. (postage 6d. extra), from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 4499. MAGIC, MEDICINE, AND RELIGION

THE PERSISTENCE OF AN IDEA*

BY

Sir SYDNEY SMITH, C.B.E., M.D., F.R.C.P., D.P.H., F.R.S.E.

Regius Professor of Forensic Medicine, University of Edinburgh

Although the probable age of the world and of living matter has been the subject of many estimations it would be unsafe to assume that they are even remotely correct. Our knowledge of anything in prehistoric days is highly conjectural, and history itself is a peculiarly inexact science even if it does not warrant the dictum of Mr. Henry Ford.

It is impossible to say when man arose, but relics of manlike creatures who lived about half a million years ago have been found in divers places. Somewhere about 50,000 years ago Neanderthal man flourished, leaving many indications of his artistic and medical skill and of his belief in an after-life, as shown by his method of disposal of the dead.

About 10,000 years ago man began to cultivate crops and to breed animals, and from that date a good deal of evidence has accumulated about his activities and beliefs. Nothing very definite could be learned, however, until some method had been devised for recording his experiences, devices which arose, strangely enough, in several different parts of the world at approximately the same time—namely, about 5,000 to 6,000 years ago. Since then we have acquired a considerable knowledge of his affairs, especially from Egyptian and Mesopotamian sources.

Disease is as old as living matter. Evidence of its presence is found in prehistoric fossil bones, and indeed one of the earliest evidences of disease in humans or manlike creatures was found in the femur attributed to the Java man, which Keith considers to be about 350,000 years old. From that time onwards much evidence of disease has been found, particularly in material from the Nile Valley, where the dry climate, together with the methods of disposal of the dead, has had a preservative effect. Evidence of disease has been found not only in the bones but also in the soft tissues,¹ and in addition to signs of various pathological processes it is interesting to note the prevalence of osteoarthritic changes and arteriosclerosis in those remote periods, which indicates that we are not necessarily correct in attributing such processes to the stress and strain of modern life.

Primitive Medicine and Religion

We may take it that disease of some kind has always afflicted man and must have led him to search for means of easing pain and curing disability. In his quest for

food he had to discriminate between things that were good for him and things that were not. By process of trial and error he obtained not only dietetic acumen but also knowledge of drugs which had a beneficial effect in disease, drugs which prevented pain, and drugs which were capable of causing death. In course of time this skill in the use of drugs became the special province of certain individuals, and by it they were able to exercise power and authority in the community. These were the original medicine men, but it would be wrong to think that they relied on drugs alone in the treatment of disease. If the condition was simple or the cause of it apparent, no doubt such herbs or simples as were available were used, together with primitive surgical procedures, but we must remember that many disabilities have no obvious cause, and for the treatment of those other methods had to be devised.

To-day we regard disease as being subject to natural laws, but before such laws were known it surely was reasonable to assume that phenomena which could not be otherwise explained were due to the action of some supernatural power. For example, the sudden onset of pain, the eruption of a fever, the convulsions of epilepsy, etc., had to be explained in some way, and in default of any natural explanation they were assumed to be due to the action of demons who had gained entrance to the body or had forced something of a toxic nature into it. Assuming this to be correct, the logical response was an appeal to a higher power to curtail the activities of the demon, to drive him out or destroy him. This entailed appeal to higher supernatural powers, and thus arose the priest, whose functions were closely associated with or were performed by the medicine man.

The fundamental aim of primitive religion as of primitive medicine was to safeguard the life of the individual, and, to effect this, steps were taken which were strictly rational, although they may have been based on false premises; hence, from the earliest times religion and medicine had similar objectives—medicine endeavouring to control natural processes by natural means, religion trying to control the same phenomena directly by appeal to some higher power. In addition, certain rites and procedures were used to combat disease, the efficacy being inherent in the rites themselves or in the user, and this constituted magic. Medicine, religion, and magic, therefore, have been associated since the beginning and have worked together for the alleviation of human suffering.

*A Finlayson Memorial Lecture delivered before the Royal Faculty of Physicians and Surgeons of Glasgow on December 10, 1952.

¹ *Palaeolithic Pathology of Egypt*, by M. A. Ruffer. 1921.

Egyptian Theology and Medicine

In Egypt, in quite remote times, there was not only a very advanced state of culture, including a well-developed system of medicine, but also a remarkably complicated system of theology. All varieties of sickness and disability were attributed to the action of gods, certain of whom had health and disease as their special responsibility. Health depended to a great extent on paying proper attention to the edicts of these gods and propitiating them with offerings. Even after death the comfort and well-being of the dead depended on such propitiation. The Books of the Dead deal in great detail with the judgment after death, the "weighing of souls" as it was called, and the various proceedings in connexion with the passage of the soul through the underworld. There was therefore, from a very remote period of history, a strong belief in the power of the gods during life and in their authority after death, for belief in existence in some form after death seems to have been present since human life began. It is interesting to note that in the trial of souls, although Osiris sat in judgment with a court of lesser gods, there is a suggestion that over and above them all there was a supreme being. This idea of a day of judgment has remained a part of human beliefs.

In addition to the inscriptions on tombs and temples a number of medical papyri have been discovered, the two most important, and probably the oldest, being the Ebers Papyrus, which is mainly medical and magical in its outlook, and the Edwin Smith Papyrus, which is surgical and rational. The Ebers Papyrus contains sections dealing with various diseases and their treatment, concerning which it shows quite a remarkable standard of knowledge. Throughout the manuscript, in addition, there are directions for the use of incantations, invocations to the gods, and the words to be recited when healing a patient, indicating the important place of religious and magical procedures in medical treatment, though there is a suggestion that the incantations may have been used to reinforce the action of the drugs and not for the value of the magic alone. Even when knowledge of the uses of drugs became more profound, medical treatment by the doctor, spiritual treatment by the priest, and magical treatment by the sorcerer continued to be used side by side in active collaboration.

The Edwin Smith Papyrus is a surgical treatise and deals in a common-sense way with lesions of a traumatic nature, beginning from the head and working downwards. The diagnosis, prognosis, and treatment of fractures, dislocations, and wounds; the effects of injuries on the brain; and the processes of healing are dealt with in a skilful manner. The method of reducing a dislocation of the jaw, for example, is the method in use at the present time. The suturing of wounds, the use of adhesive plaster for bringing the edges of a wound together, the use of properly padded splints and other retaining apparatus, a very efficient system of bandaging, and various other surgical procedures are described, indicating a fairly high degree of medical knowledge. There is one case only in which an incantation is used. The treatise as we have it is a copy of an ancient work and unfortunately is incomplete.

Breasted hazarded a guess that the original work from which the papyrus was copied was written about the time of the pyramid-builders, about 5,000 years ago, and possibly was used by Imhotep himself. Imhotep was the earliest physician that we know by name, and combined the offices of Chief Physician, Chief Magician, and Chief Vizier to Zoser, the Pharaoh of the Third Dynasty. He was also the architect of the Step Pyramid at Sakkara, the first important public building of which there is any record. Though we have little information about his medical activities we do know that his name was revered for about 3,000 years, which is rather longer than most reputations last, and, more

important from our point of view, numbers of temples were erected in his honour, where treatment of the sick by incubation or temple sleep took place. We may look upon him as the founder of psychotherapy. By the time that Egypt was conquered and overrun by the Greeks, about 300 B.C., the worship of Imhotep was general throughout the land, and the temples erected in his honour became seats of medical science and instruction.

We note, therefore, not only that the Egyptians had a relatively advanced system of medical treatment, but also that magical and religious procedures and cults existed side by side with rational medicine from the most ancient times of which we have any knowledge. In other places where there are medical records, such as in Sumeria, Babylonia, and other Eastern countries, the same relationship of religion, magic, and medicine is found.

Among the ancient Hebrews medicine as a science did not exist, and disease was looked upon as a punishment for sin which incurred the wrath of God. There appears to have been little use made of ordinary medical practices, although physicians are mentioned in the Scriptures, and the hygienic and sanitary code evolved by them was unique and masterly. Healing seems to have been the province of the priests, and possession and exorcism were of importance. The healing pilgrimage of Christ and the diseased conditions which he is recorded to have cured must have appeared miraculous. Many of the cures described by St. Luke, such as the cure of epilepsy, of chronic arthritis, and of dropsy, the cleansing of lepers, the casting out of devils, the cure of the dumb and the blind, are all strongly suggestive of actual cases, and it is a question whether Christ should be looked upon as a psychotherapist of remarkable ability or whether he was in fact possessed of divine powers. It would be unsafe to assume that the diseased conditions which he healed were all psychogenic in origin. Many of the miracles may perhaps be explained on that assumption, but certain of the cures cannot—for example, the immediate cure of a withered hand² and of a case of leprosy,³ and the restoration of a dead person to life.⁴ These cannot be explained as the result of psychological treatment, but must be attributed to something beyond our understanding.

Developments in Greece

The Greeks were no doubt impressed by the standard of medical knowledge in Egypt and particularly by the success of the religio-magical treatment by incubation in the temples of Imhotep, and as a result many such institutions were established in Greece. Not only was the system of temple healing adopted, but it is also suggested that the name Asklepios, the Greek god of healing, was derived from Imhotep. Certainly in Egypt after the Greek conquest the two names were used indiscriminately, and many of the temples founded by the Greeks in honour of Imhotep were called Asklepieia.

In early Greek medical practice emphasis was laid on the religious or spiritual element, and the importance attached to incubation or temple sleep is shown by the fact that in and about the eighth and seventh centuries B.C. there were erected something like 300 of these temples, dedicated to Asklepios. The most beautiful of these was situated at Epidauros, where in addition to the central shrine and abaton, or sleeping-place for the sick, there were baths, hostels, and gymnasia, as well as a large theatre and stadium.

On arrival at the temple the sufferer was subjected to a ritual which predisposed him to suggestion. After bathing in the cleansing waters of the fountain he was admitted to the porch of the temple, where he spent one or two days in prayer and meditation. This period, which would exert a soothing influence on his mind, was followed by sleep in the abaton, where the depth of sleep may have been assisted by narcotics. During sleep the god appeared to the sufferer, and quite often a cure was effected overnight. More frequently it required several days of treat-

ment by incubation supplemented by baths, massage, gymnastics, and strict dietary measures. The inscriptions round and about the temples and the number of votive offerings indicate that many cures resulted.

About 460 B.C. there was born in the island of Cos a man who was later to become the greatest of all physicians—Hippocrates. In Cos at that time there was a temple and shrine dedicated to Asklepios to which thousands of sick people resorted. The family of Hippocrates was associated with the temple, and the youth no doubt acquired at an early age a training in medical methods. In the fifth and fourth centuries Greece had remarkable efflorescence of genius in arts and science, in philosophy, history and drama. I need mention only Herodotus, Sophocles, Pheidias, Socrates, Plato, Aristotle. It might therefore have been expected that a great medical man would arise. With the advent of Hippocrates there began a rational system of medicine in which disease was dealt with as a natural phenomenon due to disordered processes in the body itself, and treated by paying particular attention to all the conditions which tended to preserve health. When disease occurred, the natural forces of the body were encouraged to effect a cure. All magical and religio-magical methods were dismissed, as well as the idea that disease was a punishment for sin. Even in connexion with epilepsy, which was always spoken of as the "sacred disease," Hippocrates said, "It is not in my opinion any more divine or sacred than any other disease, but has like them a natural cause and its supposed divine origin is due to man's inexperience."

The system of faith healing and magic in the temples continued, however, throughout the Hippocratic era and well beyond it, and it is difficult to credit that Hippocrates attributed no importance to suggestion in his treatment, even though he did not believe in direct divine intervention. Speaking of the way in which doctors attribute the phenomena seen in epilepsy to divine causes, he says: "In treating sufferers from this disease by purification with blood and like things they behave as if the sufferers were ritually unclean, the victims of divine vengeance or of human magic or had done something sacrilegious. It would have been better if they had taken the sick into the temples, there by sacrifice and prayer to make supplication to the gods. I do not believe that the body can be polluted by a god, but if it is polluted by some other agency the presence of a god would be more likely to purify it, for it is the deity who purifies, sanctifies, and cleanses us from sin." This suggests that Hippocrates by no means discarded the importance of the temples in the healing of the sick. He considered that most diseases were to be cured by restoring the disturbed harmony in the elements and humours of the body, such restoration being carried out by the powers of nature aided by the physician, who removed any disturbing factors. Before the Hippocratic era, Alcmaeon of Croton, a pupil of Pythagoras and contemporary of Empedocles, had already introduced the doctrine that health depended on the harmony of elements within the body and disease upon their discord. Though Hippocrates betrayed no enthusiasm for drugs, he had quite an extensive pharmacopoeia at his disposal, and many of the drugs in use then are still used.

In this wonderful period of Greek development, therefore, we find that healing by the use of drugs, by physical means, and by religious and magical procedures existed side by side. In this regard it is to be noted that in 380 B.C. Plato recognized the importance of the mind in healing. Through one of his characters, who was a physician, he said: "The cure of a part should not be attempted without the treatment of the whole. No attempt should be made to cure the body without the soul, and if the head and the body are to be healthy, you must begin by curing the mind." I shall refer to this view later when dealing with the importance of the mind.

After the death of Hippocrates about 350 B.C. medicine gradually fell from the high standard set up by him and his

followers, and the air was full of turmoil and disputation. Philosophic argument again asserted the sterilizing influence from which Hippocrates had rescued it, and in the following eras the Dogmatists, the Empiricists, the Methodists, the Eclectics rose. These sects were very dogmatic, very rational, very argumentative, and no doubt added zest to living by their scholarship; but they were of little value in progressive medicine and showed little sign of attention to psychological medicine. Aristotle (384-322 B.C.) closely followed Hippocrates, and, though not a medical man, exercised a profound influence on science generally, and as a biologist his work was of great importance to medicine. It is of interest that he also believed in the importance of balance in the humours of the body in the maintenance of health.

The Roman Attitude

In passing into the early years of the Christian era it is of interest to note what Seneca (3 B.C.-A.D. 65) thought about those things of the spirit which we have been discussing. In his *Quaestiones Naturales* he wrote: "There are many things akin to highest deity that are still obscure. Some may be too subtle for our powers of comprehension, others imperceptible to us because such exalted majesty conceals itself in the holiest part of its sanctuary, forbidding access to any power save that of the spirit. How many heavenly bodies revolve unseen by human eye! . . . How many discoveries are reserved for the ages to come, when our memory shall be no more, for this world of ours contains matter for investigation for all generations. . . . God has not revealed all things to man and has entrusted us with but a fragment of His mighty work."

These are noble words, and had the Roman attitude to religion, science, and medicine been consistently inspired by such sentiments, then Rome would surely have added a fuller measure of glory to her undoubted grandeur.

In Rome, however, indigenous medicine was never of a high standard, although the infiltration of Greek physicians and Greek writings exerted a favourable influence. Celsus in medicine and Dioscorides in materia medica stand out in this connexion. These two were followed by the colossal figure of Galen, whose views dominated medicine for centuries. Galen, though a master in the use of drugs, was well aware of the importance of the mind in treatment. "We have proof," he said, speaking of temple cures, but prophetically withal, "that many serious illnesses can be cured solely by a shock administered to the mind."

Galen was the last of the great ancient physicians. Even before his death in A.D. 200, and more so afterwards, the level of medical practice in Rome was distinctly low. The city was full of quacks, charlatans, poisoners, and magicians. Both the worlds of which I have been speaking were represented—the realm of magico-religious healing and that of systematic medical practice—but Rome made the best of neither. The genius of Rome lay in other directions and its power was waning.

The adoption of the Christian religion effected little or no improvement in the healing arts. Indeed, in some ways it was disastrous, for it appears to have favoured positive fixation at a low level instead of a negative stagnation, in which some stir and upsurge might eventually have developed. In A.D. 360 Basil, Bishop of Caesarea, insisted that disease was a manifestation of divine purpose and action, effected by means of demons, and indicated that the Church would look with disfavour on treatment by any means other than prayer.

A Vanishing Inheritance

By the seventh century the scientific attitude and the cultural inheritance from Greece were in process of vanishing. Theodosius decreed that Christianity and paganism could not both exist in the empire, pagan rites were prohibited and pagan temples destroyed, including the temples of

²From *Magic to Science*, by Charles Singer, 1928. Benn, London.

Asklepios, where the incubation ceremonies were competing successfully with the Church's own saints and shrines.

Not only was science in a moribund state and discouraged by the Roman Catholic Church, but there was also a falling away in the genuine faith healing which was a feature of earlier pagan times. The teachings of Hippocrates were forgotten, and even the influence of Galen became subversive on account of the unquestioned authority which had to be accorded to his written word.

For a thousand years or so there was no real progress in medicine or science, nor any advancement in the knowledge of the mind and its disabilities. The dominance of the Church, with its hostility towards science and intolerance of anything unorthodox, had a reactionary influence. A ferocious tenderness towards the true faith led to dreadful attempts to save the soul by torturing the body. Witches and heretics were destroyed, not only for the safety of the Church, but also for their own good. Dogma and religious observances were of paramount importance, and the needs of the body and its reaction to disease became relatively insignificant. Against this disastrous catalogue, however, there can be set at least one redeeming feature, and it is one of importance. The Christian belief in charity, not always easily discernible in action, did lead to a greater appreciation of the propriety of caring for the sick and needy. This was a Christian virtue which coloured the whole outlook of medicine when it did eventually emerge as a progressive discipline after the long depression of the Dark Ages. Fortunately the flame of science was never quite extinguished, and something of its true spirit remained alive, notably in that strange flowering of civilization among the Arabs, through whom much of the ancient learning returned to Europe and led to the Renaissance there.

It is a curious circumstance that this revival in Europe should have been partly due to the fact that the Nestorians, who were driven from Constantinople and expelled from Church and State, devoted themselves to Greek scientific writings, which they transmitted to the Persians. There they were translated into Syriac, retranslated into Arabic, and eventually translated back again into Latin, and thereby gave Europe its first access to Greek science when men's minds began to waken after the Dark Ages.

Throughout the Dark and Middle Ages Anglo-Saxon medicine was of a very primitive nature, and the magical element predominated. The Teutonic peoples had not the same belief in possession by demons which was characteristic of the Near East, but attributed many diseases to the action of elves and witches who fired baleful shafts into the body. It is pretty clear, however, that other early and mediaeval Christians accepted the doctrine that disease was due to the action of demons. St. Augustine, in the fifth century, said, "All diseases of Christians are to be ascribed to demons, chiefly do they torment the fresh baptized, yea, even the guiltless newborn infant." Under these beliefs those suffering from disease of any kind were subjected to various procedures for driving out devils, such as prayers to the Almighty God, the exposure of the sufferer to holy relics, and the laying-on of hands by a member of the Church. Medicine reverted to a form of healing which was in vogue a thousand years before Christ.

A Great Awakening

From the fifteenth century onwards there was a great awakening of the scientific spirit and improvement in the methods of treatment in comparison with those of the earlier ages, though it must be confessed that medical practice remained in a shocking state of ignorance for a very long period and only gradually approached the Hippocratic standard.

Throughout this period methods of healing by suggestion or by divine intervention continued. In addition to the healing methods already described, succeeding centuries saw the advent of newer methods of suggestion such as mesmerism, hypnotism, couéism, Christian Science, and so on, all

of which contributed in some degree to our knowledge of the effect of the mind on the body, and have led to a more scientific approach by the methods of Freud, Jung, Adler, and our modern psychologists and psychiatrists.

This brief outline of medical thought over the ages has clearly shown the close association of medicine, magic, and religion throughout, and, though the conception that disease is due to natural causes has gradually matured, man has never lost his belief that there is something beyond human knowledge which may either cause disease or cure it. We have seen the application of these beliefs in the temple treatment in Ancient Egypt, in Greece and Rome; in the exorcism of devils; in healing by anointing and by the laying-on of hands; in healing by animal magnetism and mesmerism; in healing by visits to holy shrines or exposure to holy relics; in healing by Christian Science, by psychotherapy, and by prayer and intercession by ministers of religion. It may be that all the people have been wrong all the time, but that would be an unsafe assumption on which to formulate a policy of investigation.

All of these forms of healing have been shown to be of service in combating disease, and there is no doubt that they are effective in certain cases. It is of interest, therefore, to consider how these beneficial results are produced; whether there is some common factor operative in all of them, and, if so, whether it can be defined in the light of the knowledge which we possess. In considering this problem I do not intend to enter the arena of metaphysics or discuss the possible intervention of a divine power, but to confine myself to the question whether these results are associated with definite physical phenomena in the body.

Modern "Miracles"

First, with regard to magic and miracles we should remember that many things which are accepted as commonplace to-day would have been considered miraculous not so many years ago; of these, radio and television are outstanding examples. But, apart altogether from the apparent miracles due to the application of physical science, there are many methods of medical treatment in common use to-day which produce results that would have appeared miraculous 100 years ago. For instance, when the first cretin was given thyroid gland, when quinine was first used in malaria, or when the first patient received a dose of opium, the results appeared to be miraculous then. Not so long ago myasthenia gravis was considered to be an incurable disease with permanent muscular dysfunction. A dose of neostigmine, however, causes immediate recovery of muscular power; when a sufferer from severe asthma receives an injection of adrenaline immediate recovery may occur; when cortisone was first used on arthritic cases it appeared to give immediate relief in those permanently crippled.

These cures, temporary though they may be, are quite as impressive as some of the early miracles of healing. The control of bacterial activity by penicillin and other antibiotics, and the almost immediate relief from suffering by their use, have all the appearance of magic or the exorcism of devils, the devils in this case being infective bacteria. It is to be noted that in the exorcism of devils the operator was enjoined to keep his mouth shut on account of the ease with which the demon might make an entry into his body. This is reminiscent of the modern practice of wearing a mask to keep the bacteriological demons in or out as the case may be.

The modern miracle whereby persons suffering from certain diseases of the mind are treated by shock therapy is reminiscent of the old practice of exorcism, for whether the demon is forced out by certain rites, whether it is let out as it was in ancient days by trephining a hole in the skull, or whether it is driven out by the passage of an electric current through the brain seems to me to make very little difference so far as science is concerned. In each case something is done of the nature of which we know little, and something happens of the nature of which we know less, and a "cure" results—temporary, perhaps, but a cure.

Much more could be said about these matters, but I hope to have made the point that a miracle at one period of time may be a normal method of treatment at another, depending upon the knowledge available at the particular time.

Before dealing with the method of action of the various forms of so-called faith healing or healing by suggestion, let us consider on what health and disease depend. The answer must be that health depends on the accurate, harmonious, and constant co-ordination of an enormous number of factors in the human organism, some of which we have cognizance of, such as the endocrine balance, the electrolytic balance, the correct proportion of metallic elements, the proper balance of protein and non-protein constituents of the tissues and fluids of the body, the control of the body temperature, blood glucose and oxygen levels, and hydrogen-ion concentration, and on the efficient removal of waste products of metabolism. We have little precise knowledge of how the accurate balance of all these substances is maintained, but we do know that derangement of whatever nature may throw out of harmony the whole system and cause ill-health.

This may be the result of definite physical causes, as by deprivation of essential substances, by traumata, or by infection, but, what is more important for our present discussion, it may be a result of mental processes.

Body-Mind Relationship

That definite physical phenomena can be caused by mental processes or emotion is well known. For example, anger may cause the blood pressure to rise; fear may cause it to fall; pity may produce the secretion of tears; excitement may produce insensibility to pain, terror temporary paralysis; fear may cause increased secretion of urine, increased peristalsis, and increased sweating. These physical phenomena are all produced by emotion and may be observed in the absence of any external stimulus.

