A great practical advantage of x-ray therapy is that it can be given in a few brief applications as an out-patient, thus saving the patient the ordeal of an operation and sparing hospital beds and theatre time. With correct technique radiation sickness is seldom met with, and in any case is preventable with pyridoxin. The somewhat sensational remark that "radium or deep x rays practically castrate the patient" does not carry great weight considering the age group of the patients mainly affected, most of whom are in the late forties, so that one is only anticipating the natural menopause by a few years.

In conclusion, the unpleasant sequelae of x-ray menopause have been greatly exaggerated; they are seldom distressing, except in young women, and can in any case be easily controlled by small doses of synthetic oestrogens.—I am, etc.,

Swansea.

D. K. SAMBROOK.

Dosage of Stilboestrol

SIR,—Dr. E. C. Dawson (March 21, p. 676) asks for comments on the suggested dose of 25 mg. of stilboestrol each day in a pregnant woman who has suffered from habitual abortion. It is a remarkable fact that huge doses of the synthetic oestrogens can be taken during pregnancy without any toxic manifestations.—I am, etc.,

London, W.1.

JOHN BEATTIE.

SIR,—Dr. E. C. Dawson's letter (March 21, p. 676) stirs me to admit the same perplexity concerning the large doses of stilboestrol so generally prescribed. In the early days of the agent I soon discovered the disadvantages of not keeping to small administrations, and I settled to the following routine: At first, 5 mg. three times a day until the breasts became tender or toxic symptoms developed; and then the 5 mg. were replaced by 3 mg., and, in most cases, ultimately by 1 mg.

Occasionally it is wise to swing back from the lesser to the greater quantity. In fact, many of my cases of histologically proved carcinoma of the prostate have been kept in excellent health in this way, and able to carry on their work in comfort for years. Indeed, a number have had no more than 1 mg. once a day for several years. Of my two best cases on this routine, one died at the age of 85, after 11½ years of stilboestrol, and the other died at the age of 69 after nine years of stilboestrol. Both remained ambulatory till within a few months of death.

A common feature, after treatment was well established, has been the rarity of any increase of urinary obstruction. For various reasons there are odd cases that do not do well; but it is correct to say that the majority do. I never attempt any operative radical cure, nor do I eviscerate the testes. Stilboestrol renders the latter small and soft.

Stilboestrol is certainly one of the blessings of modern medicine.—I am, etc.,

London, W.1.

H. P. WINSBURY-WHITE.

Haemolytic Jaundice of the Newborn

SIR,—Dr. George Cheselden's account of icterus gravis neonatorum quoted in your issue of March 7 ("Nova et Vetera," p. 558) is of great interest. There are a number of descriptions of severe and often mortal neonatal icterus published in the seventeenth century, of which Panarolus (1654), Kerckring (1670), Schultze (1676), Sylvius (1679), and Hagendorn (1698) are representative examples; a dissertation was published on the subject in 1673. The eighteenth century, on the other hand, seemed to provide very few new descriptions, as the dissertations of Vaetter (1753) and Müller (1788) show.

I have been unable to trace any reference to this disease occurring in several children of the same family earlier than Pearson's experience of May, 1796. In what form his description first appeared I cannot determine, but it is related, with slight differences, in Underwood's fourth edition of *A Treatise on the Diseases of Children* (1799) and in Cheyne's second *Essay on the Diseases of Children* (1802); Cheyne himself mentions another family in which two children were affected. Dr. Cheselden's observation described in his letter is thus about 70 years earlier than the first published report that I have so far been able to trace.—I am, etc.,

Cambridge.

G. FULTON ROBERTS.

Gastro-enteritis and Labyrinthitis in Influenza

SIR,—In answer to "Any Questions?" (February 21, p. 465) it is stated of gastric 'flu that "the term may be a useful label for practitioners to use, but it has no scientific basis. . . ." Surely this is not the opinion of general practitioners who deal with this common condition. Just because the bacteriologist is unable to prove the presence of the influenza virus, is it unscientific to use one's clinical experience in diagnosing a common illness and naming it by its best-known term?

I was very interested in the letter from Drs. John Malcolm and Sydney L. Churchward (February 28, p. 508) on acute labyrinthitis. During the recent influenza epidemic I had about a dozen cases, mostly also with gastro-intestinal symptoms, who had, I believe, acute labyrinthitis—one very severe—which would point to the influenza virus responsible for this epidemic being a common cause. I should be interested to know whether symptoms of acute labyrinthitis were noticeable in other areas.—I am, etc.,

Borough Green, Kent.

K. D. PINSON.

Unusual Cause of Delay in Delivery of After-coming Head

SIR,—A multipara aged 29 years was admitted to hospital in labour as an emergency because it was suspected that delivery was complicated by a carcinoma of cervix. During delivery the after-coming head was held up at the perineum. It was impossible to deliver the baby until a rubber disk 3 in. (7.6 cm.) in diameter had been removed from the vagina. Delivery was then easily completed. On further examination the disk was found to have a central hole $\frac{1}{2}$ in. (1.3 cm.) in diameter and its periphery had a fungating appearance.

The patient was subsequently questioned and offered this story in explanation. Five years previously she had received advice on the use of, and was fitted with, a diaphragm contraceptive cap. She stated that she burnt this cap, being uncertain how to use it. The patient would not admit to the knowledge that a rubber disk had been inserted and left in place. On questioning she maintained, furthermore, that the disk must have been present during a normal delivery three years ago. Unlikely as her story seemed, there was no particular reason to doubt it. This case history is published by kind permission of Mr. W. H. Peek.—I am, etc.,

Walsall.

E. R. BLAY.

Television and the Patient

SIR,—Who is responsible for sponsoring the talks on medico-scientific subjects televised from time to time? I am unable to afford television myself, so I have to rely on two of my patients for my information. The first had seen some recent advances in bone surgery, in which were discussed the plating of fractures, the use of Smith-Petersen's nail, and the prosthesis used for arthritis of the hip. In the latter my patient gathered that the present material (this would probably be acrylic resin) was shortly to be superseded by some form of compressed nylon.

The second patient had witnessed "Matters of Medicine—Pain," in which were demonstrated various methods of alle-

viating pain. Modern methods of inhalation were contrasted with the older open ether or open chloroform method, which incidentally was referred to as the "out-of-date rag and bottle method." The picture was cut short with the patient struggling during induction by an open anaesthetic. The lecturer took great pains to describe in detail how a spinal needle should be introduced into the theca. One can imagine the feelings of a patient who has seen this latter feature when asked to submit to operation under "rag and bottle anaesthesia." Won't he regard the anaesthetist as being incompetent and out of date?

Apart from ethical considerations, I doubt whether the best interests of the consumers—the public—are served by making available information which many medical men of long standing have not been privileged to gain and which can only lead to an increase in allegations of malpraxis and incompetence.—I am, etc.,

Ruthin.

TREVOR HUGHES.

Trichlorethylene in Labour

SIR,—I was interested in Dr. G. C. Steel's letter (March 14, p. 615) since his routine of pethidine, followed by gas and air, followed by trichlorethylene when the head is on the perineum, is just that which the nurse and I have used routinely for the last four years as a result of a process of evolution from the chloral and chloroform with which I started seven years ago. No doubt many general practitioners have followed instinctively the same path. I believe it combines humanity with the paramount safety of the child.

I agree that it is sometimes necessary to withdraw the inhaler to enable a hitherto normal labour to proceed because of the occasional but obvious inhibitory effect of trichlorethylene on the uterine contractions. Routines based on time and the degree of dilatation without consideration for the woman's willingness to tolerate discomfort are hardly necessary in, or worthy of, domiciliary practice, where alone can the patient be under the close and continuous observation of one midwife and, if necessary, one doctor.

If the doctor himself administers the terminal trichlorethylene analgesia he will also be immediately available to deal with, or anticipate, post-partum haemorrhage.—I am, etc.,

Amble, Northumberland.

R. P. ROBERTSON.

Overdose of Pyrimethamine

SIR,—To those of us who live in the Tropics and who have experienced the trials of administering bitter-tasting malaria prophylactics regularly to small children, the property of pyrimethamine ("daraprim") which commends itself most is its tastelessness. This very property gives rise to the hazard that, finding the bottle of pills, a child may, in play, consume more than its weekly ration. The following story demonstrates another valuable property of the drug—relative lack of toxicity.

A British female child, aged 3 years and 2 months and weighing 35 lb. (15.75 kg.), had been taking weekly doses of a half tablet (12.5 mg.) of pyrimethamine for nine weeks and thoroughly enjoyed the Sunday morning ritual. On February 28, between 10 and 11 a.m., she found the bottle and consumed 15 tablets (375 mg.)—30 times the prophylactic dose. At midday she complained of stomach-ache, but continued to play actively. At 1 p.m. she vomited after eating two spoonfuls of her lunch, but no pills were found in the vomitus. It was only at 4.30 p.m. that she confessed to having eaten the pills, and 15 were found to be missing. She continued to vomit at 30-minute intervals from 1 p.m. to 6 p.m., when she fell into an apparently normal sleep. At 1 a.m. she awoke complaining of thirst and stomach-ache and again vomited. She continued crying for water and retching and vomiting bile-stained fluid at hourly intervals until 10 a.m., but slept for short periods between the bouts. She was then given citrated milk and sodium bicarbonate, and slept until midday, when she again started vomiting. At 2 p.m. the vomiting ceased and she slept until 4 p.m., when she awoke and demanded food, which she ate. Apart from being pale and tired she appeared

to be her normal self. For the following week she was irritable, but ate and slept normally, and now, with no evidence of anaemia or other cellular damage, she seems to have suffered little from her escapade.

This case ably illustrates the remarkably wide range between a prophylactic and a fatal dose of pyrimethamine.—We are, etc.,

P. H. ABBOTT.

MAHMOUD ALI HAMDI.

Wad Medani, Sudan.

Sensitization to Antihistamines

SIR,—I have been interested in the recent correspondence in the *Journal* concerning cutaneous hypersensitivity to antihistamine creams. Whilst the condition undoubtedly exists, it should be stressed that in many cases the cream base and not the antihistamine content is the sensitizing factor.

Recently I have seen two cases, both female, who had been treated with "teevex" cream. Both complained of a burning sensation following applications, and patch tests were strongly positive. However, further testing with the constituents of the cream gave the following results: crotonyl-N-ethyl-o-toluidine, negative; N-dimethylamino-ethyl-N-p-chlorobenzyl- α -aminopyridine hydrochloride, negative; cream base, positive.

Antihistamine creams, used with care, are useful adjuncts to treatment of various itching dermatoses, particularly pruritus ani, pruritus vulvae, lichen simplex (circumscribed neurodermatitis), and lichenified eczema. In cases where sensitivity to one antihistamine cream is discovered, a change to another (in a non-sensitizing base) preceded by a simple patch test is indicated, rather than abandoning a very useful form of therapy.—I am, etc.,

London, W.1.

BENTLEY PHILLIPS.

Nikethamide by Mouth

SIR,—Many G.P.s must have been surprised at the conclusions arrived at by Dr. J. G. Macarthur in his article on "The Effect of Nikethamide by Mouth in Man" (March 7, p. 547). If it is intended we should accept his findings as conclusive, a singularly inopportune moment has been chosen for publication.

Debility, particularly cardiac debility, has been a frequent and prominent feature particularly in the elderly patient following an attack of influenza in the recent epidemic. Nikethamide by mouth I, and no doubt many other G.P.s, have found to be the drug above all others to aid a return to normal circulation and respiration.

The type of case that benefits by nikethamide by mouth is entirely different from the case that calls for the hypodermic syringe. In doses of 1–1.5 ml. by mouth three times a day absorption appears to be slow, but the action, though it may not be great, is a continuous one, beneficial both to cardiac output and to respiration. I have little doubt the stomach would rebel against massive doses, and absorption would be little or none.

Textbooks on cardiology do not mention its use by mouth. The explanation of this is, I feel, that the cardiologist only sees the more severe cases of cardiac failure, and not the lesser cases which the G.P. himself treats. I would be interested to know if many other G.P.s feel similarly to myself, and also feel that its administration by mouth should not be so condemned.—I am, etc.,

Ewell.

J. V. COPE.

The College of General Practitioners

SIR,—One of the purposes of our original letter (February 7, p. 333) was to stimulate comment on the subject of the College of General Practitioners. In this we appear to have failed, and there still appear to be continued apathy, little new comment, and no organized discussion groups. Two correspondents only made reference to our letter. It was a pleasure to read Mr. A. Wilfrid Adams's second communication (February 28, p. 508), but we still find ourselves in disagreement with Dr. H. H. Pilling (p. 507).

He considers that we have not been presented with a *fait accompli*, and that there was ample opportunity for comment. In an article by Dr. J. H. Hunt (*Supplement*, June 28, 1952, p. 335) we were informed that the steering committee would produce a report on what should be done, and we, doubtless with others, waited for their recommendations so that we could submit comments after due consideration. The committee in its report (*Journal*, December 20, 1952, p. 1321) appears to have considered that its recommendations were too good to be improved on, and proceeded to put them into operation before even publishing them. So much for the opportunity for comment, so much for democratic procedure. This surely must be considered a *fait accompli par excellence*. There is one point to which we would like to draw attention. It seems to be widely assumed that all founder members will be presented with whatever diploma may be eventually decided on. This would clearly be a catastrophe, and would for at least 20 years take away any value such a diploma might have. We know of no basis for this assumption and trust it will turn out to be incorrect, but the rumour should be scotched at once by those at present in charge.

Finally, Dr. Pilling states that he believes that the B.M.A. welcomes the venture. It seemed to us most noticeable that the leading article (December 20, 1952, p. 1344) was a plain statement of what had been done—without comment. We believe that many G.P.s feel the college to be unnecessary, its mode of formation peremptory, and its motives unknown. It is indeed high time for the B.M.A. to give us guidance, and advise members as to their attitude to this venture.—We are, etc.,

Iron Therapy

SIR,—Dr. David Haler's answer (February 7, p. 332) to Dr. R. S. Saxton's letter (January 10, p. 97) raises two points. First, with regard to his positive reply that "ferrous gluconate by itself is a more efficient haematinic than ferrous sulphate"—in our opinion the question is not yet settled, as may be seen from the literature. Jasinski^{1,2,3,4} in his papers deals only with the absorption of ferrous gluconate when introduced by mouth and with the good results obtained by the administration of ferrous gluconate to anaemic patients. According to experiments by Lüdin,⁵ the iron utilization coefficient after the administration of ferrous gluconate to anaemic patients is 22%; this value may be interesting if related to the coefficient of 14% obtained by Witts⁶ some years before, using ferrous sulphate. But we think that the comparison of the results obtained by the two different authors in such a complex field is to be regarded with caution. Gram and Leverton⁷ state that the administration of different iron compounds to women showed a daily absorption of 9 mg. with ferrous gluconate and 11 mg. with ferrous sulphate. Finally, Haler,⁸ after a study of the haematinic action of different iron salts, concludes that a ferrous gluconate solution containing aneurin, nicotinamide, riboflavin, and vitamin C is more highly haematinic than ferrous sulphate by itself. It therefore seems to us to be incautious to infer that ferrous gluconate used by itself is a more efficient haematinic than ferrous sulphate.

Secondly, with regard to the interference of vitamins with the absorption of iron compounds, we all know that the haematinic property of an iron compound administered by mouth is directly related to the quantity which enters the body. Whatever the compound used, when iron ions have passed the duodeno-jejunal wall they all behave in the same manner, and, fixed in the plasma, are transported to the various centres of consumption or to the storage organs (Ventura⁹). According to this, the haematinic capacity of an iron preparation is chiefly related to its ability to set free iron ions when subjected to the action of gastro-

duodenal secretions, and so is also related to the quantity of the ions which reach the blood. Consequently, if one iron compound is absorbed better than another it probably has a higher haematinic action. The question arises whether all the vitamins have only a general action on the haematopoietic system, or whether some of them allow a better iron absorption when administered together with iron. Many researches, including papers by Monasterio and

Increase of "serum iron" after the administration of (1) ferrous sulphate, (2) ferrous sulphate plus vitamin C, and (3) "hormo-hemina with iron."

vitamin C and of a particular compound ("hormo-hemina with iron") in which liver extract, gastric mucosa, and yeast are added to the same quantity of ferrous sulphate plus vitamin C, we find that the addition of such substances is able to increase again the iron absorption. This proves the point that a comparison of two iron compounds can be made only when the pure substances are examined. As soon as we can we will report whether ferrous gluconate is absorbed better than ferrous sulphate.—We are, etc.,

Neonatal Myasthenia Gravis

SIR,—The report of still another case of neonatal myasthenia gravis by Drs. B. Gans and D. H. Forsdick (*Journal*, February 7, p. 314) indicates an increasing awareness of the possible occurrence of this condition in offspring of myasthenic mothers. I am presenting three further cases of this syndrome as well as three probable cases in a review, "Myasthenia in the Newborn," to appear in *Pediatrics* in the near future. A patient with congenital myasthenia is also included. It is of interest that, while only three infants with neonatal myasthenia were reported up to 1948, there have been 12 additional cases reported (or in press) in the past few years. Of these 15 cases, nine, including the case by Gans and Forsdick, received adequate treatment with neostigmine, and all recovered. These cases varied in severity, and some might well have recovered without treatment. Of the remaining six who received little or no neostigmine, three recovered but three died, a mortality of 50%. In view of this high mortality in untreated and inadequately treated cases, all newborn infants of myasthenic mothers should be closely observed with the possibility of neonatal myasthenia in mind, despite the fact that many normal infants have been born to myasthenic mothers. Any such newborn infant with unexplained limpness, inability to suck or handle secretions, and a feeble cry should be given a

diagnostic test with 0.125 mg. neostigmine subcutaneously or 3.75 mg. by mouth. It is important that an adequate test dose be given, for otherwise a detectable response may not be elicited in all cases. A syringe containing 0.1–0.2 mg. atropine should be available to counteract any undesirable side-reactions due to the muscarinic actions of this drug. Once the diagnosis is established, the infant should immediately be placed on maintenance therapy, the severity of symptoms determining the size and frequency of the maintenance dose. The average duration of treatment in reported cases was about three weeks. Treatment, once instituted, should be continuous and terminated only gradually to avoid the sudden occurrence of relapse.

Three mothers, after giving birth to infants with myasthenic signs, again became pregnant. In each instance the infant born of the latter pregnancy also showed evidence of the same condition, indicating that this syndrome is prone to recur. Once noted, therefore, infants born in succeeding pregnancies should be particularly suspect and followed especially closely at term.—I am, etc.,

Boston, Mass.

SIDNEY KIBRICK.

Aphosphorosis

SIR,—At a recent combined meeting of the Midland Medical Society and the Midland Counties Veterinary Association, I learned that one of the earliest symptoms of aphosphorosis in cattle is a reduction in fertility. This disease is widespread throughout the world, and is due to a low phosphorus content of the soil, which is, of course, lower in some areas than others, the deficiency being most marked where the soil is peaty.

It seems likely that this fundamental lack of phosphorus will be reflected in the diet of humans, and may be a factor in human infertility. The threshold for phosphorus deficiency is probably different in humans, and aphosphorosis may only occur under conditions of extreme deprivation, faulty metabolism, or faddism. However, it would seem a simple matter and probably well worth while to carry out some controlled experiments in which the blood phosphorus levels of fertile and infertile women were compared, and to assess the value of supplementing the diet of infertile women with suitable phosphorus-containing foods or medicaments.

It is true that there are many factors involved in infertility, and it is unlikely that any one factor would be all-important, but if we excluded only the cases with an organic cause, and disregarded the many nebulous factors that have been postulated, we would be left with the great majority of infertile couples who would be suitable for the investigation.—I am, etc.,

Birmingham.

EDWARD COPE.

Incidence of Leukaemia

SIR,—The survey carried out by Drs. W. R. Gauld, James Innes, and H. N. Robson on the incidence of leukaemia (*Journal*, March 14, p. 585) is extremely interesting, particularly since their findings tend to show a real increase in the incidence of the disease, more particularly the chronic lymphatic form. I would like to point out that contemporaneously there has been an increase in the extent to which x-radiation has been used in the diagnosis of disease. It is, of course, common knowledge that x rays in large doses are capable of producing acute blood changes, and I think there is some evidence that continued small dosage, even at levels below that which is usually regarded as safe, are capable of producing chronic changes.

May I suggest through your columns that some group or body of research workers with suitable facilities at their disposal should investigate the question of a possible causal relationship between these simultaneous increases in the number of x-ray investigations and the number of cases of leukaemia? As a preliminary investigation it might perhaps be possible to take a large number of cases of leukaemia, more particularly the lymphatic form, and find out whether they had at any time been subjected to x-ray investigations.

and then to compare the figures so obtained with a cross-section of the general population. There is, I think, a faint suspicion in the minds of one or two radiologists that indiscriminate radiological investigation is not without attendant dangers.—I am, etc.,

Chislehurst, Kent.

H. GLYN JONES.

Epidemic Nausea and Vomiting

SIR,—Your leading article on this subject (March 7, p. 552) draws attention to a condition increasingly common, which in its acute form constitutes a public health problem, and in its subacute and chronic variants furnishes an appreciable amount of work to the general practitioner. In this practice the condition was first encountered as a mild outbreak in September, 1950. Clinically it was confused with Sonne dysentery by virtue of the combination of respiratory and intestinal symptoms. Stool cultures and blood agglutinations, however, were consistently negative. Since September, 1950, the disease has steadily entrenched itself in the community, with always one or two cases present and periodic mild outbreaks. When the outbreak is at its height (although it is never explosive) and several cases are being seen daily with acute sickness and diarrhoea, the subacute and chronic varieties begin to show themselves.

The subacute variety, peculiar to children, manifests itself as a febrile flatulent constipation with acute nausea, thirst, nasal catarrh, and brassy cough and a reversal of the ordinary sleep habit, so that the child is somnolent by day but sleeps only fitfully by night with a tendency to muscular twitchings and nightmares. On occasion the temperature may go up to 104° F. (40° C.), and there may be conjunctivitis and a blotchy rash on the face which may be mistaken for measles. In the recovery phase there is a tendency to tedious remissions.

The chronic variety, seen in adults, is characterized by a most pronounced weariness and nervous depression, flatulent indigestion, constipation, and headache. Other common symptoms include vertigo, diurnal torpor and nocturnal insomnia, increased cold sensitivity, perversions of taste and smell, thirst, polyuria, and bloodshot eyes. The signs in this chronic type are few—some upper respiratory catarrh, abdominal tympanites, a normal or rather slow pulse, and a very offensive stool. Vertigo, when present, may be so severe as to overshadow other symptoms. These cases may be the foundation of reports of epidemic vertigo. When the vertigo is accompanied by severe frontal or occipital headache and nausea it may be confused with Ménière's syndrome.

In the absence of treatment the chronic case drags on for three to four weeks, the course being punctuated by periods of well-being. This symptomatic seesaw is a prominent feature.

Treatment with succinylsulphathiazole or phthalylsulphathiazole reduces the duration to seven to ten days, while chloramphenicol may resolve the condition in one to three days. When dealing with large numbers this in itself creates a therapeutic dilemma, in view of the difference in cost.

Throughout the three-year period in which this problem has been studied three outbreaks of Sonne dysentery were also noted in this practice, in each of which positive stool cultures were readily obtained.—I am, etc.,

Uffculme, Devon.

FRANK MURRAY.

Cord Traction

SIR,—Without taking sides for or against the routine use of intravenous ergometrine in labour, may I be allowed a few comments on the subject of cord traction which Drs. J. D. Martin and J. G. Dumoulin (*Journal*, March 21, p. 643) raise, since they refer to a paper of mine?

They mention that active contraction of the uterus makes cord traction relatively safe, but do not mention a second safeguard which, in my opinion, is just as important—namely, that the fundus should be maintained as high as possible in the abdomen. In fact, they appear to advocate the use of fundal pressure and cord traction, which I consider to be a most unsafe and undesirable combination. If the placenta is in the vagina or lower uterine segment, suprapubic pressure with the minimum of cord traction is usually very satisfactory. Furthermore, while agreeing with the authors on the desirability of terminating the third stage quickly after the use of intravenous ergometrine, I would like to point out that in this case many of the placentae, though

separated, would still be in the upper segment and a few will not be completely separated. Are the authors happy to allow midwives to pull on the cord in such circumstances?

I believe suprapubic pressure and cord traction to remove the separated placenta to be safe in almost any hands provided that a test for separation has been made. I also believe that, with certain safeguards, cord traction and counter fundal pressure is a valuable procedure in certain abnormal cases in the obstetrician's hands, but would hesitate to go further than this without more experience. Finally, may I ask what happens if the shoulders become impacted and intravenous ergometrine has already been given? Many prefer to wait until the birth of the anterior shoulder is imminent in order to avoid this risk.—I am, etc.,

Borcham Wood.

The Metric System

SIR,—With reference to the recent correspondence on this subject, it seems to me that anything would be better than the present position of using the two systems in a horrid mixture. Thus, believe it or not, I anaesthetize rabbits with a mixture containing 1 grain per "mil." of solution. And even the nasty word "mil." is still only half-way there. For who is there who says that his patients have 5 million red cells per "millilil" ("What a word!" as A. P. H. would say). What is sauce for the goose is sauce for the gander, and if Mr. A. L. Bacharach (March 14, p. 619) is right in saying that we are wickedly inaccurate in talking about "ccs.", we are surely no better for talking about cubic millimetres. Perhaps he will tell us what is the exact difference between a "cc." and a "mil.", and whether the difference is enough to be of the slightest significance. I am afraid he will find that there is still a lot of glassware and syringes about unashamedly graduated in ccs., and no one seems a penny the worse.

For the mixture of measures there is surely nothing whatever to be said—see how easy it is for my horrid handwriting to make "grain" look exactly like "gram," while by far the strongest argument against the metric system is the fatal ease with which one can kill one's best friend by putting a "damned dot" one place too far to the right. It is just for this sort of reason that the lawyers omit from their documents any sort of dots whatever.—I am, etc.,

London, W.1.

J. W. SHACKLE.

Polypharmacy

SIR,—I agree with Dr. George Discombe (*Journal*, April 11, p. 836) that the introduction of unnecessary, highly priced polypharmaceutical mixtures encourages waste of public money, but I do not agree that the proper use of the preparation he mentions, which contains the principal known haemopoietic substances, is either unnecessary or wasteful. Ideally, a specific nutritional deficiency should be treated with a specific nutriment, but it is rare to meet with a deficiency of one factor without depletion of others. This is particularly true in the common anaemias, since foods low in iron are, for the most part, low in folic acid and vitamin B₁₂. For example, Litwins and Greenwald¹ have obtained a more rapid response in hypochromic anaemia when liver extract was added to iron therapy. Smith² has also presented evidence of the existence in liver of still other factors than folic acid and vitamin B₁₂ which account in part for its efficacy, which makes desirable the inclusion of liver fraction in therapeutic preparations.

As Dr. Discombe says, "No one can exaggerate the importance of diagnosis in anaemia," nor can one underestimate its treatment. The use of a preparation that combines the principal substances known to be involved in haemopoiesis would seem to be a reasonable therapeutic measure.—I am, etc.,

London, W.C.2.

Plant Seed Haemagglutinins

SIR,—Your annotation "Plant Seed Haemagglutinins" (March 21, p. 664) rightly ended with the caution that "it is too early yet to assess whether this [method] will be practicable or advantageous."

Recent work in these laboratories, shortly to be published,¹ has shown that fresh saline extracts of *Dolichos biflorus* and *Phaseolus lunatus*, while strongly agglutinating A₁ and A₂ cells, fail to react with A₄ bloods.² However, they can be used to distinguish the subgroup A₂, as *Dolichos biflorus* extracts do not agglutinate A₂ but *Phaseolus lunatus* does—a fact which we have already applied in the investigation of the subgroups of A. Plant haemagglutinins may be a useful research tool for probing the mosaic of the group A antigen, but much further work on many varieties of seeds will be necessary before human grouping sera can be displaced.—I am, etc.,

Regional Transfusion Laboratory,
Sheffield.