The state of the mind, therefore, may alter the body functions, and if health depends on their continuous harmonious relationship anything which disturbs that harmony may cause ill-health, whether the disturbance arises from known physical or mental causes or otherwise.

That being so, any form of treatment which might lead to the restoration of harmony is apt to have a beneficial effect. It may be that this adjustment can be effected by everyday medical or surgical treatment, directed towards a definite physical cause. It may be that physical manifestations produced as a result of some troubled state of the mind may be successfully treated only by restoring harmony to the mind.

Here, then, may be the explanation of the effects common to the various procedures, religious, magical, psychological, etc., which we have been considering. All of them are directed towards the restoration of the harmonious relationship in the functions of the body through the removal of some source of disharmony in the mind. This may result from so-called psychotherapy, but it may also be the result of prayer or of faith in a divine power or in the doctor, or in the drug that is used, or, in fact, in any of the procedures that we have been discussing. We have all seen the improved physical condition of patients which sometimes results at once from the visit of the doctor—an improvement in the general condition which is often accentuated when an examination of the body takes place by "the laying on of hands," and most of us, I have no doubt, have witnessed the beneficial effect of prayer. By whatever means the effect may be induced, the troubled mind seems to be calmed and harmony restored. We have been accustomed to think and talk of "psychogenic conditions" and certain diseases of an organic nature which have been described as "psychosomatic" in origin, but I want to suggest the possibility that disturbance of harmony in the body-mind relationship may be a contributory factor in producing ill-health of any kind, and that the terms psychogenic and psychosomatic are simply convenient labels for the

moment; for if worry may cause a peptic ulcer to occur it may equally well lead to the breakdown of resistance to tubercle or other pathogenic organism, and cause a general upset or a so-called nervous breakdown.

We should picture mind and body working continuously together and mutually dependent, so that any slight alteration in the rhythm of the one is at once reflected in the activity of the other. We see health as the normal outcome of this harmonious relationship and disease as the result of disharmony. It is unlikely that we shall be able to observe an early fault in this relationship until we evolve new methods of investigation, and it is to my mind certain that in such early perception lies the root of preventive medicine. By the time that we can observe signs of what we call disease the tissues have undoubtedly sustained physical damage, which may have reached the stage when restoration of harmonious relations may be a matter of difficulty or even of impossibility.

It seems to me, therefore, that much of the future in medicine lies in obtaining better knowledge of the relationship of the mind and body in the maintenance of health. We must know more about the way the balance of various substances is maintained, to what extent the mind affects the control of the bodily secretions, whether there is in fact any recognizable physical change produced by different mental or emotional states, and whether any physical or measurable effect can be produced by prayer or other forms of healing here discussed. If any deviation from the normal can be recognized early enough, we must ascertain how an adjustment can be made before physical damage occurs. In short, it seems to be essential to study these matters and conduct our researches as we have done in connexion with physical sciences.

Conclusion

We have seen, within the last decade or so, such advances in our knowledge of the structure of matter and the relationship of matter to energy that the borderline between living and non-living substances has almost disappeared, and we can expect at no remote period to hear that living matter has been produced in our laboratories. During that period we have seen something of the intricacy and interrelationships of the sex hormones in connexion with growth, of the number and complexity of the enzyme systems essential to the life of the cell, and of the importance of the endocrines individually and in relation to one another. The development of radioactive isotopes has given us further insight into the role of various elements, including the highly important trace elements, in cellular activity, and into the localization of injury within the cell from biochemical action.

Notwithstanding all this, we are still only at the periphery of knowledge of living processes, and so far as the mind is concerned and its relationship to the rhythm of bodily processes we are almost as much in the dark as our predecessors of the time of Empedocles, Hippocrates, Plato, Aristotle, and others who nevertheless saw its importance. Let us not fall into the error, however, of thinking that because a thing is unknown it is unknowable, but remember that as the miracles of yesterday are the common practices of to-day, so the mysteries of to-day may be the commonplace of to-morrow.

To attempt to unravel the relationships of body and mind in man is a formidable undertaking, but it must be undertaken, and if we could obtain insight into this relationship we should not only see the road towards the maintenance of health but also obtain light in matters which at present are quite obscure.

I have pleasure in acknowledging help in the preparation of this paper from Mr. Gilbert Watson, formerly of the Scottish Education Department; from Dr. Fidds of my own department; and from various publications, including Sigerist's *History of Medicine*, Guthrie's *History of Medicine*, Haggard's *Devils, Drugs, and Doctors*, Frazer's *Golden Bough*, various books in the Legacy series and of Professor Charles Singer.

THE ROLE OF THE ADRENAL CORTEX IN FLUID AND ELECTROLYTE METABOLISM*

BY

F. T. G. PRUNTY, M.D., F.R.C.P.

With the Collaboration of H. E. M. KAY, M.D., M.R.C.P.,
G. de J. LEE, M.D., M.R.C.P., and R. R. McSWINEY,
M.B., B.S.(From the Department of Chemical Pathology, St. Thomas's
Hospital Medical School, London)

It is apparent that in analysing the effects of the adrenal hormones on the water and electrolyte balance it is necessary to consider each separately. It is the interplay of these two factors which ultimately controls the long-term water-balance of the individual. The aspect of the problem which has received most study is the

cortone is to increase sodium and chloride reabsorption, since low serum sodium levels are rapidly elevated and excretion of these ions is decreased. Whether there is a direct effect on water reabsorption or whether this is secondary to the electrolyte change is uncertain. The work of Verné shows that under normal conditions the posterior pituitary is a rapid reactor to water losses and seems to be stimulated by hypertonicity of the plasma. In Addison's disease the plasma becomes hypotonic, and this would seem to act as a bar to the stimulation of the posterior pituitary and correction of its decreased volume.

That cortisone has a specific effect on water reabsorption, unaffected by treatment with deoxycortone, is shown by the restoration of normal diuresis to water load after the administration of 100 mg. of cortisone daily. It will be seen from the lower part of Fig. 1 that in D previous administration of 100 mg. of cortisone intramuscularly daily restored a normal diuresis in the second hour after a water load given at the arrow. The presence of an 800-mg. deoxycortone acetate (D.C.A.) implant did not modify the abnormal pattern after water-loading seen in C and E. During the diuresis in D no increase of sodium excretion occurred, and there was therefore a fall in the urine concentration of this substance. In the upper part of Fig. 1, B shows that a dosage of 20 mg. of cortisone was insufficient to restore the diuretic effect in this instance. Fig. 2 shows the same effect of cortisone in a patient with hypopituitarism who was given 1,100 ml. of water at the time indicated at the arrows. The figure also shows the tendency to reduce the volume of urine excreted during the night.

Similar observations have been made by several other workers, and under the correct conditions A.C.T.H. (commercial samples of which contain appreciable amounts of "pituirrin") has been shown to have the same effect as cortisone in patients with hypopituitarism. It therefore seems as though the effect of cortisone in these experiments is a direct one on the reabsorption of water by the distal renal tubules. However, in spite of this there is a body of evidence

FIG. 2.—Kepler tests applied in a woman aged 30 with hypopituitarism, before and after cortisone treatment.

FIG. 1.—Kepler tests applied in a woman with Addison's disease, before and after cortisone treatment. N represents urine passed between 10 p.m. and 8 a.m. At the arrow the water load was given, and 1, 2, 3, and 4 represent hourly collections of urine. The figures in quotation marks above each test represent the Kepler "factor."

renal response to these hormones, but it is now becoming clear that they may cause considerable internal transference of fluid within the body itself, and this phenomenon demands increased attention.

Water Excretion and Hydration

A patient with Addison's disease is unable to respond in a normal way to the withholding and administration of water, the basis of the "Kepler water test" for the diagnosis of this condition. Maintenance of the patient in normal hydration with deoxycortone does not rectify this abnormality. The fact that deoxycortone returns sodium and chloride losses in this disease to normal and clinically maintains hydration demonstrates that over a period of time extracellular fluid volume and composition are favourably controlled. It may be argued that an early effect of deoxy-

*Presented at the Second International Congress of Internal Medicine on September 16, 1952.

to suggest that endogenous antidiuretic activity may be increased in adrenal deficiency states, both in the experimental animal and in the human, as first suggested in the hypothesis of Corey *et al.* (1939). Gaunt (1951), using rats, and Lloyd (1952), supported by Slessor (1951) with human subjects, agree that in adrenal cortical insufficiency there is excess antidiuretic "hormone" (A.D.H.) in the blood. It has been found that "pitressin" causes retention of water but not loss of sodium in man. Hence the presence of such a substance would not account for all the findings in Addison's disease, even allowing for the fact that it would inhibit normal diuresis. Water retention by A.D.H. without comparable sodium retention would be expected to lead to a hypotonic plasma and a condition of water intoxication with cellular hydration. Study of bilaterally adrenalectomized patients by Pearson *et al.* (1952) suggests that this in fact is the case. However, more remains to be known of the effects of the medullary hormones in this regard.

The position concerning the possible increase of an A.D.H. is confused. The action of pitressin in the experiments of Chalmers and Lewis (1951) was uninfluenced by cortisone in Addison's disease, suggesting that deficiency of adrenal hormone is not responsible for the suggested decreased destruction of A.D.H. or increased renal tubular sensitivity to it. This leaves open the unlikely hypothesis that if in adrenal insufficiency posterior pituitary A.D.H. is increased there is an alteration of the response of the osmoreceptors in the face of hypotonicity. Nearly all the reported experiments on the increase of A.D.H. in adrenal insufficiency depend upon the assay technique of Birnie *et al.* (1949), using intraperitoneal injection, a method of administration criticized on the grounds of lack of specificity at a recent symposium of the Society for Endocrinology on "The Posterior Pituitary." Pending further elucidation of the problem of A.D.H. it is wisest to regard the effect of cortisone on the promotion of normal water-handling in Addison's disease as a direct one in restoring flexibility of distal tubular water reabsorption.

Effects on Sodium and Chloride Excretion

The injection of A.C.T.H. for periods of days produces now-well-recognized effects, but these are at present unpredictable in a given individual. There can, for example, be

FIG. 3.—Effect of continued A.C.T.H. injections (25 mg. six-hourly) on sodium retention in a man aged 39 with rheumatoid arthritis.

long-continued sodium and water retention with oedema formation, even requiring careful "unephral" (formerly "neptal") administration. This is largely avoidable by employment of low sodium diets. Fig. 3 is an example of this type of response. The balance data for sodium are plotted so that intake is measured downwards from the horizontal zero line and urine excretion upwards from the base. It

can be seen that between days 12 and 32 sodium retention continued to take place, as only on three days did excretion exceed intake. The rise in weight is largely accounted for by fluid retention. Plasma volume and extracellular fluid volume, as indicated by the inulin space, are seen to be increased. After reduction of dosage of the hormone,

FIG. 4.—Effect of A.C.T.H. (given intramuscularly in divided dosage six-hourly) and cortisone (given intramuscularly once daily) on sodium retention in a woman aged 64 with rheumatoid arthritis.

diuresis occurred, particularly of sodium. At the other extreme, in other individuals, sodium retention may be transitory, but even here sodium concentration in the serum has been observed to rise significantly.

Many cases seem to show an intermediate type of response. Excretion of sodium with water loss may occur, either during A.C.T.H. administration or perhaps to a greater extent after withdrawal. It has been suggested that the sodium and water loss may be due to a sudden relative adrenal cortical insufficiency after withdrawal of the hormone. The fact that sodium loss occurs during A.C.T.H. administration or during cortisone administration started at the time of stopping A.C.T.H. is against this being the only cause. Fig. 4 shows the loss of sodium and water which can occur under these conditions. Intramuscular cortisone after the end of A.C.T.H. therapy permitted continued losses. It will also be noted that on a free fluid intake this patient's intake of fluid, and urine volume, both increased towards the end of the period of observation. The presence of pituitrin in the commercial preparation of A.C.T.H. available for study renders difficult the interpretation of findings of water retention and weight gain with oedema formation so frequently observed.

Experiments using more highly purified preparations of A.C.T.H.—pepsin digest (Luft *et al.*, 1949); the oxycellulose preparation of Astwood (Renold *et al.*, 1952)—indicate that these substances have similar properties to those of the cruder protein preparations in this respect. In addition, Sprague's (Sprague *et al.*, 1951) observation with cortisone in rheumatoid arthritis has shown that this adrenal cortical steroid is capable of reproducing the same effects as A.C.T.H., and it has been shown by Fourman *et al.* (1950), too, that in experiments of three days' duration hydro-

retaining properties. Fig. 5 summarizes the classical sequence of events with regard to sodium and water retention with these hormones, showing three phases: (a) active retention, (b) the reversal of this process, and (c) a diuresis after

FIG. 5.—Effect of A.C.T.H. and adrenal cortical hormones on sodium and water excretion.

hormone withdrawal with loss of sodium, often so great as to cause the net sodium losses to exceed the initial gain. In a recent report of cases of dermatomyositis (Prunty, 1952) the tendency for A.C.T.H. and cortisone to cause diuresis in the presence of oedema was clinically valuable, and many diuretic responses are now on record in cases of subacute nephritis. We, and others, have found that not only do these substances cause increased reabsorption of sodium by the kidney, but they also cause reduction of the volume and sodium content of induced sweat, and reduction of the amount of sodium rejected in the faeces.

The ability of cortisone and hydrocortisone to cause retention of water and sodium and potassium loss in a similar way to A.C.T.H. and deoxycortone has led to the formulation of the view that a single adrenal cortical hormone (hydrocortisone) would account for all the phenomena of increased adrenal cortical activity. We have carried out balance studies in an Addisonian (Fig. 6) with D.C.A. and cortisone acetate. When entirely depleted of D.C.A. this patient's response to the intramuscular injection of 2.5 mg. of D.C.A. was compared with that of 100 mg. of oral cortisone daily. Each substance was given alone and two periods of D.C.A. administration were employed. It will be seen that during the first six days and during the 17th to 22nd day, when the patient received D.C.A. alone, she was in positive sodium balance. During the 7th to the 16th days, whilst receiving cortisone only, the sodium balance became very definitely negative. Both urine volume and fluid in-

FIG. 6.—Effect of deoxycortone or cortisone on sodium balance in a woman aged 50 with Addison's disease.

take increased and serum sodium rose during this period. She lost 2 kg. in weight. These results are in agreement with those of Sprague *et al.* (1951) under similar conditions, but using intramuscular injection of the hormone.

If it can be assumed that comparable biological doses of these substances were used there is a striking difference in their effects in these circumstances. In the absence of endogenous adrenal cortical activity (Addison's disease) D.C.A. overdosage with salt has so far been found to cause sustained sodium retention and oedema, and death from cardiac failure. In patients with intact adrenals its behaviour is more like that of cortisone, sustained dosage being accompanied by spontaneous diuresis of retained water and sodium (Luft and Sjögren, 1952). On the other hand, totally adrenalectomized patients have been kept in good condition by the use of cortisone alone by Pearson *et al.* (1952) and others. These facts are conflicting when one is considering the problem of whether there exists a natural adrenal cortical hormone of special potency in electrolyte metabolism. Ingle has again emphasized (Ingle *et al.*, 1952) that cortisone and hydrocortisone will not quantitatively account for the biological potency of natural products in his "work test," and he once more reminds us of the active material present in Kendall's amorphous fraction. Simpson *et al.* (1952) have also presented convincing evidence of the multiplicity of secretion by the separation of natural material from the adrenal blood of the monkey and dog with quantitatively far greater electrolyte effects than those of cortisone. These experiments give new impetus to the problem of the number of biologically active adrenal cortical secretions in man.

Internal Transference of Fluid and Electrolyte

It has been shown that the rapid increase of weight of patients treated with A.C.T.H., together with measurements of fluid balance, indicates that water is retained along with sodium and chloride and oedema may become a problem. However, clinically, oedema has been noticed both by us and by Soffer *et al.* (1951) to occur in the absence of obvious fluid retention, suggesting internal transference of fluid in the body from cells to extracellular fluid. It will be recalled that increases of extracellular fluid are indicated by measurement of inulin space, and plasma volume may rise to a lesser extent. Study of daily weight changes compared with calculated changes of extracellular fluid volume from chloride balances has suggested confirmation of the view that fluid shifts occur outwards from the tissues.

Fig. 7 shows the data obtained from a patient with rheumatoid arthritis. The data on the top line show the effect of A.C.T.H. on the extracellular fluid volume calculated from chloride balances. The hatched blocks represent changes in extracellular fluid volume occurring during each period, blocks above the line representing an increase, those below the line a decrease. In the same way the second line shows the weight changes from period to period, which can be taken as a fair measure of fluid retention or loss over a relatively short time period. The bottom line shows the volume changes superimposed on the weight changes. In periods 2 and 3, the volume increase far exceeds the weight increase, whilst in period 6, during diuresis, the reverse occurs. This would seem to indicate expansion of extracellular fluid, as we have previously found by this technique (Prunty *et al.*, 1948). However, recent work indicating the presence of large quantities of chloride in the tissues would seem to question the validity of this line of approach, which necessitates the assumption that significant amounts of chloride are not transferred to the tissues.

In spite of this, measurement of the extracellular space with inulin in patients on low sodium intakes receiving cortisone or A.C.T.H. has revealed in the hands of Levitt and Bader (1951) considerable increase in its volume. In this instance chloride apparently was supplied from the tissues. Potassium depletion occurring at the initiation of these changes is also indicative of tissue losses of this sub-

stance, probably associated in part with loss of tissue water, and reminds us of the need in some patients for the increased administration of this substance. Only recently have extensive studies begun to reveal the effects on renal

FIG. 7.—Effect of A.C.T.H. on fluid shifts within the body of a woman aged 56 with rheumatoid arthritis (see text).

excretion of water and electrolytes in response to expansion of extracellular fluid volume—a basic requirement in evaluating the response to cortical hormones. These observations have also stressed the importance of posture and of diurnal variation in the responses obtained. Increase in extracellular fluid volume seems to limit the water- and electrolyte-retaining properties of the adrenal hormones in the normal individual, the concentration of sodium in the fluid being a matter of secondary importance.

FIG. 8.—Working concept of effects of adrenal cortical hormones on water and electrolyte metabolism (see text).

Fig. 8 indicates a working hypothesis for the effects of these hormones, indicating how extracellular fluid volume expansion occurs, with resulting tendency to increase in water exchange and even diuresis. On the left, adrenal cortical hormone is seen to cause initial sodium and water retention. At the same time water is transferred from the

tissues to the extracellular fluid, the sodium concentration of which is often found to rise. The tissue water loss seems to account for some of the urinary losses of potassium, and, in addition, the serum level of this substance falls. With extracellular fluid thus expanded, water intake and excretion show a tendency to rise. After the action of the hormone ceases there is a large diuresis of water and sodium from the expanded extracellular fluid. This diagram admittedly glosses over many gaps in our knowledge, which we hope will be better explained after future research.

Summary

The problem of how the adrenal cortex affects abnormalities of renal handling of water and electrolytes has been examined. Primary and secondary adrenal cortical insufficiency leads to impairment of normal diuresis, and this may be corrected with cortisone and, in the case of the latter, with A.C.T.H. It is uncertain how far antidiuretic activity in the serum of these patients may be a factor in this abnormality.

Sodium and chloride retention is induced by cortisone and A.C.T.H., but may not persist as long as the hormone is administered. Under certain conditions diuresis may occur with increased excretion of these ions.

Further data on the effect of cortisone on sodium retention in Addison's disease again raise the question of the secretion of a "salt hormone" by the adrenal cortex.

It is pointed out how internal shifts of fluid from the cells occur with administration of these substances, and the difficulty of integrating all the effects observed is discussed.

Reports of initial victories made in the fight against yaws were made at a recent conference at Bangkok organized by the World Health Organization in collaboration with the Government of Thailand. Yaws is prevalent in humid tropical climates, and particularly common among undernourished people living in overpopulated areas. Doctors trying to combat its spread must break down a barrier of popular local superstition. Results so far obtained indicate that one, or at most two or three, intramuscular injections of a repository penicillin are sufficient to ensure a definite cure. Up to the end of 1952 nearly eight million people had been examined in Haiti, Indonesia, Thailand, and the Philippines, of whom some three million (mostly in Haiti) were found to be affected and have been treated. The individual figures are: Haiti, 2,270,051 examined and 2,270,051 treated; Indonesia, 3,529,831 examined and 553,587 treated; Thailand, 1,679,342 examined and 216,047 treated; and Philippines 415,000 examined and 24,000 treated. It is calculated that the cost of treatment given, including expenditure on staff and equipment, amounts to less than three dollars per head.

BENIGN FORM OF ACUTE OSTEITIS OF
THE SPINE IN YOUNG CHILDREN

BY

A. E. BREMNER, F.R.C.S.Ed.

Associate Orthopaedic Surgeon, Royal Victoria Infirmary,
Newcastle-upon-Tyne

AND

G. A. NELIGAN, M.R.C.P.

Lecturer, Department of Child Health, University of
Durham

During the year ending April, 1951, we had under our care seven young children suffering from what we believe to have been a low-grade pyogenic osteitis of the lumbar spine. The strikingly uniform clinical picture observed in these children does not seem to have been satisfactorily described, and we think it worth while to record our experience of it.

The children were aged between 9 months and 2½ years at the onset of the illness, which seems to be insidious

and undramatic. The parents did consult the family doctor within the first few days in all cases, but most of them were not unduly worried by the delay of up to four weeks which occurred before the children were referred for a second opinion. There was in most cases a further delay before admission to hospital. That this was due to the very misleading impression which the parents and children may give during an out-patient consultation and examination is apparent from Table I. The children were initially seen by five different consultants.

TABLE I.—Summary of Out-patient Experience

Case No.	Age on Admission	Duration at First Visit	Initial Diagnosis by Consultant	Duration on Admission
1	Yrs. Mths.	2 weeks	Pott's spine	3 weeks
2	2 2	4 "	Painful limp	4 "
3	1 7	4 "	? Encephalitis	6 "
4	2 4	2 "	Abdominal pain	2 "
5	1 1	1 week	? Hip lesion	5 "
6	1 5	3 weeks	? Urinary infection	10 "
7	1 11	4 "	Limp? Sacro-iliac joint	3 "
	1 7	½ week		

On admission to hospital, however, with the opportunity for more leisurely and detailed history-taking and examination, these seven children presented a strikingly uniform clinical picture. The constant outlines of the picture of spinal disease were only slightly blurred by variation in the severity of the symptoms. In four cases there was superimposed upon it a "hip syndrome" (limp, with some limitation of movement). Though at first this was misleading, we later came to regard it as reassuring evidence that the spinal lesion was likely to be pyogenic rather than tuberculous.

At the onset in all cases the symptoms of a mild or moderate febrile illness and those of a spinal lesion appeared within a few days of each other. Irritability, loss of appetite, and feverishness had been noticed in most of the cases; and a previously active child would develop a stiff back and begin to have spasms of pain and later object to sitting or walking, or even to being handled (though he might remain surprisingly active for some weeks in any posture which avoided flexion of the spine). These symptoms usually increased in severity very gradually for up to five to six weeks and then became stationary or began to improve. The four children with the "hip syndrome" were noted to have a well-marked limp at the onset or within the first two weeks of illness; and in three of them these symptoms had cleared up by the time of admission to hospital.