C. C. BOWLEY.

Venepuncture

SIR,—I agree with Dr. John Hendrie (March 7, p. 562) that the technique of venepuncture could be much advanced, but not by condemning the routine use of the antecubital site. In techniques which are mechanically straightforward, the importance of maintaining the safety of simplicity is often overshadowed by the apparent advantages of advanced equipment and the requirements of advanced anaesthetic techniques. While I cannot subscribe anything on prolonged or intermittent injection technique, a series of almost 22,000 single-dosage intravenous injections with but one sore arm recorded (this did not slough) encourages me to mention my own routine.

The site is unimportant so long as an adequate vein is selected and confirmed. The antecubital site is normally chosen. The simplest equipment is used, and adhered to, to enable a finer "feel" of the intravenous position. The syringes are all-glass with eccentric nozzle, Luer fitting, of desired capacity. The needles are fine gauge 26, with long bevel (this is still shorter than the short bevel of larger needles commonly used). The needle is inserted with the bevel down, as it is desired that the bevel, rather than the needle, shall be parallel with the vein. A length of $\frac{1}{2}$ in. is adequate for routine work.

A constant visual safety check is maintained. By using simple equipment, a fine needle, and glass nozzle, venous blood can be momentarily withdrawn to the nozzle only for inspection at the outset and at any time during injection. The check occupies three seconds, so can be repeated every millilitre if ever in doubt, and still allow a rate of injection of one millilitre per six seconds. With a metal nozzle syringe, such a simple safety check is impossible. Even the brightest lighting does not enable the blood colour to be recognized at once, because blood must be withdrawn to, and cloud, the main reservoir of solution, so that each subsequent check is increasingly difficult.

During training, none but palpable veins must be attempted. Later, if the above simple precautions are respected, the correct intravenous position can be determined throughout any injection in any vein.—I am, etc.,

London, W.1.

S. L. DRUMMOND-JACKSON.

Mental Health Research Fund

SIR,—The Mental Health Research Fund was founded in July, 1949. Last year you were good enough to draw attention to it in a leading article and by your report of the inaugural conference at Oxford (*Journal*, 1952, 1, 699). Many of your readers will have seen in *The Times* of March 10 a letter making the Fund known to the public and inviting contributions. In launching this public campaign it seems appropriate also to recall our purposes and hopes to the minds of doctors.

That research in mental health is needed is abundantly clear from the high incidence of mental illness in the com-

munity and from the growing population of our mental hospitals. Fortunately research methods are full of promise and yearly become more accurate and delicate. We hope the Fund will be able to offer grants to approved research projects, and wish to remind your readers that its outlook is catholic: as we stated in *The Times*, it is not wedded to any particular approach to this many-sided subject. The governing body is composed mainly of people who are already active in fields bearing on the mind, and the Fund works in close touch with the National Association for Mental Health.

If, as we hope, there are those among your readers who would wish to give this Fund their support, we are in a position to assure them that any contributions which they can secure for the Fund would be used to good advantage. We shall be glad to send further particulars of the Fund to any doctors or laymen who may be interested.—We are, etc.,

IAN T. HENDERSON,
Chairman, Executive Committee.

GEOFFREY VICKERS,
Chairman, Research Committee.

POINTS FROM LETTERS

Freemartins and Siamese Twins

Dr. J. I. MEIKLE (Lilliesleaf, Roxburghshire) writes: As a doctor-farmer I must challenge the statement contained in the first sentence of your annotation "Parabiosis" (March 14, p. 608). Is the calf known to cattle breeders as a "freemartin" truly analogous to a Siamese twin as stated? I do not think so if the expression "Siamese twin" is used in the customarily accepted sense. As I understand the term, "Siamese twins" refers to a viable double monster (classified as a double autosome), the twins being anatomically united and incapable of separate existence short of surgical separation. On the other hand, a "freemartin" in the customary farming sense simply implies a heifer calf of a twin pregnancy, where the other twin is a bull calf. Such twins are born and exist as quite separate individuals, although in foetal life, through a fusion of foetal membranes, they shared a common blood supply. The result of this is that a varying amount of male sex hormone circulated through the female twin effecting masculinization of varying degrees.

Smoking and Lung Cancer

Dr. E. GALLOP (London, S.W.1) writes: In their letter (February 28, p. 505) replying to some criticisms of their views on the possible effects of smoking Dr. Richard Doll and Professor A. Bradford Hill write: "The time correlation was, of course, our starting point. . . . But having applied that stimulus it ceased to have any interest whatever for us until our epidemiological inquiry was over and had alone led us to the conclusion we have quoted above" (that is, "tobacco smoking is a factor in the production of carcinoma of the lung"). This concern for objectivity is wholly admirable, for it is by no means easy to achieve. I do not think that they have done so. For example, in the discussion of the effects of inhaling (*Journal*, December 13, 1952, p. 1271) they write: "On the other hand, the observation that patients who recognize that they inhale are found no more frequently in the lung-carcinoma group than in the control group appears somewhat paradoxical." But, unless there had been an expectation that the figures would turn out differently, why should it seem paradoxical? It does not seem so to me, but then I do not think there is a causal "association between smoking and carcinoma of the lung."

The Medical Practitioner and the Law

Mr. C. R. PORTEOUS (Liverpool) writes: I was interested to read Dr. G. A. Craig's letter (March 14, p. 618) and I am sure that most people thoroughly agree with him. In a recent case, which I am glad to say did not succeed, the cost of the proceedings, which lasted over a week, amounted to many thousands of pounds. Such costs are ultimately defrayed by the taxpayer, whether through "legal aid" or a hospital board. Would it not be possible to establish a fund, or a method of national compensation, for the purpose of alleviating accidental misfortunes? An unbiased board could allocate amounts, and costly court actions would be reserved for cases of criminal negligence where the Crown would prosecute and there would be no question of damages.

Obituary

Dr. G. J. JONES died at his home at Smethwick on March 8 at the age of 76. Born at Warrenpoint, Northern Ireland, on November 24, 1876, George James Jones received his medical education at the old Queen's College, Belfast, graduating M.B., B.Ch. from the former Royal University of Ireland in 1904. After graduation he practised in Northern Ireland until 1915, when he entered the R.A.M.C. and served in France. He was invalided out of the Army in 1918, and in the same year he obtained the M.D. of Queen's University, Belfast. In 1919 he settled in general practice at Smethwick, where he quickly gained the respect and affection of his medical colleagues, for he was a man who gave careful thought to all problems affecting the profession. There was no compromise or deviation once he had made up his mind on what was right. Always ready to help, he was often asked for advice, and, if unpleasant, this was given with a sugared pill of dry, pawky humour. He served on many committees, and was chairman of the West Bromwich and Smethwick Division of the British Medical Association from 1942 to 1944. He was medical officer to various organizations, and during the last war was in charge of a first-aid post, a position which he filled admirably by reason of his strength of character and imperturbability. A doctor of the old school, his hobbies, which he always shared with his wife, were golf, pottery, and reading, and he was a keen alpine gardener. His colleagues and patients in Smethwick mourn his passing with deep sincerity, and sympathize with his wife and son and daughter.—J. S.

Another practitioner of the old school, in the person of Dr. F. C. WETHERELL, died at his home at Ipswich on March 11, within a few days of his 78th birthday. Frank Cordeux Wetherell was born on March 19, 1875, and received his professional training at Guy's Hospital, graduating M.B. from the University of London in 1901. While at Guy's he was captain of the Rugby fifteen which won the inter-hospitals cup in 1897-8. He also played tennis for the hospital and for Suffolk, and Rugby for Kent. In addition he was a good club cricketer. After holding the appointments of house-surgeon at Guy's Hospital and resident medical officer at the Ascot and Bracknell Smallpox Hospital, he settled at Ipswich, where he practised for nearly half a century. During the war of 1914-18 he helped the staff at the East Suffolk and Ipswich Hospital, and in 1919 he was appointed a physician to the hospital, continuing in that capacity until 1936, when he was accorded consultant status. Dr. Wetherell had an unassuming nature, but his patients soon realized that he had a sincere desire for their welfare and they valued his services accordingly. He had a strong sense of humour, and was held in great affection by his colleagues, who elected him chairman of the South Suffolk Division of the British Medical Association in 1935. For many years he was president of the Ipswich Male Voice Choir, in which he took a keen interest, and he was also a vice-president of the Ipswich Choral Society and of the former Ipswich Players. A widower, he is survived by one son and one daughter.

Dr. JAMES B. HANNAH sends the following appreciation: I had the privilege of working under Dr. Wetherell between 1946 and 1948. He had been in practice in Ipswich for some 50 years. In my own experience of physicians, he was the greatest of them all. I shall carry with me always the memory of his courage, his wit, and the way he practised the art of medicine—and to him it was an art indeed, into which he poured his soul as well as his science. Medicine to him was never just an application of scientific principles, even though he excelled in them, and he taught his students to respect patients rather than their diseases.

"Peace of mind," he used to say, "is what they chiefly need. Give it to them." Some of the things he taught took courage to accept, aiming at honesty rather than expedience. "Never be afraid of admitting you've made a mistake. Your patients will think all the more of you and come back to you again." He had great courage. Nearly crippled with arthritis, he used slowly to struggle out of his chair with grunts and a laugh, force his creaking joints through the first few steps and then, with his two sticks, walk jerkily along saying, "That's better." Often he would let himself painfully down on his knees on the hard ward floors so that he could better palpate an abdomen. It was his ambition to work to the end, and when he wrote this year to tell me that he had a hemianopsia the only regret he expressed was that he was "finished as a workman." In his early days he was a great sportsman. He loved music, painting, all that grew in field and garden, animals, his work, and people. In short, he loved life and understood it better than most of us ever will.

The Clan MacDougall, prominent in Scottish history since the twelfth century, has lost its 29th hereditary chief by the death of Colonel A. J. MACDOUGALL of MacDougall and Dunollie at his home at Oban on March 13 at the age of 81. Alexander James MacDougall was born at Poona, India, on January 7, 1872, the eldest son of Surgeon-General H. R. L. MacDougall, and was educated at Clifton College and at the University of Edinburgh, where he graduated M.B., C.M. in 1894. Two years later he entered the Army Medical Department and served first in India and later in Ceylon. During the war of 1914-18 he saw service in France, Egypt, Macedonia, and Palestine. From 1915 to 1917 he was in command of the 35th Casualty Clearing Hospital, and was then appointed A.D.M.S. of the 52nd Division, with the rank of temporary colonel. His war services were recognized by two mentions in dispatches, and in 1919 he was appointed C.M.G. He retired to his home at Oban shortly after the end of the war. In 1932 he was appointed a Deputy Lieutenant for Argyllshire, and he was an Honorary Sheriff Substitute for the county. Colonel MacDougall married Miss Colina Edith MacDougall, third daughter of Mr. Alexander W. MacDougall, in 1901, and she survives him, together with the three daughters of the marriage, the eldest of whom, Mrs. Leslie Grahame-Thomson—the holder of the traditional title Maid of Lorn—now becomes the chief of the Clan.

Dr. H. N. CROSSLEY died at his home in Rochdale on March 13 at the age of 62. For many years he was principal medical officer at Birch Hill Hospital. Harry Newbold Crossley was born at Burnley on November 26, 1890, and received his medical education at the University of Manchester, where he graduated M.B., Ch.B. in 1913, taking the D.P.H. three years later. After qualifying he held the posts of house-surgeon at the Manchester Royal Infirmary and resident medical officer at Withington Hospital. During the first world war he served first as medical officer at the military hospital at Nell Lane, West Didsbury, and later in France with the 61st and 50th casualty clearing stations and the base hospital at Etaples. On demobilization he spent a few months in general practice before being appointed to Birch Hill Hospital in 1920. At that time the hospital was a Poor Law institution and he was the sole resident. Those who have followed the progress of this and similar institutions can look back with great satisfaction, as he did, on the steady progress that took place during the following years. If ever dead bones came to life they did in these hospitals. Changes came fast after the local authorities took over in 1930. At Birch Hill a maternity block was built, a modern pavilion for children was added, the nurses' home was extended, and in 1940 a new operating theatre was opened, which had not only air conditioning but also the first Rothwell sterile water system in Britain. For the inventor was engineer to the hospital at the time.

In all these improvements Dr. Crossley played an important part. Lancastrian by birth and character, he was not one to rush headlong into change for change's sake, but, once convinced that a suggested alteration was a good one, he gave it his unqualified support. Though blessed with a keen sense of humour, he was more sensitive than appeared on the surface, being essentially a shy man. But to those who knew him well he was a staunch and generous friend. He had no interests outside the hospital, and as its superintendent he was shrewd and vigilant, taking pride in the fact that all went well while he was in control. He was a loyal member of the British Medical Association and served on numerous committees, being chairman of the Rochdale Division from 1941 to 1944. His last two years were shadowed by ill-health, and that he lived through them was largely due to the devoted attention of his wife, who survives him.—J. C. J.

We record with regret the death of Dr. CHARLOTTE SHIELDS at her home at Lound, near Lowestoft, on March 17 at the age of 81. Charlotte Annie Warren was born at Derby on July 4, 1871, and was educated at Derby Grammar School. At the end of her school years she decided to take up teaching as a career and was trained for that purpose at Stockwell, in London. After completing her training she held a teaching post in Derby for a time and later taught in Douglas, in the Isle of Man. She married Mr. R. H. Shields in 1900 and went to live at St. Albans, where her husband was a chemist. A year later their only child, a son, was born. In 1907 they moved to Rochford, in Essex. After a few years Dr. Shields realized that her husband's health was failing, and she knew that if their son was to have the education they wished for him she would have to take up some work herself. Medicine had for a long time appealed to her, and bravely she embarked on the necessary training at the late age of 40, entering the London School of Medicine for Women. She travelled daily from Rochford to London, and continued to do so after war broke out in 1914. Despite all, she took the M.R.C.S., L.R.C.P. in 1917, and graduated M.B., B.S. from the University of London in the following year. After qualifying, she decided to start in practice at Westcliff-on-Sea, and was the first woman general practitioner in the borough of Southend. Because of her sound clinical sense and ability, she steadily built up a flourishing practice and endeared herself to many by her patience, skill, and understanding. She also became a medical officer to the antenatal and infant welfare clinics of the borough and took a keen interest in the meetings and other activities of the British Medical Association, becoming chairman of the South-east Essex Division in 1937-8, the first woman to be thus honoured. Outside her medical activities Dr. Shields found time to interest herself in art and music, natural history, the theatre, and the cinema. She retired from practice in 1939 and went to live first at Torquay and later with her son, now rector of Lound. Dr. Shields was a remarkable personality. Only those privileged to know her intimately and work with her could realize her amazing quickness of mind and versatility and the readiness with which she absorbed and utilized new knowledge. With all this she combined patience and humility, a very real love of her fellows, and a desire to help them.—J. L. L.

Dr. W. K. CALWELL, who practised in Kensington for many years, died at his home in London on March 28 at the age of 66. Born at Holywood, Co. Down, on February 27, 1887, William Kirkwood Calwell was educated at the Upper Sullivan School, Holywood, and at Queen's University, Belfast. While at the Queen's Street Hospital he won a scholarship in medicine and the gold medal in diseases of children. After graduating M.B., B.Ch. in 1911, he took the D.P.H. two years later, and proceeded M.D. in 1920, winning a gold medal for his thesis. Having been a house-surgeon and house-physician at the Royal Victoria Hospital, and a house-surgeon at the Belfast Maternity Hospital, Dr.

Calwell joined the R.A.M.C. at the beginning of the war of 1914-18, and went to France with the first 100,000 of the British Expeditionary Force. He was with the 47th London Regiment before being wounded in 1916, and after a short time at home he went out to the Middle East and saw service in Egypt, the Sudan, and Palestine. After being demobilized he entered general practice in Kensington, where he remained for 32 years. During the last war he again served his country nobly by continuing in practice without a break, showing a wonderful example of unselfishness and devotion to duty throughout the numerous heavy air raids on London. In addition to conducting a busy practice he held several clinical assistantships at London hospitals, and was surgeon to F Division of the Metropolitan Police, chairman of a medical board at Willesden, and for a short period part-time assistant medical officer of health for Hammer-smith. Dr. "Billy" Calwell was a lovable man with a heart of gold. His generosity and kindnesses to others were unending, and yet were always quietly and unobtrusively rendered. Trusted and beloved both by patients and colleagues alike, he was the ideal family physician—sound in judgment, modest in manner, ever ready to help, and always gentle and sympathetic. His medical colleagues and patients will sadly miss him. To his wife and two sons we offer our sincere sympathy.—W. B. S.

Mr. LIONEL LOGUE, one of the best-known speech therapists in this country, died in London on April 12, aged 73. He was born at Adelaide in 1880 and educated at the Prince Alfred College there. During and after the first world war he greatly added to his reputation as a specialist in speech disorders by his work among shell-shocked Australian soldiers. In 1924 he left Australia and settled in London, where he built up a big practice. He did much to improve the status of speech therapists, being one of the original founders of the British Society of Speech Therapists and a founder fellow of the College of Speech Therapists. It is now well known that King George VI was one of Mr. Logue's patients. Some ten years before he came to the throne the Duke of York was called on to represent his father at the opening of the new Australian Parliament at Canberra. For a man with a speech impediment this was likely to prove a trying ordeal, and Mr. Logue's advice was sought. On this occasion the Duke was able to deliver his speech successfully, and thereafter Logue continued to help him overcome his difficulty. It was largely owing to Logue's ability and the trust which the Duke of York had in him that the latter was able, when he became King, to speak to the nation with confidence on important occasions, such as his own coronation, and to continue the Christmas broadcasts which his father had initiated. Logue's services were officially recognized by his appointment as M.V.O. in 1937. He was promoted C.V.O. in 1944. His wife died in 1945, and he is survived by three sons.

A general practitioner well known in Devon, Dr. W. H. BUSH died at his home at Chulmleigh on February 8 at the age of 74. Born at Huntingdon on June 21, 1878, William Henry Bush was educated at Brighton College, and then went on to Guy's Hospital, where he was ward clerk to the late Sir Charters Symonds in the days when a carbolic spray was used at operations. After qualifying L.S.A. in 1903 he held the post of house-surgeon at the Brighton and Hove Dispensary for two years, and in 1908 he obtained the diploma of L.M.S.S.A. Dr. Bush was in practice first in Yorkshire and then in Berkshire before entering the R.A.M.C. for service in the war of 1914-18, during which he was in command of the 41st British Stationary Hospital of the North-West Frontier Force in India. After the war he went into practice at Chulmleigh, where he worked for 33 years. Always busy, he was never so preoccupied as to be unable to give sympathetic aid to those who suffered, and his strong personality acted as a tonic to those in pain. He will be sadly missed both by his patients and by his

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

Dr. Frank Howarth has been reappointed University Lecturer in Pharmacology from October 1 to the retiring age, and Dr. F. H. Grundy has been appointed University Demonstrator in Pharmacology from January 1 for three years.

In Congregation on January 24 the following medical degrees were conferred:

M.D.—K. B. Dickson, A. C. C. Hughes, P. F. Lucas, T. A. Kemp, D. G. James.

UNIVERSITY OF BIRMINGHAM

In Congregation on December 19, 1952, the following medical degrees were conferred:

Ch.M.—M. J. Roper-Hall.

M.B., Ch.B.—Monica A. Axson, A. G. Clews, Anthea M. S. Connell, Sylvia J. Darke, J. A. H. Davies, G. F. Devey, J. Edgington, J. E. Evans, C. R. B. Hooper, T. H. Howells, R. C. B. Ngaronye, A. C. Pelides, A. G. Pitchford, E. C. Raybould, M. B. Skirrow, J. Wassell.

The title of University Research Fellow has been conferred on Dr. J. C. Howell, a cancer research worker.

UNIVERSITY OF SHEFFIELD

At a Special Degree Congregation to be held on June 26 a number of honorary degrees will be conferred, including that of D.Sc. on Sir Ernest Finch, Professor of Surgery in the University from 1934 to 1944.

NATIONAL UNIVERSITY OF IRELAND

The following candidates have been approved at the examinations indicated:

DIPLOMA IN CHILD HEALTH.—G. H. Cussen, Livinia H. M. Donnelly, Irene B. Finnegan, Mary G. Larnihan, Deirdre M. F. MacHale, A. Waldron.

DIPLOMA IN PSYCHOLOGICAL MEDICINE.—D. M. Brady, Alice M. Creamer, Mary B. Furlong, B. S. Kale, P. J. O'Connor.

CERTIFICATE IN PUBLIC HEALTH.—J. J. Ambrose, W. J. Bushe, D. N. Connolly, J. G. Cooney, L. F. B. Delany, E. Desmond, Carmel P. Dooley, M. J. Doyle, Margaret M. Farrell, T. M. Fitzgerald, T. Fleming, Hanora H. Forde, J. V. Gallagher, J. K. Heagney, Malachy Heenan, M. E. Kennedy, R. P. King, E. Lacy, A. Loftus, J. B. H. Lusk, E. J. McArdle, D. M. McCarthy, B. St. J. McCartie, Frances M. McCauley, T. C. McGrath, Ita McMahon, D. J. McNamara, B. Maguire, S. P. Maurer, D. E. Mellon, J. J. Molony, Madeline E. Moran, Mary I. Murphy, B. T. A. Murray, O. P. M. Murray, J. J. O'Brien, E. O'Connor, T. J. O'Dea, M. O'Dwyer, P. K. O'Flynn, J. P. O'Sullivan, A. C. O'Toole, M. J. Reilly, Eva Roith, M. T. Rynne, T. E. Scully, T. Simpson, Clare M. H. Smith, T. J. Timmons, J. H. Walsh.

UNIVERSITY OF BRISTOL

Arthur Oliver Chick and Ephraim Joshua Field, M.D., M.S., Lecturer in Anatomy in the University, have been approved at the examination for the degree of Ph.D. in the Faculty of Medicine.

ROYAL COLLEGE OF SURGEONS IN IRELAND

The following candidates were conferred with the Fellowship of the College on November 21, 1952: J. T. Carroll, D. L. T. G. Finn, S. J. Heffernan, I. C. Modebe, J. P. McMullin, O. M. O'Malley, R. D. H. Parker.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

At a meeting of the Council of the College held on November 29, 1952, it was reported that a grant of £3,000 had been received from the British Empire Cancer Campaign for research purposes.

Professor Lutherus Johannes te Groen (University of Pretoria) was elected to the Fellowship and Diaa Seif-Eldin was admitted to the Membership of the College.

Mr. Henry Roberts (Liverpool) and Mr. James Walker (Aberdeen) were appointed William Blair-Bell Memorial Lecturers for 1953.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

At a meeting of the Faculty held on February 2, with the President, Dr. Andrew Allison, in the chair, A. H. Edwards was admitted a Fellow of Faculty *qua* Surgeon.

Medico-Legal

MEDICAL PRACTICE A "BUSINESS"?

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

Mr. J. H. Williams, being anxious to provide for the future of his son, made a will in which, in addition to giving him a determinable life interest in nine-tenths of his residuary estate, he empowered the trustees to advance up to a quarter of that share to the son, after he had attained the age of 35, for the purpose of starting him in business or for the advancement of any business with which he might be concerned.

Mr. Williams died in 1937. In 1942 the son qualified as a doctor. In 1943 he reached the age of 35. He was now anxious to buy a house partly to live in and partly as a base for his medical practice, and wanted the trustees to advance the purchase price under the power in the will.

The trustees applied to the Chancery Division of the High Court to determine whether under the will they had the power to do so, and the matter was heard by Mr. Justice Danckwerts on February 6, 1953.¹

In his judgment Mr. Justice Danckwerts said that the clause in the will should not be narrowly construed and that its object was to help the son to maintain himself in a gainful occupation. From the authorities and the dictionaries the word "business" seemed to be capable of including a profession, and plainly included the profession of doctor. Referring to the B.M.A.'s *Medical Practitioners' Handbook*, he said that the evidence showed that it was often a condition of success that a doctor should be able to take over a house where he could have a surgery and where he could be available. Therefore it would be a proper thing for the trustees to buy a house for the son to reside in, provided it was bought not only for him to live in with his family but with a view to advancing his prospects in medicine.

He made a declaration accordingly.

¹ *The Times*, February 7.

The Services

A *Supplement* to the *London Gazette* has announced the following appointments in recognition of gallant and distinguished services in Korea during the period July 1 to December 31, 1952:

O.B.E. (Military Division).—Lieutenant-Colonel C. B. Caswell, M.C., 37 Field Ambulance, R.C.A.M.C.

M.B.E. (Military Division).—Major B. D. Jaffey, 37 Field Ambulance, R.C.A.M.C.

NAVAL MEDICAL COMPASSIONATE FUND

A meeting of the subscribers of the above fund will be held on May 4 at 3 p.m., at the Medical Department of the Navy, Queen Anne's Mansions, St. James's Park, London, S.W.1, to elect six directors of the fund.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending March 28 (No. 12) and corresponding week 1952.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1953					1952

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Vital Statistics

Smallpox in the North Country

Up to noon on April 14 there had been 22 confirmed cases of smallpox, including 4 deaths. The districts in which contacts remained under surveillance at that date were Oldham C.B. and Leeds C.B. At Oldham there was a fresh case since the previous week's report, in a girl already in quarantine. Aged 17, she had never been vaccinated. At Leeds an unvaccinated boy aged 8 died on April 14. The confident diagnosis of haemorrhagic smallpox awaited laboratory confirmation.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1944-52 are shown thus -----, the figures for 1953 thus ———. Except for the curves showing notifications in 1953, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Medical News

OPHTHALMIA NEONATORUM

Infectious Diseases

In England and Wales during the week ending March 28 a decrease of 1,435 was reported in the number of notifications of measles, from 27,226 to 25,791, while the largest increases were 114 for scarlet fever, from 1,625 to 1,739, and 98 for whooping-cough, from 3,104 to 3,202.

The fall in the incidence of measles was confined to the southern section of the country; in the northern section there was a small rise. The largest decreases in the number of notifications of measles were 400 in Surrey, from 1,805 to 1,405; 394 in Hertfordshire, from 1,109 to 715; 306 in London, from 1,439 to 1,133; and 239 in Middlesex, from 1,337 to 1,098; the largest rise was 177 in Yorkshire West Riding, from 1,821 to 1,998. The largest increase in the number of notifications of whooping-cough was 58 in London, from 202 to 260. The only large rise in scarlet fever was 50 in Lancashire, from 196 to 246. 20 cases of diphtheria were notified, the same number as in the preceding week. The chief feature of the local returns of diphtheria was a rise in Lancashire from 5 to 10.

46 cases of acute poliomyelitis were notified during the week, 20 more than in the preceding week. These cases were 22 more for paralytic and 2 fewer for non-paralytic cases. The largest returns were London 9 (Fulham 2, Battersea 2, Kensington 2), Lancaster 5 (Liverpool C.B. 2), Sussex 4, and Middlesex 4.

463 cases of dysentery were notified, 30 more than in the preceding week. The chief centres of infection were Leicestershire 89 (Leicester C.B. 87), London 79 (Stoke Newington 18, Islington 10), Lancashire 60 (Liverpool C.B. 30; Manchester C.B. 14), Yorkshire West Riding 59 (Leeds C.B. 24, Bradford C.B. 19), Middlesex 38 (Edmonton M.B. 25), and Lincolnshire 25 (Boston M.B. 12, Boston R.D. 8).

Influenza deaths in the great towns numbered 100; these were 33 fewer than in the preceding week.

Week Ending April 4

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,403, whooping-cough 2,508, diphtheria 11, measles 21,166, acute poliomyelitis 38, dysentery 423, paratyphoid fever 7, typhoid fever 6.