On examination the children were very mildly or at most moderately ill. There was evidence of weight loss in six of them. Case 7 was apyrexial throughout his hospital stay of 10 days; the rest had temperatures

ranging up to 103° F. (39.4° C.). All objected strongly to sitting up; two were still prepared to crawl on all fours or even to stand with support. On the whole they preferred to lie prone in their cots, when they would appear comfortable and play with their toys, though very liable to an occasional interruption by a bout of pain, apparently produced by movement. The lumbar spine was held fixed in slight lordosis by spasm of the paravertebral muscles, and we noted that attempts to flex the spine passively were more strongly resisted than was hyperextension. There was no neck stiffness. Only Case 4 had tenderness of the spinous processes of the affected vertebrae.

X-ray films of the lumbar spine showed narrowing of a disk space, with erosion of the adjacent margin of the body of either or both the vertebrae bounding it, as seen in the lateral view (see Fig. 1). These changes were evident at the time of admission in six cases, but not definite until two weeks later in Case 4. In Case 3

there was also a posterior displacement of the upper of the two affected vertebrae. In Cases 5 and 6 the antero-posterior view showed an angular scoliosis at the level of the lesion (see Fig. 5). In every case the Mantoux test was negative to a dilution of 1/100. The Wassermann reaction and agglutination tests against the *Salmonella* group and *Brucella abortus* were also negative.

All the children were treated by rest in a plaster bed (six of them being sent home in their beds

and kept under observation as out-patients). Case 4 received penicillin in addition. They were allowed up again, without any restriction in their activity, after periods ranging between 7 and 22 weeks from the onset. They have subsequently been followed for between 4 and 16 months, and all remain well.

Brief case histories of four of the cases give an idea of the range of variation in detail within the uniform general outline of the clinical picture.

Case 1

A girl aged 2 years and 2 months was admitted with her mother on March 21, 1950, with a provisional diagnosis of Pott's disease. Three weeks previously she had refused to get out of her cot one morning: her back seemed very stiff and remained so up till the time of admission, particularly when walking or picking things up off the floor. She would cry out as if in pain at times, and began to wake crying during the night. She remained fairly cheerful, and her appetite was very little impaired. X-ray examination in the out-patient department a week before admission had shown narrowing of the disk space between the fourth and fifth lumbar vertebrae with some erosion of the adjacent margins of these two vertebral bodies. Her temperature on

admission was 99.8° F. (37.7° C.). She was not obviously ill, but there was evidence of some weight loss. She was quite active and would even walk with support, but objected to sitting. Her lumbar spine was held fixed in slight lordosis, with marked spasm of the paravertebral muscles; no localized tenderness was found. She was sent home in a plaster bed to be nursed by her mother, and was not allowed out of her plaster bed until 22 weeks from the onset. Sixteen months later her back was still clinically normal.

Comment.—This case was the mildest in our series in respect of both local disability and constitutional disturbance. The patient was immobilized for a much longer period than we now consider necessary; she was the first case we saw and we were not familiar with the course of the disease with which we were dealing.

Case 4

A girl aged 1 year and 1 month was admitted with her mother on October 11, 1950; the provisional diagnosis was perinephric abscess. Her father was suffering from an attack of boils when, three and a half weeks before admission, the child had a number of screaming attacks one day and appeared to be in pain. These attacks recurred with diminishing frequency for several days, lasting up to two hours at a time; and she then became quite well again for four days. Two weeks before admission she began to get attacks of pain again; she cried if sat on her pot, and in her high chair would shuffle her bottom forward till she was nearly lying on her left side. She would no longer attempt to walk. At the same time she became feverish, and ate less than usual. She got steadily worse, and by the time of admission the parents had learnt to leave her lying in her cot, not daring to pick her up even to try to comfort her. She had eaten nothing at all for the previous four days.

On examination she was seen to be moderately ill. Her temperature was 103° F. (39.4° C.); there was no evidence of weight loss. She lay on her back comfortably, but her lumbar spine was held stiff and there was well-marked tenderness of the spinous processes of the fifth lumbar and first sacral vertebrae. The spleen was enlarged to ½ in. (1.3 cm.) beyond the costal margin. A scanty growth of haemolytic streptococcus and *Staphylococcus aureus* was obtained from her throat swab. X-ray films at that time were only suspicious, but two weeks later definite changes had developed in the fifth lumbar vertebra with narrowing of the disk space below it. The contact history, the degree of constitutional disturbance, and the splenomegaly all seemed indications for penicillin therapy: she received 50,000 units intramuscularly every three hours for three weeks. She was put into a plaster bed during her stay in hospital, and was sent home on October 31, by which time all tenderness had disappeared. She was allowed out of her plaster bed seven weeks from the onset of the progressive symptoms of spinal disease, and remained clinically well a year later.

Comment.—This child was the most severely ill in our series, and was the only one treated with penicillin. Her temperature became normal after one week's treatment, which is the expected course in severe osteitis of long bones responding to antibiotic therapy. It was impossible to be sure whether the drug affected the course of the disease, but it is noteworthy that the period from onset to resumption of unrestricted activity was shorter in this case than in any other.

Case 2

A boy aged 1 year and 7 months was admitted with his mother on May 31, 1950, for investigation of a painful limp. The mother had developed tuberculosis five years previously and her artificial pneumothorax had been let out ten months before we saw her. Four weeks before admission the boy had begun to limp on the left leg, and held his back stiff with his tummy sticking forward when

FIG. 1

FIG. 2

FIG. 3

FIG. 4

FIGS. 1, 2, 3, and 4.—A case of benign acute osteitis of fifth lumbar and first sacral vertebrae; patient aged 1 year and 7 months. X-ray films at 4 weeks, 13 weeks, 26 weeks, and 1½ years after the onset, showing early appearance of recalcification (at 13 weeks) and later sclerosis, with some bridging of the disk space posteriorly.

walking. During the second week he refused to walk, but crawled actively on all fours; he also refused to sit properly in his high chair, shuffling forward until he was half-lying on his right buttock. His appetite became poor; he was very miserable, and often woke up crying through the night. During the third week his general condition deteriorated further: he refused to eat anything at all, and was losing weight. By the fourth week he would no longer crawl; he refused to go into his high chair at all, and took his drinks lying in his cot. He was obviously feverish.

Examination was made difficult by his terror of being handled, and had to be completed under light sedation. He was moderately ill, with a fever of 100° F. (37.8° C.) rising to 102° F. (38.9° C.), and evident loss of weight. The left hip was held in 45 degrees flexion; extension and both rotations were resisted towards the limits of the normal range, but flexion was full. His lumbar spine was held stiff by spasm, and if he was sat up the lordosis became exaggerated: he preferred to lie prone with his head supported by his arms. No tenderness was found. An x-ray film showed the typical lesion involving the fifth lumbar and first sacral vertebral bodies; the appearances in the hip were normal. He was sent home in a plaster bed to be nursed by his mother (in whom we had found no evidence of active tuberculosis). He was allowed up again seventeen weeks from the onset. His back was still clinically normal fourteen months later.

Comment.—This was the only case in which the symptoms and signs of the "hip syndrome" were still present on admission. We were then unfamiliar with it, and strongly suspected two lesions (probably tuberculous in view of the mother's history). The hip signs cleared up in under a week, and relieved our minds on that score; the likelihood that the spinal lesion was tuberculous was excluded by the negative Mantoux test and by the subsequent course of the x-ray changes. We were again overcautious about releasing from immobilization this case of what was still an unfamiliar disease at that time.

Case 5

A boy aged 1 year and 5 months was admitted with his mother on November 15, 1950. The final choice of diagnosis in the out-patient department lay between osteitis of the spine and urinary infection. Five weeks previously he had fallen off a step 6 in. (15 cm.) high, appeared to have hurt his back, and refused to walk for two days, crying bitterly and frequently. He then improved for a week, but walked with a marked limp and undue prominence of the right hip. His back seemed stiff and abnormally arched. After this first week he deteriorated steadily again. He preferred crawling to walking. By the time of admission he virtually refused even to stand, and completely refused to sit on his pot, so that he passed water infrequently, and only when lying down. During the third week after the injury his appetite began to fail and he appeared to be losing weight. He also began to have screaming attacks lasting five minutes or so, during which he would clutch his right leg, but his mother could not be sure where the pain was.

On examination he was only slightly ill; his temperature was 99.4° F. (37.4° C.), and there was evidence of weight loss. He could lie flat in any position and crawled fairly freely on all fours, but resented attempts to make him sit or stand. His lumbar spine was held fixed in slight lordosis; no deformity or tenderness was detected. X-ray films showed the typical lesion at the level of the fourth and fifth lumbar vertebrae, but with minimal bone involvement as yet. He was left free in his cot for two weeks, and began to stand and even to sit spontaneously, and was eating better. But he developed an angular scoliosis, convex to the right, at the level of the lesion. This was obvious clinically and radiologically, and it was decided to put him into a plaster bed, in which he was sent home. He was allowed up again eleven weeks after the initial injury, by

which time the scoliosis was no longer detectable clinically and was much improved radiologically. This improvement was maintained ten months later.

Comment.—This is the only case with a clear history of an injury at the onset. His "hip syndrome," which dominated the picture at first, was no longer evident by the time of admission. He is one of two cases which had an angular scoliosis that was very much improved by a brief period of immobilization in a plaster bed.

Discussion

We are far from certain about the exact pathology of the condition from which these children suffered. But we think, after considering the clinical and radiological evidence, that it is probably the same condition as that form of "osteomyelitis of the spine" which has been variously described as "benign" (Smith, 1933), "gradual" (Butler *et al.*, 1941), and "chronic" (Flemming, 1935; Martin, 1946). A similar form is mentioned in the more general accounts of osteomyelitis of the spine by Wilensky (1929), Kulowski (1936), and Guri (1946). There is no direct evidence about the pathology in these reports, but there is ample direct and indirect bacteriological evidence that the infection of the spine is staphylococcal. Our confidence that the condition they describe is the same as that which we have been seeing is not very great in the case of some of these reports, none of which is concerned with patients in the same age group as ours; but we feel reasonably sure about Guri's (1946) 19 cases "with a gradual onset," since he makes up for lack of clinical details by insistence on the difficulty of distinguishing them from cases of tuberculous spondylitis, and also reproduces some x-ray films which are adequate for purposes of comparison. In four of these cases an abscess developed over the lesion in the spine, and *Staph. aureus* was grown from the pus, while another five cases had a focus of gross staphylococcal infection elsewhere in their bodies. These observations have weighed heavily with us, since in only one of our much younger patients (Case 4) did we find even indirect evidence of staphylococcal infection. Somewhat similar lesions have been described complicating brucellosis and salmonella infections, but all agglutinations were negative in our cases. Having concluded that the infection of the spine is probably staphylococcal, we have also accepted the view (embodied in the titles of the reports quoted above) that the pathology is likely to be a haematogenous infection of bone.

A different view of the pathology is put forward by Saenger (1950) in the most recent report we have seen. His "spondylarthritis in children" is the same condition as we have described: we are in no doubt about that, since he publishes fuller details and more complete series of x-ray films than any previous author. Three of his four cases were in the same age group as ours, and he argues from the admittedly better blood supply of the intervertebral disk in the young child that the infection is more likely to start in the disk itself, with only secondary involvement of the adjacent vertebrae. Yet he describes as "analogous" the condition of "acute infectious lesions of the intervertebral disks" described by Ghormley *et al.* (1940), although the youngest of their 20 cases was 9 years old, and their average age 34 years.

As to the age incidence, only Saenger has reported the condition in toddlers. Indeed, Butler *et al.* state that the sudden and fatal form of the disease occurs "as a rule" in children, and is relatively common; while they regard the form with a gradual onset as rare enough to make it worth while publishing a single case, adding that "this type is most often seen in adults." This would be in surprising contrast to the behaviour of osteitis in other sites. Excluding the neonatal period, we see eight mild cases for every severe one under the age of 3 years, whereas between 3 and 12 years the proportions are almost reversed. The discrepancy as regards age incidence between previous reports and our own experience is probably partly explained

by a freakishly high incidence of the condition in this part of the world during the year in question. But it also seems possible that some of the cases which do occur escape recognition.

That the diagnosis of osteitis of the spine may be difficult in any age group is generally agreed. One would expect the difficulty to be greater when the disease occurs in a benign form in a child who is not old enough to make known the site of his pain. The facts recorded in Table I lend some support to this view. However, little harm would probably be done in most cases by failure to detect the presence of a spinal lesion: the child is likely to make a satisfactory recovery without any treatment other than rest in bed during the active stage of the infection. The chief penalty would be the unnecessary anxiety on the part of relatives and doctors resulting from uncertainty about the cause of the trouble. The more worrying possibility is that some of these cases may be diagnosed and treated as cases of tuberculous spondylitis. This danger was emphasized by Smith: of his 17 cases, with an average age of 29 years, 11 had originally been diagnosed as tuberculous. Kulowski and Guri have been impressed by the same danger. Reference to the case histories of our children makes it clear that the differentiation will usually be impossible on the history and examination alone. However, the presence of the "hip syndrome" noted in four of our cases may lead one to suspect the correct diagnosis, since, so far as we know, it is much less common in cases of tuberculous spondylitis. Two of Saenger's cases presented the same picture; and so did two of Guri's more severe cases. Fortunately, from the patient's point of view, the tuberculin skin test will nearly always be negative in these young children, so that further confusion should be avoided. And, more important still, one can confirm opinions based on this evidence, and avoid unnecessarily prolonged immobilization in cases in which a skin test is positive for reasons not connected with the spinal disease, by observing the course of the x-ray changes.

In the early stages the x-ray films of the pyogenic lesions seem to us indistinguishable from those seen in tuberculous spondylitis of about the same duration. The picture at that stage has already been briefly described and can be seen in Fig. 1. The subsequent course of the destructive changes is very different in the two diseases, however. Recalcification of the eroded portions of the vertebral bodies is already evident within three months of the onset in the pyogenic cases; actual sclerosis soon follows (our findings are set out in Table II and illustrated by Figs. 1-4). The striking contrast between this course and that of tuberculous cases should enable the two conditions to be distinguished with confidence at this stage of the disease.

On the question of treatment there are two different aspects to be considered. Appropriate chemotherapy would seem to be indicated if we assume (as we now do) that the infection is a staphylococcal one. But by the time we reached this conclusion we had seen two cases run a satisfactory course without it, and have subsequently withheld it unless there were clear indications for its use (as in Case 4). Saenger used penicillin in two of his cases, with no more conclusive results than our own. The second aspect concerns the orthopaedic measures to be used. All our cases were immobilized in plaster beds for varying periods (see Table II).

TABLE II

Case No.	Weeks Elapsing from Onset till		
	Immobilization Started	Recalcification Evident in X-ray Films	Immobilization Ended
1	4	7	22
2	6	13	17
3	8	11	11
4	3	7	7
5	8	11	11
6	11	13	17
7	4	10	10

We know of a patient, not treated by us, who has made a good recovery without ever having been immobilized at all: he restricted his own activity by lying in his cot until eleven weeks from the onset, and then gradually resumed normal activity. But in our view the use of a plaster bed during the stage of active infection is justified in most cases by the way in which it relieves the children's anxiety about being handled and contributes to their comfort: in cases with an angular deformity there seems to be a more direct indication for its use (see summary of Case 5, and Fig. 5). But we believe, after our experience with Cases 3, 4, 5, and 7, that it is usually safe to allow unrestricted activity as soon as recalcification is evident on the x-ray film (by which time the spine was clinically normal in all our cases). Cases 1 and 2 were immobilized longer than they need have been for reasons explained. Case 6 was immobilized for an extra month because it took that long for the x-ray appearances of the angular scoliosis to improve. Saenger was much more cautious.

He used casts or braces in his first three cases for periods of seven months, a year, and seven months respectively. His fourth case seems to have been a very unusual one: he was not seen and treated until five months after the onset, and this may possibly explain why he still had to wear a body brace three and a half years later.

The ultimate prognosis for these children is not known. All our cases were still well when last seen at periods ranging from four to sixteen months after resuming unrestricted activity. We have been fortunate enough to obtain details of a case of a patient aged 1 year admitted to the Ashford County Hospital, Middlesex, in 1943, and subsequently followed for a period of five and a half years. He was still clinically normal and tuberculin-negative at that stage of his follow-up, but the grossly abnormal x-ray appearances seen in Fig. 6 had developed in spite of his having been immobilized in a plaster bed for eight months initially. None of our cases has yet shown signs of developing such bizarre radiological appearances, though sclerosis of the affected bone persists in all of them, with probable narrowing of the affected disk space. We have not seen convincing evidence of the "restoration of width" of this space, which Saenger claims for three of his cases, but we find this interesting point difficult to decide. In addition to minor variations in radiographic technique, one has to allow for the relative narrowing of disk spaces in proportion to the height of the vertebral bodies which occurs in the unaffected portions of the spine during the normal course of development at this age. It remains to be seen if any disability occurs in later life, since it appears that a radiological abnormality persists.

Summary

The clinical picture of a benign inflammatory disease of the lumbar spine which we have seen in seven children under the age of 3 years is described. There is circumstantial evidence in previous reports to suggest that the lesion is a staphylococcal osteitis.

FIG. 6.—Ashford case. Aged 1 year on admission. X-ray film taken 5½ years after the onset of benign acute osteitis of second and third lumbar vertebrae, showing gross residual radiological changes in a clinically normal boy.

The clinical picture is strikingly uniform from case to case, and strongly resembles that of tuberculous spondylitis. The distinction may be made by the tuberculin skin test, and is confirmed by the appearance of recalcification in the x-ray films within three months of the onset in the pyogenic cases.

We believe that it is wise to immobilize these children during the active stage of the disease, but that unrestricted activity can safely be allowed as soon as recalcification is evident in the x-ray films.

We are most grateful to Mr. J. A. Cholmeley and Mr. N. M. Matheson for information about the case treated at Ashford in 1943, and for permission to reproduce Fig. 6; also to Dr. Donald Court, who brought the case to our notice. We are also much indebted to Mr. J. K. Stanger for his helpful criticism of this paper.

PATHOGENESIS OF HODGKIN'S DISEASE

BY

M. H. GORDON, C.M.G., D.M., F.R.S.

Consultant Bacteriologist, St. Bartholomew's Hospital

Is Hodgkin's disease caused by the elementary bodies, and its malignancy by the allergy aroused by them? Both of these questions have been raised by the results obtained during the later stages of a combined clinical and pathological study of the aetiology of lymphadenoma. Investigation began when Mrs. T. E. Rose founded the Rose Research on Lymphadenoma in memory of her daughter, who lost her life from the disease, and also because lymphadenoma appeared to be a condition eminently in need of investigation. The fund apportioned for this research consisted of an endowment for a period of 10 years, and it was administered by the medical school and staff of St. Bartholomew's Hospital. An invaluable part was played also by St. Bartholomew's men in practice, who kept a keen look-out for acute cases and forwarded lymph glands removed by biopsy without preservative of any kind, so that if a piece should prove positive on section the rest of the gland could be used for bacteriological examination or animal test.

When the Rose research ended, the investigation was continued for the Medical Research Council, as it formed an important part of the study I was then making of virus infections generally, but mainly of vaccinia, psittacosis, and Shope's fibroma, with a view to applying the information thus obtained when searching for evidence of a virus infection in diseases such as the present one.

Although the most careful research had failed to reveal the presence of micro-organisms of known pathogenic significance in cases of Hodgkin's disease, elementary bodies (E.B.s) were found to be present in large numbers in most of them, particularly when the disease was in the acute

stage. In one of these in which the condition resembled acute tuberculosis—the glands being soft and almost purulent—films of them stained for tubercle bacilli showed no acid-fast organisms, but when the same film was counterstained with Löffler's methylene blue for several hours at 37° C. swarms of E.B.s stained blue were visible when it was mounted in water and examined microscopically. As these E.B.s were similar in morphology to those seen in other virus infections in which they have now been established as the actual *materies morbi*—for example, vaccinia—it was decided to prepare a vaccine of these Hodgkin bodies, and, after its attenuation by heat, to test its effect.

The late Dr. A. E. Gow, then senior physician to the hospital, co-operated in this, and it was found that a patient suffering from lymphadenoma was extremely allergic to even a minute dose of the E.B. suspension; so that attempts to immunize her with it were out of the question. This difficulty, however, was surmounted in the same way that had succeeded in acute cases infected by bacteria—namely, by uniting them with the specific antibodies present in immune serum before injection, and then giving the flocculated antigen a series of washings in saline so as to get rid of the serum. This sensitized E.B. vaccine was given a thorough trial in cases of lymphadenoma by Dr. E. C. Warner, who has reported on the encouraging results obtained in a large proportion of the patients, especially in young adults at an early stage of the disease. The relief, however, was only a temporary one, as lymphadenoma is a form of malignant disease at present.

When these results with the sensitized E.B. vaccine were published *La Presse Médicale*, of Paris, printed a note on the treatment, and the information spread to Chile, where great interest was aroused, as Hodgkin's disease is met with there as also in other parts of South America. Through Dr. Maxwell Chance, physician to the Chilean Legation in London, some of the sensitized E.B. vaccine was sent to Chile and tried there. Further particulars are given in the following brief account.

Photomicrograph of Hodgkin elementary bodies. (×1,250.)
(From the Rose Report on Lymphadenoma, 1932.)

The following Chilean cases were treated by E.B. vaccine in 1937, and the report on them was received through Dr. Chance and translated by him from the Spanish in July, 1937.

Report on Chilean Cases

(Lymphadenoma sensitized vaccine. Specimen used: suspension of E.B.s from patient's gland flocculated with antiserum twice over. Strength of original gland suspension, 1:100,000; sent to Chile by aeroplane by Dr. Maxwell Chance on March 4, 1937.)

Case 1: H.I.O. Antofagasta; 22 Years; Single

A young man came to consult me for glandular swelling of the neck, which had been present for less than seven years. The glands were hard, not attached to the skin; evening temperatures, obstinate itching, night perspiration, pain in the bones. Early symptoms of mediastinal compression. Neutrophil leucocytosis. Biopsy, Hodgkin's disease.

Subcutaneous injections given weekly: 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1.0, 1.1, 1.2, 1.33 ml.

Results.—With the first injection loss of weight and increase of evening temperature up to 38.5° C. were observed. After the fourth injection, disappearance of temperatures, but the other symptoms persisted. After the seventh injection, disappearance of pain in the bones, perspiration, and itching. After the eleventh injection the number of leucocytes was normal, but the neutrophilia remained high. The laboratory made a note that the pathological alterations of the neutrophils had disappeared. After the twelfth injection the symptoms of mediastinal compression, which had already begun to diminish after a few previous injections, disappeared; but with the thirteenth injection a temperature of 40° C. appeared, and lasted three days. As the symptoms had fully regressed, except for the neutrophilia, and as we did not possess sufficient experience about prolonging the treatment, we agreed to suspend it and keep the patient under observation.

Comment.—We would be profoundly grateful to Professor Gordon if he would give us advice about the future of our patient. This surprising result has caused great astonishment at the medical clinic of Professor Pradotag, who offered a vote of thanks to Professor Gordon at a conference given by the undersigned.

(Signed) Dr. R. ALLENDES, M.

Comments by M. H. G.—Dr. Allendes misunderstood my directions, which were *not* to raise the dose if a reaction occurred. He increased it each time, and after the fourth injection, still more after the seventh, the case improved. ? *Desensitization* here to E.B.s the reason.

Case 2: Signor G.K. Santiago; 28 Years

A patient who had suffered from Hodgkin's disease in the last six years. He had more or less prolonged intervals of freedom as the result of three series of radiotherapy.

He consulted the undersigned in October, 1936, who advised a new series of radiotherapy combined with blood transfusion, extracts of liver, and iron for the severe hypochromic anaemia (red cells 1,700,000). Did not obtain success. Advised arsenious acid and symptomatic therapy. Regression of nearly all the objective symptoms was observed, but the unfortunate anaemia, the alterations in the haemoglobin (neutrophil leucocytosis), and the consistent size of the abdominal glands persisted. In April of this year, as the result of a sharp wound with haemorrhage, the anaemia increased—R.B.C. 850,000. At the same time a syndrome of mediastinal compression appeared through increase of the glands in the region, with stubborn diarrhoea, itching, and obstinate perspiration. Fever 39.5° C.

The family refused a thorough course of treatment, but with the repeated suffering of the patient the physician recommended symptomatic therapy for mitigation, and they accepted the use of the Gordon vaccine but rejected other very important measures, such as blood transfusion.

The undersigned recognized that after the seventh injection used in the same dosage as in Case 1 above, the injections being given for five days, symptoms of relief such as diminution of the mediastinal compression, the neutrophilia, the diarrhoea, the itching, and the perspiration had resulted.

Unfortunately, the anaemia, each time more pronounced, caused a series of syncopal attacks with peripheral circulatory failure which terminated with the life of the patient.

(Signed) D. R. ALLENDES, M.

In August, 1937, the Chilean legation applied for more sensitized E.B. vaccine, to be tried under the care of the Minister of Health in Chile, Dr. Edward Cruz Coke, so I sent some to go out in the official bag of the Embassy. Nothing came of it. They wanted more, but I refused because no reports were made.

As I have now retired no further attempts have been made to prepare vaccine of the sensitized E.B.s of Hodgkin's disease. It is, however, interesting to note that, by employing E. W. Goodpasture's method of cultivating viruses in the embryonated egg, confirmatory evidence of the presence of a virus in Hodgkin's disease has been obtained by W. L. Bostick (1948), of the pathological department of the Uni-

versity of California, San Francisco, and also by H. Lundbäck and S. Löfgren (1950), of the State Bacteriological Department and Virus Laboratory at the Caroline Institute, Stockholm.

PUBERTAS PRAECOX CAUSED BY INTERSTITIAL-CELL TUMOUR OF TESTICLE

BY

J. ANAGNOSTOU, M.D.

Professor of Pathological Physiology

AND

G. J. FRANGOPOULOS, M.D.

(From the Laboratory of Pathological Physiology, University of Athens)

It has been proved by many authors that the interstitial cells of the testis are the part of the testicle which secretes testosterone. In cases of precocious puberty caused by interstitial-cell tumours of the testis large amounts of the hormone have been found. Tumours consisting of such cells have been characterized as false tumours by Altmann and by Oberndorfer (1926), but others (Kaufmann, Chevassu, Durk) have recognized in them the characters of a true tumour. Masson (1943) regarded them as true tumours, and said that they were usually malignant and gave rise to secondary deposits after a long period. He thought they were reported as benign because the patients had not been observed for a long enough time after operation.

Cases of precocious puberty of such aetiology have been described by Rowlands and Nicholson (1929), Stewart, Bell, and Roehlke (1936), Sutherland (1948), Sandrom (1948), Werner *et al.* (1942), and, in Greece, by Demetriadis *et al.* (1948). The removed testicle of this last case was examined by us and proved to be of interstitial-cell origin. Sacchi (1895) described a similar case, but did not give a clear pathological report.

The case described by Budd (1937) is unique. An interstitial-cell tumour of the testicle developed in a man and gave rise to impotency and gynaecomastia, which subsided after removal of the tumour, found to contain large amounts of oestrogens.

Case History

We have had the chance to study a case of interstitial-cell tumour of the testicle causing precocious puberty. The patient, a 6½-year-old boy without any important familial

FIG. 1. — The patient before operation.

or hereditary history, developed normally until the end of his fourth year, when his voice began to become deeper and his penis increased in size.

His physician found a smooth swelling in his left testicle, thought to be of tuberculous origin. The patient was growing rapidly and hair gradually appeared in his pubic area and lower limbs.

We examined the boy two and a half years later; he was then 6½ years old.

His physique was that of a 15-year-old boy; he weighed 42 kg. and was 140 cm. tall. His upper limbs were in normal proportion to his trunk, while the lower limbs were shorter and robust. Hair growth was abundant in the pubic area, thighs, and legs. His face had a velvety appearance due to fine hair. No axillary hair was present. The cardiovascular and respiratory systems were normal. His teeth were normal for his true age. No abnormalities were found in the nervous system. The fundi of the eyes were normal. His psychological state and behaviour were those of his true age. The penis was of adult proportions (see Fig. 1). The left testicle showed a hard swelling the size of a small apple, with a round smooth surface. The epididymis was normal. The right testicle was normal, the size of a walnut. No erections, ejaculations, or masturbation were reported by his parents.

FIG. 2.—The compact and in some places strap-like disposition of the neoplastic cells is shown. The neoplastic tissue is divided into islet-like gatherings by bands of connective tissue containing blood vessels. ($\times 120$.)

FIG. 3.—The neoplastic cells are closely packed, and have relatively abundant protoplasm with vacuoles and clear limits, giving a mosaic-like picture. No nuclear divisions can be seen. ($\times 540$.)

Laboratory Examinations.—X-ray examination showed a normal sella turcica. Nothing abnormal was found in the kidney regions. X-ray films of the hands showed the bone formation of a 15-year-old person. The basal metabolic rate was -20% . Blood examinations gave: red cells, 4,160,000 per c.mm.; white cells, 9,800 per c.mm. (polymorph neutrophils 62%, proleucocytes 3%, polymorph eosinophils 1%, lymphocytes 32%, monocytes 2%); thrombocytes, 250,000 per c.mm.; haemoglobin, 80%; blood sugar, 0.106%; blood calcium 13 mg. per 100 ml.; red-cell Cl. 0.199%; red-cell NaCl 0.315%; plasma Cl. 0.333%; plasma NaCl, 0.549%; blood cholesterol, 0.164%. Wassermann reaction, negative; Mantoux reaction, negative; glucose-tolerance test showed a normal curve; urine, normal.

The only positive finding, then, was the tumour of the left testicle, and the probable diagnosis was that of an interstitial-cell tumour.

In July, 1947, his left testicle was removed. The pathological examination of the tumour showed the following. The removed testicle was $4 \times 4 \times 3$ cm. in size with a normal epididymis. In section a diffuse growth of a whitish-grey neoplastic tissue was seen. The normal tissues were pushed to the surface. Microscopically, large neoplastic cells were seen, having in the majority a polyhedral shape, sometimes ellipsoidal, with abundant eosinophil protoplasm. The nuclei were round, with a fine net of chromatin, and had a nucleolus. These cells were closely packed, and formed masses, between which there was very little connective tissue. The new growth was divided by bands of connective tissue containing blood vessels, in different-sized areas. In some places the nuclei of the neoplastic cells were different in size and coloration, but nuclear divisions were rare. Generally no tense proliferation was found. In some places cloudy degeneration of the protoplasm was seen, and many small droplets of fats and lipoids were present in the protoplasm of the neoplastic cells (Figs. 2 and 3).

Professor Catsaras concluded that it was a myeloid neoplasm, arising obviously from the interstitial cells of the testicle, with no characters of malignancy.

The patient was examined nine months after the operation and found healthy. Somatic growth continued, although not as rapidly. Weight, 43 kg.; height, 146 cm. The hair growth in the thighs and legs appears to be diminished, but remained the same in the pubic area. His voice was still deep. Behaviour was normal.

Two and a half years after the operation the weight was 55 kg. and height 148 cm. Hair was scanty in the lower limbs. He had a childish expression and his voice was now much less deep. The size of the penis had diminished. There was no evidence of metastases.

Summary

A case of interstitial-cell tumour of testis causing precocious puberty is described.

No evidence of metastases was found 2½ years after operation.

Anaesthetists and surgeons from nine Western European countries recently took part in a two weeks' course on anaesthesia in London. The course was arranged jointly by the British Council and the Faculty of Anaesthetists of the Royal College of Surgeons of England. Members of the course visited several of the London teaching hospitals to watch practical demonstrations of modern methods of anaesthetic technique in all fields of surgery, and at the end of each day they were able to discuss current problems with the demonstrators. Countries represented at the course included Austria, Finland, France, Germany, Italy, the Netherlands, Norway, Sweden, and Switzerland.

THE CEREBROSPINAL FLUID PRESSURE

BY

DAVID BOWSER, M.B., B.Chir.

(From the Department of Anatomy, University of Liverpool)

In the course of a study of the effects of variations in pressure within the azygos venous system it was discovered that such variations are reflected in alterations in cerebrospinal fluid pressure. Since this feature could be used experimentally as a method of investigating changes of pressure within the subarachnoid space, it was decided to undertake a full examination of the dynamic factors concerned in changes of cerebrospinal fluid pressure.

Theoretical Considerations

Fluids are virtually incompressible, and so do not obey Boyle's law. Fluid may not therefore be contained under pressure in a closed rigid container, as once the container is full it is impossible to introduce more fluid. If the container, for example a glass cylinder, is open to the air by

FIG. 1.—A rigid system, full of fluid, connected to the exterior by a U-tube. The level of fluid in the distal limb (D) of the U-tube is the same as that of the uppermost part of the fluid in the cylinder.

a side-tube, the level in the side-tube will be that of the uppermost part of the fluid in the cylinder, as shown in Fig. 1. Any further fluid introduced into the cylinder will be displaced volumetrically into the distal limb (D) of the U-tube, and the height of this displacement would vary with the diameter of the U-tube.

Fluid contained in an elastic-walled tube has pressure exerted on it by the sides of the tube, and if such an elastic-walled tube is contained within a rigid cylinder filled with

FIG. 2.—A rigid system (glass cylinder) through which is running an elastic-walled tube. If water is running through the tube, and a pressure is exerted on its walls, this will be transmitted to the fluid in the glass cylinder, and will be measured by the height (H) in the limb (D) of the U-tube. It should be emphasized that this is a true pressure and is not affected by the diameter of the U-tube.

fluid and open to the exterior the average pressure within the elastic-walled tube will be transmitted to the surrounding fluid, and will show as a height (H) in the distal limb of the manometer-tube (Fig. 2). This height H, being a measure of true pressure, will be constant whatever the diameter of the U-tube.

Supposing that the rate of flow through the rubber tube is such that the tube is partially collapsed—that is, its cross-section is not round but elliptical—it still exerts a pressure on the contained fluid; but if more fluid is now passed through the rubber tube so that it just increases its cross-section from an ellipse to a circle, the cross-sectional area is increased with practically no increase of pressure (Fig. 3).

If these conditions obtain in the system shown in Fig. 2, a volume increase in the rubber tube, bringing it from an elliptical to a circular cross-section, will cause no increase of pressure, but will displace a volume of fluid into the limb (D) of the U-tube equal to the increase in volume of the rubber tube. Thus the level of fluid in the limb (D) will rise by a new height (h_1) above H, but the amount of this rise will obviously depend on the diameter of the tube. Thus, to summarize, the height H is constant, and, being a measure of true pressure, is independent of the diameter of the tube, while the additional height (h_1) caused by distending the rubber tube is a measure of volume of fluid displaced, and so depends on the diameter of the tube.

FIG. 3.—Graph representing rise of pressure with gradual distension of elastic-walled tube (modified from Ryder, Molle, and Ferris, 1944). In the segment A-B the cross-section of the tube is changing from the elliptical to the circular, with corresponding increase in volume but very little increase in pressure.

Application of the Theory to C.S.F. Pressure

The cerebrospinal fluid (C.S.F.) is contained in the subarachnoid space between the arachnoid mater and the pia mater. The former lines the dura and the latter the central nervous axis, so for practical purposes the C.S.F. may be regarded as lying between the dura mater and the central nervous axis. The dura is inelastic, and Holbourn (1943) has shown the brain to be virtually incompressible. Thus these structures cannot exert pressure on the C.S.F. However, the subarachnoid space also contains a large number of elastic-walled blood vessels, and the resting pressure of the C.S.F. must be due to the transmitted pressure of these vessels, expressed as an average of all the pressures exerted in the spinal subarachnoid space. The resting pressure is thus the same whatever diameter manometer tube is used in lumbar puncture (see Table).

Volumetric Displacement of C.S.F. Caused by Compression of the Abdominal Inferior Vena Cava. The Differences in Resting Pressure are Due to the Zero Mark on the Manometer not being quite Level with the Puncture Needle

	Diameter of Manometer Tube		
	0.2 cm.	0.5 cm.	1 cm.
Initial (resting) pressure	9 cm.	10 cm.	8 cm.
Pressure on abdominal compression	20 "	13 "	8.8 "
Rise in height of fluid (h)	11 "	3 "	0.8 "
Volume of fluid displaced ($\pi r^2 h$)	0.6 ml.	0.6 ml.	0.6 ml.

Ryder, Molle, and Ferris (1944) have shown that in partially collapsed veins the cross-section area, and therefore the volume, can be increased from an ellipse to a circle without increase in pressure as in elastic-walled rubber tubes (see Fig. 3). If, when the abdomen is compressed, the rise of C.S.F. "pressure" is due to diversion of blood from the pelvis and lower extremities into the internal vertebral venous network rather than the inferior vena cava, the rise

in "pressure" would in fact be a volumetric displacement and would thus differ according to the diameter of the manometer. This supposition has been confirmed by an experimental lumbar puncture in a man of 55 in whom the resting pressure and the pressure after manual compression of the abdomen was measured with three manometer tubes of differing bore (see Table). In this subject, then, 0.6 ml. of fluid was displaced into the manometers in all cases by compressing the abdominal vena cava. The rise was immediate, and the level was maintained for the total time during which compression was exerted. On removing the compression the pressure immediately fell to the resting level.

It has hitherto been held that when venous pressure is raised, as by abdominal compression or Valsalva's test, the pressure gradient between the C.S.F. and the veins surrounding the arachnoid granulations and elsewhere is abolished, but that C.S.F. formation by the choroid plexuses continues. Thus the rise observed in C.S.F. "pressure" was believed to be due to continued formation and failure of absorption of C.S.F. Masserman (1934) has shown that C.S.F. is formed at the rate of 0.3 ml. a minute. In the case cited in the Table the displacement of fluid was immediate, whereas if the reabsorption theory be true it would take two minutes to form the amount of fluid actually displaced (0.6 ml.).

The above experiment, while largely invalidating the previous theory of failure of reabsorption of the C.S.F. being the cause of physiological rises in pressure, does not, of course, prove that venous distension is the cause of the rise.

It is known that the intradural and extradural vertebral veins communicate with the caval system of veins (inferior and superior venae cavae, the azygos vein, and the deep neck veins, such as the vertebral, deep cervical, and occipital) at every intervertebral interval; this pattern has been thoroughly investigated by Breschet (1829), Northway and Greenway (1944), and Robinson (1949). Moreover, Batson (1940), in his classical work on the spread of prostatic cancer, has shown that, when the abdominal vena cava is compressed, blood from the pelvic veins travels upwards in the veins of the vertebral system.

It can be shown by the following experiment that C.S.F. "pressure" can be raised by diverting pelvic venous blood into the vertebral venous system.

A kitten was heparinized and then killed. Cisternal puncture was immediately performed and the C.S.F. pressure stood at 6 cm. A small cannula was inserted into an internal iliac vein, and saline, at a pressure of 10 cm. of saline, was infused. The abdominal vena cava was digitally compressed, and after the infusion of about 1.5 ml. of saline the C.S.F. "pressure" rose by 2.5 to 8.5 cm. Immediately compression of the vena cava ceased the pressure fell again to 6 cm., proving that the saline had not diffused out of the veins into the C.S.F.

The rise of C.S.F. pressure may similarly be produced by diversion of blood from other veins—for example, the azygos vein—into the vertebral veins, as in an experiment performed on a fully grown Alsatian dog. This was killed by electrocution; unfortunately it was not possible to heparinize the animal before death, but the experiment was performed within an hour of death and gave satisfactory results, indicating that extensive intravascular clotting had not occurred. Cisternal puncture was performed, and the resting pressure was found to be 12 cm. A cannula was tied into the azygos vein at its arch and saline infused retrogradely at a pressure of 30 cm. of saline. The cisternal "pressure" rose by 3.5 to 15.5 cm.

It would appear that every time intrathoracic pressure rises—that is, in expiration—some blood is pushed out of the valveless azygos system (Gruber, 1866; Charpy, 1898) into the internal vertebral venous network, whereas when intrathoracic pressure falls in inspiration the azygos vein distends and blood flows in the opposite direction, from the internal vertebral veins to the azygos. It is suggested that this to-and-fro flow between the azygos and the vertebral veins is responsible for the normal respiratory variation in

the C.S.F. pressure, the level of fluid rising in expiration and falling in inspiration. This contention was confirmed by performing cisternal puncture on a rabbit which had been given a lethal dose of pentobarbitone sodium. The level of C.S.F. in the manometer tube (1-mm. polythene tubing) was 9 cm., with a respiratory variation of about 0.25 cm. As the animal died of respiratory failure, ending in a complete expiration, the C.S.F. pressure rose 2 cm. This can be explained only by the mechanism suggested above. In another such experiment on a moribund rabbit it was shown that the respiratory excursion ceased as soon as the thoracic cavity was widely opened to the atmosphere, although the lungs and diaphragm continued to contract for a short time.

When Queckenstedt's test is performed, blood from the cerebral sinuses and upper part of the jugular veins, through their connexions with the intradural and extradural vertebral veins, returns by a collateral route in these vessels. As the intradural veins distend so C.S.F. is displaced into the manometer, causing the "pressure" to rise. The intracranial sinuses are held open by the layers of dura between which they lie, and they probably do not increase much in volume when jugular compression is applied, but the smaller cerebral veins which are tributary to the sinuses increase in volume, and they and the spinal intradural veins between them cause the increase of C.S.F. "pressure." The outflow from these spinal intradural veins probably occurs just below the point of compression, into the deep cervical veins, so that if the subarachnoid space is blocked below this level the C.S.F. below this point will not be displaced. However, it is well known that, in some cases of subarachnoid block, jugular compression still causes a rise of C.S.F. "pressure" below the block. In these cases it must be presumed that the blood in the cervical spinal collateral channels does not return to extradural channels immediately below the point of jugular compression, but continues further down the spinal subarachnoid space, past the block, to produce the effects of venous distension in the lumbar region.

Exercise, or any other cause of a rise of venous pressure, has long been known to produce a rise in C.S.F. pressure, and this is presumably due to increased venous volume within the subarachnoid space.

It may be concluded, then, that, apart from space-occupying lesions within the cranial or spinal subarachnoid space (including haematomata), the chief cause of so-called increase of C.S.F. pressure is displacement of C.S.F. into the manometer by increase in volume of the intradural veins.

Discussion

Many previous investigators, notably Weed and his collaborators, have studied the pressure of the C.S.F., but in general more attention has been paid to changes in pressure than to the resting pressure. Weed and Flexner (1932) conceive of the total C.S.F.-containing system as a rigid tube with an elastic membrane at either end; as a result of their tilting experiments, they postulate that the elastic membrane at one end (the spinal end) must be of greater elasticity than that at the other (the cranial end). They also state that the dura must be regarded for practical purposes as being relatively inexpandable—that is, its coefficient of elasticity at physiological pressure is negligible. However, they do not make a clear distinction between expansibility (power to undergo deformation) and elasticity (power to resist deformation). The rigidity of the dura had in fact already been demonstrated by Weed (1922) and Weed and McKibben (1919), when they showed that negative intradural pressures could be produced by the intravenous administration of hypertonic solutions. If the dura were capable of collapsing inwards, such negative pressures could not be produced. The dura must therefore be looked upon as adhering to the cranium and vertebral canal.

Weed, Flexner, and Clark (1932) and Weed (1933) have calculated the overall coefficient of elasticity of the dural sac and its contents. They found the coefficient of elasticity

(E) to be on average 4.2×10^5 dynes per cm.² in dogs. Clark (1933), working on the excised veins of dogs, found E for veins at a pressure of 3–4 cm. of mercury to be 4.2×10^5 dynes per cm.²

Despite this obvious comparison, no previous author has precisely maintained that the resting C.S.F. pressure is dependent mainly on the pressure exerted by the elasticity of intradural veins. It must be emphasized, however, that the resting C.S.F. pressure represents an average of the pressures of all the intradural vessels, including arteries. Because there are many more veins than arteries, two conclusions follow. First, although C.S.F. pressure is higher than venous pressure, it approximates far more nearly to venous than to arterial pressure; secondly, given the inelasticity of dura and central nervous axis, the coefficient of elasticity of the total intradural contents will approximate very nearly to that of the veins alone.

To increase the C.S.F. pressure for experimental purposes Weed and his collaborators have used almost exclusively the method of vertical tilting. By this method, with the manometer open to the air, the pressure recorded must be equal to the hydrostatic pressure of a column of C.S.F. from the needle to the highest point of the intradural space, plus or minus the effects of elasticity and/or collapse of the intradural vessels, as has been pointed out by Merritt and Fremont-Smith (1937). The present paper is concerned with the rise in "pressure" brought about by the various techniques of venous compression; or, rather, techniques which divert blood from the caval to the intradural veins. Weed (1922), in his classical experiments on decrease of C.S.F. pressure by the intravenous injection of hypertonic saline, noted that, although hypertonic saline eventually reduced the pressure considerably (even to negative values), during the time of injection there was a rise of C.S.F. pressure. This can have been due only to increased venous volume. Stookey (1924) realized the importance of venous dilatation when he stated that a rise of C.S.F. pressure on straining was probably due to a temporary block of venous outflow from the cranial cavity and vertebral canal; though, of course, as Batson (1940) has shown, it is a diversion of blood into the vertebral veins rather than a blockage of outflow that occurs.

Weed and Flexner (1933), referring again to tilting experiments, state: "With the experimental increase of cerebrospinal pressure brought about by the introduction of fluid into the subarachnoid space, a certain diminution of intradural venous volume must follow; but the pressure in these cerebral veins remains unaltered. Conversely, when the pressure of cerebrospinal fluid is reduced mechanically or by tilting, the cerebral venous bed apparently compensates by dilatation, the venous walls expanding and permitting an increase of intradural venous volume, though maintaining in these expanded channels the same pressures." It requires only a short step from this, aided by the work of Ryder, Molle, and Ferris (1944), showing that veins do in fact dilate without increase of pressure, to the hypothesis put forward in the present paper—namely, that, owing to diversion of blood from the caval to the extradural and intradural vertebral venous system, the intradural veins do in fact dilate without increase of pressure, and thus volumetrically displace a corresponding amount of C.S.F.

Summary

There has been a fundamental misconception with regard to spinal manometry; Boyle's law of gas pressure does not apply to liquids.

It is suggested that the resting pressure of the C.S.F. is due to the pressure transmitted from the walls of blood vessels within the spinal and cranial subarachnoid space.

Rise of "pressure" above the physiological norm is thought to be due to the increase in volume, without

rise of pressure, of the veins within the subarachnoid space which displace an equal volume of C.S.F. into the manometer.

This research has been performed during the tenure of a John Rankin Research Fellowship of the University of Liverpool, and has been aided by a grant from the Medical Research Council. I wish to thank Professor R. G. Harrison for his advice and encouragement, and Dr. T. G. Richards, of the Department of Physiology, University of Liverpool, for helpful advice.