The Industrial Spectroscopy Group, Institute of Physics, has formed a panel of members interested in direct reading equipment for spectrochemical analysis. These devices combine spectrographs with electronic equipment in such a way that the intensities of characteristic spectral lines give a direct reading of the percentage of the elements present in the specimen. The panel is to organize meetings serving the interests of users and potential users of this equipment. Readers who would like notices of the meetings on this subject are invited to join the Group. Further particulars may be obtained from the secretary, Institute of Physics, 47, Belgrave Square, London, S.W.1.

W.H.O. Regional Health Education Conference.—This week delegates from 18 European countries have been meeting at B.M.A. House to discuss health education of the public. The Conference, sponsored by the European Regional Office of W.H.O., is under the joint chairmanship of Professor J. M. Mackintosh, of the London School of Hygiene and Tropical Medicine, and Dr. Eugene Aujaleu, of the French Ministry of Public Health and Population. The principal speakers have been Dr. John Burton (London), medical director of the Central Council for Health Education, whose subject was "Health Education of the Public—Present Scope and Future Growth," and Professor Pierre Delore (Lyons), who spoke on "The Role and Possibilities of Health Workers in Health Education of the Public." Other subjects discussed have been "Planning for Health Education of the Public" and "Methods and Techniques in Health Education." The conference was opened on April 11 by Sir John Charles, Chief Medical Officer of the Ministry of Health, and ends on April 18.

Medical Team for Indonesia.—The World Health Organization has recently sent several international teams of medical specialists to countries in the Near and Far East. Each team has comprised about a dozen or so members, all of whom are acknowledged experts in their subjects. The teams remain for two or three months, and the members work alongside their opposite numbers, sharing their experience. One of these teams went to India at the beginning of the year (see *Journal*, February 7, p. 345). Another has just gone to Indonesia for seven weeks. The latter includes four British professors among its thirteen members—Dr. E. W. H. Cruickshank (professor of physiology, Aberdeen), Dr. M. L. Rosenheim (professor of medicine, London), Dr. R. R. Macintosh (professor of anaesthetics, Oxford), and Dr. A. C. Stevenson (professor of social and preventive medicine, Belfast).

Association of Clinical Biochemists.—The inaugural general meeting of the Association of Clinical Biochemists was held at the Postgraduate Medical School of London last month. The formation of the Association goes back to May, 1952, when regional societies of clinical biochemists in Glasgow, the Midlands, North-Western and Southern England set up an interim committee under the chairmanship of Professor E. J. King. The association now formed will be both scientific and professional in the scope of its activities. On the professional side it will concern itself with the status of scientifically qualified biochemists working in hospitals or allied laboratories, who have not hitherto been specifically provided for by professional associations. On the scientific side it will work in the rapidly expanding field of clinical biochemistry, where pathology, clinical medicine, and biochemistry overlap. The association will hold regional and national meetings, at which papers will be read and demonstrations given. Anyone wishing for further information about the association should write to the Secretary, Dr. A. L. Tárnoky, Royal Berkshire Hospital, Reading.

Hunterian Society's Gold Medal Essay Competition.—The subject for this year's essay is "The Management of Peptic Ulceration in General Practice." The competition is open to all general practitioners, and further details may be obtained from the hon. secretary of the Hunterian Society, Mr. A. W. Badenoch, 110, Harley Street, London, W.1. The Society's gold medal for last year's essay competition has been awarded to Dr. D. G. French, of Kidsgrove, for his essay on "The Management of Hypertension in General Practice." A *proxime accessit* award was made to Dr. A. E. de la T. Mallett, of Wimborne.

Missing Harveian Oration.—The library of the Royal College of Physicians of London possesses copies of all the published Harveian Orations with the exception of one—

that delivered in 1849 by Dr. J. C. Badeley. The particulars of this oration, as taken from the Surgeon-General's catalogue, are:

BADELEY (Joh. Carr.) Oratio ex Harveii Instituto in ædibus Collegii Regalis Medicorum habita pridie calend. Julii, A.D. 1849. 20 pp. 8°. London, J. Churchill, 1849.

Anyone who has a copy of this oration for disposal is asked to communicate with Professor E. C. Dodds, F.R.S., Harveian Librarian, Royal College of Physicians, Pall Mall East, London, S.W.1.

Scientific Instruments and the Customs.—Delicate scientific instruments have sometimes to be sent from country to country, and unless very carefully packed they are liable to breakage in transit. In order to avoid their unpacking at frontier customs stations Unesco has recommended the adoption of a special label. Countries participating in the scheme designate the laboratories entitled to use the labels. When one of these laboratories wishes to export an instrument it is packed in the presence of a customs officer, and the label affixed. This will ensure that the package is not opened until it reaches its final destination, where it will be unpacked in the presence of another customs officer. The scheme was originally proposed to Unesco by Britain, and considerable interest is being shown in it. The only British laboratory so far chosen as a participant is the National Physical Laboratory, Teddington.

Medical Photography.—An exhibition celebrating 100 years of medical photography is being held until the end of April at the Royal Photographic Society, 16, Prince's Gate, London, S.W.7 (Mondays to Fridays 9.30 a.m. to 5.30 p.m., Saturdays 9.30 a.m. to 5 p.m.). An unusual collection of old photographs is on view, many of them being of historical interest. A few of the modern ones are in colour, though they hardly display the full possibilities of colour photography in medicine. The modern black-and-white photographs show, as might be expected, a high degree of excellence.

La Presse Médicale's Film Competition.—The results of the second competition for medical films, organized by *La Presse Médicale*, were decided by a jury of expert assessors in Paris last month. The first prize (50,000 francs) and two second prizes (25,000 francs each) went to French exhibitors. Mr. J. T. R. Edwards, a consulting surgeon from Newport, Monmouthshire, was one of four to receive an award of 10,000 francs. His film was called "Resection of the Oesophagus."

Medical Symposium in the Lebanon.—Four British delegates are attending the third Middle East Medical Symposium at the American University, Beirut, thanks to the British Council. They are Dr. C. H. Andrewes, F.R.S., who is speaking on the virus theory of cancer and on poliomyelitis, Professor J. W. Cook, F.R.S., whose subject is "The Chemical Aetiology of Cancer," Professor L. P. Garrod, who is to review antibiotic therapy, and Professor Robert Cruickshank, who is discussing controlled chemotherapeutic trials. After the conference Professor Cruickshank will visit Turkey, and Professor Garrod Syria.

Air Marshal Sir Harold Whittingham has, for the fourth year in succession, been elected chairman of the Standing Medical Committee of the International Air Transport Association, whose recent meeting in Portugal was referred to in the *Journal* of April 11 (p. 843).

COMING EVENTS

Hastings Lecture, 1953.—Professor F. A. E. Crew, F.R.S., professor of public health and social medicine in the University of Edinburgh, is to give this year's Hastings Lecture of the British Medical Association, on May 6 at 6.30 p.m. in the Great Hall of B.M.A. House. His subject is "Medicine and Social Policy." Mr. Walter Elliot, C.H., F.R.S., will be in the chair. The Hastings Lecture is expressly intended for the lay public, and it is hoped that doctors will bring this function to the notice of lay people

who might be able to attend. Admission is free by ticket obtained in advance on application to the Public Relations Department, B.M.A. House, Tavistock Square, London, W.C.1.

Cambridge Medical Society.—A dinner of the Cambridge Medical Society will be held at the University Arms Hotel, Cambridge, on April 22 at 7.30 p.m. Members may bring wives and friends, and tickets (price 21s. per head) are obtainable from the secretary, 22, Parkside, Cambridge.

Medical Art Exhibition.—The annual exhibition of the Medical Art Society, which opened on April 13 at Walker's Galleries, 118, New Bond Street, London, W.1, will remain open daily from 10 a.m. to 5 p.m. (Saturday 10 a.m. to 1 p.m.) until April 25. Admission is free.

Postgraduate Course at Cambridge.—The next symposium arranged for postgraduate students by the Cambridge University Medical School will be on cardiovascular diseases, and will take place at Addenbrooke's Hospital, Cambridge, on April 25 at 10.30 a.m. Those wishing to attend are asked to notify the secretary, Cambridge University Medical School, Tennis Court Road, Cambridge.

Spanish-American Odontology Congress.—The first Spanish-American Congress of Odontology is to be held in Seville from May 1 to 7. The main subjects for discussion will be dental caries, total prosthesis, periodontal disease, and social services. Further details may be obtained from the secretary of the Congress, Villanueva 5, Madrid, Spain.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, April 20

- HUNTERIAN SOCIETY.—At Talbot Restaurant, 7 for 7.30 p.m., annual general (dinner) meeting. Mr. C. Robert Rudolf: Hunteriana—Part III. LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.—5.15 p.m., Professor Philip Drinker (Harvard): The Engineer and the Physician in Industrial Hygiene.
- ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. H. J. Seddon: Periphereal Nerve Injuries; 6.30 p.m., Mr. A. J. Gardham: Tumours of the Pharynx.

Tuesday, April 21

- CAERNARVONSHIRE AND ANGLESEY PAEDIATRIC CLUB.—At Clinic, Sackville Road, Bangor, 4.30 p.m., Miss Isabella Forshall: Surgery of the Newborn.
- ROYAL COLLEGE OF SURGEONS OF ENGLAND.—3.45 p.m., Erasmus Wilson: Demonstration by Dr. B. E. Heard: Structure of Tumour Cells.
- ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. R. Guy Pulvertaft: Care of the Injured Hand; 6.30 p.m., Sir Stanford Cade: Bone Sarcoma.
- SOCIETY FOR THE STUDY OF ADDICTION.—At Medical Society of London, 8 p.m., annual meeting. Dr. W. R. Bett: Vincent Van Gogh (March 30, 1853-90): Artist and Addict.

Wednesday, April 22

- HARVEIAN SOCIETY OF LONDON.—8.15 p.m., discussion to be introduced by Dr. John Hawksley and Professor M. Maizels: P.U.O.
- NORTH-WESTERN TUBERCULOSIS SOCIETY.—At Aintree Hospital, Liverpool, 5.30 p.m., Dr. W. S. Sutton: Bronchiectasis.
- ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.30 p.m., Urology Lecture by Mr. Arthur Jacobs: Uretero-colic Anastomosis. The Indications, Methods and Results.
- ROYAL COLLEGE OF SURGEONS OF ENGLAND.—6.30 p.m., Professor W. V. Mayneord: Some Clinical Applications of Radioactive Isotopes.
- ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Mr. W. B. Purchase: Experiences at the Bar and as a London Coroner.
- SOCIETY OF CHEMICAL INDUSTRY: FOOD GROUP—NUTRITION PANEL.—At Burlington House, 6.15 p.m., papers on synthetic food potentialities. Speakers, Dr. W. F. J. Cuthbertson, F.R.I.C., and Mr. P. N. Williams, F.R.I.C.

Thursday, April 23

- HONYMAN GILLESPIE LECTURE.—At University New Buildings, Edinburgh, 5 p.m., Dr. A. Rae Gilchrist: Coronary Sclerosis.
- ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Sir Francis Fraser: Privileges of a Learned Profession.
- ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. F. W. Holdsworth: Management of Paraplegia; 6.30 p.m., Professor C. Wells: Transplantation of the Ureter.
- ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Mr. R. Mailer: Treatment of Peptic Ulceration.
- ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. D. Curran: post-graduate demonstration in psychiatry.

Friday, April 24

- INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—3.30 p.m., discussion for general practitioners. Mr. S. E. Birdsall: Otitis Externa.
- MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.—7.30 p.m., general meeting. Dr. C. S. Nicol and Dr. D. G. ff. Edward: Role of the Pleuropneumonia Organisms in Genital Infection.
- ROYAL COLLEGE OF SURGEONS OF ENGLAND.—6 p.m., Professor F. A. R. Stammers: Use and Abuse of Antibiotics.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Thyroid Adenoma and Malignancy

Q.—What is the magnitude of the risk of simple adenoma of the thyroid becoming malignant? How should the adenoma be treated?

A.—True simple adenoma of the thyroid is a rare condition and can be correctly diagnosed only after removal and histological examination; malignant change in such a tumour is exceedingly uncommon. Nodules (of one sort or another) are, however, a common finding on palpation of the thyroid, and the important thing is to decide whether they are multiple or solitary. Multiple nodules in the thyroid are typically seen in adults living in an area of endemic goitre, but they not infrequently appear sporadically in non-goitrous areas, being particularly common, for example, in London. It is unlikely that a malignant change occurs more often in such glands than in apparently normal ones. Even allowing for the fact that suspicion of a malignant change in a multinodular goitre will lead to its removal, the incidence of cancer in such glands removed by operation is rarely over 5%.

Solitary nodules, however, especially if seen in young patients, should always suggest the possibility of malignancy, and should therefore be removed with a margin of healthy thyroid tissue. If malignant, they are usually of a papillary type of carcinoma which is slow growing, spreads typically by the lymphatics, and even local removal frequently leads to apparent cure. The criteria for deciding to excise such nodules naturally vary according to the views of the individual clinician, but the incidence of malignancy in solitary nodules removed from younger people has been found to be somewhere around 15%. It must be added that, even after removal of the nodule from the patient's thyroid, the pathologist may have great difficulty in deciding whether it is malignant or not. Perhaps it is for this very reason that the reported incidence of malignancy in thyroid nodules has varied greatly in different clinics.

Overdose of Adrenaline

Q.—What is the explanation of extreme pallor, thready pulse, and a severe throbbing headache following the injection of 15 minims (0.9 ml.) of adrenaline for an attack of asthma? Does the reaction contraindicate further adrenaline for the patient concerned, and, if so, what alternative treatment is advised for his asthma?

A.—The amount of adrenaline required in an attack of asthma varies according to the severity of the attack. The symptoms and signs described indicate that too much adrenaline was given for that attack. Further immediate adrenaline would be contraindicated, and, if the asthmatic attack was persisting, intravenous aminophylline (0.5 g. per 20 ml.) given slowly would be advisable. There would be no contraindication to adrenaline being used in subsequent attacks, but much smaller dosage (3 to 6 minims—0.18 to 0.36 ml.) might be tried and repeated if the initial dose was ineffective. It is usually possible to find a suitable dose for the individual patient which will relieve the majority of attacks with little side-effect. It is assumed that the patient is an adult and measures such as ephedrine, aminophylline, neb. adrenal. et atrop. co., and isopropyl-noradrenaline have been tried and found ineffective.

"Butazolidin"

Q.—What are the indications for butazolidin? How should it be given, in what dosage, and for how long? What side-effects must be watched for?

A.—Butazolidin (phenylbutazone) has been used to treat arthritis and related conditions, including typical progressive rheumatoid arthritis, osteoarthritis, gout, ankylosing spondylitis, degenerative joint disease of the spine, and Paget's disease. Symptomatic relief has been reported in a high proportion of cases, many of which had failed to respond to physiotherapy, rest, or gold treatment. Pain and tenderness were lessened and grip improved, but there is little evidence that swelling was reduced or that the E.S.R. was lowered, or that the drug had any effect other than that of a good analgesic and antipyretic agent.

Butazolidin has been administered intramuscularly, 0.6–1 g. daily for 10 days, then every second day for 10 more days, and every third day for three further injections. Prolonged pain and inflammation often occurred at the site of injection. It has also been given orally, 1 g. daily in divided doses for three days, then 1 g. on alternate days for two to four weeks, after which the dose was reduced to the lowest effective level, usually three to four 200-mg. tablets two or three times a week. Relief began 24 to 36 hours after starting oral treatment. Symptoms returned in a few days or weeks after treatment ended.

Toxic effects are considerable, especially with doses above 600 mg. daily. Nausea, diarrhoea, and drug rash are frequent, but usually mild. Fluid retention occurs commonly, and the drug should therefore not be given to older patients or to those with diminished cardiac reserve. It is also contraindicated when peptic ulcer is present or suspected, as it has caused severe gastric haemorrhage. Fatal agranulocytosis has been reported. Frequent counts of white blood corpuscles and platelets must be made (see *Journal*, 1952, 2, 1401).

A Rabbit's Blood Pressure

Q.—How can I take a rabbit's blood pressure? Is it possible to use the tail as in rats?

A.—The length and hairlessness of a rat's tail positively invite the plethysmographic method used for measuring a rat's blood pressure, but it could not be applied to the fluffy brevity of a rabbit's scut. A simple method exists, however, in the Grant capsule,¹ by which that pressure is measured which, when applied directly to one ear, just obliterates the central artery (to direct inspection). The results agree well with the mean femoral arterial pressure measured directly (provided certain simple precautions are taken), and are about 10–15 mm. mercury below carotid arterial pressure.

REFERENCE

- ¹ *J. Physiol.*, 1934, 81, 265.

Recurrent Unilateral Conjunctivitis

Q.—What is the aetiology of recurrent attacks of unilateral conjunctivitis without discharge, most marked on the palpebral conjunctiva, accompanied by some oedema of the lids and provoked by cold winds? The condition is rapidly controlled by mild silver proteinate, but how can it be prevented?

A.—The findings suggest that these attacks have a vasomotor rather than an infective basis in spite of the favourable response to silver proteinate. Exposure to cold probably acts as a trigger, setting off attacks to which the patient is already predisposed. A search should be made for sources of irritation or infection in the nasal sinuses and teeth; if found, these would probably be on the same side as the affected eye and their elimination should relieve the condition. As the condition is unilateral, allergy to exogenous agents appears unlikely, but conjunctivitis due

to endogenous allergens, usually bacterial, is not infrequent. Of these the commonest is perhaps the *Staphylococcus aureus*, infection with which may be found in the patient's lids, anterior nares, or nasopharynx, swabs from which should be taken. If this organism is found, chemotherapy, even with agents to which it is sensitive, is unlikely to be of more than ephemeral benefit. The indiscriminate use of vaccines has quite deservedly fallen into disrepute, but bacterial or allergic inflammation of the lids and conjunctiva caused by *Staphylococcus aureus* appears to be one of the probably few conditions in which a three-months course of vaccine injections helps to a considerable extent, and investigation along these lines might well form the second line of attack.

Suffocation in a Fire

Q.—When a person is suffocated in a fire, are unconsciousness and death due to lack of oxygen or to the effect of poisonous gases? If the latter, which gases are principally concerned? What is the correct treatment?

A.—Although, in the past, it was thought that accumulation of carbon monoxide and carbon dioxide was the principal menace to life in fire fumes, it has become increasingly clear that shortage of oxygen (partly owing to its being used in burning and partly owing to its displacement by fire fumes and smoke) is by far the more sinister factor. Measurement of the carbon monoxide saturation of the blood in fire deaths seldom gives readings of over 30–35%, and in the presence of adequate oxygen (even at atmospheric partial pressure) this would not in itself menace life. In many cases, in fact, the carbon monoxide reading is a mere 12–20%, and it is quite plain from the profound cyanosis and many anoxal petechiae which are present that shortage of oxygen is the significant factor.

Oxygen—without carbon dioxide—is plainly urgently required, and, provided the air passages are not choked with sooty mucus and that there is an effective circulation, assisted respiration (with oxygen if possible) is all that is immediately desirable: the air passages must be cleared of mucus. It is no longer thought that methylene blue or other dye injection improves the oxygen-carrying capacity of the blood, or assists the action of cell oxidases. Some hours must elapse before the stable compound of haemoglobin with carbon monoxide (it is 300 times as stable as that with oxygen) is dispersed by the new oxygen made available. Treatment must not be considered adequate because immediate improvement ensues, and hospitalization is desirable wherever unconsciousness has occurred, however short-lived it may have been.

Thrombosis and Intravenous Infusion

Q.—What factors predispose to thrombosis during and after intravenous infusions? What preventive measures are worth taking?

A.—It is probable that the duration of the infusion is the most important factor in determining the onset of thrombosis when relatively bland fluids are injected into veins. It follows that one important preventive measure is not to allow an infusion to run into any particular vein for more than eight hours. When patients have to receive intravenous infusions for longer periods than this a fresh needle or cannula must be inserted into a vein at a new site.

Another factor which is known to predispose to thrombosis is the injection of solutions which are strongly hypertonic—e.g., 50% glucose. If such solutions have to be given to a patient over a long period it is best to pass a polythene tube up an arm vein until the tip reaches a very large vessel such as the superior vena cava. In such a site the infused fluid will be so rapidly diluted that damage to the vein is very unlikely and the tube can be left in position for many days.

NOTES AND COMMENTS

Pregnancy after Subarachnoid Haemorrhage.—Dr. W. GRIFFITH LOVE (Burton-on-Trent) writes: With reference to the question on this subject ("Any Questions?" April 4, p. 793) the following notes may be of interest. Mrs. M. W., aged 26. August, 1947, normal confinement, male child, healthy. Puerperium normal. February, 1949, admitted to Burton General Infirmary with severe subarachnoid haemorrhage. April, 1949, discharged from hospital with "very guarded prognosis." This patient became pregnant again in 1952. Apart from slight hyperemesis which was easily controlled by "avomine," the pregnancy was uneventful. She was confined on March 18, 1952. Duration of labour was eight hours. Trichlorethylene was administered during the second stage. The puerperium was quite uneventful.

Troublesome Cough in a Child.—Dr. MARGARET EGAN (Manchester) writes: The answer about troublesome night cough in a child ("Any Questions?" February 14, p. 413) suggested a post-nasal drip stimulating the cough reflex. Sinus and antrum infection is much commoner in children than is generally known, and if successfully treated usually clears up the discharge and obviates the cough.

Dr. MORRIS WITKIN (Johannesburg) writes: With reference to the "Any Question?" on this subject (February 14, p. 413) I would suggest the following approach. As this girl of 5 does not cough much during the day the cause of the trouble may be found in her bedroom. Place the bed preferably between two inside walls. Discard woollen or fluffy blankets; use cotton ones instead. Try a new pillow and use two pillow-slips. Replace old curtains and carpets with washable rugs and light curtains. There must be nothing underneath the bed or on top of the wardrobe. Ensure scrupulous cleanliness and minimum of furniture. Taboo embrocations and liniments. Forbid strong perfumes and pungent floor polish in the room. Keep pets out. Bedding must be aired daily. Give light supper and try daily bath in morning. Ventilate the room freely when not in use and see there is sufficient aeration at night.

OUR EXPERT writes: Dr. Egan's comment that "sinus and antrum infection is much commoner in children than is generally known" is certainly correct. The trouble is that the condition is so difficult to treat. I believe that the best policy is to give the ephedrine drops recommended in my answer, and quite often they work. Surgical treatment on the nose of a child, even just an antral washout, is most unpleasant and is not to be recommended unless really thorough treatment with ephedrine drops has failed and unless the child is suffering in health.

With regard to Dr. Witkin's letter, asthma may in early childhood present as a nocturnal cough, but the one in question followed colds, and seems much more probably to be the sequel of upper respiratory infection: this is, after all, very common in infancy during the winter. Dr. Witkin suggests a regime which is going to cause an upheaval in the home and which will be both difficult and costly to carry out. If an asthmatic element were thought to be present, some steps on the lines he has suggested would be worth taking; his emphasis on good ventilation of the bedroom is certainly of value.

Spontaneous Combustion of Alcoholics.—Dr. H. H. MACWILLIAM (Liverpool) writes: With regard to the question on this subject ("Any Questions?" April 4, p. 793) I remember a case in which death was rapidly followed by the development of an extreme degree of generalized oedema. When the skin was punctured gas escaped with a loud hissing noise. I ignited the gas, and it went on burning like an old-fashioned gas jet until tired of the spectacle.

THE HAZARDS OF PREGNANCY IN WOMEN WITH HEART DISEASE*

BY

CRIGHTON BRAMWELL, M.D., F.R.C.P.

Professor of Cardiology in the University of Manchester

It is a terrible disappointment to a young woman to be told that, because she has a bad heart, it would be unwise for her ever to have children. Fortunately, in the great majority of cases, heart disease is no contraindication to pregnancy. The risk has in the past been grossly exaggerated, because writers on the subject have based their opinions on general impressions, which are notoriously fallacious.

In my clinic at the Manchester Royal Infirmary, during the last twenty-five years, my colleagues and I have followed through pregnancy, labour, and the puerperium more than 1,600 patients with organic heart disease. Many of these patients have been followed through more than one pregnancy, and others have been kept under observation for a year or more after delivery. Two samples from this group have been carefully analysed. In 1938 Edith Longson and I reported our findings in the first 350 cases (Bramwell and Longson, 1938), and an analysis of 500 of the more recent cases, studied by my colleagues Morgan Jones (1952) and Samuel Oleesky, has now been completed. It is interesting to compare these two series of cases and to see how our views regarding the management of this condition have changed during this period.

Assessment of the Risk

In attempting to assess the probable risk of pregnancy in patients with heart disease, it is convenient to classify cases in three groups:

I. In the first group are those patients in whom the heart disease is so trivial that it does not add appreciably to the risk of childbirth. Provided they are kept under medical supervision, these patients rarely cause any anxiety.

II. The second is the largest group. It consists of patients in whom the heart disease is such that it does add appreciably to the risk, but the risk is not regarded as prohibitive. The more severe cases in this group call for much discrimination and judgment on the part of the physician. Many factors other than the severity of the heart disease, such as the age of the patient, the facilities for antenatal and post-natal care, and the number of children in the family, must be taken into account in arriving at an assessment.

III. The third and smallest group consists of those patients in whom the risk is obviously so great that it

*A lecture to the Dundee Branch of the British Medical Association delivered on December 16, 1952.

would be unwise to sanction pregnancy, or if pregnancy is already established termination should be advised. Unfortunately some patients in this group are not seen until pregnancy is far advanced, and the risk of termination may then be greater than the risk of allowing pregnancy to continue. When termination of pregnancy is refused on religious grounds the decision is clearly no longer in the hands of the physician.

In assigning patients to their respective groups we have relied, in the first instance, on an estimate of the functional efficiency of the heart, based on the patient's exercise tolerance prior to pregnancy. I emphasize the words "prior to pregnancy," for as pregnancy proceeds the tolerance for exercise diminishes, and if a patient is not seen till late in pregnancy a false impression may be formed of her cardiac disability.

Roughly speaking, Group I consists of patients who had been able to undertake their household duties and other normal activities without breathlessness or other symptoms, while Group III consists of those who had experienced one or more episodes of congestive heart failure prior to pregnancy and also those in whom the rheumatic process appeared to be still active, or the cardiac condition showed evidence of rapidly progressive deterioration. Patients whose mobility had been limited to a greater or lesser extent, but who had not actually been in failure and whose heart disease appeared to be quiescent, are placed in Group II.

We must, however, consider not only the risk to the mother but also the prospect of a successful pregnancy which makes that risk worth taking. In our later series, four out of five pregnancies yielded living children, but of 53 patients with severe heart disease, who either refused termination or were first seen too late to terminate pregnancy, only one in four had a living child.

The Hazards of Pregnancy

(1) Congestive Heart Failure

Clearly the most important consideration in these patients is the risk of death from heart failure. There were 15 deaths from this cause in our earlier series, and these cases may be divided into two groups.

Four were women aged 39 or over (Table I), three of whom were in their seventh or later pregnancy, and three had established auricular fibrillation. In these four cases the patients' expectation of life was already very limited owing to the advanced state of the disease. Any additional strain, whether physical or due to intercurrent infection,

might have proved fatal. In their case the strain happened to be pregnancy. They were, in fact, all cases in which we should regard pregnancy as contraindicated, and would have advised termination had they been seen earlier in pregnancy.

The other 11 cases (Table II) were of quite a different type. They were younger women, seven of them primigravidae, their heart disease was less advanced, and all but

two had normal rhythm. There was another common factor in this group—only one of these patients had attended the antenatal clinic, the other 10 had been admitted to hospital in the later months of pregnancy as "urgencies" on account of heart failure. This we regard as most significant, for it is our experience that, in women who are pregnant, congestive heart failure, if recognized early, responds well to treatment, and it is only when the condition is allowed to run on unchecked that it becomes irreversible. Adequate antenatal supervision is, we believe, the most important single measure in limiting the risk to which these patients are subject.