TRANSVERSE ARREST OF HEAD AND THE OCCIPITO-POSTERIOR POSITION

BY

BRYAN WILLIAMS, M.D., F.R.C.Sed., F.R.C.O.G.
Senior Obstetrician and Gynaecologist, Middlesbrough Maternity Hospital and North Ormesby Hospital

The occipito-posterior position is generally thought to be a common cause of difficult and prolonged labour, carrying a high risk to mother and baby, causing much worry to midwife and doctor, and often ending in a difficult instrumental delivery. Evidence is presented, however, that these risks and difficulties have been greatly overestimated in those cases in which the occiput is found posteriorly late in labour, or the true persistent occipito-posterior positions. On the other hand, if the occiput fails to rotate anteriorly from a lateral position there is serious foetal risk and often great difficulty in operative delivery. It is these cases which have given the occipito-posterior position its bad reputation, as they are usually looked upon as posterior positions in which incomplete rotation has occurred. It is probable, however, that in most of them the head has been lying transversely throughout labour, and to describe them as occipito-posterior positions is therefore incorrect. The methods of operative delivery, moreover, differ in the two complications, and it now seems desirable to separate transverse arrest of the head from the persistent occipito-posterior position.

Incidence

The figures given in the literature for the incidence of the occipito-posterior position vary widely, and this is doubtless due to the differing times in pregnancy or labour at which examination has been made and to varying criteria of diagnosis. Munro Kerr and Chassar Moir (1949) have also pointed out the importance in this respect of the incidence of abnormal pelvic types in the material studied.

In practice, however, it is important to know the proportion of cases in which anterior rotation of the head fails with conservative midwifery, and also the exact position of the head in these cases. Such figures have been obtained from the records of Walton Hospital, Liverpool, for the year 1937, and are given in Table I. This gives the posi-

TABLE I.—Incidence, Method of Delivery, and Results of Transverse Arrest of the Head and the Persistent Occipito-posterior Position in 2,958 Labours

	Transverse Arrest	Persistent Occipito-posterior Positions
Total No. of babies ..	54 (38 primigravidae, 16 multigravidae)	53 (22 primigravidae, 31 multigravidae)

Results:		
Maternal mortality ..	0	0
" morbidity ..	11 (20%)	1 (2%)
Foetal mortality ..	13 (24%)	9 (17%)

tion of the vertex in these cases at the time of delivery or intervention, together with the method of delivery and the results to mother and baby. In that year great attention was paid to accurate diagnosis of position, and diagrams were often drawn in the records. A few cases are excluded in which a caesarean section was done for disproportion and in which the exact position of the head was not noted. It is probable that in these cases transverse positions of the head were more common than occipito-posterior positions.

The figures in Table I show that transverse arrest is more common in primigravidae and that operative delivery is always required, except in a few cases in which spontaneous delivery of a transverse head occurs, and in these the baby is usually small. The true occipito-posterior position, on the other hand, is more common in multigravidae and spontaneous delivery is frequent. The greater incidence of difficult labour and intervention in transverse arrest is reflected in a higher morbidity rate. Although there is no marked difference in the figures for the combined stillbirths and neonatal deaths, analysis of the causes of these, however, shows that in transverse arrest at least 11 out of 13 deaths were due to complications of labour, whereas in the persistent occipito-posterior position 8 out of 9 deaths were due to developmental abnormality or prematurity. The craniotomies were all carried out on dead babies, and two of them were in "failed forceps" cases.

In Table II the forceps deliveries in the same year are classified according to the position of the head at the time of interference. These figures show that with conservative

TABLE II.—Position of Head in 172 Forceps Deliveries

	Anterior Positions	Transverse Arrest	Persistent Occipito-posterior Positions

Incidence of forceps delivery, 5.8%.

midwifery transverse arrest of the head is a more frequent indication for forceps delivery than the persistent occipito-posterior position, and that such delivery has a much higher risk for mother and baby.

As the number of cases of the persistent occipito-posterior position delivered with forceps in one year was small it seemed advisable to review a larger series to determine the risks to mother and baby, and Table III shows

TABLE III.—Results in 63 Face-to-pubes Deliveries with Forceps

	Primigravidae	Multigravidae	Total
No. of cases ..	55	8	63
Maternal mortality	2 (both from shock following manual removal of the placenta and pregnancy toxæmia)	0	2 (3%)
Maternal morbidity	3	0	3 (5%)
Foetal mortality ..	1 (tentorial tear)	3 (hydrocephalus; prolapse of cord, baby 3½ lb. (1.6 kg.); asphyxia, baby 10½ lb. (4.8 kg.))	4 (6%)

the results in 63 patients delivered in the course of six years, from 1936 to 1941 inclusive, with forceps in the face-to-pubes position. These figures show the striking fact that in 55 primigravidae there was only a single foetal death, and do not support the view usually held that this method of delivery has a high risk for the baby.

The problem of the non-rotated head, therefore, is seen to be mainly that of the transversely arrested head and not that of the persistent occipito-posterior position. The former demands intervention more often, and delivery is usually difficult and carries a high foetal risk.

Mechanism of Transverse Arrest

Transverse arrest of the head is a complication familiar to all obstetricians and was well described by Smellie. While American and Continental obstetricians lay stress on it, however, it receives inadequate attention in this country, and it is usually looked upon as a stage in the mechanism of the occipito-posterior position. This is doubtless the result of the standard teaching that the head normally enters the brim in one of the oblique diameters, and the transverse head is therefore considered to be an occipito-posterior position in which partial rotation has occurred.

There has long been clinical evidence, however, also going back to the time of Smellie, and referred to by Munro Kerr and Chassar Moir, that the head most commonly engages in the transverse diameter of the brim. The terms "occipito-lateral" and "occipito-transverse" are in common use. Radiological evidence now supports these clinical findings. Caldwell, Moloy, and D'Esopo (1934) showed that the head entered the brim transversely in 60% of their cases, and Steele and Javert (1942) found a slightly higher percentage of transverse heads both at the brim and in the cavity of the pelvis. Clinical observation shows that in those cases in which transverse arrest occurs the head has been transverse throughout labour. It seems inaccurate, therefore, to describe these cases as persistent occipito-posterior positions, and it is better to separate them from the true occipito-posterior positions.

The adjective "deep" is commonly used in connexion with transverse arrest. This term presumably refers to the depth inwards from the pelvic outlet at which arrest occurs rather than to the depth downwards from the pelvic brim. While arrest is most common in the pelvic cavity it may take place at any level, and as the term seems to have little value its use might be discontinued, as also might the use of inverted commas with the words "transverse arrest."

In face presentation a similar problem may arise, though such cases are infrequent. The figures for the incidence the various positions in face presentation are often con-

by the inclusion of cases of anencephaly, in which the position of the chin is of no importance. The so-called persistent mento-posterior position is usually a transverse arrest of the face, and might well be included under the heading of "transverse arrest of the head."

Diagnosis

The signs of the non-rotated head have been well described by Douglas Miller (1930). Early in labour the occipito-lateral and occipito-posterior positions can usually be differentiated by abdominal examination. In the occipito-lateral position the smooth back will be felt in one flank with the anterior shoulder some way out from the midline, limbs will not be prominent, the foetal heart sounds will be heard on the same side as that on which the back is found and will usually be faint, and the forehead will be felt well laterally till a late state of labour. In the occipito-posterior position there is a characteristic flattening or even a depression above the symphysis, the back and anterior shoulders are well out posteriorly with limbs easily felt on the opposite side and sometimes showing active movements, and the foetal heart sounds will be heard either well out in the flank and faintly or nearer the midline and more loudly.

Although in most cases the position of the head may be diagnosed from that of the back and vice versa, there is occasionally much twisting of the neck in labour. This has been found radiologically by Hedley (1932), and by Munro Kerr and Chassar Moir. In two remarkable cases reported by Smith (1949) much untwisting of the neck had to be carried out before delivery could be effected with forceps.

Vaginal examination is rarely called for early in labour, and later on the ease with which the classical features of the sutures and fontanelles can be recognized will depend on the extent of caput formation. It is often advised that before any intervention is carried out a final diagnosis of position should be made by palpation of the ears and face. This, however, needs deep general anaesthesia, and a degree of manipulation that is undesirable, and should be unnecessary, in a case followed throughout labour. Useful diagnostic features not often stressed are the characteristic feel of the external occipital protuberance and the saw-like edges of the parietal bone commonly found in the region of the posterior fontanelle.

In the real occipito-sacral position when the head is low and well moulded the incorrect diagnosis of a fully rotated occipito-anterior position is easily made. This mistake is due to the sagittal suture being found in the midline and to the frontal suture being inconspicuous. If forceps are applied the blades lie easily on the sides of the head, though early perineal distension on traction should make one suspect the accuracy of the diagnosis. The mistake, fortunately, is not a serious one, as will be shown later, but it can usually be avoided by careful abdominal examination.

In those cases in which the head has entered the pelvis but has failed to reach the perineum after an adequate period of good contractions it will usually be correct to assume that transverse arrest has taken place. In patients seen for the first time later in labour an exact diagnosis of position by clinical methods is often difficult. Abdominal examination in a restless patient may be inconclusive, and a ring is often present and the uterus tightly moulded round the foetus. A large caput may obscure the usual landmarks looked for on vaginal examination.

Facilities for intra-partum x-ray examination of such cases should now be available in maternity units, and this method of investigation will also be of great help in deciding the best technique of delivery. Otherwise examination under general anaesthesia with all its disadvantages may be necessary, and even then an exact diagnosis of position may be impossible. Early in labour, however, an accurate diagnosis by ordinary clinical methods will rarely be difficult.

Treatment

There has long been clinical evidence that deformities of the pelvic outlet in particular are commonly associated with defective rotation of the head (Plass, 1916). In recent years the extended use of x-ray examination has greatly increased our knowledge of the mechanism of labour in both normal and abnormal pelvises. Caldwell and Moloy (1938) showed the importance of basing the method of operative delivery on the type of pelvic abnormality present as shown by stereoscopic radiological studies, and they found, moreover, that these studies decreased the incidence of difficult forceps delivery. The importance of uterine action, and the resistance of the soft parts, however, is shown by the fact that normal delivery may take place, and, indeed, is usual in subsequent labours, although intervention has been necessary for transverse arrest in the first one.

The incidence of mid-forceps operations can nowadays be greatly reduced by the extended use of caesarean section with an improvement in foetal mortality and a decrease of maternal injuries. Nevertheless the minor degrees of pelvic deformity still present difficulties in treatment, and a small number of cases of mid-cavity arrest will occur with conservative practice. Among the most disappointing cases in obstetrical practice are those in which, in spite of good antenatal care, slow and difficult labour occurs as a result of the combination of inertia, slow dilatation, minor pelvic contraction, and delayed rotation of the head. If labour is allowed to continue unduly in the hope that spontaneous delivery, or at any rate a low forceps delivery, will be possible the optimum time for abdominal delivery may be passed, and the difficulty of extracting the foetus by lower-segment caesarean section is then great and the risk to the baby therefore high. In such cases the use of x-ray examination during labour, if it has not been carried out before, is of great help.

The method of delivery of the non-rotated head still gives rise to much controversy. The technique usually advised is that of manual rotation followed by the application of forceps. It is probable, however, that manual rotation is still advised too lightly and that its difficulties and dangers are underestimated. It may be very easy in a multigravida with a deficient perineum to rotate the head through two right angles and to complete delivery with forceps. In such cases the failure of rotation is due to deficiency of the pelvic floor or perhaps to some other factor such as deflexion of the head by an arm under the chin or to increased extensor tone in the neck muscles.

In a primigravida with a transversely arrested head, however, the problem is different. The outlet is usually narrow, and manipulations are difficult. Failure of rotation is due to the head having failed to reach the pelvic floor. Rotation at the level of arrest cannot take place, and in most cases the manipulation is inadvisable and should not be attempted. Caldwell and Moloy have shown the risks of attempts at anterior rotation in certain types of pelvis, and this has been supported more recently by Williams and Arthure (1949) as a result of their radiological studies of the pelvic outlet.

In considering the technique of delivery it becomes important to distinguish between the transversely arrested head and the persistent occipito-posterior position. The former should be delivered as an occipito-anterior position, while the latter should in most cases be delivered in the face-to-pubes position. Occasionally spontaneous delivery of a small head may occur in the transverse position, as shown in Table I, and this receives little mention in the textbooks. Irving Potter (1928) has also recommended deliberate delivery of the head in the transverse position when carrying out forceps delivery in order to save the perineum. Nevertheless it is usually agreed that delivery should be effected with the head fully rotated, and if forceps traction alone without any other manoeuvre is carried out spontaneous rotation will nearly always occur.

In view of the attention which is always paid to manual rotation it must be emphasized that the trouble is not failure of rotation but failure of the head to reach the level of the pelvis at which rotation normally occurs. Manual rotation is therefore not only impossible in most cases but attempts to carry it out may increase the risk to the foetus and need deep anaesthesia and much manipulation. In many of the cases in which it is thought to have been successful the position of the forceps marks on the baby's head will show that the blades have been applied to a more or less transverse head.

The pelvic application of the classical forceps with the use of axis traction is commonly employed in these cases. This involves an unsatisfactory grip with one blade over the forehead and carries a high risk of tentorial tears and eye injuries. The use of the Kielland forceps in this type of case is very satisfactory and is now widely recommended. The classical method of rotating the anterior blade of this instrument inside the uterus cannot, however, be free from risk either to the baby or to the uterus and anterior vaginal wall, and is nowadays unnecessary. This blade can be passed into position over the face by a wandering, gliding, or migratory movement. Sometimes the anterior blade is easy to apply and the posterior one difficult, and sometimes the reverse is found. Study on the manikin and considerable practice are required, and even then it is occasionally difficult to obtain a perfect cephalic application. Deep general anaesthesia is unnecessary and the instrument may be applied with only two fingers in the vagina. Spontaneous rotation usually occurs as the head reaches the pelvic floor, but this may be aided with the forceps.

The Kielland forceps is no more or no less dangerous than any other one. The application of forceps to the non-rotated head should be carried out only by those of experience, and all who practise obstetrics should master the use of the Kielland forceps. The exact diagnosis of position and the careful following of the proper mechanisms of labour which are both necessary with this instrument are perhaps largely responsible for its success. In skilled hands, as pointed out by Caldwell and Moloy, good results may be obtained by other methods and other instruments. In America a few authors have written enthusiastically of the Barton forceps, which has a hinged anterior blade and gives a cephalic grip of the transverse head. Some obstetricians recommend a cephalic application of the classical forceps. Nevertheless the delivery of a transversely arrested head with the Kielland forceps provides nowadays one of the most satisfactory experiences in obstetrics.

The type of anaesthetic needed will depend largely on the operative procedure. For manual rotation general anaesthesia of some depth is necessary, with all its disadvantages to mother and baby. The application of the Kielland forceps, however, may be carried out under some form of conduction anaesthesia, such as spinal anaesthesia. Although there has been much discussion about the risks of spinal anaesthesia for caesarean section there is little dispute over its safety for vaginal delivery, and it has been warmly advised in recent years by several authors in this country. Anderson (1946) has particularly recommended its use for difficult forceps deliveries. The records of 3,000 obstetrical cases in which spinal anaesthesia was used in Walton Hospital in 11 years up to the end of 1946 show that, although two deaths followed its use for caesarean section, there were no deaths or major complications due to its use for vaginal delivery. Its only serious disadvantage is the occasional occurrence of troublesome headache, though there is some evidence that the use of a very fine needle to puncture the theca may greatly reduce the incidence of this distressing complication. For the delivery of the non-rotated head a rather bigger dose is required than is necessary for perineal anaesthesia. This method of anaesthesia is so safe for mother and baby and so satisfactory to the obstetrician that it should now no longer

be considered to be on trial, but it is rather the continued use of general anaesthesia which should be justified for difficult forceps deliveries.

In face presentation the anomalies of rotation are similar to those of vertex presentation, and the so-called "persistent mento-posterior position" is usually a "transverse arrest of the face." The true mento-posterior position is rare, and differs from the persistent occipito-posterior position in that delivery with the chin posteriorly, either spontaneously or with forceps, must be exceptional, and caesarean section will usually be needed for it. The same treatment is required for transverse arrest of the face as for transverse arrest of the vertex, and the Kielland forceps is also valuable, in these cases. One point of distinction, however, between face and vertex presentations which is not emphasized enough is that in face presentation the caput may involve the upper air passages and cause increased foetal risk from pulmonary and feeding complications, and a less expectant attitude than in vertex presentations is therefore advisable.

In occipito-posterior positions the desirability of manual rotation has also been overemphasized. In practice many face-to-pubes deliveries are carried out with forceps in cases in which the correct diagnosis of position is not made until the appearance of the face from under the pubes causes discomfiture to the obstetrician. When the head is low and well moulded manual rotation should not be attempted, and its dangers here also have been shown by Caldwell and Moloy. This position is often found with the anthropoid pelvis, which is an efficient type of pelvis, and a deliberate face-to-pubes delivery does not usually present great difficulties if the normal mechanism is followed, though there is undoubtedly a great risk of lacerations, and extensive episiotomy is often necessary. The figures given in Table III show that there was only a single foetal death from cerebral haemorrhage in 55 primigravidae delivered with forceps as face-to-pubes cases. It would seem, therefore, that forceps delivery in the occipito-posterior position is no more dangerous than in the occipito-anterior position, and this is doubtless due to the forceps blades lying easily on the sides of the head and causing no stretching of the tentorium.

The presentation of a slightly bigger diameter has been traditionally put forward as the explanation of the difficulty with delivery of the occipito-posterior position, but a more reasonable one is the theory advanced by Chassar Moir (1938) of the maladjustment of the foetal and pelvic curves. The same idea is found in the "pivot points" theory of Buchanan (1920) and demonstrated by his very ingenious models.

The high incidence of easy spontaneous delivery and the low foetal risk of face-to-pubes delivery with forceps in occipito-posterior positions are in contrast with the findings in transverse arrest of the head, and it seems advisable, therefore, to consider these two forms of the non-rotated head separately. In both complications, however, a fascinating opportunity for the exercise of obstetrical judgment and skill is offered, especially with the rare need nowadays for axis traction and with our increased knowledge of the mechanism of labour obtained from radiological studies.

Summary

The head is usually found to be transversely arrested in cases of the so-called persistent occipito-posterior position which give rise to difficulty in labour. Transverse arrest of the head is not a stage in the mechanism of the occipito-posterior position, and the two conditions should be separated.

A cephalic application of forceps and traction without rotation is the best treatment for the transversely arrested head, and the Kielland forceps is very suitable for this purpose.

In the true occipito-posterior position a deliberate face-to-pubes delivery with forceps is usually indicated when the head is low, and this has a small foetal risk.

SUBARACHNOID HAEMORRHAGE IN PREGNANCY

BY

JOHN N. WALTON, M.D., M.R.C.P.

(From the Department of Medicine, King's College,
University of Durham, and the Royal Victoria Infirmary,
Newcastle-upon-Tyne)

Since Lazard (1899) reported a case of cerebral haemorrhage arising during labour, many authors have described spontaneous intracranial haemorrhage occurring during pregnancy. Cerebral haemorrhage, often with extension to the subarachnoid space, has been noted in patients with eclampsia (King, 1933; de Carle, 1949) and toxæmia (Masten, 1935; Strauss and Tarachow, 1937), and these observations have inspired the view that generalized vascular changes are usually responsible for subarachnoid haemorrhage in pregnancy, labour, or the puerperium (Dahle, 1946). While this is true of many cases it is now evident that subarachnoid haemorrhage of aneurysmal or angiomal origin is an occasional complication of an otherwise normal pregnancy.

Of the 312 cases of spontaneous subarachnoid haemorrhage reported elsewhere (Walton, 1952a), two occurred during pregnancy; these cases are here reported in detail.

Case 74

A housewife aged 35 was admitted to the Royal Victoria Infirmary under the care of Professor F. J. Nattrass on January 27, 1948. Six years previously she had had an illness which began with sudden headache and prostration, and she spent three weeks in an isolation hospital, with a diagnosis of meningitis. For several months afterwards she had occasional headaches. On the day before admission, when in the thirtieth week of her first pregnancy, she was straining at stool, when a bursting frontal headache developed; this was followed by a generalized epileptic fit and a period of unresponsiveness lasting twenty minutes.

On examination on admission, twenty-four hours later, she was rational though drowsy and irritable; there was moderate neck stiffness, but no other abnormal signs were found in the central nervous system. The pulse was 60 a minute, blood pressure 140/90 mm. Hg, and temperature 99.2° F. (37.3° C.). Lumbar puncture revealed a deeply supernatant fluid under a pressure of 200 mm., and the blood-stained fluid was bright yellow. The urine contained small amounts of albumin and sugar.

The patient improved steadily and was transferred to the Princess Mary Maternity Hospital on February 13; she came into spontaneous labour on April 10 and was delivered of a healthy baby. Labour and the puerperium were uneventful. Although troubled for some months by headaches and anxiety symptoms, she is now living a normal life.

Comment.—The illness suffered by this patient six years previously was probably subarachnoid haemorrhage. In the absence of signs of toxæmia it is likely that both attacks arose from rupture of an intracranial aneurysm or angioma. There is no evidence that pregnancy was related to the haemorrhage, and normal labour did not provoke a recurrence of bleeding.

Case 273

A housewife aged 40 was admitted to the Princess Mary Maternity Hospital on October 25, 1942, for investigation. Three days previously, while in the twenty-sixth week of her third pregnancy, she was found to have albuminuria. Her blood pressure was normal and she had no symptoms. Shortly after admission she suddenly became confused and irrational; two hours later a generalized epileptic convulsion occurred, she became comatose, and neck stiffness was noted. She was transferred to the Royal Victoria Infirmary under the care of Dr. F. J. Nattrass three hours later.

On examination she was comatose, with Cheyne-Stokes respiration. The pulse was 68 a minute, blood pressure 140/90 mm. Hg, and temperature 100° F. (37.8° C.). There was severe neck stiffness and Kernig's sign was positive. A large subhyaloid haemorrhage was seen in the right eye; the retinal veins were engorged and small flame-shaped haemorrhages were seen in both retinae, but there was no papilloedema or any evidence of arteriopathy. The pupils were widely dilated and non-reacting; all four limbs were flaccid, and the left plantar response was extensor.

Lumbar puncture five hours after the ictus revealed deeply blood-stained fluid under high pressure; the supernatant fluid was faintly yellow. The urine contained a considerable quantity of albumin but no sugar. The patient deteriorated, and died eight hours after the onset.

At necropsy the following day much blood was seen in the basal cisterns and cerebral sulci. A ruptured aneurysm, 0.5 by 0.5 cm. in diameter, was found at the junction of the left anterior cerebral artery with the anterior communicating. The corpus callosum was ploughed up and haemorrhage had entered the right frontal lobe, reaching the lateral ventricle. Histological examination of the renal and cerebral vasculature showed no evidence of acute vascular pathology. The hepatic parenchyma was also normal on section. A normally formed six-months foetus was found in utero.

Comment.—Although albuminuria was noted before subarachnoid haemorrhage developed, there was no clinical or pathological evidence of toxæmia, and the necropsy findings were such as are commonly seen in non-pregnant patients with ruptured intracranial aneurysms; it cannot be suggested with any authority that the coexistence of pregnancy provoked the haemorrhage or influenced the outcome.

Discussion

Clinically typical attacks of spontaneous subarachnoid haemorrhage complicating normal pregnancies have been reported by Sands (1929, 1 case), Russel (1933, 1 case), Moskowitz and Schneider (1938, 3 cases), Richardson and Hyland (1941, 3 cases), Dahle (1946, 1 case), Rhoads (1947, 2 cases), Hamby (1948, 4 cases), Garber and Maier (1948, 3 cases), Ramstad (1948, 1 case), Olivecrona and Riives (1948, 1 case), de Carle (1949, 3 cases), Bell (1949, 2 cases), Gershenfeld and Savel (1950, 1 case), Ask-Upmark and Ingvar (1950, 2 cases), and Conley and Rand (1951, 8 cases). This complication may pose important problems of management, and, as Mackenzie (1933) has pointed out, diagnostic difficulties may arise, since hypothalamic irritation by subarachnoid blood may produce hypertension and albuminuria. If these signs are discovered in a comatose patient a misdiagnosis of eclampsia is possible, particularly if no search is made for signs of meningeal irritation. Even in a confirmed case of subarachnoid haemorrhage it may be difficult to be sure that toxæmia has not played some part in the aetiology (Conley and Rand, 1951). However, many

cases have now been reported in which toxæmia could be excluded completely, but no authoritative evidence is yet available to confirm the significance of the association.

Before an opinion on this point can be expressed and a rational scheme of management formulated, the following questions must be answered: (1) Does subarachnoid haemorrhage occur significantly more often in cases of non-eclamptic pregnancy than in other female members of the population in the same age group? (2) Is the aetiology of the illness different during pregnancy? (3) Is the time relationship of the illness to the stage of pregnancy constant enough to suggest a connexion between the two? (4) Does the coexistence of pregnancy affect the outcome of the illness?

1. *Incidence.*—De Carle (1949) found only three cases of subarachnoid haemorrhage complicating normal pregnancy in 15,417 deliveries, whereas subarachnoid bleeding, usually secondary to intracerebral haemorrhage, had occurred in 15 eclamptic patients in the same series. In the Newcastle series of 312 cases of subarachnoid haemorrhage there were 48 female patients between 20 and 45 years of age, and two of them were pregnant. By taking the average birth rate in the years 1940-9 it is possible to estimate that at any one time during that period approximately one in 20 to 25 women in the given age group would be pregnant. Thus the incidence of pregnancy in these cases was identical with that to be expected in the general population. Although somewhat greater in the series reported by Richardson and Hyland (1941), Dahle (1946), Hamby (1948), and Ask-Upmark and Ingvar (1950), the incidence was never high enough to nullify this conclusion.

2. *Aetiology.*—About 80% of cases of spontaneous subarachnoid haemorrhage arise through rupture of an intracranial aneurysm, perhaps another 10% through bleeding from an angioma, and in the remainder many pathological conditions may be implicated (Walton, 1952a). Ruptured aneurysms have been demonstrated by angiography or at necropsy in many pregnant patients (Sands, 1929; Richardson and Hyland, 1941; Rhoads, 1947; de Carle, 1949; Conley and Rand, 1951), while in at least three cases (Olivecrona and Riives, 1948; Conley and Rand, 1951) an arteriovenous angioma was the cause. Although in Thompson's (1949) three cases the bleeding was of unusual origin, the available evidence does not suggest that the aetiology of the illness in non-eclamptic pregnancy differs significantly from that in the general population.

3. *Time of Occurrence.*—It has been suggested that the burden of pregnancy and the strain of labour are responsible for provoking bleeding. If physical stress is the operative factor it would be expected that most cases would occur in labour or the early puerperium. Conley and Rand (1951) have pointed out that this is not so. They tabulated 20 reported cases and added eight of their own; when the two cases reported by Ask-Upmark and Ingvar (1950) and the two described here are added, it is seen that, of 32 cases, only four (12.5%) occurred during labour. In 18 (56%) the haemorrhage developed before birth (usually late in the second or in the third trimester) and in 10 (31.5%) after birth (within twenty-four hours of delivery in six). Clearly the time relationship is by no means constant.

4. *Outcome of the Illness.*—Of the 32 patients mentioned above, 13 (40%) died and 19 (60%) recovered. Separate consideration of the 10 cases occurring during labour or in the first twenty-four hours afterwards has shown that half of them survived. In 1,300 reported cases of subarachnoid haemorrhage the mortality rate was 45% (Walton, 1952a); it is clear that the prognosis of the illness during pregnancy, labour, or the puerperium is similar. Of the patients who recover from subarachnoid haemorrhage, 10.5% suffer a further attack within six months (Walton, 1952b), but there is no evidence that such recurrent haemorrhage is more likely to occur, even during labour, in a patient who has survived an attack in pregnancy; indeed, recurrent bleeding after an interval during the same pregnancy has been reported in only one case (Rhoads, 1947).

In the two cases reported above, the onset, progress, and outcome of the illness did not appear to be related to the associated pregnancy. Subarachnoid haemorrhage seems to occur no more commonly during a normal pregnancy than in an unselected group of women of the same age. The aetiology of the illness is not unusual in pregnant women, and the coexistence of pregnancy does not affect the prognosis. Admittedly most cases occur late in pregnancy or during labour or the early puerperium, when physical stress is greatest; as in any case of subarachnoid haemorrhage, exertion may promote rupture of an anomaly which was

about to bleed spontaneously (Walton, 1952a). However, from the evidence quoted, it seems that the association of subarachnoid haemorrhage with non-eclamptic pregnancy is, in general, fortuitous.

Management

If an attack of subarachnoid haemorrhage begins during labour, alleviation of physical strain is an urgent matter; in selected cases, depending upon the stage of labour, emergency caesarean section or instrumental delivery will be indicated before adequate treatment for the subarachnoid haemorrhage, whether conservative or surgical, can be implemented. Occasional cases of grave outlook in later pregnancy may require caesarean section in order to save the child. During pregnancy or the puerperium, however, it is usually wise that each patient should be treated as would any other case of subarachnoid haemorrhage. Details of treatment have been discussed elsewhere (Walton, 1952a); probably, if surgery is indicated, the pregnancy should not influence the decision on the optimum time of operation.

Rhoads (1947) has suggested that when a patient has recovered from subarachnoid haemorrhage during pregnancy termination is the wisest course; one of his patients suffered a fatal recurrence of bleeding during labour. However, this event is apparently unique, and it has been shown that restriction of activity is of no value in the avoidance of recurrent bleeding, while undue emphasis on caution may lead to disabling psychiatric sequelae (Walton, 1952b). It is suggested, therefore, that termination is unjustifiable and that the pregnancy should be allowed to progress to term. After four to six weeks in bed, and if the pregnancy is progressing normally, graduated activity should be permitted in patients who have made a good recovery. The obstetrician must then consider the most satisfactory method of delivery. Conley and Rand (1951) have suggested that caesarean section is indicated in order to avoid undue effort. This view may have some validity if bleeding has occurred within two or three weeks and the causal lesion has not been given adequate time to heal, but it should be remembered that the procedure carries with it the risks of a major abdominal operation. In view of the evidence quoted on the infrequency of recurrent bleeding, it is surely preferable in the majority of cases to allow spontaneous labour in hospital, with adequate analgesia and sedation, and possibly instrumental assistance in the second stage.

It will undoubtedly be asked whether a woman who has recovered from an attack of subarachnoid haemorrhage should undertake further pregnancies. In the series of cases reported by Symonds (1923), Sands (1929), Ask-Upmark and Ingvar (1950), and Walton (1952a) many women had weathered previous pregnancies, uncomplicated by subarachnoid bleeding. Five patients in the Newcastle series have passed through uncomplicated pregnancies since recovery from the illness. It seems that recurrent haemorrhage is no more likely to occur in pregnancy than during ordinary activity, and hence there is no justification for advising against further pregnancies when satisfactory recovery has occurred.

Summary

Two cases of spontaneous subarachnoid haemorrhage complicating otherwise normal pregnancies are reported.

From a study of these and of 30 similar cases previously reported it is suggested that the incidence of pregnancy in patients with subarachnoid haemorrhage is no greater than in the general population. The aetiology of the illness is not unusual in pregnant women, nor does the association affect the prognosis. It is concluded that the two conditions are associated fortuitously, except in so far as the burden of pregnancy or the exertions of labour may provoke rupture of a vascular anomaly which is about to bleed spontaneously.

Except during labour, when caesarean section or instrumental delivery may occasionally be necessary

for the alleviation of physical stress, patients should be managed as would any other case of subarachnoid haemorrhage.

After recovery from the acute illness, pregnancy should be allowed to progress to term. Spontaneous delivery, with adequate pharmacological and instrumental assistance, is advised, save in cases with recent haemorrhage, when caesarean section may occasionally be indicated.

After recovery has occurred there is no justification for advising against further pregnancies.

I am grateful to Professor F. J. Nattrass for permission to publish these cases and for his advice and encouragement.

Medical Memorandum

Acute Appendicitis in the Newborn

Acute appendicitis is rare in young infants, and extremely so in the first few weeks of life. The literature on this subject has been widely surveyed by Etherington-Wilson (1945), who reported an additional case in an infant aged 16 days. Including his own case, Etherington-Wilson found sixteen cases in the age group 0-4 weeks. In six of these the appendices were in hernial sacs; in the remaining ten the diseased appendices were intra-abdominal. Of the sixteen infants ten died and six recovered. In all six recoveries the appendices were in hernial sacs.

A further search of the literature has revealed one other case, reported by Ch'eng and K'ang (1937). The infant was 3 days old, and presented with constipation, intense meteorism, and vomiting. A diagnosis of acute diffuse peritonitis was made. The treatment was expectant and the child died on the 12th day of life. Necropsy showed an acute gangrenous appendicitis, without macroscopic perforation, which had given rise to a diffuse purulent peritonitis.

CASE REPORT

The infant, a first-born male, was premature and weighed 4 lb. 12 oz. (2,150 g.) at birth. There was no abnormality of labour or delivery, but the infant was stated to be feeble at birth. At first he had difficulty with sucking, but by the age of 10 days he had improved and was taking expressed breast milk satisfactorily from a bottle.

On the eleventh day difficulty in breathing was noticed, and pneumonia was diagnosed. Penicillin was started and there was some clinical improvement, followed by a

relapse. He was then transferred to Southmead Hospital, where he was found to be pale and wasted, with gross dehydration. The abdomen was enormously distended and tympanitic. There were many visible coils of bowel. No abnormal mass was felt, and the liver, spleen, and kidneys were not palpable. Rectal examination was normal and the stools were small, hard, and yellow. The heart, lungs, and nervous system were normal, and there was no abnormality of pulse, temperature, or respiration rate. The left tympanic membrane was inflamed.

An intravenous infusion of glucose-saline was begun. This produced an apparent improvement in the general condition, but diarrhoea had now developed, and there was much mucus in the stools. Sulphaguanidine and penicillin were given without effect, and deterioration was rapid. A generalized oedema was now present; the respiration rate became rapid, the temperature rose, and the left ear began to discharge. Death occurred suddenly on the 20th day of life.

At necropsy the significant findings were: (1) Gangrene of the appendix, with the formation of an appendix abscess. The appendix had sloughed off about 0.5 cm. from its base and lay in an abscess cavity, whose walls, formed from the caecum, terminal ileum, and omentum, were held together by delicate fibrinous adhesions; the cavity contained about 3 ml. of thin pus. Organisms present: *Staphylococcus aureus* (coagulase-positive), and *Bact. coli*. (2) Left otitis media: *Staphylococcus aureus* (coagulase-positive) and *Proteus vulgaris* were found.

COMMENT

In the above case the diagnosis of an acute intraperitoneal condition was not considered; the symptoms and signs were thought to be due to acute otitis media, with secondary diarrhoea leading to dehydration and a marasmic state. The diagnosis of acute intra-abdominal appendicitis in the very young appears to be fraught with difficulty, and so far does not seem to have been made at a stage early enough for treatment to be effective.

Localizing signs are more often absent than present (Holt and McIntosh, 1940), as in the case here reported. Abt (1917), in his review of 80 cases under the age of 2 years, and Etherington-Wilson (1945), both emphasize the fact that vomiting is almost invariable. However, vomiting is a feature of many neonatal states and therefore cannot be of much value in diagnosis. In the present case it was absent throughout.

Abdominal distension seems to be a frequent finding, and, if associated with constipation and visible peristalsis, may mimic intestinal obstruction. Diarrhoea may further confuse the diagnosis. On several occasions the condition has been mistaken for pneumonia on account of the rapid respiration rate.

If the diagnosis could be made early enough, before the apparently inevitable gangrene and perforation have occurred and before peritonitis has become general, operation would surely save some of these infants. Etherington-Wilson is convinced that spinal analgesia is the anaesthetic of choice, and this, combined with proper fluid and electrolyte replacement and antibacterial therapy, should go far towards improving the prognosis of this rare but very fatal condition.

I am indebted to Dr. H. J. L. O'Sullivan for details of the infant's birth and early life, and to Dr. R. Sandry for the report on the necropsy.

Reviews

A TEXTBOOK OF THERAPEUTICS

Pharmacology in Clinical Practice. By Harry Beckman, M.D. (Pp. 839; illustrated. £3 3s.) Philadelphia and London: W. B. Saunders Company. 1952.

This is an unusual but refreshing book. Its first sentence runs as follows: "You will probably observe, as I have, that allergists are an apprehensive group." The text occupies over 700 pages, and on the whole the standard of the first sentence is well maintained. The serious purpose of the book is to look at pharmacology from the point of view of the doctor standing by his patient, and not to teach the subject as a science. While a list of references concludes each chapter, the writing is didactic and few authors are quoted. One would expect that an ill-considered and inaccurate work would result, but surprisingly enough this has not happened. Wherever details of the scientific background are filled in, as, for example, in discussing the relation of vitamin B₁₂ and the intrinsic factor, it appears that the author is well acquainted with the most modern research. This, then, is a textbook of therapeutics. It is an excellent work written with good judgment and wide knowledge, in advance of books on therapeutics which are available in Britain. On the whole the book is a reflection of American medicine, but the outlook is often wider. Thus, in the treatment of heart disease the use of digoxin is compared with that of lanatoside C and of digitoxin to the advantage of digoxin. As is well known, digoxin was introduced in Britain and in consequence has received little attention in American literature.

There are, nevertheless, odd features. On page 462 the author gives a list of analgesics. It contains a large number of substances, and among them occur curare and acetylcholine, mustard, and turpentine. It is true that the text on analgesics is written with sanity, but why the author should include in this list mustard and turpentine is almost impossible to guess, and why he should include curare and acetylcholine is quite beyond conceiving. He would rightly fail in any examination if he made statements like that; curare has no effect on sensation, and acetylcholine causes pain. But probably most readers would not notice the substances in the list, and so no harm would be done. The book is to be recommended to the consultant as well as to those in general practice, for it is a comprehensive and very practical guide to modern therapy.

J. H. BURN.

CHADWICK'S CAREER

Edwin Chadwick and the Public Health Movement 1832-1854. By R. A. Lewis. (Pp. 411; 24s.) London: Longmans, Green and Co. 1952.

Edwin Chadwick is receiving his full meed of recognition. We recently reviewed Professor S. E. Finer's authoritative biography of Chadwick in this *Journal*, and we now have this detailed and documented study by Dr. R. A. Lewis before us.

Chadwick's career was a failure, albeit a glorious one. This occurred not only because he was in many respects a hundred years before his time—his arguments for State intervention in public health which now seem self-evident to us alarmed the early Victorians—but chiefly because of his aggressive personality. This book shows that he was his own worst enemy. He was conceited, arrogant, and rude; he refused to compromise and advocated central control when it was most inopportune. In contrast one has only to recall the great achievements of Sir John Simon at a later date to see how much could be won for public health by enlightened medical knowledge guided by conciliation and tact.

Chadwick was not a doctor, but he was instructed by Southwood Smith, Arnott, and Kay in the sanitary evils that prevailed in the first half of the nineteenth century and in the means of combating them.

"And from the first," writes Dr. Lewis, "when Chadwick sent Arnott, Kay, and Southwood Smith on their tour of investigation in 1838, the doctors were the strongest supporters of the sanitary movement, from the Queen's physician, Sir James Clark, and the University professor, W. A. Guy, down to the dispensary and hospital physicians, Joseph Toynbee, Thomas Laycock, William Duncan, and the unnamed rank and file of the Union surgeons and general practitioners."

Chadwick, in his self-exaltation, would never acknowledge his debt to these medical pioneers. He refused to give doctors the first place in the campaign for public health reform, and tried to subordinate their efforts to those of the administrator and engineer. He held that as sanitarians eliminated the causes of disease from the environment the traditional ministrations of the doctor would become less necessary. He even quarrelled with the inoffensive Farr when he pointed out statistical errors in Chadwick's statements.

Chadwick was wrong in thinking that the prevention of disease was solely a matter of environmental hygiene, although this was of great importance. But his driving energy and fanatical zeal aroused the public conscience, and he achieved the following important results before he was forced to retire from the General Board of Health in 1854: first, his *Report on the Sanitary Condition of the Labouring Population*, 1842; secondly, the first Public Health Act, 1848; and thirdly, the setting up of a central health authority with a medical department in the same year. Then he established the linking of State medicine with the medical profession, the importance and desirability of medical officers of health, the value of co-operation with the Registrar-General and the guidance afforded by vital statistics, the principle of medical inquiry by the State into disease and the sanitary condition of the nation, and the encouragement of voluntary agencies for the education and public health service of the people.

This book will be read with interest by public health workers. It is well printed and produced.

ARTHUR S. MACNALT.

DREAM ANALYSIS

The Handbook of Dream Analysis. By Emil A. Gutheil, M.D. (Pp. 710; 85 illustrations. £2 8s.) New York: Liveright Publishing Corporation. London: George Allen and Unwin. 1952.

The author hopes that this book, "a product of thirty years of research and practice, will help move scientific dream interpretation forward towards the advanced position which several other psychoanalytic techniques have attained." About 600 pages are devoted to interpretations of as many dreams, but the final result is disappointing. This is not because there is little in the book that is fresh or scientific about dream interpretation. Dreams have occupied a central place for half a century in the writings of Freud and Jung and their pupils, and, in view of all the accumulated knowledge and experience, any major revision of theory or approach would scarcely be expected. The disappointment is, rather, related to the author's endeavour in the book to use dream analysis as a basis for teaching psychotherapy.

Dr. Gutheil clearly has much insight into patients' emotional conflicts, as many of his interpretations of their dreams show. But by devoting attention too exclusively to dreams he gives the impression that he is creating a "dream book" rather than presenting the basic principles of unconscious dynamics from which the student can understand the neurotic patient as a whole as well as his dreams. Moreover, certain other features do little to dispel this impression. First, there are far too many assertions made about what is or is not established. Secondly, the author is sometimes inconsistent about the role of unconscious dynamics.

Thus, although he states that artificial or invented dreams can be interpreted as if they were real ones (because unconscious forces go into the selection of the content), later on he is worried about the unreliability of the free associations of many patients because they are influenced by reading psycho-analytic literature. Thirdly, the author tries to cater for students much too diverse in their backgrounds. The glossary, for example, includes the following: "*Haemorrhage*: Bleeding; *Typical*: Pertaining to a type, an example, or a characteristic." In short, for the elementary student, as for the experienced psychotherapist, there is not much here that is not to be found in the classical texts.

J. D. SUTHERLAND.

CORRELATIVE CARDIOLOGY

Correlative Cardiology: An Integration of Cardiac Function and the Management of Cardiac Disease. By Carl F. Shaffer, M.D., F.A.C.P., and D. W. Chapman, M.D., F.A.C.P. (Pp. 525. £2 7s. 6d.) Philadelphia and London: W. B. Saunders Company. 1952.

My dictionary states that to correlate means "to connect together by the disclosure of a mutual relation." A conscientious teacher of cardiology spends much of his time correlating, and it is good to see that the authors of this book for students emphasize this important didactic principle in their preface, even to the exclusion of all other matters. The shock comes at once, for the work is presented in summary form, an impossible medium for serious correlation.

Students undoubtedly like lists when preparing for examinations, and it may be fairer to judge the book as a means of "hastily filling the mind with information for a temporary purpose." Scanning the lists of concise statements, a reviewer, if human, finds himself on the alert for error; for one of the great dangers of the summary form is that it favours the parrot mind and, being unencumbered with explanatory text and references, can impart almost any information, correct or false, without exciting the critical faculty. Unfortunately serious errors of fact, of omission, and of judgment are rather obtrusive; these, together with the lack of good pen portraits of clinical syndromes, poor differential diagnosis, indifferent physiology, substitution of fine drawings for skiagrams, electrocardiograms, and other photographs or tracings, and a bad index, make this book difficult to recommend.

PAUL WOOD.

MÉNIÈRE'S DISEASE

Ménière's Disease. By Professor Henry L. Williams, M.D., M.S. in Otol. (Pp. 349. £2 10s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1953.

The most interesting part of this monograph is the full account of Ménière's original work and his explanation of the labyrinthine origin of the paroxysms of vertigo and vomiting, which had previously been considered to be cerebral in nature. The author emphasizes the importance of Ménière's contribution and explains the facts about the famous necropsy in which a haemorrhagic effusion was found in one labyrinth. He makes it clear that Ménière did not consider this to be the usual lesion of the disorder to which his name was later given. He also points out that Knapp suggested hydrops of the labyrinth as the cause of Ménière's disease in 1871, some 67 years before it was demonstrated pathologically.

Dr. Williams thinks that the basic disturbance in the disorder is an allergic vasospasm with resulting labyrinthine hydrops, but describes a second group of cases in which there are typical attacks of labyrinthine vertigo without clinical evidence of cochlear involvement; he assumes without pathological proof that in these cases there is vasospasm but no hydrops. The section on differential diagnosis is rather inadequate, no mention being made of

paroxysmal positional vertigo or of vestibular neuronitis, which may easily be confused with Ménière's disease, and the author gives scant consideration to episodes of vertigo as an early symptom of disseminated sclerosis. He discusses in detail the possible lines of treatment, in general favouring a low fluid and salt regime together with vasodilator drugs, and in cases where surgery is needed preferring destructive labyrinthotomy to intracranial section of the vestibular nerve.

This monograph should be useful to doctors who often see sufferers from Ménière's disease, for it gives a large amount of information about previous writings on the condition and an adequate account of cochlear and labyrinthine tests. But unfortunately there is a good deal of repetition, and there is no assessment, based on an adequate series of cases, of the natural history of the disease and the prognosis. That would have been invaluable in a monograph of this type.

J. W. ALDREN TURNER.

PRACTICAL DERMATOLOGY

Dermatology: Essentials of Diagnosis and Treatment. By Professor Marion B. Sulzberger, M.D., and Jack Wolf, M.D. 4th ed. (Pp. 592; 65 figures, and 8 plates. \$10 or £3 18s.) Chicago: Year Book Publishers. London: Interscience Publishers. 1953.

In this fourth edition of their work the authors are presenting a practical textbook of dermatology dealing with a wide range of common dermatoses but omitting any discussion of rare affections, aetiological theories, general pathology, and histopathology. In the foreword the work is commended to the student and the busy general practitioner, and both will find it a useful book of reference; but the dermatologist will find it of interest also.

The plan of the work, the introduction, and the exposition of the principles of diagnosis, topical medication, and management generally are excellent. The authors draw attention to the physical characters of the applications and the purpose they serve, and they discuss in detail the methods of application and removal and the techniques of bandaging, enjoining their readers to know everything about a few useful remedies and to administer them properly. Not only must the physician give instructions, but he must himself demonstrate these procedures and techniques and must repeatedly check the results of treatment. This is all most admirable and might well be studied by nurses as well as students and doctors.

The authors consider that infantile eczema and the so-called "atopic dermatitis" of adolescent and adult are allergic diseases distinct from eczematous dermatitis of external and unknown origin. They pay great attention to keeping away from potential allergens, especially by elimination diets and by making bedrooms "allergen free" or at least "hypoallergenic." Moving to a warm dry climate is advocated. In discussing pyoderma they emphasize the value of antibiotics applied locally, impetigo being cured in three to five days. Some regard this procedure as unwise and likely to favour the spread of resistant strains of organisms. Leg ulcers and chilblains are not discussed.