Intercurrent complications, especially bronchial infection and anaemia, are apt to precipitate heart failure in patients with rheumatic heart disease. Bronchitis, influenza, and even the common cold must be treated with great respect in these patients. In foggy weather they should be confined to the house, crowds and places of public entertainment should be avoided, and in the event of infection they should be put to bed and kept there until they are fully convalescent. In our experience anaemia is often overlooked. This is particularly unfortunate, since adequate treatment of the anaemia will usually relieve the heart failure.

The common sequence of events in the later stages of mitral stenosis is the development of auricular fibrillation followed by congestive heart failure. The onset of heart failure is usually insidious, with gradually increasing oedema of the dependent parts of the body, enlargement of the liver, and engorgement in the veins of the neck. These signs are easily recognized. A few weeks' treatment in hospital will generally suffice to restore the normal balance, and the cardiac function may be satisfactorily controlled throughout the remainder of pregnancy, provided the patient is kept under supervision. If this were the only danger we had to face, assessment of the risk would be easy, but occasionally things take quite a different course.

(2) Acute Pulmonary Oedema

When congestion affects the pulmonary instead of the systemic circuit, heart failure manifests itself by paroxysmal dyspnoea (cardiac asthma) and acute pulmonary oedema. The suddenness with which these symptoms may develop contrasts strikingly with the more insidious onset of congestive heart failure in the systemic circuit. They constitute a grave emergency, which may prove rapidly fatal. In our

later series, 7 of the 11 deaths from heart failure which occurred during pregnancy or within eight months thereafter were due to this cause, a very heavy mortality considering that only 16 patients in the whole series developed acute pulmonary oedema.

Acute pulmonary oedema used to be regarded as a rare complication of mitral stenosis, and its greater frequency in association with pregnancy was attributed to the increased blood volume and the increased retention of salt and water in the body. The successful surgical treatment of mitral stenosis, however, has led to a more intensive study of this valvular lesion and has shown that acute pulmonary oedema is not nearly such a rare complication as we used to believe. It is, in fact, one of the most urgent indications for mitral valvotomy.

In the earlier years of investigation we did not fully appreciate the importance of acute pulmonary oedema, and regarded it merely as a type of heart failure. In 1941, however, our attention was urgently directed to the matter by two cases under my care, both of which proved fatal. The post-mortem findings in these two patients (reported by Bramwell and Jones, 1944) were illuminating. During life both had normal rhythm with a very loud crescendo presystolic murmur, and at necropsy were found to have a buttonhole mitral stenosis with great hypertrophy of the wall of the left auricle. This combination suggested that the rheumatic process had hit the valve hard, but spared the muscle. In spite of the extreme degree of stenosis the hypertrophied auricle had for many years been able to maintain ventricular filling, when suddenly, under the strain of pregnancy, it failed, the lungs were flushed with blood, and pulmonary oedema developed, rapidly proving fatal.

It is in cases such as these, with normal rhythm and a loud presystolic murmur, that pulmonary oedema is most likely to develop. Whereas in children the murmur of mitral stenosis is generally heard in mid-diastole, in older patients the most striking feature is the crescendo murmur in presystole. This difference can be accounted for by the fact that in young subjects the blood flow from auricle to ventricle is most rapid when the mitral valve first opens, whereas in older people the auricle, having had time to hypertrophy, expels its contents much more forcibly, and consequently the rate of blood flow through the mitral orifice attains its maximum during auricular systole. In patients with a loud crescendo presystolic murmur during life, an extreme degree of narrowing of the mitral orifice is often found at necropsy. The high degree of mitral obstruction having called forth a compensatory work-hypertrophy in the auricle, which manifests itself clinically by a loud crescendo presystolic murmur. Such hypertrophy occurs only when the heart muscle is healthy; a damaged auricle, when subjected to strain, fibrillates.

The grave nature of acute pulmonary oedema makes it vitally important to be on the look-out for any signs which give warning that it may develop, for if these are manifest during the early months of pregnancy therapeutic abortion is indicated. Unfortunately, acute pulmonary oedema usually first makes its appearance in mid-pregnancy, by which time emptying the uterus has become a much more serious matter on account of the dangers of embolism, shock, and haemorrhage. An isolated attack of acute pulmonary oedema should always be regarded as a warning that further trouble of a similar nature must be expected in the future. Although systemic and pulmonary congestion often occur together, pulmonary congestion may lead to fatal acute pulmonary oedema before any systemic oedema or other signs of right heart failure are evident, and it is then that it is most likely to take us by surprise.

The importance of the early recognition of pulmonary congestion cannot be over-emphasized. Its clinical manifestations are paroxysmal dyspnoea and repeated haemoptysis; later, persistent moist rales appear at the lung bases. A rapid increase in weight during mid-pregnancy should lead one to suspect excessive water retention in the body. There is a progressive diminution in vital capacity, but the most

convincing evidence is derived from radioscopic examination of the chest, which yields direct visual proof of the congested state of the lungs. In any clinic devoted to heart disease in pregnancy, facilities for x-ray screening are an absolute essential. The electrocardiogram, on the other hand, gives us little help in these cases.

Before the introduction of mitral valvotomy we used to advise termination of pregnancy in all such cases, but within the last few months Baker, Brock, Campbell, and Wood (1952), in London, and Logan and Turner (1952), in Edinburgh, have reported cases in which valvotomy has been successfully performed during pregnancy, and the pregnancy allowed to proceed to a normal termination. In patients with pulmonary congestion, valvotomy should be undertaken before they become pregnant.

Brock also suggests, on theoretical grounds, that patients with coarctation of the aorta who are pregnant should be submitted to operation. With this suggestion I cannot agree. This is a very serious operation which carries a high mortality, and the only risk these patients run is rupture of the aorta at the time of delivery, a risk which can be avoided by caesarean section.

(3) Auricular Fibrillation

This is a common precursor of heart failure. It is a milestone well down the road of rheumatic heart disease and a warning that heart failure is not far ahead. As such, it merits especially careful consideration in assessing the risk of pregnancy.

In the early days of this investigation we were unduly afraid of this complication, having been impressed by the high mortality reported by some earlier workers (Table III).

TABLE III.—Auricular Fibrillation

	Cases	Deaths
Carr and Hamilton (1933) ..	14.	6
Robinson (1927) ..	18	13
Hunt (1926) ..	22	8

Further experience, however, has led us to believe that under favourable circumstances it is not incompatible with successful pregnancy.

In our earlier series of cases, 24 patients developed auricular fibrillation either before or within six months of delivery. Of these, seven died. This is a heavy mortality, but careful scrutiny (Table IV) of our fatal cases suggests that the picture is not quite so gloomy as it appears at first sight.

TABLE IV.—Fibrillators who Died

Fibrillation Developed	Parity	Age	Remarks
Before pregnancy	14	39	Cerebral embolism. C.S.
	1	35	
	1	30	
During pregnancy	2	32	"Urgency" Induced 36 weeks. "Urgency"
	1	26	
	7	43	
After delivery ..	5	39	

C.S.—Caesarean section.

In three cases pregnancy was clearly contraindicated, and termination would have been advised had they come under observation earlier in pregnancy. Two were women who developed fibrillation after delivery in their fifth and seventh pregnancies respectively. They were aged 39 and 43. In both of these patients the strain of labour undoubtedly precipitated a final breakdown in a heart which was nearing the end of its tether in the normal course of the disease. The third was a woman of 39 in her fourteenth pregnancy who had fibrillation when first seen. Of the remaining four fatal cases in this group, two died of intercurrent post-operative complications and one other had not received adequate antenatal care. Thus it is conceivable that under the most favourable circumstances we might have lost only one of these seven patients.

These considerations led us to modify our previous opinion and to believe that, although auricular fibrillation does undoubtedly add to the risk of pregnancy, it does not constitute a bar to pregnancy, provided the patient can be kept under observation and receive adequate treatment. In our later series 19 patients had auricular fibrillation, and only two died.

(4) Other Considerations

In patients in Group II, who have never actually been in failure but whose tolerance for exercise is limited to a greater or lesser extent, the strain on the heart adds in varying degree to the risk of pregnancy. Those in whom there is considerable limitation of activity are the most difficult to assess, and various factors other than the severity of the heart disease must be taken into account in framing the prognosis.

Clearly a previous trouble-free pregnancy affords the surest ground for optimism, provided the patient's cardiac condition has not deteriorated since her last confinement. The first pregnancy eliminates most of those likely to succumb. Women under 35 are better risks than those over that age. Consequently the risk is smallest in young women who have already had one or more children.

Some workers have attached more weight than others to the size of the heart in assessing the risk of pregnancy. Our own experience leads us to believe that it is much less important than the functional efficiency of the heart as estimated by the exercise tolerance, and in this connexion it is especially significant that many patients who develop acute pulmonary oedema have but little cardiac enlargement.

When we embarked on this investigation we expected to find that patients whose only valvular lesion was mitral stenosis would do better than those who had both a mitral and an aortic lesion. This forecast has not proved to be correct. Whereas, in our earlier series, amongst 260 patients with uncomplicated mitral stenosis there were 20 deaths (8%), there was only one death (3%) amongst the 31 patients with both mitral stenosis and a lesion of the aortic valve. Our experience is similar to that of most other workers in this country.

Aetiology

Let me refer very briefly to the question of aetiology. About 90% of cases of heart disease in pregnant women are rheumatic, and most of the remaining 10% congenital.

In rheumatic heart disease the orthodox teaching was that the more attacks of rheumatic fever or chorea from which a patient had suffered, the more severe was the heart lesion likely to be. This seemed a reasonable assumption, since each attack was likely to add to the previous damage. It therefore came as somewhat of a surprise to us to find that the mortality was highest in those cases in which there was no history of rheumatic infection, and in which heart disease, previously unsuspected, had been discovered either at a routine medical examination or when the doctor had been called in to attend the patient for some minor ailment.

Out of 293 cases of mitral stenosis, admittedly a rheumatic lesion (Table V), 173 gave a history of rheumatic fever or chorea, and, of these, nine died before or within six months

TABLE V.—Mortality in Patients with Mitral Stenosis

History	No. of Cases	No. of Deaths
Rheumatic fever or chorea ..	173	9 (5%)
No previous illness ..	32	9 (28%)

of confinement. Of the remaining 120, 88 dated their symptoms from an attack of muscular rheumatism, tonsillitis, or some other acute infection, while in 32 there was no history of any antecedent disease, their first manifestation of ill-health having been cardiac. Of these 32, 9 died before or within six months of confinement. Thus the mortality in patients with a rheumatic history was 5%,

whereas the percentage of those with no previous history of illness was 28%. I think the explanation of this is that children with acute articular rheumatism or chorea are put to bed and kept there to prevent cardiac damage, whereas in those whose joint and nervous manifestations are minimal the true nature of the illness is apt to be overlooked, and consequently no such precautions are taken.

There were 19 cases of congenital heart disease in our earlier series, and in 13 of these the lesion was of a relatively trivial nature. The only patient who died was a 3-para of 27 with cyanotic heart disease and great cardiac enlargement, first seen at the eighth month of pregnancy.

Subacute bacterial endocarditis is an important complication of pregnancy. In 1946-7 my department participated in the investigation, planned by the Medical Research Council, on the treatment of this condition with penicillin (Bramwell, 1948). Of the first 33 cases in our series 22 were women, 7 of whom were pregnant. Of these seven, two were moribund when first seen, the true nature of the condition having escaped recognition, and the infection having been present for many weeks before treatment was started. Both these patients died, but their babies survived. The other five patients came under our care much earlier in the course of the disease and all survived, the infection having been satisfactorily controlled. In these seven cases we lost only one child—a macerated foetus.

Unexplained fever in any patient with valvular or congenital heart disease who is pregnant calls for immediate blood culture, since the duration of infection is one of the most important considerations in prognosis in subacute bacterial endocarditis.

Remote Prognosis

Now what about the ultimate prognosis in these patients? Most earlier workers believed that pregnancy always produced a permanent aggravation of the cardiac disability. We now know that is not true. As patients grow older the disability resulting from rheumatic heart disease tends to increase, and if deterioration is observed it is often difficult to say whether this is attributable to pregnancy or merely to the normal course of the disease.

Gilchrist and Murray-Lyon (1933) made some interesting observations on this point. They studied the age at death in 109 cases of mitral stenosis that came to necropsy, in all of which death was directly attributable to heart disease. Forty of these cases were males and 69 were females—28 nulliparous and 41 parous. The average age at death was 39.3, 42.1, and 42.0 respectively. I think we can hardly blame pregnancy for the earlier death in the male group, though Mr. Punch, in one of his most famous cartoons, did suggest that childbirth was a great strain on the father! In the case of the females there is no appreciable difference between the parous and nulliparous women as regards the average age of death, but one must take into consideration the fact that only the fitter women marry, and, of those who do marry, the fitter are more likely to have children.

In these three groups there was little difference in the number of survivors at different ages, and had pregnancy exerted a detrimental influence one would have expected a higher mortality amongst the parous women during the child-bearing period.

Our own observations have convinced us that, in young patients at any rate, pregnancy is rarely detrimental. Morgan Jones followed up his cases after delivery until the cardiac condition had either shown deterioration or been stabilized at its previous level. Twenty-five patients died, and it was found that, of the 475 who survived, 427 (90%) showed no obvious deterioration as the result of pregnancy.

Treatment

If I were asked what I regarded as the most important consideration in the treatment of patients with heart disease who were pregnant, I should have no hesitation in saying that it is never, under any circumstances, to interfere with

pregnancy in a patient with heart failure until all has been done that can be done—and that is often a great deal—to relieve the heart failure. When a woman is admitted to hospital as an “urgency,” desperately ill with a failing heart, it is tempting to think that, to save life, the termination of pregnancy is indicated. It is not. In these circumstances surgical intervention is an unjustifiable risk. It is surprising how well many of these patients respond to treatment. A few days’ rest in bed, with skilled nursing, digitalis, and sedatives, will often convert what was a hopeless case into a reasonable surgical risk. When the heart condition has been stabilized, and not before, is the time to consider whether pregnancy should be terminated.

In such cases, when the heart failure had been relieved, we used to recommend caesarean section; but further experience has convinced us that normal delivery carries less risk, and, with the single exception of coarctation of the aorta, in which condition there is danger of rupture of the aorta at the time of labour, we always advise that, in the absence of obstetric indications, pregnancy should be allowed to pursue its normal course. Workers in other centres have come to the same conclusion (Haigh and Gilchrist, 1949).

The more we have studied this problem the more reluctant have we become to interfere with pregnancy. This change in policy is, we believe, partly responsible for the improvement in our results, seven deaths in our earlier series having been due to post-operative complications following termination of pregnancy.

When we first embarked on this investigation it was generally thought that the strain on the heart increased progressively as pregnancy advanced, and on this account the induction of premature labour (or caesarean section) before full term was often advised in women with heart disease to avoid the strain of the final month of pregnancy. We now know that the blood volume and cardiac output do not increase, but actually diminish, during the last few weeks of pregnancy. These facts have led us to modify our views regarding the management of such cases. There is little danger of heart failure developing during the last month of pregnancy if it had not been present previously, and there is therefore no purely cardiac indication for terminating pregnancy at this stage, since the strain on the heart will not be increasing but diminishing. Admittedly the presence of a cardiac lesion would justify operative intervention in those borderline cases in which there is some obstetric complication that by itself alone might not have done so.

Finally, let me remind you once again of the importance of adequate antenatal supervision. When Edith Longson and I came to analyse the first 350 cases in our series we found that 325 had attended the antenatal clinic and only 25 had been admitted as “urgencies.” Fourteen of the urgencies and 11 of the quiet cases proved fatal, so that the death rate among urgencies was 56%, as compared with 3% among quiet cases.

Similar results had been reported elsewhere (Table VI).

TABLE VI.—“Urgency” Death Rate

	No. of Cases	Total Deaths	“Urgency” Deaths
Bramwell and Longson (Manchester)	350	25	14 (56%)
Carr and Hamilton (Boston)	500	32	16 (50%)
B. P. Watson (1933) (New York)	240	17	8 (47%)

But we can go a step further, for in 10 of our 25 fatal cases death was due not to heart failure but to other causes. In the 15 patients who died of heart failure the figures are even more striking. Of these, 11 were urgencies and only 4 quiet cases. Thus the death rate from heart failure in our quiet cases was 1% as compared with 44% amongst urgencies. These figures convinced us of the importance of adequate antenatal supervision.

In our pregnancy cardiac clinic at the Manchester Royal Infirmary the almoner plays an important part. Her experience enables her to resolve many of the patients’ difficulties and to arrange home help, to tide over the emergency, in case of need. From the psychological aspect, also, we believe this special clinic has proved useful. The newcomers get talking with the old hands, who have been through the mill before, and begin to realize that heart disease is not nearly such a terrible thing as they had been led to believe.

James Mackenzie

I cannot conclude my lecture without reference to the work of a very remarkable man—a man who was keenly interested in this problem and who wrote a book on heart disease in pregnancy (Mackenzie, 1921). He must have been a familiar figure to the older members of my audience, for he spent the Indian summer of his life in St. Andrews.

James Mackenzie was a Highlander. He was educated at Perth Academy and Edinburgh University. The next twenty-five years—the most productive years of his life—were devoted to general practice in Burnley. His work there is commemorated by a tablet on the wall of the house in which he practised. During the war this tablet was removed, for the powers that be considered that the word “Burnley,” which appeared in the inscription, might prove helpful to the enemy in the event of invasion.

As an undergraduate Mackenzie won no special academic distinction. Later, however, he proved himself to be an investigator of outstanding merit and a man who made the fullest possible use of his opportunities. Mackenzie will probably go down to history as the man who solved the riddle of the cardiac irregularities. This he did by means of his clinical polygraph; all the earlier models of this instrument were made for him by Mr. Shaw, a local watchmaker.

But far more important was his work on prognosis, based on his own clinical observations. I have never ceased to marvel that such a popular and busy family doctor could find the time, and have the energy, to keep such wonderful records of his cases. The hours for research were literally snatched from the rush of general practice. It was these records of his cases in Burnley which enabled Mackenzie finally to overthrow the dictatorship of the stethoscope, which had dominated cardiology for nearly a hundred years.

Summary

The chief dangers to be faced in patients with heart disease who are pregnant are acute pulmonary oedema and congestive heart failure. The former calls for special vigilance on account of the suddenness with which it may develop, and in every case of mitral stenosis clinical or radiological evidence of pulmonary congestion must be regarded with grave apprehension. Congestive heart failure with oedema, if recognized early, usually responds well to treatment.

Auricular fibrillation, though a recognized precursor of heart failure, is not necessarily a bar to pregnancy, provided adequate antenatal and post-natal care can be assured. In assessing the risk, the previous obstetric history, age, economic conditions, and temperament of the patient must all be taken into account.

In patients with heart failure, surgical intervention should never be contemplated until the heart failure has been treated. Patients with heart disease tolerate pelvic delivery better than caesarean section.

In patients with advanced heart disease pregnancy is contraindicated. If, however, pregnancy is already established and the patient is seen within the first three months, it should be terminated, but, if she is not seen until later, it should be allowed to run its normal course. Alternatively, mitral valvotomy may be considered.

There is no purely cardiac indication for anticipating normal delivery.

All patients, however trivial their heart disease, should be kept under observation throughout pregnancy, and intercurrent infection and anaemia promptly treated.

C. A. ST. HILL, M.B.

(From the Royal Southern Hospital, Liverpool)

In 1951 we published a preliminary report on the treatment of 51 cases of genito-urinary tuberculosis (Ross *et al.*, 1951). The present communication includes a record of a further 47 patients similarly treated, and a follow-up of the earlier series. It is necessary to emphasize once more that a long-term view must be taken of this disease, as it is possible to encounter patients who have survived for many years after a bilateral renal lesion has been confirmed and in spite of the absence of treatment of any kind.

Classification.—No patient was accepted for treatment until a positive guinea-pig inoculation test put the diagnosis beyond all reasonable doubt. At the same time no case, however serious, was refused treatment. The patients were divided in five groups: (1) minor unilateral lesion or subclinical focus; (2) lesion of one kidney with cystitis and nephrectomy; (3) bilateral disease and nephrectomy of the worse kidney; (4) infection of the remaining kidney; and (5) severe bilateral disease. We realize that this is not a perfect classification, but for the purpose of uniformity in assessing the results we have not altered it on this occasion.

Method of Treatment

In addition to the regime described below, the ordinary surgical measures, such as nephrectomy and epididymectomy, were carried out when required, with the proviso that the optimum time was selected for the operation. For example, nephrectomy was often performed during the second or third course of streptomycin.

The whole course of treatment lasted six months, during which time the patient received the usual sanatorium regime at Wrightington Hospital. The three drugs used were: (a) “Ethizone” (*para*-ethylsulphonylbenzaldehyde thiosemicarbazone, or T.B.3), beginning at 50 mg. daily and gradually increasing by weekly increments of 200 mg. daily. Ethizone was given continuously for the six-months course of treat-

ment. (b) *Para*-aminosalicylic acid (P.A.S.), 18 g. daily, given at three-hourly intervals for periods of 25 days, alternating with (c) dihydrostreptomycin, 1 g. twice a day for a period of 35 days. A mixture containing 30 gr. (2 g.) of potassium citrate and 5 gr. (0.32 g.) of potassium iodide was given thrice daily throughout the streptomycin periods.

Originally it was a difficult matter to render and maintain the urine alkaline, but as a result of recent extended tests we have found the following mixture both palatable and effective:

Potassium citrate	..	..	30 gr. (2 g.)
Sodium citrate	..	..	30 gr. (2 g.)
Potassium acetate	..	..	20 gr. (1.3 g.)
Syrup of lemon	..	..	7½ min. (0.45 ml.)
Extract of liquorice	..	..	7 min. (0.42 ml.)
Aqua	..	..	ad ½ oz. (14 ml.)
½ oz. (14 ml.) four times a day			

We have already given our reasons for this method of treatment (Ross *et al.*, 1951), which has been gradually evolved as a result of experience. Briefly these reasons are:

(1) Each of the three drugs probably exerts a different effect on the tubercle bacillus, and it seems logical to use all three in the hope of achieving the maximum effect.

(2) Lattimer *et al.* (1950) have shown that in order to maintain an adequate concentration of streptomycin in the blood it is desirable to give 1 g. every twelve hours. The concentration in the blood following intramuscular injection of 1 g. of streptomycin is as follows:

1 hour	..	14-31 u./ml.	6 hours	..	8-15 u./ml.
2 hours	..	22-38 "	7 "	..	6-10 "
3 "	..	18-22 "	10 "	..	5-9 "
4 "	..	14-18 "	12 "	..	3-4.5 "
5 "	..	10-13 "			

(3) Lattimer *et al.* also pointed out that the incidence of toxicity rapidly increased after 60 days and was invariably present at 120 days, using 2 g. of streptomycin daily. We have therefore adopted the intermittent method of administering streptomycin to counteract this tendency.

(4) By using the alternating technique we hoped not only to prevent the emergence of resistant strains of tubercle bacilli, but also to diminish the intolerance of patients to the larger doses of P.A.S.

(5) Ethizone was given continuously, as it has been shown by Domagk *et al.* (1946) that the best results were obtained after prolonged administration. Ethizone seems to be the most active and least toxic of the thiosemicarbazones (Hoggarth *et al.*, 1949; Hoggarth and Martin, 1950). There is evidence to show by the "corneal screening" test that the effects of both P.A.S. and streptomycin are enhanced by ethizone (Rees and Robson, 1950, 1951).

Surgical Measures

During the course of treatment nephrectomy was performed on 13 patients, the ureter being excised only as far as the pelvic brim. The wound was invariably closed without drainage, and in every case healed by first intention. With the introduction of antibiotics it would seem that partial or polar nephrectomy may prove of value. Partial nephrectomy has not been carried out in the present series, but has been performed on several occasions in the third group of cases, to be published at a later date.

Epididymectomy was found to be necessary in 12 patients, and was carried out by the Ross (1948) technique. Healing was satisfactory, and in no instance did atrophy of the testicular body occur.

Three patients required transplantation of the ureter of the remaining kidney into the colon. All three were advanced cases (type 4), and two patients died some months after the operation. The third patient has remained well. We believe that the two deaths were due to acidosis and uraemia, and hope to eliminate these tragedies in future by maintaining a close watch on the blood chemistry for a prolonged period. As routine measures we insist on a low-salt diet, a strong alkaline mixture, and three-hourly evacuation of the bowels day and night.

Toxicity

In view of the fact that potent drugs were being used over an extended period of six months it seemed important that signs of toxicity should be recognized and dealt with at the earliest possible moment.

P.A.S.—This has been extensively employed in the treatment of all forms of tuberculosis, and many workers experienced in its use have testified to its low toxicity (Nagley, 1949; McAnally and Seymour, 1948). In spite of this we have found some minor toxic symptoms in 35% of our patients, especially nausea, vomiting, anorexia, and mental depression. In a further 25% the drug had to be discontinued because of severe vomiting, despite the fact that all varieties and forms, such as the calcium salt, cachets, and enteric-coated granules, were given a trial. We have not encountered haematuria or albuminuria (Nagley and Logg, 1949), nor have we seen any skin eruptions. Two patients developed toxic hepatitis (Gow, 1951) similar to those previously reported (Cuthbert, 1950; McKendrick, 1951). There was no clinical evidence of potassium depletion (Heard *et al.*, 1950; Cayley, 1950) in this series. Thus it can be seen that until a less toxic form of P.A.S. is available the full value of the drug cannot be achieved in an appreciable number of patients. For this reason we are now using the calcium salt of B.P.A.S. (N-benzoyl *para*-aminosalicylic acid) (Gow, 1953).

Dihydrostreptomycin.—In spite of using the intermittent method of administration outlined above, we have encountered an appreciable number of toxic manifestations. In the present series of 47 patients deafness has occurred in six, dizziness in eight, and both symptoms in two. Skin rashes were found in three cases. The dizziness and skin rashes were transient and disappeared quickly when the drug was stopped. Desensitization was often effective, and was carried out by beginning with a daily injection of 0.1 g. of streptomycin, gradually increasing up to 1 g., the course lasting a fortnight. The administration of "avomine," one of the antihistaminic drugs, was also helpful. Deafness was a more serious symptom, and appears to be permanent. These figures correspond with those quoted from a smaller series (Cathie and Garrow, 1951; Don and Gregory, 1952; etc.). It would seem that the percentage of patients becoming deaf with dihydrostreptomycin is much higher than with streptomycin sulphate, although the activity of the two preparations is the same. In future, therefore, we intend to use the latter.

Ethizone.—We have not seen any of the more severe complications described, such as liver or renal damage, but as a precautionary measure we have carried out at regular intervals the thymol turbidity test on patients' sera. All findings were below 4 units, which, at the very least, indicates that there has been no gross liver damage. In a few instances, in which toxæmia from the disease was severe, there has been a progressive anaemia, which improved, irrespective of the ethizone, when the tuberculous focus producing the toxæmia was removed. In no case was the ethizone stopped. All patients were able to tolerate 150 mg. daily, but 30% were not able to take 200 mg. for prolonged periods. Intolerance of the higher dose was manifested by anorexia, depression, and mental apathy. Patients under treatment with thiosemicarbazone, and ethizone in particular, should abstain from alcohol on account of its reaction. The symptoms of this are palpitation, flushing of the skin, and a full bounding pulse. If the effect is severe, collapse may occur. These symptoms may last two to three hours. They can also be experienced in a minor degree for about seven to ten days after the ethizone has been discontinued.

Results

As in our previous communication, we have attempted to assess the results in the following way: (a) sterilization of the urine; (b) radiographic changes; (c) cystoscopic improvement, including an increase in bladder capacity and

an improvement in the appearance of the mucous membrane or ureters; and (d) clinical improvement—for example, frequency of micturition, dysuria, gain in weight.