"Irritancy," "allergenicity," "morbidity," and "zoonoses" for diseases due to animal parasites are not attractive terms. "Sharply focussed history" and "symmetrical paired comparison" are expressions that need explaining. The latter refers to the use of different applications to symmetrical sites on the patient to judge which may be the more effective. It is a common practice but not one calculated always to increase the confidence of the patient. The experience of the authors with A.C.T.H. and cortisone is particularly interesting, for it is so much more extensive than that of anyone in Britain. The presentation is balanced and impressive. This is a stimulating and useful textbook; it will be welcomed by dermatologist and general practitioner.

GAMMA GLOBULIN AND POLIOMYELITIS

The preliminary reports of the strictly controlled studies by Hammon and his colleagues on the value of American Red Cross gamma globulin in the prophylaxis of paralytic poliomyelitis were recently reviewed in this *Journal*.¹ The gamma globulin used gave substantial protection from the end of the first week to the end of the fifth week after inoculation. In the pilot trial made in Utah in 1951 the incidence of poliomyelitis in the control group, whose members received an injection of a gelatin solution, was apparently no higher than in the uninoculated of the same age. And there was no undue incidence of paralysis in the right leg—in which all inoculations were made. But the figures for the larger trials in 1952 in Texas, Iowa, and Nebraska have not yet been published. We must wait for a detailed analysis before we know whether the administration of gamma globulin interferes with the production of active immunity in people who are exposed to infection but do not develop symptoms. Now that the protective power of gamma globulin has been demonstrated, this is the most important question to be answered, for upon the answer will depend the readiness with which passive immunization will be accepted as a practical procedure in the control of poliomyelitis. "Silent" active immunization does not occur in measles contacts exposed to infection while protected with gamma globulin. It may occur in infectious-hepatitis contacts under similar conditions, and there is experimental evidence that it occurs in monkeys infected with poliomyelitis virus and given gamma globulin at the same time.

Medical authorities in the U.S.A. are now making plans to meet the prodigious demands for gamma globulin they expect in future epidemics. The American National Red Cross has undertaken to expand its programme for the collection of blood, and blood-fractionation plants have been asked to work at full capacity. For all purposes, including transfusions, the American Red Cross estimates it will require five million pints of blood a year. Presumably commercial firms in the U.S.A. will also attempt to increase the supplies of globulin from blood plasma and placentas.

¹ *British Medical Journal*, 1952, 2, 1035.

The gamma globulin issued by the American Red Cross was prepared from large pools contributed by "tens of thousands of donors" and contained antibodies to the three known types of poliomyelitis virus—Lansing, Brünhilde, and Leon. Most of the first 100 strains of virus typed in the U.S.A. belonged to Brünhilde type, and this is probably the one most commonly associated with paralytic cases there. In North America epidemics have been common for the last fifty years; in Britain extensive epidemics have occurred only in the last seven years. The prevalent type of virus here is not known, and we do not know the antibody content of gamma globulin prepared from plasma from British donors, though MacCallum has found Lansing antibody in a small number of batches he has tested. In Britain gamma globulin is prepared from small pools of plasma, and, even if antibodies to Brünhilde and Leon types of virus are found in some batches, they may not be present in batches from all parts of the country. Much of our ignorance here could be quickly dispelled if appropriate investigations were put at the top of the small list of virus research projects possible with the facilities available.

The supply and distribution of gamma globulin raises more difficult problems. It is a generous assumption that about 1 g. of gamma globulin is prepared from a pint of blood. For the 27,000 children given gamma globulin in the American trials about 30,000 g. of gamma globulin were used, representing donations from some 30,000 donors. With the aid of these assumptions we can calculate that roughly one paralytic case was prevented for every 1,000 g. of globulin administered in the trials. The present supply of gamma globulin in Britain is about 1,800 g. annually. It has been issued through the Public Health Laboratory Service for the prophylaxis of measles or infectious hepatitis, and for these diseases the demands greatly exceed the supplies, which are restricted to children in hospital, children suffering from intercurrent diseases, and children aged between 6 months and 2 years. In the near future, when new buildings and plant at the Lister Institute have been completed, the supply of gamma globulin may be increased to about 9,000 g. annually. Even then the total annual output will obviously be inadequate for the protection of large numbers of persons in a widespread poliomyelitis epidemic. More buildings and plant would be needed to increase production beyond 9,000 g. annually, and to satisfy expected minimal demands 50–75% more blood donors would be required. There are now some 500,000 donors in the Blood Transfusion Service, and almost all the blood is issued as whole blood or plasma.

If all these difficulties could be surmounted, and if gamma globulin were available in unlimited quantities, the question of whom to inoculate would still have to be settled.

Paralytic disease in the close contacts of cases is uncommon. By the time a case is diagnosed, three-quarters of the family contacts are already excreting virus in the stools. These contacts have probably begun to develop their own immunity, which is usually sufficient to prevent a paralytic infection. Therefore the protection of family or other close contacts is unlikely to reduce the incidence of the disease much. About 84% of notified cases of poliomyelitis are in people below 25 years of age. Should everyone in this age group be inoculated when poliomyelitis is epidemic in an area? The decision might be taken to carry out such a blunderbuss attack in a town of 100,000 inhabitants (though the case fatality rate is much higher in people aged over 25). Arrangements would have to be made to inoculate 34,000 people, for whom 34,000 donors would have to contribute about one pint each. The protection would last for five weeks, during which time a few might develop an active immunity without symptoms of infection. At the end of the five weeks, if, as might well happen, cases were still occurring, the 34,000 people would have to be inoculated again, and a further 34,000 blood donations would be required. If there were a number of epidemic foci, huge quantities of gamma globulin would have to be made available at short notice, and medical practice in the areas would be disorganized. Every year in which epidemics broke out the process would have to be repeated. We do not pretend to know how the problems which have been raised by the careful field studies of Hammon and his colleagues can be solved. Passive immunization has never been satisfactory for the control of any infectious disease and will certainly not be the method of choice in poliomyelitis.

APNOEA IN ANAESTHESIA

Times change—and with them the meaning of words. The danger signal of yesterday becomes a desirable thing to-day. Respiratory arrest, till recently regarded as warning of approaching death, is now something which the anaesthetist sets out to induce. No longer is it ominously called "respiratory arrest," but, with some familiarity, "apnoea." The profound depression of deep general anaesthesia has very largely given way to other methods. For example, the method, introduced by Mushin,¹ of combining nitrous oxide, pethidine, and a relaxant is now widespread. The patient is not far from consciousness, and his

quiescence during the operation is largely due to the relaxant. In these circumstances the apnoea of to-day differs very much from the respiratory arrest of yesterday. Respiratory arrest after the administration of large doses of, say, ether or thiopentone is still a danger signal, since it indicates that the respiratory mechanism has been poisoned and has ceased to function. Spontaneous breathing will not take place until some of the drug is excreted from the nervous system. Apnoea, on the other hand, is the result of administering a peripherally acting relaxant in sufficient dose to paralyse the respiratory muscles. The anaesthetist maintains adequate ventilation by rhythmically squeezing a bag containing oxygen connected to the patient's respiratory tract. The central nervous system is little depressed, since the accompanying anaesthesia is light.

The advantages offered to the patient and the surgeon by such methods are great. Profound depression of the brain and vital organs by drugs generally regarded as anaesthetics is avoided, and delayed convalescence due to complications becomes more of a rarity. The surgeon is given a nearly motionless field of operation, with muscles relaxed to a degree hitherto almost unknown. The patient's recovery is rapid, and the hazards to which he is exposed when slowly coming round from profound anaesthesia have been almost eliminated.

The practice of deliberately inducing apnoea for major abdominal and thoracic surgery is spreading throughout the world. The present position was summarized a short time ago in this *Journal* by Gray and Rees,² who maintained that apnoea should "be looked upon as an integral feature of the technique for anaesthesia in major surgery and not as something to be avoided if possible, or regarded as a nuisance if inevitable." In describing the role of apnoea in anaesthesia, they pointed out, among other things, that the physical effort of breathing was removed, so that strain on the patient was to that extent lessened. Depression of the central nervous system by the anaesthetic was minimal, and at the conclusion of the operation, when the relaxant was neutralized, recovery was almost immediate. An additional advantage of the use of controlled respiration was that smaller doses of relaxant were needed to maintain the desired state of muscular quiescence.

It must be clearly realized that the patient with paralysed respiratory muscles becomes wholly dependent upon his anaesthetist for the maintenance of his life. The latter must therefore be well aware both of the pharmacological actions of the relaxants and

¹ *Proc. roy. Soc. Med.*, 1951, 44, 840.
² *British Medical Journal*, 1952, 2, 891.

of the dangers inherent in any interference with the mechanism of respiratory control. In addition he needs to know not only what to do to maintain efficient ventilation, but also how to do it in the best possible manner. The rhythm and volume exchanges of artificial ventilation should so approximate to those of normal life that metabolism continues unaltered. Further, the differential pressure changes occurring in the lungs and respiratory tract should not be such as to cause disturbance to the cardiovascular system.

ADDISON'S DISEASE

The diagnosis and the treatment of chronic adrenal insufficiency were discussed at a recent meeting of the Royal Society of Medicine, subjects in which there have been some important advances in the last five years. In many instances a correct diagnosis can be made on clinical grounds, and Professor Dunlop painted a vivid picture of the patient with Addison's disease who suffers invariably from weakness, tiredness, and loss of weight, almost invariably shows increased pigmentation and a fall in blood pressure, and often has associated gastro-intestinal symptoms, such as nausea or diarrhoea, and a tendency to develop hypoglycaemia after fasting. But in one-third of 62 cases the diagnosis was not clinically obvious to physicians experienced and familiar with the disorder, and various tests were required to establish the diagnosis.

The large number of tests available suggests that none is entirely satisfactory and is an indication of the many functions normally influenced by adrenocortical hormones. A radiograph of the abdomen showing calcification in the adrenal area is highly suggestive of tuberculosis of the adrenal glands. A decrease in the serum sodium and an increase in the serum potassium concentrations, together with dehydration, haemoconcentration, and a raised blood urea, may be observed, but so effective are the homeostatic mechanisms that these changes may not be present until the patient goes into an adrenal crisis. Similar abnormalities may be found in febrile patients and those who are losing sodium and extracellular fluid through vomiting, diarrhoea, or renal insufficiency. Evidence of decreased adrenal secretion of androgenic hormones may be obtained by estimating the urinary excretion of 17-ketosteroids. Women with Addison's disease usually excrete less than 1 mg. in 24 hours, but in men higher values are obtained because of androgens secreted by the testes. Moreover, low 17-ketosteroid excretion may occur in many conditions in which adrenal hypofunction cannot be directly implicated, and the estimation requires a well-equipped laboratory and is costly in time and money. The decreased ability of a patient with adrenal insufficiency to excrete a given water load forms the basis of the Robinson-Power-Kepler test.¹ This

is a relatively simple test to perform, carries no risks, and is of considerable diagnostic value. Unfortunately it is not specific, and a decreased diuretic response may occur in other conditions, notably hypothyroidism, cirrhosis, and some cases of nephritis. The response of the adrenals to adrenocorticotrophin (A.C.T.H.) is the simplest and the most informative test if carried out properly. The original four-hour Thorn test,² in which the eosinophils were counted for four hours after a single intramuscular injection of 25 mg. of A.C.T.H., has not proved reliable, because this may not be an adequate stimulus. Thorn himself has found this,³ and his experience is shared by de Mowbray and Bishop.⁴ However, 25 mg. of A.C.T.H. infused intravenously over an eight-hour period is an adequate stimulus, and the Boston workers now recommend this procedure.⁵ The most direct diagnostic approach is to estimate the concentration of adrenocortical hormones in the patient's plasma, and Bayliss, Hunter, and Steinbeck reported that negligible amounts were present in the plasma of patients with Addison's disease and that the concentration remained at zero after an eight-hour infusion of 50 mg. of A.C.T.H.

"The principle of treatment in Addison's disease is to provide satisfactory replacement of the adrenal cortical substances which are lacking or are present in insufficient quantities," wrote Abbie Knowlton in a recent article.⁶ At the R.S.M. Simpson spoke of the value of deoxycortone acetate (D.C.A.) as replacement therapy, and emphasized the danger of implanting too much of this compound, causing sodium retention. There was general agreement that, after the patient had been stabilized on intramuscular injections, pellets of D.C.A. could be implanted at the dosage of 80 mg. by implant, being equivalent to 1 mg. by injection. The pellets are effective for about nine months, and finer adjustment of sodium balance is achieved by varying the salt intake. Spence spoke of his experience with deoxycortone trimethyl acetate in microcrystalline form, a single injection providing adequate control for one month. But D.C.A. is by no means complete replacement; the patient may continue to develop hypoglycaemia, and, as Dr. F. T. G. Prunty and his colleagues point out elsewhere in this issue, the ability to excrete a given water load is not restored. Both these defects are corrected with cortisone. Although many patients remain comparatively well on D.C.A. therapy alone, the addition of 12.5 or 25 mg. of cortisone a day by mouth causes a striking improvement in their sense of well-being and in their ability to work and withstand the stresses of everyday life, and allows them to take their place in a competitive world.

BENIGN HODGKIN'S DISEASE

Sometimes a patient diagnosed on pathological evidence as suffering from malignant disease or other disease carrying a grave prognosis survives unexpectedly long and escapes the expected sequelae. Review of the pathological material may necessitate revision of the original diagnosis. Harrison¹ has recently recorded several cases diagnosed as Hodgkin's disease up to twelve years previously and now apparently healthy. Re-examination

of the original biopsy material disclosed in each case a characteristic histological picture. Harrison identifies it with a supposedly benign form of Hodgkin's disease earlier described by Jackson and Parker.² They called it "paragranuloma" to distinguish it from the ordinary form of Hodgkin's disease, which they called "granuloma." Paragranuloma was said to arise mainly in isolated groups of superficial nodes and to be unusually benign. Progressive involvement of other groups of nodes could occur, but the characteristic appearances often remained unaltered and the benign course continued. Unfortunately, at any time and unpredictably the condition could change to classical Hodgkin's disease with its unfavourable prognosis. Of 28 patients, 5 were well fifteen years or more after diagnosis of paragranuloma, another 10 were well five years or more afterwards, but 7, in whom the disease changed its character, died of classical Hodgkin's disease within 10 years of the original diagnosis.³

The existence of a benign variant of Hodgkin's disease has not been generally accepted in Britain. This is mainly because the wide variations in survival time, and the infinitely subtle gradations in the histological patterns from predominantly cellular to densely fibrosing lesions, have not appeared to justify attempts at subdivision. Further, as Peters⁴ has pointed out, the benign course of paragranuloma may be related to the fact that it often arises in a single group of superficial nodes rather than to any particular histological features. Ordinary Hodgkin's disease also has a better prognosis when its first appearance is local and superficial. As to the pathology of the condition—a subject touched on by Dr. M. H. Gordon in an article at p. 860—Harrison considers that the appearance of various non-specific chronic inflammatory reactions could fulfil the diagnostic criteria of paragranuloma as defined by Jackson and Parker. Further, if the change from paragranuloma to the graver form "is common, it would make recognition of paragranuloma relatively valueless."

It is clearly important to determine whether paragranuloma is a distinct entity, for a diagnosis of ordinary Hodgkin's disease bears serious implications for the patient and his family. Moreover, if the incidence of unrecognized paragranuloma is high in a particular series of cases recorded as Hodgkin's disease, then long average survival will be erroneously attributed to the superiority of whatever treatment was given.

The microscopical appearances of the lymph nodes in Harrison's six cases were remarkably uniform, and the pleomorphism so characteristic of classical Hodgkin's disease was lacking. The main features were that the nodal architecture was largely destroyed and the tissue subdivided by coarse and fine bands of collagen and reticulin; there was diffuse uniform infiltration by small lymphocytes, and among them were scattered variable numbers of typical Hodgkin giant cells. Eosinophils and a few plasma cells were also present. Since all the elements characteristic of ordinary Hodgkin's disease are found, the diagnosis must rest on an assessment of

their relative proportions, density, distribution, and general pattern. It is not surprising, as Jackson and Parker recognized, that transitions between paragranuloma and ordinary Hodgkin's disease are met with. What is perhaps more serious is that, when lymphocytic infiltration is much in excess of the Hodgkin giant cells, the case is likely to be mistaken for lymphosarcoma, as happened to a boy of 12 years in Harrison's series. Harrison nevertheless believes that paragranuloma is morphologically distinct from ordinary Hodgkin's disease and that it is a form of progressive lymphadenopathy: in two of his cases the response to radiotherapy and the subsequent recurrence seemed to exclude a simple reactive lymphadenitis. But he is uncertain whether the clinical course is sufficiently often distinct from that of Hodgkin's disease to make it important to distinguish the two conditions. To decide this will require careful and long clinical and pathological follow-up of large numbers of cases. Harrison is to be congratulated on presenting "benign Hodgkin's disease," as he prefers to call it, as a problem requiring solution rather than as an established fact.

ENGLAND'S HEALTH

If the health of a country could be defined and epitomized in a single figure, many people would choose the infant mortality rate as that index. By this test the health of England and Wales has been steadily improving for many years. Even so, much remains to be done, as the Chief Medical Officer of the Ministry of Health points out in his latest report.¹ In 1951, the year he is reviewing, the rate was 29.7 per thousand live births, whereas in the previous year it was 29.6. The difference is negligible, but the fact that the rate did not decline is disappointing, for in some towns, even large ones, the rate is much lower. In Bristol in 1951, for example, it was 20, and in Croydon it was 19; while in Southgate M.B., with a population of 78,000, it was 15. Analysing infant mortality rates in county boroughs, Martin² has recently shown that the decline of the rate experienced in all towns during the last 30 years was smaller in most of the northern towns than the southern. While the standard of nutrition throughout the country has approached a common level during these years, it is surprising to find that the disparity between the infant mortality rates in its several parts has actually increased.

Surveys of the nutritional state of children since the end of the war have shown almost no evidence of malnutrition or under-nutrition, but some surprising observations have been made in the west country. The data at first indicated that mean heights, weights, and haemoglobin levels of 14-year-old boys were, as might be expected, higher in those boys who were on better diets. But when they were analysed a different picture appeared. Boys from grammar schools were found to be on the average taller and heavier than boys from modern schools whatever the "dietary pattern." Simi-

larly, those whose parental care was assessed by a health visitor as good were taller and heavier, irrespective of diet, than those in whose homes parental care was judged to be normal or bad. The same conclusion was reached after analysing parents' occupation by social class. Again, whatever the social class, school, and family size, the 154 boys who shared beds were on the average lighter than those who did not. The publication of fuller details will be awaited with interest. While dysentery "continues to be as inexplicable as ever," the report also mentions the condition sometimes called epidemic nausea or winter vomiting, which we commented on recently,³ another presumed infection whose epidemiology and even cause are at present obscure. A number of outbreaks have been investigated by medical officers of health and the Public Health Laboratory Service, but further investigation is badly needed.

Every chapter in this report is a tacit tribute to the work of the public health service. To preventive medicine we owe much of our opportunity to live in better health and for longer than our forefathers did. It is to be hoped that legislation will never be blinded by the sometimes spectacular achievements of curative medicine to the no less beneficial achievements of preventive medicine recorded in these annual reviews.

SEXUAL PRECOCITY

Sexual precocity is less rare than is often believed, although some causes of the condition are very uncommon. Drs. J. Anagnostou and G. J. Frangopoulos give an example of one of these rare causes in this week's *Journal* at page 861, where they report the case of a boy aged 6½ years with an interstitial-cell tumour of the testis. Only 14 other cases of this condition have been reported.

Sexual precocity occurs more often in girls than boys; in a recent survey Jolly¹ describes 49 cases in girls and 19 in boys. The causes of the condition fall into three main groups—cerebral, adrenal, and gonadal, with the cerebral group claiming most of the cases. It is only in this cerebral group that true puberty is initiated as shown by spermatogenesis in the male and ovulation in the female. Two main subdivisions of the cerebral group are found—"constitutional" and organic. The constitutional group covers all those cases of a spontaneously early, but otherwise normal, puberty in which no organic cause exists. This type, though rare in boys, is relatively common in girls. In Jolly's survey there were 30 girls in this category, comprising almost half the children in the study. The prognosis for children with constitutional precocity is excellent, and on no account should any form of therapy be attempted. The only permanent disadvantage is that, as with all varieties of sexual precocity, the epiphyses unite early. Consequently, despite rapid growth at first, the patients end up well below the average adult height. The girls should be closely supervised, since pregnancy is possible. The famous Peruvian child, Lina Medina, described by Escomel,³ was one such: at the age of 5 years 8 months she was delivered of a live baby.

The organic cerebral group is of particular interest, since these cases give some indication of the physiological mechanism controlling the onset of normal puberty. Only lesions involving the posterior hypothalamus can cause sexual precocity, and in addition the anterior pituitary must be intact. It is believed that the anterior pituitary initiates puberty and that normally throughout childhood inhibitory impulses pass from the posterior hypothalamus to the pituitary in order to prevent the onset of puberty. If the posterior hypothalamus is damaged, these inhibitory impulses no longer go out, and consequently puberty is released, provided the pituitary has not also been damaged.

In the adrenal group the precocity results from cortical overactivity; this is due most often to hyperplasia of the cortex, but sometimes to carcinoma. Most of the cases of sexual precocity from this cause are boys, since the lesion in girls usually results in virilism, a condition not included in sexual precocity. These boys have to be distinguished from those with precocity of cerebral origin, and here there are two main points to be considered. First, in precocity of cerebral origin spermatogenesis has taken place and the testicles are of adult size, whereas in adrenal precocity they remain infantile. Secondly, in cerebral precocity the urinary 17-ketosteroids are normal or only slightly raised, whereas in adrenal precocity very high figures are obtained. The diagnosis of adrenal hyperplasia from carcinoma used to be very difficult except by laparotomy, but now cortisone has made it much easier. If it is given to a patient with adrenal hyperplasia, the 17-ketosteroids immediately fall. No such drop occurs in the patient with an adrenal carcinoma. Because of this fall, patients with adrenal hyperplasia are also being successfully treated with cortisone. Surgery in these cases is contra-indicated, for the hyperplastic tissue recurs.

The gonadal cause of sexual precocity in the female is the granulosa-cell tumour of the ovary and in the male the interstitial-cell tumour of the testicle. Fortunately, in all the reported cases of a granulosa-cell tumour causing precocity an abdominal mass has been palpable by the time signs of precocity have developed. Therefore surgery is indicated only if an abdominal mass is present. This means that girls with suspected constitutional precocity need not be subjected to an unnecessary laparotomy for fear of overlooking a granulosa-cell tumour. Even when a mass is palpable and laparotomy performed, the majority will still be found to be constitutional cases with an associated follicular cyst of the ovary rather than the very rare granulosa-cell tumour. The diagnosis of an interstitial-cell tumour of the testicle is made on the finding of one enlarged testicle in a child with sexual precocity. This tumour, like the granulosa-cell tumour, is usually benign, but both should be removed as soon as the diagnosis is made. But it is as well to bear in mind always that many cases of sexual precocity need no treatment, since much the largest group of them is the constitutional.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

INJURIES TO THE BACK—I

BY

E. A. NICOLL, C.B.E., M.D., F.R.C.S.Ed.

Surgical Director of Orthopaedic and Accident Services, Chesterfield Royal Hospital and Mansfield General Hospital; Surgeon, Harlow Wood Orthopaedic Hospital

The human spine was originally designed to be supported at both ends, so that when our remote ancestors assumed the erect posture a structure designed as a crossbar was converted into a flexible tent pole eccentrically placed on a narrow base, with its guy ropes tethered so close to the pole that their mechanical advantage was reduced to a minimum. It is this poor architectural arrangement that makes the human spine so vulnerable to injury and so prone to backache resulting from failure of its supporting mechanism. On the other hand, the hips are soundly constructed and

ments (Fig. 2). The anterior common ligament is the chief check to hyperextension. The neural arches are united by strong elastic ligaments—the ligamenta flava—and the spinous processes by the supraspinous and interspinous ligaments, which are also strong except at the lumbo-sacral junction, where they may be defective or even absent, thus further weakening this already weak spot. This region is in fact the site of numerous anatomical abnormalities the clinical significance of which is still a matter of controversy.