(a) Sterilization of the Urine

We have always believed that the sterilization of the urine is the absolute criterion of the efficacy of any particular method of treatment. We have therefore taken special care to ensure that the technique employed should eliminate as many sources of error as possible.

During the period of treatment the urines were investigated for the presence of tubercle bacilli at approximately six-weekly intervals. Every effort was made to isolate the bacillus, and the methods used for this were modified from time to time in order to improve the results.

In the early stages of the investigation the six-weekly search for tubercle bacilli was carried out on the total quantity of urine passed by the patient over a period of 40 hours. The collection of this urine was carried out as follows: (a) A 24-hour pooled specimen. (b) The "first morning" specimen passed by the patient after the end of the 24-hour period. (c) A catheter specimen obtained from the patient four to five hours after the first morning specimen had been passed.

The 24-hour specimens were allowed to stand for 48 hours, and 150 ml. of the deposit was removed and centrifuged. The centrifuged deposit was treated for a minimum time with 3% sodium hydroxide to destroy contaminating organisms. After neutralization it was inoculated on two Löwenstein-Jensen slopes and, except in some of the earlier cases, into two guinea-pigs.

From the first morning specimen 100 ml. was centrifuged and the deposit, after treatment with 3% sodium hydroxide, was inoculated on two Löwenstein-Jensen slopes.

The catheter specimens were used in an effort to overcome the possibility that the sodium hydroxide needed to destroy contaminating organisms might reduce the number of positive results by its lethal action on the tubercle bacilli. Each specimen was collected with the utmost aseptic precautions, using a no-touch technique. The whole specimen was centrifuged and a small part of the deposit inoculated on to a blood-agar plate. If no growth appeared on overnight culture the specimen was regarded as free of contaminants and inoculated without further treatment on two Löwenstein-Jensen slopes. If contaminating organisms grew on the blood-agar plate the deposit was treated with sodium hydroxide before inoculation.

Thus each investigation entailed the inoculation of six Löwenstein-Jensen slopes and two guinea-pigs. The results obtained from these specimens are given in Table I. These

TABLE I

Type of Specimen	No. of Specimens	Positive	
		No.	% (Approx.)
24-hour: culture	99	8	8
guinea-pig	48	13	27
First morning: culture	97	7	7
Catheter, no contaminants (no sodium hydroxide used)	39	1	2.5
Catheter, contaminated (treated with sodium hydroxide)	47	1	2

results revealed a number of facts: (a) That early morning specimens were giving results equally as good as those obtained from the 24-hour specimens. (b) That, in spite of the greatest possible care, more than half the catheter specimens were bacteriologically contaminated. (c) That the results of culture of catheter specimens compared unfavourably with those obtained from early morning and 24-hour specimens. This applied whether the catheter specimens were treated or untreated with sodium hydroxide. (d) That guinea-pig inoculation of the deposits was giving better results than cultural methods.

For these reasons both the methods of collecting specimens and their examination were changed. The specimens were limited to 24-hour pooled urines and first morning specimens.

The 24-hour specimens were allowed to stand for 48 hours. At the end of this period the whole of the thick deposit ("sludge") was withdrawn. An equal volume of the urine lying immediately above it (supernatant) was also withdrawn into a separate container. These two specimens, each about 50-100 ml. in volume, were centrifuged, and the deposits treated with sodium hydroxide and neutralized. The resultant mixtures were divided into two. One-half of each was inoculated on two Löwenstein-Jensen slopes. The other half of one of them was inoculated into two guinea-pigs.

The first morning urine was treated in the same manner as in the early cases, except that the deposit was inoculated on two Löwenstein-Jensen slopes and also into two guinea-pigs. By this means, on each six-weekly investigation the deposits from 36 hours' urine were inoculated on six Löwenstein-Jensen slopes and into four guinea-pigs. The results are given in Table II.

TABLE II

Specimen	No.	Positive	
		No.	% (Approx.)
Early morning: culture	102	6	6
guinea-pig	102	18	18
24-hour "sludge": culture	108	5	4.5
guinea-pig	62	7	11
"Supernatant": culture	99	7	7
guinea-pig	47	4	8.5

Examination of results at this stage led us to draw certain inferences: (a) That once again the results from the early morning specimens were at least as good as those from the 24-hour pooled specimens. (b) That guinea-pig inoculation was still giving better results than cultural methods. (c) That the distribution of tubercle bacilli in the "sludge" and the urine layer immediately above it was more or less uniform. (d) That the use of smaller volumes of deposit from the 24-hour specimens was apparently leading to somewhat poorer results.

A further change was therefore made in the technique. The 24-hour specimens were allowed to stand for 48 hours and a minimum of 200-300 ml. was centrifuged, the resultant deposit being treated with sodium hydroxide and inoculated on two Löwenstein-Jensen slopes and into two guinea-pigs. The whole of the early morning specimens were centrifuged and the deposit was inoculated on two Löwenstein-Jensen slopes and into two guinea-pigs. The results obtained by this method are given in Table III.

By this means we obtained the greatest proportion of positive results both in the early morning specimens and in the 24-hour specimens. Once again guinea-pig inoculation

TABLE III

Specimen	No.	Positive	
		No.	%
Early morning: culture	93	12	13
guinea-pig	93	26	28
24-hour: culture	135	13	8
guinea-pig	135	42	31

TABLE IV

Specimen	No.	Positive	
		No.	%
Early morning: culture	292	26	8.9
guinea-pig	193	46	24
24-hour: culture	441	22	5
guinea-pig	284	68	24

gave better results than artificial culture, and the results from the early morning specimens were at least as good as those from the 24-hour specimens.

The total figures for the whole period are given in Table IV.

Table V reveals that out of the total of 47 patients investigated the urines of 36 (76.5%) were sterile at the end of the six-months course of treatment. Of the 11 (23.5%) who were

(b) Radiographic Changes

In no case was there any convincing improvement in the pyelographic appearances during treatment (Table VI). Intravenous pyelography has been carried out in every patient and a bilateral retrograde pyelogram whenever possible. We do not agree with Ericsson and Lindbom (1950) that retrograde pyelography is dangerous, and we have seen no complications in many hundreds of such examinations.

TABLE V.—Sterilization of Urine and Sensitivity of Organisms to Streptomycin

Group	Initially Guinea-pig Positive	After 2-3 Months' Treatment		After 3-4 Months' Treatment		After 5-6 Months' Treatment		Remarks
		Guinea-pig Positive	Sensitive to Streptomycin	Guinea-pig Positive	Sensitive to Streptomycin	Guinea-pig Positive	Sensitive to Streptomycin	
1	16	No. 4 25	All sensitive to 0.25 u./ml.	No. 6 37	5 sensitive to 0.25 u./ml., 1 resistant to 32 u./ml.	No. 5 32	4 sensitive to 0.25 u./ml., 1 resistant to 64 u./ml.	Of 4 patients who were guinea-pig positive after 2 months, 3 remained positive and 1 became negative. After 4 months' treatment, 3 patients who were guinea-pig negative reverted after 4 months' treatment. Two of these remained positive after 6 months.
2	8	5 62	" "	5 62	4 sensitive to 0.25 u./ml., 1 resistant to 64 u./ml.	3 37	2 sensitive to 0.25 u./ml., 1 resistant to 64 u./ml.	No new guinea-pig positives were noted during the course of treatment.
3	10	5 50	4 sensitive to 0.25 u./ml., 1 resistant to 32 u./ml.	3 30	1 sensitive to 0.25 u./ml., 2 resistant to 32 u./ml.	3 30	1 sensitive to 0.25 u./ml., 2 resistant to 32 u./ml.	One patient who was guinea-pig positive at the fourth month became negative at the sixth month of treatment and 1 who was guinea-pig negative reverted to positive at the end of the sixth month.
4	9	5 55	All sensitive to 0.25 u./ml.	2 22	Both sensitive to 0.25 u./ml.	—	—	The 2 patients who were positive at 4 months had transplantation of the ureter into the colon.
5	4	1 20	Sensitive to 0.25 u./ml.	—	—	—	—	The patient who was positive died during the fourth month of treatment with silicosis and acute bronchopneumonic spread.
Total	47	20 42	19 sensitive to 0.25 u./ml., 1 resistant to 32 u./ml.	16 34	12 sensitive to 0.25 u./ml., 4 resistant to 32 u./ml.	11 23	7 sensitive to 0.25 u./ml., 4 resistant to 32 u./ml.	

positive four were resistant to streptomycin, two of whom had had over 150 g. of streptomycin elsewhere, before beginning our course of treatment. Occasionally tubercle bacilli have reappeared (after previous negative guinea-pig tests) in the urine of a patient during the latter half of the course of treatment. It is probable that the excretion of tubercle bacilli is intermittent except when the lesion is large and has a free communication with a calix. Again, the kidney may be reinfected from an active focus elsewhere, such as the spine or lung. It must be remembered that sometimes a secondary infection with other organisms, usually *Bact. coli*, may complicate matters and require treatment by the appropriate antibiotic. It is unfortunate that, owing to the somewhat indiscriminate and widespread use of antibiotics without bacteriological control, so many resistant strains of organisms were encountered.

It is desirable to carry out the retrograde pyelogram under direct vision in order to obtain an accurate picture of the pelvi-caliceal system. Recent experience with partial or polar nephrectomy has, however, made it clear to us that relatively extensive lesions may lie alongside a calix showing minimal deformity.

(c) Cystoscopic Improvement

In the course of this investigation over 200 cystoscopies and 150 ureteric catheterizations were carried out in the period January 1 to December 21, 1951. All cystoscopic examinations were done by two of us (J. C. R. and J. G. G.), and in each case a careful description of the bladder mucosa and the ureteric orifices was written without reference to previous cystoscopic notes. Definite improvement was found in all cases in the present series (in which the bladder

TABLE VI

Group	No. of Cases	Clinical Improvement				Cystoscopic Changes				Pyelographic Changes			
		Frequency of Micturition		Pain on Micturition		Bladder Appearance		Bladder Capacity		Normal		Deteriorated	
		Normal	Unchanged	Improved	Deteriorated	Normal	Unchanged	Improved	Deteriorated	Normal	Unchanged	Improved	Deteriorated
1	16	10	—	6	—	14	—	2	—	11	gained, average 10 lb.; 5 lost, average 3 lb.	—	—

3	10	—	2	8	—	2	2	6	—	6	gained, average 8 lb.; 4 lost, average 2 lb.	—	—
4	10	—	6	3	1	—	10	—	—	7	gained, average 6 lb.; 3 lost, average 4 lb.	—	—
5	4	—	—	4	—	—	1	3	—	2	gained 12 lb.; 2 lost, 14 lb., 16 lb.	—	—

was diseased) except for three (Table VI). The improvement consisted in the healing of granulations and ulceration and replacement of these by scar tissue, in addition to an increase in bladder capacity.

(d) Clinical Improvement

We have noticed that clinical improvement usually occurs at an early stage of the course, but in some patients it appears later, sometimes after three months' treatment. In almost every patient a clinical improvement was achieved and was assessed in terms of degree of frequency, nocturia, dysuria, etc. It is customary to denigrate in scientific communications all references to symptoms, but the symptomatic

The follow-up included a three-monthly cystoscopy and an inoculation of guinea-pigs with the deposit of both 24-hour and ureteric specimens of urine. It must be pointed out that the six patients given all three drugs were advanced cases falling into either type 4 or type 5. On the whole, the alternating method of treatment described here seems to be standing up to the test of time.

Two patients appeared to merit special mention, as they illustrated the fact that no case should be regarded as hopeless. The first man was admitted with active pulmonary and vertebral lesions, a tuberculous kidney, cystitis, and epididymitis. During his six months' treatment his extra-renal lesions healed and we were able to remove the non-functioning right kidney. Incidentally, this was the only patient in the series in whom complete healing of the epididymal lesion took place without operation.

In a second patient with a disorganized kidney operation revealed the presence also of a large solitary cyst. This is only the third case of tuberculous nephritis in which a solitary cyst has been recorded. It is interesting that the amount of streptomycin in the cyst was 250 u./ml. fluid, whilst the greatest amount in any ulcero-cavernous lesion was 8 u./ml.

Summary

An investigation begun two years ago has been carried a step forward by treating a further 47 patients.

The six-months course consists in a sanatorium regime, the usual surgical measures, and a combination of streptomycin, P.A.S., and ethizone. Our view still remains that the three drugs are not a substitute for surgery or sanatorium treatment, but that each is a complement to the other.

Assessment of the results has been carried out not only for the present series of patients but also for the original group of 51 reported a year ago. The most important single factor is the elimination of tubercle bacilli from the urine. To be certain of this, most exhaustive and searching tests were found to be necessary. Of the original group 62% of urines were sterile at the end of eighteen months, while 77% of urines of the present series were sterile at the end of a year.

While it is necessary to keep in mind the chronicity of the disease, the course of treatment suggested by us seems to achieve satisfactory results and to hold out a promise for the future.

We are grateful to Mr. J. Dobson, surgeon-superintendent, Wrightington Hospital, for his assistance and constant encouragement, to Herts Pharmaceuticals Ltd. for their interest,

TABLE VII.—Effect of the Regime on the Extrarenal Lesion

Chest lesions	No. of Cases	Improved	Deteriorated	Unchanged	Remarks
12	3	1	1	8	4 quiescent before treatment began
Bone and joint lesions	No. of Cases	Improved	Deteriorated	Unchanged	Remarks
3	2	1	1	—	2 quiescent before treatment began
Bone and joint and chest lesions	No. of Cases	Improved	Deteriorated	Unchanged	Remarks
3	1	1	—	—	1 quiescent before treatment began
3	2	1	1	—	2 quiescent before treatment began

improvement is vitally important from two points of view. The improvement is important to the patient not only because he is able to obtain more comfort and sleep, but also because he is encouraged to continue and complete his six-months course. The results are shown in Table VI.

Table VII shows the results in patients having combined lesions affecting also lungs, bones, joints, etc. In combined cases there is no significant improvement of the extrarenal lesion when compared with cases treated with streptomycin alone, or, as in the case of the lungs, with streptomycin and P.A.S. One important fact which should be mentioned, however, is that the seven patients whose sputa remained positive for tubercle bacilli at the end of the six-months period were all sensitive to 0.25 u./ml. of streptomycin.

Follow-up of Previous Series (Table VIII)

The group of 51 patients discussed in a previous article (Ross *et al.*, 1951) have been followed up on the lines indicated above. With few exceptions symptomatic and cystoscopic improvement has been maintained up to the present time, eighteen months since the completion of treatment. Of the remaining 43 patients of the original series still alive, the urine of 27 was sterile at 18 months.

TABLE VIII

Treatment	No. of Cases	6 Months	12 Months	18 Months
Streptomycin alone	18	13 remained sterile 3 positive 2 sterile, reverted to positive	9 sterile 3 reverted 1 given other course 3 died after transplantation of ureter 2 sterile	9 sterile 2 reverted 1 not traced

THE SIGNIFICANCE OF THE THYROID IN PSYCHIATRIC ILLNESS AND TREATMENT

ROUTINE EXAMINATION WITH A RADIOACTIVE TRACER METHOD

BY

M. REISS, M.D., D.Sc.

R. E. HEMPHILL, M.A., M.D., D.P.M.

R. MAGGS, M.B., Ch.B., D.P.M.

C. P. HAIGH, Ph.D., A.Inst.P.

AND

JEAN M. REISS

(From the Research Department, Bristol Mental Hospitals)

In previous communications we reported that abnormal indices of thyroid activity occur in a fair proportion of psychiatric patients (Reiss *et al.*, 1951b). Changes in the thyroid activity of such patients after E.C.T. and treatment with pituitary anterior lobe hormones were described (Reiss *et al.*, 1951a).

The thyroid activity is now investigated as a routine in the majority of patients admitted to our hospital, so that we have extended the studies further, and here report on some of the results of this work in more than 1,000 patients in 1949-50 and 1950-1. The question of whether there is a real causal interrelationship between ascertained thyroid disturbance and mental illness is examined in the light of these research results.

Methods.—The radioactive tracer methods used have already been described (Haigh and Reiss, 1950; Reiss *et al.*, 1952). The normal ranges are seen in Fig. 3. For the determination of the basal metabolism rate the usual spirometric method was used. Where complete relaxation of the patient could not be obtained the investigation was carried out under thiopentone. Methods of treatment are referred to in the description of each case.

Results

Distribution of Thyroid Indices

Figs. 1 and 2 are histograms of the distribution of the I_t values in 302 male and 244 female psychiatric patients in 1949-50, and of 222 male and 271 female similar cases in 1950-1. Fig. 3 shows the histograms of the patients in

1949-50 superimposed on the histograms of 1950-1. The distribution of thyroid indices in about 1,000 unselected psychiatric patients in two successive years is seen to be almost exactly the same. For comparison, the limits for normal controls are plotted above the histograms of Fig. 3, and the arithmetic mean values are in good agreement for the corresponding values of the normal controls. These normal control values never overlapped the values recorded in patients who had clinical evidence of hypothyroidism or hyperthyroidism. It is clear that the spread of the patient material is much wider than the spread of the normals, and that among the patients there are a number in whom thyroid function lies outside the normal range but in whom clinical evidence of thyroid abnormality is lacking. The number of these borderline cases is appreciable, amounting to about 20%. The mean values of the thyroid indices in males are lower than in females, both in patients and in normal controls. In male borderline cases thyroid function tends towards hypothyroidism, and in females to hyperthyroidism.

Distribution of Thyroid Indices According to Certain Psychiatric Disease Categories

The cases were classified in a number of fairly well defined psychiatric categories, and the relation between these psychiatric disorders and their associated thyroid values is shown in Fig. 4. For this purpose the thyroid values were classified in four standards, as follows: the normal range was divided equally into upper and lower normal; outside these limits are the regions of underfunction and overfunction, which comprise mainly borderline cases.

In most groups there seems to be no significant relationship between the disease and the standard of thyroid function. There are, however, the following exceptions. In the female anxiety group there is a tendency to thyroid hyperfunction, more than 60% of the cases being in the upper normal or overfunctional range. In contrast, in the male anxiety group there is a tendency to thyroid underfunction, about 36% being lower normal and 38% underfunctional.

In 40% of female patients with recent schizophrenia the thyroid index was above the upper range of normality, but in female chronic schizophrenia this was seldom observed. In male recent schizophrenia, by contrast, underfunction of the thyroid was more usual.

Changes in Thyroid Function Accompanying Changes in the Psychiatric Illness Occurring Spontaneously or after Treatment

We have previously reported (Reiss *et al.*, 1951a) the effect of E.C.T. on thyroid function. The cases investigated were mainly depressives, which usually recover with E.C.T., and the series was small (34 cases). We have extended the investigation to include a more representative group of 183 cases of most common forms of psychiatric disorder treated in various ways or remitting spontaneously. Thyroid function was assessed before and after treatment, and compared with the clinical result. The forms of treatment included E.C.T., modified insulin, coma insulin, carbon dioxide, leucotomy, psychotherapy, and various combinations. A number of cases in which there was a spontaneous remission were also investigated.

In 76 of these patients there was evidence of disturbed thyroid function before treatment, and normal values in 107. Changes in the thyroid values of all the patients after treatment are shown in Tables I-III. In 82 of the 107 euthyroid cases (Table I) treatment produced no change or

TABLE I.—Changes in the Thyroid Activity During Treatment of Euthyroid Patients

Direction of Change	Changes in Mentation	
	Improved	Not Improved
No change	7	3
Changes inside the normal range	57	15
Change to hypofunctional range	12	7
Change to hyperfunctional range	5	1

FIG. 1.—Distribution of $\log_{10} I_t$ values in male patients, 1949-50 and 1950-1.FIG. 2.—Distribution of $\log_{10} I_t$ values in female patients, 1949-50 and 1950-1.

changes only within the normal range; there was some slight change beyond the normal limits in the remaining 25 cases, 17 of whom made a clinical recovery. It is interesting that of the 82 patients who showed no change or change within the normal range only 22% failed to improve after treatment; while 39% of the patients whose thyroid levels became subnormal did not improve. Although suggestive, this difference is not statistically significant ($\chi^2 = 1.124$, with a corresponding P value of >0.20).

TABLE II

Thyroid Activity		Psychiatric Changes	
State Before Therapy	Change During Therapy	Improved	Not Improved
Underfunction	Normalized	20	0
	Not normalized	12*	5
Overfunction	Normalized	25	3
	Not normalized	7*	4

* The I_t in 12 of these 19 cases was improving, but the normal range was not yet reached at the time the mental improvement was detected. In one of the hyperthyroid patients of this group the I_t was also decreased but below the normal range, and only 6 of the cases showed no change of the I_t in the right direction.

From inspection of the results in Tables II and III it is clear that there is no significant difference in the proportions of "normalized thyroid" improved and not-improved patients in the underfunction and overfunction categories.

TABLE III

Treatment	No.	Psychiatric Change		Thyroid Activity		Correlation Between Change in Thyroid and Psychiatric Change	
		Im-proved	Not Im-proved	Normal-ized	Not Normal-ized

and that the proportions of "not normalized thyroid" improved and not-improved patients in these categories are also very similar. For statistical purposes, therefore, the underfunction and overfunction categories are combined, the proportion of "normalized thyroid" improved to not improved being compared with the proportion of "not normalized thyroid" improved to not improved, regardless of whether thyroid activity had shown underfunction or overfunction before treatment. This comparison indicates that there is a highly significant relationship between psychiatric improvement (as opposed to no change or deterioration) and normalization of thyroid activity. (The value of χ^2 is 7.076, using Yates's correction for continuity. This corresponds to a P value of <0.01 , thus indicating that this relationship could occur by chance only once in 100 times.)

Treatment According to Thyroid Indications

It appeared reasonable to treat ascertained thyroid disturbances and observe the effects on the mental state. A number of patients suffering from various psychiatric illnesses were therefore given specific treatment on thyroid indications only.

We are well aware how controversial and sometimes conflicting have been the results of endocrine therapy in psychiatry reported by various authors, and how difficult it is to allow for the usual degree of apparent improvement after patients have settled down in hospital environment. We have therefore endeavoured to relate treatment and its results to suitable laboratory investigations and to have all patients followed up after discharge by doctors or social workers. We are still checking and revising our results in the light of what we know about the subsequent history of our patients. The thyroid disturbances were usually treated as follows.

Thyroid Underfunction.—Most patients were treated initially with thyrotrophic hormone for two weeks. If thyroid activity had been increased on reassessment with I_t at the end of this period it was assumed that the thyroid underfunction was secondary to primary pituitary underfunction, and treatment with thyrotrophic hormone was continued until the thyroid index became normal. If thyrotrophic hormone was ineffective primary thyroid underfunction was assumed, and the patients were then treated with dry thyroid tablets, or thyroxine or "thyranon" injections, until the B.M.R. became normal, as the tracer method cannot be reliably used during administration of thyroid hormones.

Thyroid Overfunction.—It may be assumed that in many cases hyperfunction of the thyroid is due to increased production of thyrotrophic hormone by the pituitary anterior lobe. Attempts to determine thyrotrophic hormone in blood to settle this question are being made in our department, but the method is not yet in clinical use. Nevertheless, in thyroid hyperfunction the direction of treatment at first is to suppress the production of thyrotrophic hormone with oestrone or A.C.T.H. Generally, 50,000 units of oestradiol were administered daily. In some cases the thyroid level fell to normal or below normal in the course of ten days. If there was no result treat-

ment was continued with methylthiouracil (0.2 g. thrice daily) and 100 mg. of sodium iodide daily.

In some cases the thyroid value measured by I_t may be normal or subnormal, but the B.M.R. increased. Measured under strictly controlled conditions this seems to be due to hypersensitivity to thyroid hormone (see Reiss *et al.*, 1952), and these cases have been treated with ergotamine tartrate.

Although, for reasons mentioned before, we are not prepared at present to give statistics of the results of treatment, the following four cases are reported in some detail by way of illustration of the methods of treatment.

Case 1

A female university student aged 18 was admitted on November 26, 1950. Diagnosis: hebephrenic schizophrenia of gradual onset; duration about a year. There was considerable thought disorder, with hallucinations. She was deteriorating. November 28: thyroid index, $I_t=18.8$ (considerably increased); B.M.R. (under thiopentone) +27%; no clinical signs of hyperthyroidism. Treatment: methylthiouracil, 0.2 g. t.d.s., combined after a week with 100 mg. NaI daily. The B.M.R. (under thiopentone) on January 8, 1951, was -5% and on February 2 was -1%. The B.M.R. (without thiopentone) was +0% on February 13, +3% on February 28, and -3% on March 20.

Clinical Progress.—January 8, 1951: marked improvement in thinking; disappearance of hallucinations; good insight; gained 12 lb. (5.4 kg.) in weight. March 10: discharged symptom-free. June 15: social worker reported that patient was teaching at a small school; mentally normal. October 27: normal; had resumed work at the university. February 1, 1952: attending regularly as an out-patient; began to relapse; much thought disorder with delusions and completely incongruous emotion. February 16: readmitted; I_t at time of admission 15.0 (again increased); psychiatric state as before. March 6: "oestron," 3,000 units daily, with NaI, 100 mg. daily. March 20: state unchanged; B.M.R. now reduced to -13%. April 7: thought disorder as before. June 9: much improved and mentally clear; rational but a little dull; B.M.R. -3%. July 9: remained improved; $I_t=0.4$, B.M.R. -8%. August 26: remission; awaiting discharge; contemplating taking up a teaching post.

Case 2

A married woman aged 31 was admitted on December 8, 1950. Diagnosis: anxiety state, moderately severe, with

FIG. 4.—Thyroid values in psychiatric disorders.

panic attacks, palpitations, much somatic discomfort, and disturbance of sleep. Immature personality. Acute onset five months before admission. December 1: $I_t=16.8$ (increased value). December 20: B.M.R. +25%. Treatment: patient showed positive prolan I reaction, and general hyperfunction of the pituitary anterior lobe was assumed. Treatment was therefore with oestrone instead of thiouracil. January 4, 1951: 50,000 units oestroform and 100 mg. NaI daily. January 29: oestrone dose reduced to 9,000 units daily. February 1: $I_t=0.3$.

Clinical Progress.—She began to improve more quickly than is usual with thiouracil treatment, and ten days after treatment started she was eating and sleeping well and the panic attacks had disappeared. February 18: discharged, recovered; still remains well.

Case 3

A labourer aged 20 was admitted on February 10, 1949. Diagnosis: chronic hebephrenic schizophrenia; duration two years; marked thought disorder, with delusions and hallucinations. Unemployable. May 9: $K=0.37 \times 10^{-2}$ (very reduced value); 17-ketosteroid excretion, 12.2 (normal); cortin excretion, 2.6 (normal). Treatment with thyroid, 1 gr. (65 mg.) twice daily, for hypothyroidism. May 23: if anything, worse. May 30: marked subjective and objective improvement. Discharged on July 2. Although symptom-free, probably a little slow. Instructed to continue taking thyroid, 1 gr. (65 mg.) twice daily. Remained so well that in February, 1950, he stopped taking tablets, and two weeks later he relapsed and was readmitted in much the same state as previously.

March 24, 1950: $I_t=1.3$ (subnormal); treated with thyrotrophic hormone. April 12: $I_t=2.9$ (normal range); rapid improvement. Discharged on May 6. Thyroid, 1 gr. (65 mg.) twice daily, continued. Remained well while continuing treatment for the next 10 months. Relapsed on July 4, 1951, and readmitted as before. July 5: $I_t=0.5$ (very subnormal); treatment as before with thyrotrophic hormone. August 17: $I_t=2.1$ (normal). Considerable psychiatric improvement. Maintenance therapy begun by replacing thyrotrophic hormone by thyroid sicc. twice daily. Discharged on November 12. At this time there was still some flattening of effect and dullness, but no florid symptoms. He has remained symptom-free and at work, and is still taking thyroid, 1 gr. (65 mg.) twice daily. August 26, 1952: patient has remained well on thyroid, 1 gr. (65 mg.) twice daily.

Case 4

A male clerk aged 46 was admitted on April 18, 1951. Diagnosis: chronic anxiety neurosis of 17 years' duration, with panic states, various phobias, lack of confidence, and inability to sleep, most pronounced for six months before admission. He had given up work. April 26: $K=0.52$; $I_t=0.8$ (very subnormal). May 17: condition rather worse; treatment begun with 400 units thyrotrophic hormone daily. May 22: $K=1.05$; $I_t=1.7$ (still subnormal). June 14: $K=2.2$ (lower normal range).

Clinical Progress.—From about May 31 some improvement. A fortnight later, more confidence and less anxiety. Discharged on June 29. Still mildly anxious, but phobias had disappeared. More confident and capable of handling business.

Discussion

The distribution of values of thyroid activity in the psychiatric hospital population presented here agrees in general with our previous reports dealing with much smaller numbers of patients.

It seems fairly clear, as we have discussed before, that there are a great many intermediate states and borderline cases of thyroid disturbance in psychiatric patients as compared with normals. This might be regarded as a reflection of a general constitutional abnormality or weakness in some psychiatric subjects and not of aetiological importance. We think this is not the case, for when the case material

is broken down into groups it will be seen that hypofunction and hyperfunction are more commonly found in some disorders than in others; and, further, that thyroid function is usually corrected in patients who recover, and in some cases it corrects itself as psychiatric recovery takes place.

On the basis that there is a neuro-endocrine interrelationship, the disturbances of the thyroid may be a consequence or a cause, primary or contributory, of mental disorder. However, in most cases the whole disorder has progressed so far that there is a vicious circle, so that we can only speculate on the primary pathological factor.

The statistical evaluation of a large group of patients in whom there was disturbed thyroid activity before treatment, and who showed mental improvement parallel with normalization of the thyroid function, points significantly to a close correlation between the processes of mental and thyroid restoration. We do not think it likely that the changes in the thyroid and mental disorder could have occurred independently without causal interrelationship. It is obvious that in some cases mental improvement may have been responsible for the thyroid normalization, but in others—especially where the improvement in thyroid state preceded mental improvement—it is possible that the thyroid disorder was primary, or was part of a complex endocrine disturbance responsible for mental abnormality.

The most convincing proof that abnormal thyroid activity in some cases is responsible for mental disturbance is the remission of symptoms in patients treated for the thyroid disorder alone. Although we have reported here in some detail four satisfactory cases, a very large series would have to be produced to prove this point and to provide case material for further research in causation.

The purely empirical treatment of psychiatric disorders with hormones and drugs alike is rightly in discredit. We are of the opinion that reporting small numbers of cases who have improved, apparently as the result of hormone treatment, only adds to the confusion unless in each case there have been systematic and continued laboratory investigations. With the methods at present at our disposal this is an ideal very hard to achieve, but—in the case of the thyroid—not outside the possibilities of many of the larger psychiatric research units.

Summary

The indices of thyroid activity in 1,000 psychiatric patients, using the I^{131} tracer method, have been studied in two successive years.

About 20% were outside normal limits.

The histograms of the distribution of indices in 1949–50 and in 1950–1 are almost identical.

Thyroid function in relationship to various psychiatric disorders, treatments, and spontaneous remissions have been studied and discussed.

In a significant number of cases in which the thyroid indices were abnormal before treatment normalization of the thyroid accompanied mental improvement.

Our thanks are due to Dr. K. R. L. Hall and his staff for the statistical evaluation of the results.

Last year the Pharmaceutical Society initiated legal proceedings in 43 cases under the Pharmacy Acts (1852–1941), the Penicillin Act (1947), and the Summary Jurisdiction Act (1848); only five of these cases proved unsuccessful. This fact is among information contained in the Registrar's Report of the Pharmaceutical Society for 1952, which was published recently.

ANTICOAGULANTS IN MYOCARDIAL INFARCTION

BY

I. S. L. LOUDON, B.M., B.Ch.

House-physician, Radcliffe Infirmary, Oxford

J. C. PEASE, D.M., M.R.C.P.

Senior Registrar, Radcliffe Infirmary, Oxford

AND

A. M. COOKE, D.M., F.R.C.P.

Physician, Radcliffe Infirmary, Oxford

The treatment of myocardial infarction with anticoagulants is generally accepted in the United States of America. In Great Britain a number of physicians do not treat their patients in this way, although most papers published here support the American view. The decision to use anticoagulants impels most physicians to admit their patients to hospital for a stay of several weeks, a matter of economic as well as medical importance. The present paper attempts to provide further evidence on the efficacy or otherwise of anticoagulant therapy and the suitability of certain types of patient for this treatment.

The problem was approached by a study of the effects of anticoagulant therapy on the prognosis of patients admitted to hospital with myocardial infarction, by determining if anticoagulant therapy was of equal benefit to all patients of all ages and with different degrees of shock, and by the analysis of notes and post-mortem reports to find how anticoagulant therapy affected the mortality.

Material

Two hundred patients admitted to the Radcliffe Infirmary as emergencies between January, 1945, and May, 1952, were suitable for the investigation; 125 of them were controls and 75 received anticoagulant therapy. In this hospital the duty of admitting medical emergencies is shared between four physicians. There is no selection of the type of case admitted under each physician; one physician admits medical emergencies on Mondays, and the other three in turn for periods of three days in succession.

The notes of all patients admitted between January, 1945, and May, 1952, with a diagnosis of myocardial infarction have been reviewed. Cases were rejected if the diagnosis was in doubt, if the notes were inadequate, or if the use of anticoagulant therapy was contraindicated,—for example, by an accompanying cerebrovascular accident or by a recent history of melaena. The diagnosis was based on the clinical history and positive electrocardiographic evidence in 179 cases, the clinical history and post-mortem evidence in 18 cases, and the clinical history alone in three cases. Of the 70 patients who died, 52 were submitted to a post-mortem examination.

The patients in the control group fell into two categories—75 admitted before 1950, in which year anticoagulant therapy was coming into general use in the Radcliffe Infirmary, and 50 admitted in and after that year. As the death rates in the two categories were 39% and 44% respectively it was felt that all the patients were suitable for inclusion in the control group. In fact, the use and choice of anticoagulants was determined by the views of the physician under whose care the patient was admitted, and there was no obvious medical reason why the patients in the second category did not have anticoagulant treatment.

The case notes of both series have been analysed to show the following facts:—(1) Age. (2) Sex. (3) Time from the onset of infarction to admission and to discharge or death.

(4) Cardiac function before the onset of infarction; four categories being used: (I) no cardiac symptoms, (II) mild angina pectoris or a reduction in exercise tolerance, (III) severe angina pectoris or a great reduction in exercise tolerance, and (IV) frank heart failure. (5) Signs of previous cardiovascular disease before admission: this was judged to be present, absent, or not recorded; if present, one or more of the following signs of cardiovascular disease had been recorded—abnormal rhythm, hypertension, enlarged heart, or evidence of previous infarction. (6) The degree of shock at onset and on admission was assessed as "none or mild," "moderate," "severe," or "not recorded" by consideration of the severity of the pain and its duration and response to opiates, blood pressure, pulse rate, and appearance of the patient. (7) The electrocardiogram. (8) Further thrombo-embolic accidents. (9) The post-mortem report. (10) Cause of death.

In the treated group the following facts were also recorded: type of anticoagulant used, whether heparin, dicoumarol, or ethyl biscoumacetate ("tromexan"); time from the onset of infarction to the beginning of effective anticoagulant therapy, which was taken as the giving of 10,000 i.u. of heparin intravenously or a fall in prothrombin efficiency to under 20% of normal; the duration of effective anticoagulant therapy; and the occurrence of complications resulting from treatment.

Control of Anticoagulant Therapy

Heparin was used in some cases, but only to initiate treatment, and no laboratory tests were necessary, because the dosage used was not large enough to cause lengthening of the clotting-time for a whole 24-hour period. Dicoumarol and ethyl biscoumacetate therapy were controlled by the one-stage prothrombin test as described by Biggs and Macfarlane (1949). When dicoumarol was used the aim of treatment was to maintain the clotting-time between one and a half and two times that of the normal control. This change in clotting-time interpreted from the dilution curve given by Biggs and Macfarlane represents a range of prothrombin efficiency between 10 and 20% of normal. With ethyl biscoumacetate a slightly smaller margin of safety was allowed because it was found that the level of clotting-time could be adjusted more rapidly. With this drug the therapeutic range of clotting-time was taken to be one and a half to two and a half times the control clotting-time, or 7.5 to 20% of prothrombin efficiency, a range similar to that used by Tulloch and Gilchrist (1950).

Results

The mortality in the two groups of cases is shown in Table I.

TABLE I.—Mortality

Group	No. of Cases	No. that Survived	No. that Died
Control	125	74 (59%)	51 (41%)
Treated	75	56 (75%)	19 (25%)

The calculation of χ^2 gives a value of 4.27, corresponding to a probability of about 0.04.

As the mortality rate might have been influenced by factors other than anticoagulant drugs, the two groups were further analysed to try to find out if there were any patients for whom the prognosis was strikingly good or bad in either the control or the treated group. The time from onset to admission was similar in the two groups (Table II). The importance of taking this into considera-

TABLE II.—Cases Admitted in First 48 Hours and in First Seven Days

Group	Admitted in	
	First 48 Hours	First 7 Days
Control	68%	83%
Treated	59%	82%

tion when comparing methods of treatment has been demonstrated by Tulloch and Gilchrist (1950) and by Yater *et al.* (1948).

Cassidy's (1946) series of 1,000 cases had a male-to-female ratio of 3.5 to 1. In the present series the ratio was approximately 2 to 1, the figures in the control group being 82:43 and in the treated group 50:25.

Other factors which might influence the prognosis are age, degree of shock, and cardiac function before the infarction. In Tables III, IV, and V the two groups are compared for each of these factors and shown to be similar, except in degree of shock at onset, where the number of severely shocked patients was larger in the treated group.

The notes of the two groups were examined for evidence of objective signs of previous cardiovascular disease, but it was found that in about half of the cases no information was available. In the remaining half there was a record of some kind of cardiovascular disease in all but four of the control group and all but two of the treated group. This means that the state of the myocardium before the infarction had to be assessed on the subjective evidence of cardiac function, since objective evidence was lacking in a large number of cases.

The cases were then divided up into those mildly, moderately, and severely shocked, and the mortality in each section was considered separately. The results are shown in Table VI, which brings out the influence of the severity of shock on the prognosis of patients not treated with anticoagulants, and suggests that anticoagulants are of value in patients who are moderately and severely shocked. This point is clearly emphasized by Gilchrist (1952), whose article appeared after the present paper had been prepared.

The state of the myocardium before the infarction naturally affects the prognosis, and the figures in Table VII

TABLE III.—Number of Patients in Each Decade from 40 to 90

Group	Age in Years				
	40-49	50-59	60-69	70-79	80-89
Control	19 (15%)	27 (22%)	45 (36%)	28 (22%)	6 (5%)

suggest that only those patients with a good cardiac function before infarction receive benefit from anticoagulant treatment. In Table VIII the influence of age on mortality in the control and treated groups is considered.

The results in the present series suggest that older patients have a worse prognosis if untreated, but a more striking reduction in mortality when anticoagulants are used. Thus age, degree of shock, and cardiac function are shown to influence the mortality from myocardial infarction and the benefit received from anticoagulants. Tables IX and X show that these three factors are independent of one another and are not, as might be expected, due only to the influence of age. In 11 cases it was impossible to decide from the notes what the cardiac function was before the infarction.

It is generally accepted that the prognosis is better for older patients and better for women than for men. In Table XI the greater reduction in mortality for women as a result of the use of anticoagulant therapy may be due to the fact that the women were on the whole older, 70% being over 60, whereas only 50% of the men were over 60.

Discussion

The prognosis of so common a disease as myocardial infarction is uncertain because it is difficult to ascertain the incidence and death rate. In the present paper we

have necessarily had to confine ourselves to a study of those patients who survived long enough to reach hospital. We found that the mortality rate was reduced by anticoagulant therapy from 41 to 25%, a difference that is statistically significant and comparable with the figures of Tulloch and Gilchrist (1950).

The groups of patients who appeared to receive most benefit from anticoagulants were those over 60 years of age, those who were moderately and severely shocked, and those whose cardiac function immediately before the myocardial infarction was impaired slightly or not at all.

It is not merely a question of academic interest to decide what type of patient is most likely to benefit from anticoagulants, because most physicians find treatment practicable only in hospital, and many more cases of myocardial infarction are admitted now than formerly. Table XII

TABLE XII.—Number of Patients Admitted with Myocardial Infarction each Year from 1945 to May, 1952, and the Proportion Receiving Anticoagulant Therapy (Only the Cases Included in the Present Series are Recorded)

Year	No.	No. Treated with Anticoagulants
1945	4	0
1946	20	0
1947	14	0
1948	4	4 (17%)
1949	24	2 (11%)
1950	18	15 (83%)
1951	32	36 (55%)
1952	66	18 (27%)
Jan.-May, 1952	22	18 (82%)

shows that more patients were admitted to the Radcliffe Infirmary in 1951 (66) than in the four years 1945-8 (62). Unless there is a change in the management of patients with myocardial infarction which allows satisfactory treatment in the home, the number of patients admitted to hospital will increase. This is an important economic fact, because anticoagulant therapy does not shorten the period in hospital. In the control group the average stay was 39 days and in the treated group 45 days. The number of persons in the age groups with the highest incidence is increasing, and the cost of a hospital bed in the Radcliffe Infirmary reached the figure of £17 12s. 3d. a week in 1951.

The death rate in the series of 800 cases reported by the American Heart Association was 24% in the controls and 15% in the treated group. The difference was thought to be due chiefly to a reduced incidence of thrombo-embolic deaths. One of our chief difficulties in making a retrospective survey was that vital information about the patient's mode of death is so often lacking, and even with very comprehensive post-mortem notes the exact cause cannot be found, although contributory causes may be evident, and in many cases no more precise diagnoses than those listed in Table XIII could be made. It is for this reason that the admittedly vague terms "sudden death," "continued shock," and "heart failure" had to be used.

TABLE XIII.—Causes of Death

Cause	Control Group	Treated Group
Sudden death	25	11
Continued shock	10	2
Heart failure	12	6
Ruptured ventricle	2	0
Haematemesis	2	0

An attempt is made to answer the question posed in a leading article in the *British Medical Journal* of October 28, 1950 (p. 991), of how many of the deaths were inevitable. By inevitable we mean, for instance, a severely shocked patient dying within an hour of admission or a patient found after death to have a ruptured ventricle.

Table XIV shows the numbers in each category after the inevitable deaths have been subtracted, and has been

TABLE XIV.—Causes of Death After Subtraction of Inevitable Deaths

Cause	Control Group	Treated Group
Sudden death	25	9
Continued shock	4	1
Heart failure	10	1

included although we realize that the word inevitable as used here has no absolute value but is a retrospective assessment. For the same reason no deduction of inevitable deaths has been made throughout the paper.

Thrombo-embolic accidents other than myocardial infarction which developed while the patients were in hospital numbered 27 (21%) in the control group and 11 (15%) in the treated group. The incidence is low because adequate records of suspicious incidents were sometimes lacking.

Thus in the present paper there is no definite indication how anticoagulant therapy lowers the mortality rate from myocardial infarction, although it is quite clear that there is a significant reduction.

While we do not feel that it is yet justifiable to withhold anticoagulant therapy from any patient suffering from myocardial infarction, provided no contraindication exists and proper laboratory facilities are available, our results suggest that certain types of patient may be specially suitable for that treatment.

Summary

The case histories of 200 patients admitted to the Radcliffe Infirmary with myocardial infarction between January, 1948, and May, 1952, have been reviewed.

The death rate in hospital was 41% in the control group of 125 cases and 25% in the treated group of 75 cases, a difference which is statistically significant.

Anticoagulant therapy seemed to be of most value to patients over 60 years of age, moderately or severely shocked, and with little or no previous impairment of cardiac function.

No complications resulted from anticoagulant therapy.

We wish to thank the physicians of the Radcliffe Infirmary for permission to use the case reports of their patients; Dr. A. H. T. Robb-Smith, Dr. R. G. Macfarlane, and Dr. Rosemary Biggs for the pathological and haematological data; Dr. I. Sutherland and Dr. D. J. Finney for advice and the statistical calculations; and Miss Betty Merry, of the Records Department, Radcliffe Infirmary.

The Sixth Laboratory Animals Bureau Congress was held at the Royal Veterinary College, London, on March 27 and 28. Some 250 technicians from all parts of the country attended. The congress was opened by the secretary of the Medical Research Council, Sir Harold Himsworth. Six shop papers were read by technicians, and one long one, on reproduction in mammals, by Dr. I. W. Rowlands, of the Agricultural Research Council Institute of Animal Physiology, Babraham. Visits were paid to the National Institute for Medical Research, Mill Hill, and to the Lister Institute at Elstree, and a programme of films of zoological interest was shown at the College. The final session was "Questions." Chairmen at the four sessions were Professor S. Bedson, F.R.S., Dr. L. Harrison Matthews, Dr. R. Love and Professor R. E. Glover. The proceedings of the Congress will be published in full in the journal of the Animal Technicians Association.

RUPTURE OF THE HEART AS A RESULT OF BR. ABORTUS ENDOCARDITIS

BY

G. H. GRANT, B.M., B.Sc

Pathologist, Royal Salop Infirmary, Shrewsbury

AND

C. L. STOTE, M.D., M.R.C.P.

Physician, Royal Salop Infirmary, Shrewsbury

Undulant fever is not a rare disease in this country; yet endocarditis due to *Brucella* organisms has only twice been recorded here (Rennie and Young, 1936; Hart *et al.*, 1951), and only in the latter case was it confirmed bacteriologically at necropsy. Dalrymple-Champneys (1950), in his series of 983 cases of undulant fever, does not record a single example. In the foreign literature we have found accounts of a further 21 cases confirmed bacteriologically at necropsy; most of these have been reviewed by Hart *et al.*

There seems to have been no previous example of a sudden fatal termination by massive haemorrhage into the pericardium.

Case History

A 51-year-old forestry nurseryman had had no previous severe illness. In July, 1950, he complained of sudden partial loss of vision in the right eye. An ophthalmologist found pale patches below and to the nasal side of the disk, with a complete central scotoma. The blood pressure was 75/50.

When admitted to hospital on September 25 he was a thin ill-looking man with pigmented patches on the forehead. The blood pressure was 95/60; Hb 78% (11.5 g. %), and the white blood cells numbered 4,500 per c.mm. (76% polymorphs). The Wassermann reaction and Kahn test were negative. The urine contained a trace of protein and scanty hyaline casts.

A rigor occurred the day after admission, but following this his temperature showed only an occasional rise to 99° F. (37.2° C.). On October 17 his serum agglutinated a standard suspension of *Br. abortus* in a dilution of 1/3,200. His general condition improved steadily, the sight in the affected eye gradually returned, and his temperature settled. In view of this no specific treatment for the abortus infection was given. He seemed well in himself on discharge on October 26, but his E.S.R. remained high—54 mm. in one hour (Wintrobe).

A month later his ankles began to swell and he became breathless on exertion. During the following week, early in December, he was readmitted with nocturnal dyspnoea and a temperature of 100–101° F. (37.8–38.3° C.). This pyrexia settled after four days, and was assumed to be due to an associated bronchitis.

Examination showed oedema of the ankles and sacral region, and some clubbing of the fingers. The pulse rate was about 100, with frequent extrasystoles, and a systolic murmur could be heard over the whole praecordium. A chest x-ray film showed moderate enlargement of the heart, chiefly left ventricular; the blood pressure was 95/60. The symptoms of congestive failure improved with treatment and the oedema practically disappeared, but a temperature of 99–100° F. (37.2–38.8° C.) recurred during the week before he was allowed to return home on December 23, for Christmas.

When readmitted on January 6, 1951, the signs of congestive failure had returned more severely, the legs were grossly oedematous and the breathing was distressed. The pulse rate was 100 and regular, and the blood pressure 105/75. No cardiac murmur could now be heard. The

only electrocardiographic findings were slurring of the P-R interval with a depressed T wave in all leads except CF 4; both auricular and ventricular extrasystoles were occurring. A blood count showed Hb, 11.1 g. % (75%); white cells, 5,500 per c.mm. (banded polymorph neutrophils 3%, segmented polymorph neutrophils 88%, lymphocytes 5%, monocytes 4%). He remained afebrile and a single blood culture at this time was sterile. Yet he steadily became worse and died suddenly on January 14, eight days after his readmission and six months after his first symptoms.

Thus the clinical course of the illness was that of a mild *Br. abortus* infection with apparent spontaneous recovery, followed by rapid congestive heart failure. He had had comparatively few of the usual signs and symptoms associated with bacterial endocarditis. The original blindness may have been due to an embolus, but none other was observed. The spleen was never palpable and the patient was afebrile during most of his illness.

Necropsy Findings

A post-mortem examination was carried out 50 hours after death. The heart (275 g.) was not enlarged. The left ventricle was 17 mm. thick, the right ventricle 6 mm. The coronary arteries were healthy. The tricuspid, pulmonary, and mitral valves were normal. The aortic valve was bicuspid, a single large cusp replacing the usual right and non-coronary cusps (see Figs. 1 and 2). This combined cusp was smaller than two normal ones but larger than a single one: it measured 40 mm., while the other (left) cusp measured 33 mm.

FIG. 1.—Diagram of transverse section of heart at level of aortic valve. L.A.=left auricle. R.A.=right auricle. R.V.=right ventricle. I.A.S.=interauricular septum. I.V.S.=interventricular septum. P.A.=posterior aortic cusp. A.A.=anterior aortic cusp. L.C.=left cusp. C.C.=combined cusp. Black areas show perforations in cusps. O represents coronary orifices.

FIG. 2.—Part of aortic valve, opened out after cutting through the left cusp. The top of this cusp with attached vegetations has been removed to show opening into posterior aneurysm. Lettering as in Fig. 1.

Opposite the centre of the combined cusp a low ridge ran along the wall of the aortic sinus in the long axis of the aorta. It was 3 mm. wide and less than 1 mm. high, with a rounded outer surface and parallel borders—an appearance almost pathognomonic of a congenital lesion (Koletsky, 1941). Microscopical examination of serial longitudinal sections through the ridge confirmed this. They showed a thickening of the elastic-containing media only and no evidence of an inflammatory reaction. If the lesion had been acquired, such a central ridge should have contained fibrous tissue from the annulus fibrosus on the lumen side of the elastic tissue of the aortic media (Lewis and Grant, 1923).

There were large friable vegetations on both cusps, especially posteriorly, where their margins were fused together for a distance of 1.5 cm. Microscopically these vegetations consisted of fibroblasts with a few lymphocytes and histiocytes, covered by blood clot, fibrin, hyaline necrotic material, and masses of Gram-negative coccobacilli. The posterior third of the combined (right) cusp had been almost completely destroyed by ulceration; only a narrow band at the free margin remained attached to the aorta posteriorly; beneath this was a ragged hole about 2 cm. in diameter. There was also a smaller hole in the other (left) cusp near its attachment anteriorly. Both cusps were slightly thickened. Microscopically the larger cusp showed fibrosis (maximum thickness 3 mm.), and at its junction with the aorta some small deposits of calcium were identified by von Kossa's method. Such changes are common in congenital bicuspid valves in the absence of infection (Lewis and Grant, 1923).

The myocardium, although its cut surface appeared normal to the naked eye, was under the microscope diffusely inflamed, especially just beneath the endocardium. Numerous small foci of necrosis scantily infiltrated with mononuclear and occasional polymorph cells were seen, and also collections of similar cells unassociated with muscle necrosis and having a very occasional central foreign body giant cell. Near the aortic valve there was an occasional acute abscess full of polymorph leucocytes. No fibrosis of acute muscle was seen apart from a patchy area in the intermuscle. Since none of these lesions resembled an Aschoff nodule, and since the mitral valve and the endocardium of the left auricle appeared healthy, old rheumatic infection seemed unlikely.

The aortic sinuses opposite the two holes in the cusps were greatly dilated to form localized smooth-walled aneurysms. The smaller (anterior) aneurysm had a narrow orifice opposite the perforation in the left cusp—that is, in the extreme anterior part of the sinus; it extended for about 1.5 cm. to the left beneath the undilated part of the sinus. The larger (posterior) aneurysm involved an area about 1.5 cm. in diameter, and was situated in the most posterior cm. of the sinus; it extended posteriorly, upwards, and quarter to right and left for about 1 cm. Externally its bulging to right and left could be seen between the aorta and the left upper dome could be seen between the aorta and the left auricle. The smooth walls of these aneurysms and the presence of the congenital bicuspid valve suggested at first that they might be congenital in origin. There is, however, no recorded case of a congenital aneurysm of the left aortic sinus, presumably because its formation is not affected by the aorto-pulmonary septum. Furthermore, when the posterior aneurysm was investigated microscopically by studying serial horizontal sections at 1-mm. intervals, it was found to have a smooth uninfamed fibrous wall 2 to 3 mm. thick, containing peripherally numerous histiocytes filled with iron pigment. It was continuous below with the fibrous tissue of the annulus fibrosus; at the sides and above the elastic tissue of the aortic media was bent outwards before abruptly giving place to the fibrous tissue of the aneurysm wall. If the aneurysms were congenital, one would expect at least the upper part to be lined by elastic-containing media, even if the lower part were lined by fibrous tissue from the annulus fibrosus.

The blood reaching the pericardial cavity had burst through a small hole in the left wall of the posterior aneurysm and emerged between the left auricular appendage and the aorta, tracking for about 0.5 cm. beneath the visceral pericardium. Microscopically this hole was an acute inflammatory sinus, but serial sections taken above and below it showed a closed cavity filled with pus cells in the wall of the aneurysm (see Fig. 3). This suggests that

FIG. 3.—Transverse section through posterior wall of aorta and upper part of posterior aneurysm at level of top of aortic valve. (×24. Verhoeff's elastica.)

the perforation was not due to inflammation of the inner surface of the aneurysm but to an abscess in the wall, which may have been embolic in origin or, more probably, arose by direct spread from the vegetations near the attachment of the left cusp.

Other Organs.—The lungs were oedematous (right 800 g., left 550 g.), and there were bilateral pleural effusions, each about 200 ml. The spleen (500 g.), liver (1,800 g.) and lymph nodes were all congested. Microscopically they contained scattered collections of inflammatory cells and small granulomata consisting of epithelioid cells with a varying amount of collagen and an occasional foreign body giant cell but no central caseation. The kidneys, normal in size, had microscopically a non-specific interstitial inflammatory reaction. The remaining organs showed no unusual features.

Bacteriological Findings.—*Br. abortus* was isolated from the patient's bone marrow, and also by guinea-pig inoculation from part of an aortic-valve vegetation which had been washed repeatedly in sterile saline and 70% alcohol and ground before injection into the animal. (The guinea-pig's serum agglutinin titre to *Br. abortus* rose to 1 in 320 in five weeks.) The cultures of *Br. abortus* were identified by their nutritional requirements, and by biochemical tests, dye inhibition tests, and serology. This confirmed the diagnosis of *Br. abortus* carditis and septicaemia.

Comment

Of the 22 cases of *Brucella* endocarditis confirmed at necropsy, 14 were due to *Br. abortus*, the organism causing undulant fever in Great Britain. In addition to the case described by Hart *et al.* in this country, 10 cases have been recorded in America (Scott and Saphir, 1928; Spink and Nelson, 1939; Smith and Curtis, 1939; Spink *et al.*, 1942, 1948; Wechsler and Gustafson, 1942; Call *et al.*, 1944; Quintin and Stalker, 1946; Voth, 1949), and three in Central Europe (Matzdorff, 1933; Steyrer, 1934; Rothman, 1935). All were males, reflecting the curiously high incidence of brucellosis in men (Stableforth, 1952), and all died after an illness lasting 3 to 11 months. One case of recovery has been described (Spink *et al.*, 1948).