Finally, the whole system is supported by muscles (the guy ropes referred to above), which according to their attachments can flex, extend, or rotate the spine. The most important of these muscles—and the most vulnerable—is the complex extensor system known collectively as the erector spinae.

The fulcrum of movement between any two vertebrae is not, as might be thought, at the intervertebral joints, but at a point towards the posterior aspect of the intervertebral disk occupied by the nucleus pulposus. The structures that resist a flexion force, which is the commonest form of trauma, are therefore all those ligaments and muscles behind this fulcrum—namely, the intervertebral joints and their capsular ligaments, the ligamenta flava, the supraspinous and interspinous ligaments, and the erector spinae muscles. Any or all of these may be overstretched or even ruptured, leading to the familiar and by far the commonest of all back injuries, the "sprained back."

FIG. 2.—Anatomical diagram of spine. 1. Fulcrum of movement. 2. Anterior common ligament. 3. Intervertebral disk. 4. Intervertebral joints and their capsular ligaments, the ligamenta flava, the supraspinous and interspinous ligaments, and the erector spinae muscles. Any or all of these may be overstretched or even ruptured, leading to the familiar and by far the commonest of all back injuries, the "sprained back."

mechanically strong, so that in bending and straightening against resistance, as in lifting weights, the spine should be fixed in the neutral position while the actual movement occurs at the hips and knees (see Fig. 1a). This is the correct method as used by professional weight-lifters and furniture removers, and it should be impressed on all patients with "weak backs," whether resulting from trauma, "disks," postural defects, or any other cause.

Anatomy

The vertebral column is divided into cervical, dorsal, lumbar, and sacral segments, each of which has its characteristic curvature. The cervical and lumbar segments are convex forwards, while the dorsal and sacral segments are convex backwards. Exaggeration of the dorsal curve is called kyphosis and of the lumbar curve lordosis. The weak spots are at the junctions of these curves; the dorso-lumbar region is the common site for fractures and fracture-dislocations; the lumbo-sacral region for sprains, prolapsed intervertebral disks, and spondylolisthesis. In considering the effects of trauma on the spine it is necessary to think in terms of the soft tissues as well as the bones, because the former are injured far more often, and the fact that they cannot be seen on an x-ray film makes them liable to be overlooked.

The individual vertebrae are joined in front by a system of shock absorbers—the intervertebral disks—and behind by the intervertebral joints with their strong capsular liga-

Soft-tissue Injuries

It used to be thought that ligaments were in the nature of check reins, and that they came into full stretch only when the muscles failed. This is not so. In the normal spine, for example, electro-myographic studies have shown that during certain phases of flexion and extension the erector spinae muscles are acting strongly, while at other phases, even under load, they are relaxed, so that the patient is literally "hanging on his ligaments." It follows that if the ligaments have been damaged the muscles are suddenly called on to "take over" during certain phases of movement in which they are normally relaxed, thereby giving rise to spasm and pain.

Sprains can occur in two ways: by hyperflexion or rotation injuries, or by violent muscle contraction producing localized rupture of muscle fibres—the equivalent of the footballer's "pulled muscle." The first is exemplified in mining accidents in which the victim is "jack-knifed" by a fall of earth. This can overstretch ligaments as well as muscles. The second is exemplified in the common "lifting sprain," and is a lesion of the erector spinae muscles, practically always in the lumbar region. In both varieties the

patient complains of sudden pain in the back, and often adds that he "felt something go." On examination the lumbar muscles are in spasm with the patient standing erect (they are relaxed in this position in the normal subject) and there is an area of localized deep tenderness. The pain may persist for three to four weeks and the patient often complains that a slight stoop, as in leaning over a wash-basin, is the most uncomfortable posture of all to maintain. This is explained by the fact that in the fully erect position the spine is balanced and the muscles are relatively relaxed, whereas with the slightest degree of forward bending they contract strongly to fix the spine against the effects of gravity while the actual movement takes place at the hips.

The overstretched muscles and ligaments take three to four weeks to heal, and during that time rest is essential and all movements apt to stretch the healing tissues should be avoided. In severe cases an initial period of rest in bed is advised till pain subsides, followed by a plaster-jacket for three weeks. All cases of any severity should be radiographed to exclude a compression fracture, the lesser degrees of which are not clinically obvious. Radiant heat, massage, and local injections of lignocaine are helpful during the first three weeks, and after that carefully graduated remedial exercises should be carried out. In six to eight weeks the patient should be fit for heavy work. If the symptoms persist beyond this, in spite of efficient treatment, some underlying cause should be looked for, such as a pre-existing arthritis or postural defect.

It may sometimes be difficult to differentiate between a severe lumbo-sacral sprain and an acute disk prolapse, either of the central type or before sciatic radiation has occurred. Both may show painful limitation of forward bending and straight-leg raising with a lumbar spine fixed by spasm. If recovering from the flexed position is more painful than actual flexion—that is, coming up is more painful than going down—it is more likely to be a muscle sprain. In some cases, however, the true diagnosis becomes clear only as the result of future developments, so in any doubtful case it is advisable to be on the safe side and insist on two to three weeks' complete rest in bed. Many prolapsed disks with a fully developed clinical picture give a history of past episodes in which the diagnosis could not have been made and which might well have been regarded as sprains at the time.

Fractures and Fracture Dislocations

At one time all fractured spines were regarded as terrible calamities. The patient learned that he had a "broken back" and promptly wrote himself off as a permanent cripple. This was particularly true of mining communities, in which the injury is much more common than elsewhere. It is an entirely unjustifiable attitude, for, whereas some fractured spines are extremely dangerous, the majority are of no serious significance and, properly handled, give the same high proportion of good results as in other fractures. There is no doubt, however, that traumatic neurosis is much more frequent after back injuries than after limb injuries, and this is in no small measure due to the ill repute which still surrounds the term "fractured spine" or "broken back" in the mind of the patient. He should therefore be reassured at once and disabused of any ideas that may be forming the basis of a future neurosis, particularly in the less serious cases, which include all isolated fractures of the transverse and spinous processes and all stable compression fractures. There is no doubt that many patients in this category would be better off if their fractures were never discovered, or at any rate never disclosed to them, but, as this is indefensible, the next best thing is to make the patient see his injury in its proper perspective.

Bony injuries of the spine can be divided into four clinical types, and their relative frequency is as follows:

Isolated fractures of the transverse or spinous processes	42%
Simple compression fractures	42%
Fractures of the laminae	5%
Fracture dislocations	11%

These figures are from a series of 200 consecutive cases seen by me over a five-year period. Of these types, the first two are stable and relatively innocuous; the last two are unstable and dangerous. It will be seen that 84% of the cases fall into the relatively benign class.

Isolated Fractures of Transverse Processes

These are really avulsion fractures produced by muscular violence. The transverse processes give attachment to several very powerful muscles—psoas, quadratus lumborum, and the deeper parts of erector spinae. When these muscles contract strongly in response to a sudden flexing or twisting force they can produce avulsion fractures of the transverse processes (Fig. 3). The degree of damage is roughly proportionate to the degree of separation of the fragments. Once separation has occurred, replacement is impossible and fibrous union inevitable. This does not prevent a perfect result, however, and all these cases should be treated as severe musculo-ligamentous injuries, which indeed they are. If plaster fixation is used it should be for the same reason as in severe sprains—namely, to rest the healing soft tissues—and not with any idea of promoting bony union of the fractures.

FIG. 3.—Radiograph of fractured transverse process.

Isolated Fractures of the Spinous Processes

The spinous processes give attachment to the erector spinae muscles, and a violent extension effort may produce an avulsion fracture. A professional footballer attempted to head a ball backwards. He misjudged it, missed the ball altogether, and was carried off the field with a severe pain in the neck. An x-ray film showed a fracture of the spinous process of the fifth cervical vertebra. "Shoveller's" fracture, seen occasionally in labourers and stokers, is an avulsion fracture of the spinous process of the seventh cervical vertebra produced by sudden contraction of the rhomboid muscle. Like isolated fractures of the transverse processes, these cases should be treated as soft-tissue injuries.

[Part II will appear in our next issue.]

In his report for the year 1952 Dr. J. F. Warin, school medical officer for Oxford, remarks favourably on the results obtained with a sweep test pure-tone audiometer. He concludes that this technique constitutes a big advance over the gramophone audiometer for purposes of routine audiometry in schools. 663 school entrants have been tested, and 25 children have been referred for specialist advice because they failed to pass the test. Three of these 25 children have been found to have a moderately severe hearing loss, though none had been thought to be deaf by either parents or teachers. Dr. Warin writes: "The advantages of the sweep test are that it is quick and easy to carry out; it can be used on school entrants; it does not depend on intelligence or on a knowledge of figures; and can be carried out in any school without difficulty, as no special accommodation is required."

A MODIFICATION OF THE HUBBARD TANK

BY

J. B. STEWART, M.B., Ch.B., D.Phys.Med.

Consultant in Physical Medicine to the Cirencester, Pewsey, and Swindon Hospital Management Committees, Oxford
Regional Hospital Board

During the course of work amongst mentally defective children with spastic paralysis, the Hubbard tank was found to be a most useful means of securing relaxation, or in imparting to the patients a sensation of free movement, such as they often fail to obtain on a treatment table or even with a springs and slings apparatus.

In order to retain the full confidence of small patients it was felt that a movable platform or false bottom in the tank would be an advantage. Such a platform would have to fulfil the following requirements: it must be moved with minimum effort on the part of the physiotherapist; it must move very gently, with freedom from jerking or other sensation of instability; it must be readily and easily detached from the tank for cleaning purposes; and it must be under the complete control of the physiotherapist.

The Apparatus

Standard Jackall hydraulic jacks as motive power have been used. They are relatively cheap and easy to install and have the supreme advantage of being easily serviced with standard spare parts, if required. The Jackall pump unit and fluid reservoir are mounted at one end of the tank. An extension arm is fitted to the pump release valve with

Photograph showing the movable platform in a Hubbard tank.

a control knob mounted on the flange of the tank. Four standard Jackall jacks are mounted on the outer sides of the tank and give an upward thrust to the extension arms of the platform.

The platform or false bottom is made of two light aluminium sheets screwed to a framework of piping. At the four corners of the platform the piping is extended upwards and welded to an inverted metal cup, which rests on the jack head. In order to give complete stability to the platform during movement, a second pipe has been welded to the cup by means of a short piece of metal. This second short length of piping passes through a close-fitting hole in the flange of the tank and also through a small guide mounted on the outer side of the tank, near its base. The entire platform can therefore be easily removed, as it simply rests on the jack heads.

The platform is pumped up and warm water is run in through a thermostatically controlled mixing valve, to a depth of 6 in. (15 cm.) above the level of the platform or

false bottom (see Fig.). By means of the control valve the platform can be made to sink slowly, giving an additional depth of approximately 8½ in. (21.5 cm.). The platform can, of course, be kept at any intermediate depth if so desired.

So that additional warm water may be added without distracting the patient by splashing from taps, the water inlet to the tank is in the form of a hood projecting downwards and opening close to the bottom of the tank. Provision is also made for overflow to take place at a constant level.

No fixed head-rest is fitted to the tank. A standard 16-in. (40-cm.) air cushion partially inflated, doubled on itself, and secured by a tape, has been found to give enough buoyancy when placed under the nape of the neck. It does not have the disadvantages associated with ordinary water wings in hydrotherapy.

Experience gained by the physiotherapy staff during the past nine months has shown that this type of platform has a wide field of usefulness not only amongst cerebral palsy cases but also in cases of poliomyelitis.

Exercises in the bath can be given either with gravity almost eliminated and the patient fully immersed or with the platform raised and the patient only partially supported by water. By means of a simple knob, the physiotherapist can adjust the platform to suit the type of exercise she wishes to give the patient.

Summary

A hydraulically operated platform for incorporation in a Hubbard tank is described and illustrated.

The device has been found to be exceedingly useful in hydrotherapy during the course of treatment of cerebral palsy and poliomyelitis cases.

I wish to record my thanks to Mr. Kenny, chief engineer, and his staff at Pewsey Hospital for the Mentally Defective, who carried out this work for me. A similar platform is being constructed at the Marlborough Children's Convalescent Hospital by Mr. Jefferies and his staff, of Swindon Hospital Management Committee.

BRITISH COUNCIL FOR REHABILITATION

The hope that a blue-print to guide the activities of all concerned in the rehabilitation and resettlement of disabled persons will emerge from the deliberations of the new Committee on the Disabled* was expressed by Sir Walter Monckton, Q.C., Minister of Labour and National Service, at the annual general meeting of the British Council for Rehabilitation, held at the Royal Institution on March 25. He said that the setting up of the committee was proof of the Government's wish to learn from the far-reaching developments that had taken place and the knowledge gained since the interdepartmental committee under the chairmanship of the late Mr. George Tomlinson issued its report 10 years ago.

The Minister went on to say that he thought one of the most encouraging trends of the past 10 years had been the ever-widening interest in the problems of rehabilitation, and he paid a warm tribute to the work of the British Council for Rehabilitation in this field. With regard to the work of his Ministry, Sir Walter Monckton said that there were 14 industrial rehabilitation units with a total capacity of 1,500 places; these were usually filled to 85% of their capacity, and over three-quarters of the men and women came from hospitals and medical practitioners. More than 70% of those who completed courses at the units were placed in employment, and the fullest use was being made of the training facilities provided at residential colleges operated by voluntary organizations.

*Sir Walter Monckton announced in the House of Commons on March 12 that, in conjunction with the Minister of Health and the Secretary of State for Scotland, he had decided to set up a committee under Lord Piercy's chairmanship to review the existing provision for the rehabilitation, training, and resettlement of disabled persons.

Following the Minister's speech there was a film illustrating rehabilitation work in America which was shown by the courtesy of the American Ambassador. At the business meeting of the Council the chairman, Lord Sempill, was re-elected. A working party which had been set up to deal with the special problems of patients with heart disease had completed the collection of preliminary data, and it was hoped that another working party on peptic ulcer in industry would begin its labours during this year.

SUPPLEMENTARY LIST OF APPROVED NAMES

The General Medical Council has authorized the following "approved names" selected by the British Pharmacopoeia Commission. This list supplements the consolidated list of names published in January, which included all the approved names issued since 1948, together with some issued earlier for substances not dealt with in official monographs.

Approved Name	Other Names
Benethamine penicillin	N-Benzyl-2-phenylethylamine salt of benzylpenicillin
Bismuth glycolylarsanilate	Bismuthyl N-glycolylarsanilate. "Milibis."
Cetrimonium chloride	Hexadecyltrimethylammonium chloride.
Hexachlorophane	Di-(3:5:6-trichloro-2-hydroxy-phenyl)methane. "Hexachlorophene."
Hyaluronidase	Enzymes which depolymerize hyaluronic acid.
Iodothiouracil	4 - Hydroxy - 5-iodo-2-mercaptopyrimidine. "Itrumil" is the sodium derivative.
Iopanoic acid	2-(3-Amino-2:4:6-tri-iodobenzyl)-butanoic acid. "Telepaque."
Methylpentynol	3-Methylpent-1-yn-3-ol. "Oblivon"; "somesin."
Nitrofurazone	5 - Nitrofurazone-2-aldehyde semicarbazone. "Furacin."
Pentaerythritol tetranitrate	2:2 - Bishydroxymethyl-1:3-propanediol tetranitrate. "Pentaerythritol tetranitrate."
Phenylephrine	(-) - 1-m-Hydroxyphenyl-2-methylaminoethanol. "Neophryn" is the hydrochloride; "neosynephrine" is the hydrochloride.
Procainamide	4 - Amino - 2-(diethylaminoethyl)-benzamide.
Procyclidine	1 - cycloHexyl - 1-phenyl-3-pyrrolidinopropan-1-ol. "Kemadrin" is the hydrochloride.
Sulphasomidine	6 - p-Aminobenzenesulphonamido-2:4-dimethylpyrimidine. "Sulfisomidine"; "elkosin."

WORLD HEALTH DAY

The fifth birthday of the World Health Organization was celebrated on April 7 at a meeting arranged by the United Nations Association at Caxton Hall, London, where the speakers were the Minister of Health, Mr. Iain Macleod, and Dr. H. S. Gear, Assistant Director-General of the Organization.

Mr. Macleod said he thought the specialized agencies of U.N.O. were all too often overlooked to-day; in contrast, much publicity was given to the happenings in the General Assembly and in the Security Council. It might well be that the agencies' contribution towards peace would not be less than that of the political organizations. It was at least certain that W.H.O. had an immense part to play in bringing about peace. In this country, with its National Health Service and standards of medical care second to none in the world, it was difficult to understand the problems confronting professional men, scientists, and administrators in some

of the more primitive communities. Here a child at birth had an expectation of 63 years of life; in many of the more primitive countries the expectation was only half this. In some of the undeveloped countries grim and dreadful diseases were part of the ordinary pattern of life. The aim in view was that the countries which were assisted by W.H.O. should be able themselves to take over in due course the projects that had been started. There was nothing more cruel than to embark upon grandiose projects that were incapable of being maintained. It was important, therefore, that whatever new techniques or modern methods were introduced into the undeveloped communities should fit easily into the ordinary community life.

The expert committees which had been formed by W.H.O. were immensely important, as they afforded an opportunity for experts from many different countries to get together and discuss their problems. He also thought that the new international sanitary regulations which had come into force in most countries in October, 1952, were a great step forward.

Dr. Gear then explained the working of W.H.O., its machinery and staffing, and its achievements during the first five years of its life. Part of its work was in helping countries which had a particular problem and had applied for assistance and advice. W.H.O. would then seek out the appropriate expert, wherever he might be found, and send him, with any necessary assistants, to the country concerned, where he would develop a control plan, launch it, and hand it over as a going concern to the national health administration. Problems so dealt with included health matters, water supplies, nursing services, and so on. Other activities of W.H.O. were concerned with education and training and the introduction of medical standards.

Nova et Vetera

SIR JAMES MACKENZIE

Sir James Mackenzie, "the beloved physician," was born at Scone, Perthshire, on April 12, 1853. After qualifying at Edinburgh he settled in general practice in Burnley from 1879 to 1907, during which time he began the exhaustive and patient studies which lasted until his death. These included the researches into the nature of arrhythmias which first aroused widespread interest in Mackenzie and his work. He invented a polygraph to take his records, and his *Study of the Pulse* (1902), recording his earlier observations, stimulated others to take up similar work.

In a series of papers in this *Journal* (1905) he demonstrated the remarkable effect of digitalis in auricular fibrillation, while in 1908 his *Diseases of the Heart* included a classical clinical description of this condition and also embodied fuller studies of the pulsations as well as rich experience of cardiovascular disease in general. Another outstanding work was his monograph on *Angina Pectoris* (1923), a disease from which he himself suffered for fifteen years and to which he succumbed on January 26, 1925.

In 1907 Mackenzie moved to London and entered consulting practice. In 1918 he left for St. Andrews, where he founded the Institute for Clinical Research, but he soon returned to the more kindly climate of London.

His character is admirably assessed by Sir Thomas Lewis, who wrote: "Mackenzie's vigorous and impressive personality, blunt but enlivening humour, combative form of argumentation, and clear vision of essentials, combined to make him a teacher of great stimulating power. An uncommon faculty of criticism, a deep-rooted distrust of authoritative statement, gave him rare discrimination between the known and the unknown; this, associated in unusual degree with originality of mind, a retentive memory, and determined purpose, underlay his success as an investigator. A true appreciation of his character and of his work can be obtained only if it is remembered that his chief discoveries were made in time snatched during the routine of a heavy industrial practice."

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Chloroform for Bronchography in Children

SIR.—We read with great interest the suggestion by Drs. M. I. Griffiths, T. Culbert, and N. Sher (*Journal*, March 14, p. 601) that chloroform should be used for bronchography in children.

The only advantage in the use of chloroform seems to be its non-explosibility. In our experience the whole secret of success in the employment of an open method of anaesthesia for this procedure is the rapid attainment of a short period of deep anaesthesia. Even for a matter of minutes deep anaesthesia with chloroform seems to us undesirable for children. Furthermore, as the authors state that "by the time the child leaves the x-ray department he is invariably a good colour," one is led to suppose that at one time during the procedure he may not have been. A combination of hypoxia and chloroform would appear to be particularly lethal.

The method we advocated (Temple and Gray¹) is exactly that suggested by Griffiths, Culbert, and Sher, but ether, for the reasons stated above, was preferred to chloroform. A minor difference was that we did not find the routine use of an airway necessary. We are assured by our radiologist colleagues that modern x-ray apparatus is spark-proof, and the danger of explosion following the administration of open ether is, in practice, non-existent. This opinion is confirmed by the fact that we have employed our method routinely for the last five years with success and without incident.—We are, etc.,

L. J. TEMPLE.
CECIL GRAY.

Liverpool.

Radioactive Phosphorus in the Treatment of Menorrhagia

SIR,—I would like to congratulate Professor H. C. McLaren and his fellow authors on the article (*Journal*, February 14, p. 358) on an ingenious technical therapeutic device, but some shortcomings and possible dangers of the method are apparent.

The first question to be considered in judging the suitability of this method must surely be the cause of the original menorrhagia. Although occasionally no local cause can be found, or a general disorder such as congestive heart failure is responsible, in the majority of cases the underlying disorder is an excessive or unbalanced production of oestrin by the ovaries, often accompanied by the well-known hypertrophic endometrial changes of metropathia or by fibroids, or both. Even from the point of view of immediate results, either of these conditions would militate against the success of the method, because the thickness of the disordered endometrium or irregularity of the uterine cavity would prevent adequate uniform destruction of the endometrium. Even supposing that a sufficiently extensive area of surface endometrium may be destroyed to cause temporary amenorrhoea, when regeneration eventually occurs, will not menorrhagia recur also from the continued operation of the original cause? The authors themselves appreciate that no more than temporary haemostasis can be expected of the method. It is not clear why they should consider that "menstruation when re-established might be normal." The pathology of menorrhagia surely lies deeper than in the superficial 3 mm. of the endometrium. In the case of younger women, where it is desired to preserve ovarian function, one would question the likelihood of normal pregnancy occurring in a patient suffering from menorrhagia and treated by this method.

A more serious, though as yet unproved danger—also mentioned by the authors—is that of the induction of malignant change. A section illustrated shows areas of "irradiation distortion" of the regenerated endometrium three months after P³².

It is precisely from such areas that malignant change might be expected to arise later. X-irradiation of the ovaries has the great advantage that it attacks the cause of the trouble—namely, hyperoestrinism of ovarian origin. Whatever the first cause of ovarian dysfunction (anovular menstruation, failure of luteinization, or excessive follicular activity), x rays destroy the radio-sensitive Graafian follicles, and lead within a few weeks to marked reduction of the output of oestrin and subsequent regression of metropathia, fibroids, and endometriosis, if present. Correction of hyperoestrinism would seem desirable from other points of view—for example, its possible carcinogenic action on the breasts.