Although in at least two cases (Rothman, 1935; Spink and Nelson, 1939) the heart valves attacked were apparently normal, the infection resembles *Streptococcus viridans*

endocarditis in usually seeking out valves which have been previously damaged by rheumatism or which are congenitally deformed. In nearly all the recorded cases, including the two previously described in England, old rheumatic valvulitis has been found. Our case is the fourth example of infection superimposed upon a congenital bicuspid aortic valve (Wechsler and Gustafson, 1942; Voth, 1949; Spink *et al.*, 1948).

Cases of bacterial endocarditis due to *Brucella* organisms have certain distinctive characteristics. These are well illustrated by our case, and may be summarized as follows:

1. The aortic valve is usually attacked. Occasionally the mitral valve is also involved, but in only two cases was the disease confined to it (Rennie and Young, 1936; Spink *et al.*, 1942).

2. There is a great tendency to produce ulceration. The valve cusps become perforated and there are often haematomata in the myocardium or in the auricular or ventricular septa. In the first case described by Call *et al.* (1944) the inflammatory process had ulcerated through the root of the aorta as far as the epicardium, but, unlike our case, rupture into the pericardium had evidently not occurred.

3. Aneurysmal dilatation of the aortic sinuses is common. Probably (see Jones and Langley, 1949) inflammation of the sinus wall causes separation of the annulus fibrosus from the aortic media, so that blood passes through the wall of the aorta and stretches the exposed muscle of atrium or septum. It then clots and eventually becomes organized, so giving rise to an aneurysm lined by fibrous tissue. That this is the correct explanation in our case is supported by the presence of the surrounding histiocytes filled with iron pigment.

4. A persistent leucopenia is common, but, unlike uncomplicated brucellosis, there is a relative neutrophilia rather than a lymphocytosis, apart from one exception (Steyrer, 1934).

5. Extremely low blood pressure, which was a prominent feature in this case—the systolic pressure being only once recorded as above 100 mm.—has also been found in other cases. In one of these (Gounelle and Warter, 1935) a pressure of 60/45 was recorded, and five others had pressures of 105 mm. systolic or less at one time or another. Furthermore, evidence of alteration in conduction of the heart muscle has been demonstrated in several cases, although not in ours. Both these factors may well be due to the severe myocarditis commonly present.

6. The accompanying bacteraemia often gives rise to a variety of focal lesions in the viscera, such as the granulomata, suppurative lesions, and focal necroses seen in our case (compare Matzdorff, 1933; Sprunt and McBryde, 1936; Rabson, 1939; Call *et al.*, 1944) as well as embolic lesions.

7. There may be improvement in symptoms and cessation of pyrexia for a period, even when infection remains active (Call *et al.*, 1944; Voth, 1949; Hart *et al.*, 1951), so that a patient with *Brucella* endocarditis may appear deceptively well—an important practical point, well illustrated by our case. There was little evidence of septicaemia, only slight pyrexia, no definite embolic manifestations, and no clinical enlargement of the spleen, at a time when the histological evidence suggests that the endocarditis was progressing.

The possibility of such rare complications reinforces the need for the early diagnosis of all cases of undulant fever and their treatment with full courses of antibiotics.

Summary

A case of *Brucella* endocarditis is reported. It was superimposed on a congenital bicuspid aortic valve and gave rise to aneurysms of the aortic sinuses. Terminal rupture of the heart resulted from a small abscess in the wall of one of these aneurysms.

The characteristics of this type of endocarditis are described in the light of this and previous cases.

The possibility of such a serious latent complication emphasizes the need for early diagnosis and treatment of all cases of brucellosis.

We wish to thank Dr. A. C. Jones and Mr. P. Everall for the bacteriological work in this case, and Mr. R. T. Ross for technical assistance.

OBSERVATIONS ON GOLD THERAPY IN RHEUMATOID ARTHRITIS

BY

R. A. PEEBLES BROWN, M.B., Ch.B., F.R.F.P.S.
M.R.C.P.

Senior Registrar

AND

J. P. CURRIE, M.D., F.R.F.P.S., M.R.C.P.

Physician

Rheumatism Unit, Glasgow Royal Infirmary

Gold salts have been widely used for the treatment of rheumatoid arthritis for about 20 years, and during that time many reports of the results have been published. Although some of these reports have been of small numbers of cases, others have been extensive; for example, Forestier (1935) reported on over 550 treated patients, and Hartfall *et al.* (1937) on 690. The general impression from these reports is that a favourable response may be expected in about 80% of cases. Thus Short *et al.* (1946) analysed the results of gold treatment in cases collected from 35 published reports. Making allowance for the different criteria adopted, they found that it was claimed that 84% of 1,943 cases showed definite improvement of any degree, 59.3% of 2,924 showed noteworthy improvement, and 22.6% of 1,825 were arrested. It is probably true to say that on this basis gold has become the most widely accepted single therapeutic weapon in the treatment of rheumatoid arthritis.

Need for Controlled Trials

Unfortunately, none of the results in the early series were controlled in any way, and even now the number of reports of controlled series is strikingly few. Control of results in rheumatoid arthritis is essential for two reasons. The first is that spontaneous improvement and arrest can occur at any time; it seems to occur more often in patients who have developed the disease at an earlier age and in earlier stages of the disease, and it is notable that it is for such patients that gold is said to give the best results. The exact course and the natural history of untreated rheumatoid arthritis are difficult to assess, as with such a prolonged and disabling condition it is impossible to keep patients entirely without treatment, either from their doctor or from friends. Few figures are available even for the results of simple and non-specific treatment, but Short *et al.* (1946)

assessed such results for 274 patients in 1937, after a period of six months to seven years. They found 52.9% with noteworthy improvement and 16.4% in which the condition was arrested. In a later paper (Short and Bauer, 1948), covering 250 cases followed for a further 10 years, 53.2% were found to be improved and 15.9% in remission, with 9% arrested for five years or longer. They did not consider that their own results for gold treatment in 35 patients were any better than this. They quote Furlong (1942) for the opinion that 60–70% of patients receiving general measures show improvement. Thompson *et al.* (1938) also claimed that various measures other than gold resulted in marked or moderate improvement in 76.5% of 274 patients, with 6% classified as being well.

The second difficulty in assessing results lies in the determination of objective improvement. In 1937 Hartfall *et al.* stated that they had been unable to eliminate the psychological effect of injection therapy, but thought that "most observers will no doubt agree that psychogenic factors do not play an important role in the majority of patients." In recent years the effect of the emotional state of the patient and of the emotional atmosphere on subjective tests of improvement has been increasingly noted. Clark (1951) has stressed the effect of placebo treatment, and Bedford (1951) has shown that the response to subjective tests may vary from hour to hour even in the absence of any therapy. There is as yet, however, no agreement on which tests may be considered objective. Quin *et al.* (1950) accept tenderness, power of grip, and speed of movement as suitable tests, and Janus (1950) accepts tenderness and grip. As Clark has pointed out, these tests depend on the co-operation of the patient, and changes in the emotional tone may, by varying the threshold of sensitivity to pain, cause variations in the results obtained. Strictly objective tests that may be used include the measurement of joint size, temperature, and blood flow; estimation of the E.S.R. and degree of anaemia; and estimation of plasma viscosity and C-reactive globulin. The difficulty of using many of these tests in routine assessment of improvement is obvious.

Results in the Literature

The first report of a controlled trial of gold salts was by Ellman *et al.* (1940). They treated 30 patients with large doses of gold salts and 30 with small doses; 30 patients were observed as controls. They claimed that in 14 of those on large doses, 8 on small doses, and 1 of the controls became inactive, and that 14, 20, and 22 respectively showed some improvement. These findings were supported by E.S.R. estimation and measurement of joint swelling. After one year the results in the treated cases remained better than in the controls.

Fraser (1945) carried out a carefully controlled investigation on 110 patients, 61 being treated with sodium aurothiomalate ("myocrisin") and 49 with control injections. The results were assessed after one year. He found that 82% of those on gold improved clinically, compared with 45% of the controls, although 75% of the latter claimed subjective improvement. He did not claim arrest in any cases, but 56% of those on gold were considered to show great improvement, compared with 33% of the controls. Fraser believed that, although gold was the best single form of treatment available at the time, the good results claimed by the majority of observers were unjustifiably high owing to the lack of adequate controls.

Waine *et al.* (1947) are quoted by Egellius *et al.* (1952) as having treated 58 of 120 patients with gold. After an average of 2.9 years they found 56.9% of the treated cases symptom-free or greatly improved, compared with 29.1% of those treated physically.

Adams and Cecil (1950) treated 106 of 189 patients with gold. After one year they claimed complete remission in 78.7% of cases on gold and in 29.8% of controls for cases of less than six months' duration, while in those in which the disease was present for a longer period remissions oc-

curred in 48.9% and 16.7% respectively. After an average of four years, 55.7% of gold cases and 36.1% of controls remained in remission. These figures are high for cases showing complete inactivation; by using the strict "therapeutic criteria" of the New York Rheumatism Association (Steinbrocker *et al.*, 1949) they are lowered to 44.8% for gold and 27.7% for controls; such figures indicate how varying criteria may affect the results obtained in uncontrolled series.

Merliss *et al.* (1951) treated 28 patients with aurothioglycoanilide ("lauron") and 44 controls with saline, serum, or antireticulocytotoxic serum. They found no essential difference in the results of the two groups, and again stressed the great variation of results with a varying emotional atmosphere.

The introduction of cortisone has shown what effect can be achieved by a really potent remedy in suitable cases of rheumatoid arthritis, and has given a standard against which the results of gold therapy can be set. Since it is widely agreed that gold may produce dangerous toxic effects, it is essential to be sure that any benefit obtained is great enough to warrant its continued use. Gold treatment will not necessarily be discarded completely through the introduction of cortisone, and indeed its use to potentiate or prolong the action of cortisone is under investigation. In these circumstances, and considering the varying results reported, it seems essential that further controlled studies of the results of treatment should be carried out.

Present Investigation

A course of treatment lasting 13 weeks was given to 220 patients. All were treated in the out-patient department of the Glasgow Royal Infirmary and were seen once weekly for treatment and observation. The diagnosis of rheumatoid arthritis was based on the following criteria: polyarthritides; radiological confirmation or lack of evidence of other joint pathology; normal blood uric acid; negative Wassermann reaction; negative gonococcal complement-fixation test; negative serum agglutination test for abortus fever; acceptable clinical history and picture; and raised E.S.R. and raised plasma viscosity. The patients were assessed for improvement at the end of the course, again three months later, and, finally, one year after treatment had ceased. Assessment of subjective improvement was by pain, performance, well-being, and appetite; objective improvement by joint measurements, E.S.R., plasma viscosity, and degree of anaemia.

Treatment was as follows:—(1) Gold: weekly intramuscular injections of sodium aurothiomalate (total dose 0.8–1 g., divided over 13 doses). (2) Copper: weekly intravenous injection of "cuprelone" (1st dose, 10 mg.; 2nd and 3rd doses, 25 mg.; 4th and 5th doses, 50 mg.; 6th and 7th doses, 75 mg.; 8th and 9th doses, 100 mg.; 10th and 11th doses, 150 mg.; 12th and 13th doses, 200 mg.). (3) Saline: weekly intramuscular injections of 3 ml. of sterile normal saline. (4) Physiotherapy: weekly treatments of various forms of heat therapy and gentle massage. (5) Arsenic: weekly intravenous injections of neoarsphenamine (1st dose, 0.15 g.; 2nd to 13th doses, 0.3 g.). (6) Aspirin: 10 gr. (0.6 g.) acetylsalicylic acid powder three times a day for 13 weeks; inter-viewed weekly.

The results at the end of the course for all patients are set out in Table I. These results are not, however, strictly comparable one with another, as the cases treated by gold and

TABLE I.—Results at End of Course; All Cases

Treatment	No. of Cases	% Symptomatically Improved	% Objectively Improved
Gold	38	75	50
Copper	60	50	33
Saline	60	42	33
Arsenic	21	70	50
Physiotherapy	22	50	33
Aspirin	19	50	25

arsenic had been selected in that they were all early and frankly active cases with an E.S.R. of over 40 mm. in one hour. The remaining groups included patients over 50 years of age and with advanced disease.

Table II shows the results adjusted by the removal of such patients from each group. The figures in this small series indicate that the results of a single course of treatment with gold salts are no better than those obtained by the other methods described.

TABLE II.—Results Adjusted to Exclude Elderly and Inactive Cases

Treatment	No. of Cases	At End of Course		At 3 Months		At 1 Year	
		A	B	A	B	A	B
Gold	38 (0)	75	50	62	28	53	30
Copper	40 (20)	77	52	66	32	50	33
Saline	38 (22)	74	53	60	36	55	30
Arsenic	21 (0)	70	50	60	30	50	29
Physiotherapy	16 (6)	70	43	58	29	48	30
Aspirin	13 (6)	77	38	59	25	60	25

A=Percentage symptomatically improved. B=Percentage objectively improved.

Figures in parentheses show the number of cases eliminated from each group to make the basis for selection comparable to that for gold therapy.

Summary

Attention is drawn once more to the small number of reports of controlled trials of gold therapy and to the variation in the results obtained.

A series of 220 patients have been treated by a variety of measures, 38 of them receiving gold. No appreciable difference in the results has been found, either immediately or after one year.

Miss Patricia Hornsby-Smith, M.P., Parliamentary Secretary to the Ministry of Health, was the guest speaker at the annual general meeting of the Central Council for the Care of Cripples, which took place on April 10. She said she sympathized very much with the point of view of the council on the edict of the General Nursing Council preventing nurses from starting their training until they are 18, and thus eliminating the year of orthopaedic pre-nursing which many girls of 17 had been doing, but she hoped that some compromise might yet be reached in this matter. The Ministry of Health readily acknowledged and appreciated the voluntary work which the council was doing, and was glad to support the project being launched for the sale of goods made by cripples. A committee was being set up by the Ministry to inquire into the rehabilitation and training of all those physically handicapped. Miss Hornsby-Smith said that, following a circular to 129 local authorities asking them to submit schemes for the care of their physically disabled, 65 had already submitted schemes to the Minister. She thought local authorities had a difficult task in deciding which service to expand and which to create without increasing the rates.

DISSEMINATED ASPERGILLOSIS AND MONILIASIS ASSOCIATED WITH AGRANULOCYTOSIS AND ANTIBIOTIC THERAPY

BY

N. E. RANKIN, M.B., B.S.

(From the Department of Pathology, the Royal Infirmary, Gloucester)

Pulmonary aspergillosis and local infections with monilia are not rare, but the disseminated forms are much less common. The use of antibiotics in the presence of these fungous infections is dangerous. The following case is of interest because both fungi were present in the lesions.

Case Report

A window cleaner aged 45 was seen on April 3, 1951, with an abscess of the thigh. He was treated with sulphonamides, and was admitted on April 18 for evacuation of the pus (culture, *Staphylococcus aureus*). He later developed consolidation of the right lung. This was treated with penicillin, 14 million units, and resolved slowly. Albuminuria developed on May 28 and persisted. The white-cell counts on April 26 and July 26 were 4,600 and 4,300 per c.mm., respectively. He was discharged on August 31, and shortly afterwards developed ulceration of the throat, which responded to chloramphenicol. He was readmitted on October 5 and agranulocytosis was found (white cells 1,800, polymorphonuclears 108 per c.mm.), and this persisted. Chloramphenicol was continued (total dose, 30 g.), with oral and intramuscular penicillin. Pyridoxine, 250 mg., "livadex" 20 ml., and three blood transfusions of 1 pint (570 ml.) were given. Consolidation of both lungs developed on November 1 (sputum culture, *Ps. pyocyanea*) and he died on November 7.

At necropsy on November 8 fibrinous pleurisy was present on both sides. A large infarct was found in the right upper lobe and a smaller infarct in the middle lobe; the pulmonary arteries to these areas showed thrombosis. In the left upper lobe was a pale area of consolidation 6 cm. in diameter, but no cavitation. A typical red infarct was present in the left kidney, and both kidneys showed several smaller dark-red areas in the cortex. The liver was enlarged (3,500 g.), pale, and firm, with numerous firm white nodules up to 1.5 cm. in diameter with some hyperaemia at the edges. There were a few similar areas in the spleen. The oesophagus was covered throughout with a ragged soft membranous exudate covering shallow ulcers. There was one small acute ulcer in the stomach. In the duodenum and jejunum there were numerous ulcers up to 1 cm. in diameter with a yellowish base and raised haemorrhagic border. A few ulcers were found in the ileum and one in the caecum. Red marrow was present in the sternum and vertebral bodies. Exploration of the left thigh showed fibrosis at the site of the abscess, but no pus or involvement of the femur.

Sections of the lesion in the left lung showed a central area of necrosis, in which only the outlines of the blood vessels could be distinguished. Surrounding this was a zone of inflammatory infiltration in which plasma cells and macrophages predominated. No polymorphonuclears or eosinophils could be seen. Branching mycelium was present throughout the necrotic zone, invading the inflammatory zone and large and small vessels at the edge. The left lung showed a typical infarct with mycelium in the thrombi. The kidney contained an infarct with mycelium in the lumen of the artery. Sections of liver and spleen revealed areas of necrosis similar to that in the lung, but with a very dense network of mycelium, which extended on to the peritoneal surface of the liver. The ulcers in the alimentary tract showed necrotic centres surrounded by the inflammatory reaction, and invasion of the muscularis and blood vessels by mycelium.

Dr. J. T. Duncan kindly examined the sections and made the following comments on the morphology of the fungi. "The tissue sections showed infection by two different fungi, neither of which can be identified specifically without a culture. One of the fungi shows a coarse septate mycelium bearing tufts of stunted terminal branches, indistinguishable from the vegetative mycelium of *Aspergillus fumigatus* in parasitic life, yet not sufficiently distinctive to be identified with this species in the absence of conidial apparatus. This was the only fungus seen in the lung and kidney sections, but it was present also in other tissues, often within the blood vessels. In fact, like *A. fumigatus*, it seemed to have a marked predilection for the blood vessels, and this accounts for the renal infarct. I would judge that this mould infection originated in the lung and was carried to other organs by the blood stream. The other fungus, which was seen in all of the tissues except the lung and kidney, showed general morphology of *Candida*, which is particularly well shown in the sections of liver and spleen. In many of the tissues both fungi are present, and in some areas they are intimately mixed. However, the *Candida* infection is chiefly associated with the mucosa of the alimentary tract."

Discussion

Disseminated aspergillosis is often associated with infarcts, especially in the kidney (Wahl and Erickson, 1928; Abbott *et al.*, 1952; Dr. H. G. Close, personal communication). Very widespread dissemination has been described (Cawley, 1947; Grekin *et al.*, 1950), as have two cases of (Cawley, 1947; Grekin *et al.*, 1950), as have two cases of the mouth endocarditis (Zimmerman, 1950). Infection of the mouth and alimentary tract with monilia is a common complication and agranulocytosis. Several cases of disseminated infection of agranulocytosis. The portal of entry may be the alimentary tract, as in the present case and in those of Lederer and Todd (1949). Duhig and Mead (1951) discussed the possibility of introduction into the blood stream during intravenous therapy. This probably occurred in the cases described by Joachim and Polayes (1940) and Wikler *et al.* (1942) in drug addicts, and by Geiger *et al.* (1945). The bacterial flora of the alimentary tract is known to change during antibiotic therapy, and fungi often appear (Tomaszewski, 1951) owing to suppression of the normal flora and other factors. It is probable that in the present case dissemination of the fungi was promoted by chloramphenicol therapy. The association of agranulocytosis with chloramphenicol was not well known at the time this patient was treated.

Summary

A case of fatal generalized aspergillosis and moniliasis is described. The patient's illness started with a staphylococcal abscess in the thigh, followed by pyaemia with lung lesions. He later developed agranulocytosis and was treated with chloramphenicol. Recent reports indicate the danger of this drug in agranulocytosis. Aspergillosis and moniliasis were found at necropsy. Reference is made to other cases of generalized fungous infections in the literature.

I wish to thank Mr. P. M. Birks and Dr. R. F. Jarrett for permission to publish this case; Dr. E. N. Davey for his advice in preparing this paper; and Dr. H. G. Close, of Dartford, for allowing me to examine material from his case. Dr. J. T. Duncan's help and advice on the mycology have been invaluable. I am grateful to Miss B. Summers for the histological preparations.

Medical Memoranda

Monilia Peritonitis

Powerful wide-spectrum antibiotics will suppress the growth of susceptible bacteria, and these may be replaced by monilia or other yeast-like organisms which can in certain situations become pathogenic. Oral and intestinal lesions are well recognized (Woods *et al.*, 1951), and cases of monilia pneumonia (Ormerod and Friedmann, 1951; Wolff, 1952) and moniliasis of the urinary tract (Taylor and Rundle, 1952) have been reported in patients treated with aureomycin or chloramphenicol. So far as we know monilia peritonitis has not hitherto been reported.

CASE REPORT

A man aged 49 was admitted to hospital with foot-drop, fever, and abdominal pain. While in hospital the fever continued, wrist-drop developed, and signs of active carditis appeared. The usual investigations of a pyrexia of unknown origin were negative, and in spite of parenteral penicillin the patient deteriorated and developed bronchopneumonia. He was thought to be suffering from polyarteritis nodosa, and, although he was known to have a duodenal ulcer, it was decided that he should be treated with 100 mg. of A.C.T.H. and 2 g. of aureomycin daily. After three days on this regimen he complained of severe abdominal pain and his abdomen became distended with fluid. He was judged unfit for surgical intervention and 60 oz. (1.7 litres) of brownish viscid fluid was aspirated from the peritoneal cavity. The A.C.T.H. was stopped, the stomach aspirated, and an intravenous drip of glucose-saline begun together with intravenous terramycin. Three days later a further paracentesis was necessary and 100 oz. (2.8 litres) of very viscous fluid was withdrawn.

Large numbers of monilia were found on direct examination of the fluid, with pus cells but no other organisms, and a pure growth of *Candida albicans* was obtained on culture. Gentian violet, 1 g., was given daily by intraperitoneal injection, but fluid continued to reaccumulate and the patient went downhill and died after a further four days. At necropsy 3 litres of fluid was found in the peritoneal cavity, the viscera were coated with fibrino-purulent material, and there was a large perforated ulcer in the first part of the duodenum.

COMMENT

The aureomycin must have altered the patient's intestinal flora until *C. albicans* was the dominant organism, and when the ulcer perforated as a complication of treatment with A.C.T.H. it was this organism which obtained access to the peritoneal cavity and set up infection. Powerful new remedies of necessity bring with them new complications, and it is important that these should be recorded, as, with the increasing use of these agents, similar cases are to be expected in the future.

We are grateful to Dr. R. L. Vollum for the bacteriological findings and to Professor L. J. Witts for permission to publish this report.

Congenital Hypertrophic Pyloric Stenosis in Twins

When a disease process of uncertain cause affects one or both of twins speculation is immediately aroused whether hereditary influences, maternal toxins, placental abnormalities, and the like may have some bearing on the causation. The present paper records the occurrence of congenital hypertrophic pyloric stenosis in both members of a pair of identical twins.

CASE REPORT

Richard and Joseph were born on September 16, 1950, in hospital. There was another child, aged 7, alive and well. The mother's age was 25; her general health was good, her diet was satisfactory, and she had had no miscarriages. There was no history of infection during pregnancy nor a family history of twinning or congenital abnormality. She was admitted to hospital two weeks before delivery because her blood pressure was raised, and she was stated to have toxæmia. Both babies were born spontaneously, both at full term. Joseph was born first, and weighed 6 lb. 11 oz. (3,033 g.); Richard weighed 6 lb. 10 oz. (3,005 g.). The placenta weighed 2 lb. 13 oz. (1,276 g.), and was uniovular.

Both twins were breast-fed, but they needed occasional complementary feeds. They took feeds quite well until October 6 (3 weeks old), when they both began to vomit. This vomiting was at first slight, but it soon became projectile in character. The feeding was changed to mainly a half-cream proprietary milk food, but after some relief the vomiting became projectile again. Breast-feeding was not completely stopped, however. The babies were constipated and always hungry. Visible peristalsis was observed in a child welfare clinic, and the babies were admitted to hospital on October 10.

On admission Joseph weighed 7 lb. 12 oz. (3,515 g.). He was well developed and showed no signs of dehydration. Visible gastric peristalsis was observed, and a typical pyloric tumour was palpated on October 11. He had been given treatment with glucose-saline and an antispasmodic. There was some relief from vomiting, but this recommenced early on October 12. Richard weighed 6 lb. 4 oz. (2,835 g.), and was a little dehydrated. As with Joseph, visible gastric peristalsis was seen and a tumour palpated. Under treatment he gained 6 oz. (170 g.). On October 12 he started to vomit again. It was therefore decided to submit both twins to operation. Joseph was operated on first. Typical pyloric tumours were found in each case, and Fredet-Ramstedt operations were performed.

Joseph had occasional vomits post-operatively, and on the third day after operation he had three large vomits. The stomach was washed out with saline and a large quantity of mucus was removed. His vomiting ceased, his bowels functioned normally, and he began to gain weight. Richard's convalescence was complicated by incessant vomiting. Stomach wash-outs relieved him only a little. Both babies were being fed with expressed breast milk with complementary feeds of half-cream dried milk. It was noted that Richard's vomits were associated with the dried-milk feeds. He was therefore fed wholly on "bank" breast milk. He then ceased to vomit and began to put on weight. Joseph was discharged on October 17 and weighed 7 lb. 10 oz. (3,460 g.). Richard weighed 6 lb. 12 oz. (3,060 g.) when he was discharged on October 23. After discharge the mother fed Richard mainly on the breast, but within a few weeks both were having breast milk and complementary feeds. They were last seen on April 19, 1951, and were then being fed on breast milk and solids. Each weighed 16 lb. 9 oz. (7,510 g.). They looked very alike, having the same features, and hair and eyes of the same colour.

COMMENT

The occurrence of the same disease in twins at the same time is always an interesting phenomenon. When the disease is one such as congenital hypertrophic pyloric stenosis this interest is heightened. Moore (1924) seems to have been the first to report pyloric stenosis affecting both

members of uniovular twins. Since then the number of reported cases has not been large. Laubscher and Smith (1947) collected 13 such reports. Wagner and Baratz (1951) and Lamy and his co-authors (1949) have since added one case each.

The suspicion that a genetic factor plays an important part in the aetiology of congenital hypertrophic pyloric stenosis is substantiated by the increasing number of reports of its occurrence in twins, siblings, and near and distant relatives. Cockayne (1934) has propounded the view that the disease has a genetic basis, but adds that "the way in which the condition is inherited is still uncertain, and an environmental factor may be necessary for its production, in addition to the genetic one." Sheldon's (1938) thoughts on the subject, that "when pyloric stenosis affects uniovular twins both twins show the condition," and "when pyloric stenosis affects binovular twins the disease is likely to occur only in one twin," are in the main true, and reports such as this and those of Ward-McQuaid and Porritt (1950) and of Cockayne and Penrose (1943) add further support to his views. There are, however, exceptions to this, as amply shown by Lasch (1925), O'Donnell and Klein (1941), Laubscher and Smith (1947), Hughes, Small, and Macky (1949), Garrison (1949), Powell and Carter (1951), and Sheldon himself. All these writers have given instances of pyloric stenosis affecting both members of binovular twins. Conversely, Sheldon, Powell and Carter, and Lasch have reported only one member of uniovular twins being affected.

In this report the type of twinning has not been so completely elucidated as were the cases reported by Ford, Brown, and McCreary (1941). The evidence available points to the twinning being uniovular. The fact that there was one placenta, the obstetrician's opinion that the placenta was uniovular, the similarity in sex, the striking likeness in features, colour of hair, eyes, and complexion, and their general progress are strong pointers to the conclusion that these babies are monozygotic twins. Thus the occurrence of congenital hypertrophic pyloric stenosis in them affords further evidence to substantiate Sheldon's assertion. However, there are so many exceptions, and the number of cases involved is so small, that the truth of the matter cannot yet be correctly assessed.

My thanks are due to Mr. W. A. Thompson for his kind permission to treat these patients and to publish this case report. The babies were admitted under his care to the Royal Liverpool Children's Hospital.

The Court of the University of Edinburgh has appointed Miss G. B. Carter, B.Sc., S.C.M., S.R.N., to the Boots Research Fellowship in Nursing tenable in the Department of Social Medicine. Miss Carter, during her tenure of the Fellowship, is to undertake (a) a review of the educational needs of the sister tutor in relation to her responsibilities; (b) an examination of the courses of instruction offered in Great Britain to the candidates for the sister tutor's certificate; and (c) an examination of the desirability and of the possibility of instituting in this country an academic degree in nursing which would be of advantage to such as hold senior positions within the nursing profession.

Reviews**SYMPATHETIC CONTROL OF BLOOD VESSELS**

Sympathetic Control of Human Blood Vessels. By Professor H. Barcroft, M.D., M.R.C.P., and H. J. C. Swan, M.B., B.S., M.R.C.P. Monographs of the Physiological Society, No. 1. (Pp. 165; illustrated. 18s.) London: Edward Arnold and Co. 1953.

This monograph is the first of a series started by the Physiological Society under the editorship of Drs. Bayliss, Feldberg, and Hodgkin, whose names guarantee a high standard of quality. It is an excellent opening number and a good omen for its successors.

There are two types of monograph, each distinctive, each useful to the reader, and each, according to its content and authorship, authoritative within its field. The first is a survey of the whole ground embraced by the title, the second is the record of a voyage indicating the problems seen, the thoughts, experiments, failures, and successes; it carries the reader in the spirit of adventure and, when well written, holds him with radar eyes even though viewing through a sea mist or a Celtic twilight. This is of the second type. Of the monograph writers in this class, among the best was the father of the senior author of this work. It is with nostalgic pleasure one is taken into the author's confidence, one sees the design of the experiment being built up, one watches colleague-collaborator achieve his answer, and, that problem disposed of, one follows through to the next step, sharing the experimenters' *joie de vivre*.

This method has the virtue of joining with the authors in their Odyssey, but it has the weakness that one only visits the islands Ulysses visited. One would have liked to know the position of the work of Paton and Zaimis and the hexamethonium drugs in this picture—especially as Fig 10.2 tantalizingly refers to this group, but in the text of the book they are not mentioned. In many respects the most useful and also the most interesting portions are the accounts of the experimental methods designed and followed in settling the relative functions of neural and humoral factors. The logical processes pursued hold the interest. The appendix on plethysmography is a useful account of the history of the subject, and the authors discuss the technique and the methods in a way invaluable for the non-physiologist or the honours student. Two clinical conditions are most illuminatingly considered—phaeochromocytoma and fainting—and well illustrate the value of the experimental method in and well illustrate the value of the experimental method in clinical problems. The illustrations are plentiful and useful though compact. So far as the reviewer knows, the answer to Professor Barcroft and Dr. Swan's question on p. 143-4 ("Where did Brodie and Russell do their experiments?") is, In Professor Barcroft's own laboratory, where Brodie was head and Russell demonstrator.

A. ST. G. HUGGETT.

VISCERAL CIRCULATION

Visceral Circulation. A Ciba Foundation Symposium. Edited for the Ciba Foundation by G. E. W. Wolstenholme, O.B.E., M.A., M.B., B.Ch., assisted by Margaret P. Cameron, M.A., A.B.L.S., and Jessie S. Freeman, M.B., B.S., D.P.H. (Pp. 278; 72 illustrations. £1 10s.) London: J. and A. Churchill. 1952.

This is the text of a symposium on the visceral circulation which was held at the Ciba Foundation in London in July, 1951. The first part is on the architecture of the visceral circulation, of which so many beautiful pictures have been produced in recent years, and where arterio-venous shunts and pre-capillary sphincters are the topics of the day. The second part is on general factors in blood-flow regulation, with particular reference to the actions of adrenaline and noradrenaline. The third part is on regional blood-flow regulation, the investigation of which requires complex and arduous techniques, and the fourth and final part is on the interaction and integration of the general and visceral circulations.

As has happened in other fields, the study of the circulation has become not less but more complicated as more data have been collected, but it is in disorders of the visceral circulation that we may have to look for an explanation of the mechanism of some unsolved diseases, more especially diseases of the skin and the alimentary tract. The symposium is well edited and contains some excellent photographs; it will be a useful work of reference, not only for those attending the conference but for the large number of other workers in this field.

L. J. WITTS.

THORACIC SURGICAL MANAGEMENT

Thoracic Surgical Management. By J. R. Belcher, M.S., F.R.C.S., and I. W. B. Grant, M.D., M.R.C.P.Ed. Foreword by Sir Clement Price Thomas, K.C.V.O., F.R.C.S. (Pp. 196; 65 figures. 16s.) London: Baillière, Tindall and Cox. 1953.

The authors of this book, both men well versed and skilled in their subject, have set out to place their knowledge and experience at the disposal of others. They have achieved their purpose with commendable directness and economy of words, realizing that real insight and understanding on the part of the resident staff is imperative in the working of any successful thoracic team. The book will be no less valuable to the team's nurses and physiotherapists.

Because of the mechanics of the chest and heart, operative success or failure depends largely on scrupulous pre- and post-operative care. In no other branch of surgery is the strict training of resident medical and nursing staffs more important. An occluded bronchus, an uncontrolled thoracic-cage deficiency, a leaking bronchus after pulmonary resection, a sudden intrathoracic haemorrhage, or the appearance of cardiac irregularity, or other serious post-operative incident, may mean death to the patient unless correctly diagnosed and remedied at once.

In relating the cost of the book to the pockets of its readers, the authors have perhaps limited its practical value by the exclusion of x-ray pictures. This could be remedied in subsequent editions. Then too, since ideas on many procedures, especially in relation to tuberculosis, are changing, an indication of relative values would have been helpful. For instance, the minor operation of phrenic crush, so lightly undertaken perhaps with the expectation of recovery of function in six to twelve months' time, may so cripple a patient with already impaired respiratory function that, in the absence of regeneration, future major surgery may be made difficult or impossible.

The book is clearly printed and well illustrated. It is full of fundamental information and will prove invaluable to a large number of men and women both at home and abroad. Mr. Belcher and Dr. Grant deserve the warmest congratulations on having analysed in a small space knowledge hitherto handed on only by word of mouth and precept. They have pointed out many pitfalls into which the unwary may stumble only too easily. This compact volume is strongly recommended to all those interested in thoracic medicine and surgery.

DONALD BARLOW.

PSYCHIATRIC RESEARCH

Prospects in Psychiatric Research: Proceedings of the Oxford Conference of the Mental Health Research Fund, March, 1952. Edited by J. M. Tanner, M.D. (Pp. 197. £1 1s.) Oxford: Blackwell Scientific Publications. 1953.

This book is one of the most stimulating psychiatric publications in recent years. The newly formed Mental Health Research Fund collected together 50 research workers and clinicians, eminent in various fields of psychiatry, sociology, neuroanatomy, biochemistry, pharmacology, and the like, to discuss ignorance hampering advances in the treatment of mental illness and the most profitable lines of future research. We now have available the full transcript of their two days' discussion at Oxford, which was at the time the subject of a leading article in this *Journal* (March 29, 1952, p. 699).

Parts of such a book are bound to be better than others, but an extremely high standard is maintained throughout.

Professor Le Gros Clark's contribution is outstanding on the possibilities of research into various regions of the brain whose function is little understood. As the cutting of a few tracts in the prefrontal lobes has resulted in the discharge of so many incurable patients from mental hospitals, other tracts in the brain must soon be explored. Dr. Eliot Slater is refreshingly outspoken on genetic research, and diagnoses some of our present troubles as "too many people who know all the answers (and) have found the key to the universe." The need for more psychological and physiological work in animals is repeatedly emphasized. This book also contains a host of other problems for those trained in all branches of medicine.

Future generations are bound to be bewildered about why, in the presence of so much mental disorder and psychopathic crime, so little is now being done to finance and organize research to combat it. The book's introduction stresses the incalculable cost in terms of human suffering. This, however, may be partly due to suspicion about the amount of supposed "trick cycling" prevalent in this specialty. Anyhow, those having such abilities might still be useful if they learn from this book how to produce more genuine rabbits out of the ridiculously small financial research hat provided at the present time.

WILLIAM SARGANT.

NUTRITION AND HEALTH

Nutrition and Health. By Sir Robert McCarrison, C.I.E., M.A., M.D., D.Sc., LL.D., F.R.C.P., with a postscript by H. M. Sinclair, M.A., D.M., B.Sc. Being the Cantor Lectures to the Royal Society of Arts in 1936, together with two earlier Essays. (Pp. 125. 12s. 6d.) London: Faber and Faber, 1953.

Sir Robert McCarrison went to India at the age of 23 and spent 30 years in working on nutritional problems. He attained the rank of major-general in the Indian Medical Service, and founded the well-known Nutrition Research Laboratories at Coonoor. In 1936, some years after retiring from his duties in India, he gave a series of Cantor lectures on the influence of diet upon health before the Royal Society of Arts. From his vast experience in both clinical and laboratory work he concluded that perfectly constituted food is the greatest single factor in the acquisition and maintenance of good health. In support of this view he correlated the fine physique of the northern Indian races—Sikhs, Pathans, Mahrattas, and Hunza and Nepalese hillmen—with their good diet based on wheat, milk, and vegetables. In contrast the more southern Indian races, including the Bengali and Madrassi, who subsist mainly on rice, were greatly inferior both in their physique and in their resistance to disease.

Proof that diet was the deciding factor was obtained by feeding seven groups of rats on the foods of selected races. The animals given the diet eaten by Sikhs became large and healthy, and those given the other diets were graded in their growth and resistance to disease in the same order as had been found in their human counterparts. Thus the rats given the Madrassi diet came at the bottom of the list, with a growth rate of only about one-third that observed in the rats given the Sikh diet. From these investigations McCarrison concluded that in India faulty diet not only increases the liability to infections, such as tuberculosis, but also gives rise to minor manifestations of ill-health which cannot be given a diagnostic label. These less obvious manifestations of deficiency disease, in his opinion, may have vastly greater practical importance than more obvious but less common diseases such as scurvy, beriberi, and rickets.

The present book, which is well produced and illustrated, will serve a useful purpose in bringing home to the rising generation the lessons taught in the Cantor lectures. During the last 20 years, as Dr. Sinclair emphasizes, our knowledge of the science of nutrition has greatly expanded. We have even learnt some hard lessons in its practical application: during the relief of starving Holland expensive protein hydrolysates were eaten willingly only by

lunatics. It still remains difficult, however, to disentangle the effects of nutrition from those of other factors which affect public health. When we attempt to decide how far imperfect food is responsible for ill-health in Britain and other European countries, the pioneer work of McCarrison at least indicates that all is not necessarily well because frank signs of deficiency are not immediately evident.

T. MOORE.

CARDIOVASCULAR DISEASES

Lehrbuch der Krankheiten des Herzens und der Blutstrombahn. By Professor Fritz Lange. (Pp. 631; 192 figures. M. 71.) Stuttgart: Ferdinand Enke, 1953.

It is interesting to see a textbook of the diseases of the heart and circulatory system by Professor Lange, for it is based on Romberg's book, the third edition of which the reviewer studied over thirty years ago. The present volume is probably a good indication of thought and practice in this subject in Germany to-day. One finds remarkable differences from the ideas fashionable in Britain. In the general section the part on the metabolism of the heart is very well done indeed and most interesting. It follows a good section on the dynamics of the heart. In the section on physical examination it is curious to learn that a percussion hammer and pleximeter are still used: this must surely shock some for whom the art of percussing the heart at all is almost extinct. It is curious to associate the anacrotic pulse with hypertension. Pulses, by the way, are given Latin names, but sometimes the Latin is wrong. Gallop rhythm, however, is hardly mentioned. In the chapter on infective endocarditis there are some very complicated diagrams which do not illuminate the subject. It is interesting to gather that there seems to have been a considerable increase in the incidence of this disease in Germany much in the same way as it increased in Britain in 1918. In the chapter on congenital heart disease the operation advised by Brock in this country is not mentioned.

In discussing infarction the author claims that one can distinguish the anterior infarct from the posterior by the type of symptoms produced, noting that a posterior infarct produces pain referred to the abdomen, whereas anterior ones are likely to cause acute oedema of the lungs or sudden death. In treatment one is surprised to see that leeches receive more space than venesection and that the vogue for bathing, once so popular in Germany, is still maintained. One wonders whether one should really consider "diuretin" before the mercurial diuretics in these times: these are recommended for administration either intramuscularly or intravenously, but no preference is suggested. There is a considerable section on disease of the arteries and of the veins, so that anatomically, at any rate, the whole of the circulation is fully discussed.

Some of the illustrations seem to be familiar, coming from a source in this and another country which is not acknowledged. The print is good and the variety of type helpful. The x-ray photographs are clear and the cardiograms satisfactory. Emphasis is laid on the effort-cardiogram in diagnosing angina pectoris.

In general this book seems somewhat old-fashioned and hardly emphasizes what in Britain would be considered important. It is, however, interesting to read the opinions of those with a different point of view.

TERENCE EAST.

Garrod, Batten, and Thursfield's *Diseases of Children*, the fifth edition of which is edited by Professor Alan Moncrieff and Dr. Philip Evans, includes a number of new sections on the causes of congenital malformation, endocrine disorders, the alimentary tract, congenital heart disease, and other subjects. The text has also been extensively revised. The illustrations have been as thoroughly revised as the text, and there are many new ones. The two volumes are paginated continuously, with an index at the end. They are published by Edward Arnold and Co. for £7. The 19th edition of B. N. Ghosh's *Pharmacology, Materia Medica and Therapeutics*, which incorporates new material, is published by Hilton and Co., Calcutta, for 30s. (London agents, H. K. Lewis and Co.).

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY APRIL 25 1953

THE REPRESENTATIVE BODY

A series of articles on the constitution of the B.M.A. is brought to a close in this week's *Supplement* with an article by Dr. Alfred Cox on "The Jubilee of the Representative Meeting," the first of which was held in Swansea on July 28, 1903. Dr. Cox is the only surviving member of the Constitution Committee of 1900, and we are much indebted to one to whom the Association is so much indebted for this lively and interesting account, written with undiminished mental vigour at the age of 87 years. At the beginning of this century, Dr. Cox tells us, there was despair, resentment, and "even desperation," because of the abuses of contract medical practice and of the inertia of the ruling body of the B.M.A.—the Council. The reason for the inactivity of the Association was "that it was unable to do anything effective because under its constitution it had no means of voicing either the opinion of the profession as a whole or even of its own members, and no machinery by which it could have organized effective resistance." The stimulus to reform came in the shape of a letter to the *Journal* of September 16, 1899, in which Dr. Samuel Crawshaw, on behalf of the Manchester Medical Guild, announced the holding of a conference of "delegates from all associations of general practitioners in England and Wales."

The dominating force at this conference was Mr. (later Sir) Victor Horsley. Dr. (later Sir James) Smith Whitaker was its principal draughtsman and subsequently the first Medical Secretary of the Association. The third force was Dr. Alfred Cox, of Gateshead, who years later succeeded Smith Whitaker as the B.M.A.'s Medical Secretary. It was Dr. Cox's proposals that the conference embodied in the following epoch-making resolutions¹:

"(1) That the present need in medical organization is concentration;

"(2) That the multiplication of associations other than those purely local is to be deprecated;

"(3) That the size, position, and wealth of the British Medical Association make it the most suitable national medical organization; and

¹ *History of the British Medical Association, 1832-1932.* Compiled by Ernest Muirhead Little, F.R.C.S. Published by the British Medical Association, 1932.

"(4) That the efforts of all medico-ethical and similar associations and of the conference should be directed to the conversion of the British Medical Association into an energetic body really representative of the majority of the members of the profession."

Victor Horsley led the deputation from this conference which met the Council of the B.M.A. in Ipswich in the same year, the outcome being the Council's appointment of a Constitution Committee, whose crowning triumph was the first Representative Meeting in Swansea in July, 1903. Dr. Cox believes that, besides himself, there are only two or three other surviving members of this meeting. As the B.M.A. is meeting at Cardiff this year it is apposite to recall that Mr. (now Sir) Ewen Maclean was Chairman of the Representative Body during the struggle over the National Health Insurance Act in 1911, and was elected President of the Association in 1928. To these and many other notable figures in our history the Association owes a debt of deep gratitude, but in this Jubilee Year of constitution-making we hail in particular the work of Dr. Alfred Cox, Sir Victor Horsley, and Sir James Smith Whitaker.

A jubilee year is a time for commemoration and also for taking stock. Much has happened since 1903. There have been two medical revolutions—in 1911 with the passing of the National Health Insurance Act and in 1946 with the passing of the N.H.S. Act. With the first there appeared the first autonomous body within the B.M.A.—the Insurance Acts Committee and its associated Panel Conference. Since 1946 the autonomy of the I.A.C. has become vested in the General Medical Services Committee and its associated Conference of Local Medical Committees. The consultants followed suit in obtaining autonomy for the Central Consultants and Specialists Committee of the Association. Restlessness about the autonomous position of these two important bodies has found expression in a resolution of the Representative Body that their autonomous powers should be renewed each year. And anxiety about this position has been voiced in articles and correspondence on the constitution of the B.M.A. in recent issues of the *Supplement*. In his letter of March 21 Dr. Cox says, "The idea of autonomy inside a parliament is unusual and seems to me potentially dangerous." Dr. F. B. Winfield (*Supplement*, April 18, p. 139) believes that the power and efficiency of the Representative Body have been impaired by the autonomous bodies. Dr. Metcalfe Brown (*Supplement*, March 28, p. 81) considers that the dangers of autonomy are less than might appear, that "autonomy is incompatible with

true unity," but that it should disappear gradually and by agreement and not by any revolutionary measure. What is fundamental is that the power of the two autonomous bodies should not lead to sectionalism within the profession, with a consequent conflict of interests. What is needed is integration of interests and efforts, and so unity in a profession whose real aims and objects should be, and indeed are, one. It was, no doubt, with this in mind that the Winchester Division in its important memorandum on the Representative Body (*Supplement*, February 28) advocates election to it of four members of the Central Consultants and Specialists Committee, four of the General Medical Services Committee, and four of the Public Health Committee. The R.B. is the Parliament of the profession and the policy-making body of the Association. Its powers in this respect must be maintained and not weakened, and there can be little doubt that in general the R.B. feels that its position in the constitution of the B.M.A. is not what it was.

The other big change in the B.M.A. since 1903 is its great increase in membership, an increase which has paralleled the increase in registration of doctors, and now more closely approximating to it. In 1903 there were about 36,000 doctors on the *Medical Register*, and membership of the B.M.A. was 18,000. At the beginning of 1952 the number of persons on the *Register* was 82,256 (including 2,036 foreign doctors); membership of the Association was just over 66,000. In an article commenting on the Winchester Memorandum (*Supplement*, March 7) figures were given showing the corresponding increase in the size of the R.B. The numbers appointed by the home constituencies were 210 in 1920, 278 in 1938, 360 in 1947, 425 in 1951: the possible number for this year is 448. If to this are added the overseas members (31), the public health members (4), Council members, the secretariat, and the Press the Winchester Division estimates that a hall is needed large enough to allow for 600 people to "move about comfortably." Such a great increase in size must affect the quality of the work done in the four days allotted to the R.B. at the Annual Meeting. Complaints about this have been made at the meeting itself and in the *Journal*. The matter has been debated in Council and in the R.B., and at Dublin last year the R.B. accepted the Council's recommendation that its numbers should not be reduced. In general it was felt that the educational value to those present outweighed disadvantages. But the Winchester proposals for a reduction in the size of the R.B. to 329 members is strongly supported by one of its founders, Dr. Cox,

in a letter to the *Supplement* of March 21. "At present," he writes, "it seems more like a public meeting than a legislative body." It must be difficult for a Representative Body of its present size to have any feeling of unity and concentration of purpose. It might, too, be argued that the place for education in the work of the Association is at the periphery, in the meetings of the Branches and Divisions that go on throughout the year.

Increase in numbers must lead to diffuseness of debate and to what the Winchester memorandum calls "a lack of balance in the conduct of business." The memorandum also makes a criticism which is of great importance—namely, "The Representative Body is not *truly representative of the profession* in that the majority of its members are general practitioners, so that the view expressed by the Representative Body on any subject tends to be the general practitioners' view, and is *unfortunately so regarded by other sections of the profession*. Consequently the decisions of the Representative Body are not always implemented by the Standing Committees of the Association." As the Chairman of the Winchester Division, Dr. R. Gibson, is a general practitioner and the first signatory of the memorandum this criticism has added force. The memorandum calls for reduction in membership of the R.B., a balanced representation of all sections of the profession, and a system which allows for adequate time for discussion of matters of first importance. The profession is now faced with medico-political problems of quite a different order from those which faced it 50 years ago, problems which affect all sections and not predominantly general practitioners. In dealing with these many and complex matters it needs now, more than ever, unity of purpose, integration of effort, the avoidance of sectionalism, and a concentration on objectives that would appear to many to be difficult to obtain in a body the present size of the R.B. The Winchester Division has done well to keep the debate open. Perhaps the outcome of this might be the formation of still another Constitution Committee.

ENDOCRINES IN TREATMENT OF CANCER

Recent experimental and clinical work suggests that endocrine therapy will eventually play an important part in the treatment of certain types of malignant growth. Thus neoplasms induced by hormonal stimulation may in the future be prevented or held in check by medical or surgical modification of the host's endocrine system.¹ Dr. Charles Huggins and his

colleagues in Chicago, working initially on experimental animals and later clinically, have confirmed the importance of endocrine therapy for certain types of cancer of the breast and prostate gland. Huggins's approach to this problem has been scientific rather than empirical, and has arisen from experiments on hormone-dependent tumours in animals. According to these experiments not all endocrine secretions, or substances with similar action to that of the recognized hormones, possess carcinogenic properties. The oestrogens and gonadotrophins are the only ones at present known to have them, and Huggins states that "when an oestrogen is a carcinogen its neoplasm-inducing properties are eliminated by testosterone; when a gonadotrophin is a carcinogen tumours are eliminated by gonadal steroids." Suppression or elimination of steroid hormones from the testes, ovary, or adrenal cortex causes regression of both mammary and prostatic growths, provided they are hormone-dependent neoplasms.

For more than a generation the ovaries have been regarded as an important factor in the causation of mammary cancer. Yet only rarely has complete regression of mammary growth been attained by ovariectomy in the human subject. An apparently successful case has recently been reported by Raven.² According to Huggins, the reason why ovariectomy influences occasional cases of human mammary cancer is that these particular neoplasms are independent of adrenal cortical function, whereas most mammary tumours are dependent for sustained growth upon adrenal steroids. This has been shown experimentally by Shimkin and Wyman,³ who found that adrenalectomy reduced the incidence of mammary cancer in mice. Other experimental data⁴ also support the contention that the adrenal cortex plays some part in the genesis of certain mammary tumours in animals. Such evidence, together with Huggins's own work, led him to believe that certain hormone-dependent growths of the mammary and prostate glands would regress when the adrenal factor had been eliminated by surgical removal.

Bilateral adrenalectomy in man was first successfully performed by Huggins and Scott in 1945. The initial results on patients suffering from cancer were not entirely successful, because at that time the post-operative hormonal maintenance of the patients was unsatisfactory owing to inadequate supplies of 11-

oxygenated steroids. But some regression of prostatic growths was observed. Now that cortisone is available, bilateral adrenalectomy should no longer be regarded, according to Huggins, as a risky procedure. Total adrenalectomy for patients suffering from reactivated prostatic carcinoma, followed by the appropriate post-operative therapy, has also been recently advocated by Harrison, Thorn, and Jenkins,⁵ who confirm the results previously obtained by Huggins.

In collaboration with Ling-Yuan Dao, Huggins⁶ has recently reported that adrenalectomy also causes remission in both male and female human breast cancer. Bilateral adrenalectomy, performed at one operation on 42 patients suffering from either breast or prostatic cancer, has resulted in only two deaths, the last group of consecutive cases all surviving. One post-operative death occurred among eight patients with advanced mammary cancer. Four of the survivors showed very satisfactory remission of the disease, while in the remaining three the response was considered to be poor. The four patients in good condition seven to eleven months after adrenalectomy were considered by Huggins to have suffered from "adrenal-dependent mammary cancers." He lays great stress on the form of anaesthesia and on the post-operative hormonal maintenance with cortisone acetate, the details of which have been published separately in collaboration with Bergenstal.⁷ Local or spinal analgesia is inadequate and details are given of the surgical technique for one-stage adrenalectomy under nitrous-oxide-oxygen-ether anaesthesia after sodium pentothal induction. The posterolateral approach is preferred through an incision 20–25 cm. long made directly over the twelfth rib, which is resected. It is claimed that the operation can be completed in 60–90 minutes even with little experience.

Certain breast cancers in women may be ovary-dependent rather than adrenal-dependent. For these Huggins advises ovariectomy before, or simultaneously with, adrenalectomy. He recommends a two-stage operation in which the right adrenal and ovary are removed on one occasion, followed in about two weeks by removal of the left adrenal and ovary.

The difficulty still remains that it is impossible to determine before operation whether a mammary neoplasm is adrenal-dependent. Dependence seems to be a physiological phenomenon not necessarily accompanied by any distinctive morphological characters. The most favourable prognostic sign of the adrenal-dependent mammary tumour, in Huggins's

view, is the presence of enlarged adrenal glands with hypertrophy of the zona glomerulosa. Experience has also shown that well-differentiated mammary tumours give the best response to adrenalectomy.

In a more recent and detailed review of this problem Huggins¹ admits that many questions relating to the treatment of appropriate neoplasms by adrenalectomy remain unsolved. He does not attempt to predict what percentage of patients with advanced mammary or prostatic cancer will respond or what the duration of remission will be. There seems to be little danger of adrenalectomized patients developing the Addisonian syndrome provided they are given the correct substitution therapy. In fact most of them seem to be maintained in excellent health, and many after a short time in hospital can resume their ordinary occupations.

GOLD UNDER SCRUTINY

It is only in recent years that the technique of the therapeutic trial has come to be studied with some degree of precision. New drugs are now born into a more rigorous climate than that which greeted their parents and grandparents, and their survival has been made far more difficult. They must undergo strict examination to decide whether they should reach maturity or oblivion. It may be salutary to speculate from time to time on the fate which would overtake some drugs now in regular use if they were to appear for the first time to-day unhallowed by tradition. But it is not necessary to assume that, because a treatment is empirical, therefore it would automatically be discarded under these circumstances. If a paper were to be published in this issue announcing the discovery of the potent effects of colchicine in acute gout, there is little doubt but that adequate evidence could be brought forward in support; yet no account of its mode of action could be given in our present state of knowledge.

In this issue we publish an investigation by Dr. Peebles Brown and Dr. J. P. Currie into the effects of gold therapy in rheumatoid arthritis. They failed to find any evidence that gold, when administered in the accepted manner, had any beneficial effect in 38 cases of rheumatoid arthritis. The cases were assessed after 3 months and at one year. Forestier¹ originally used gold salts in this disease because of claims that they were beneficial in tuberculosis and with the idea that rheumatoid arthritis might be a similar chronic infective condition. Despite the lack of evidence in favour of his original premises, gold has continued, almost alone, to hold its place in the treatment of this condition for nearly 25 years. Yet Short, Beckman, and Bauer² as recently as 1946 wrote, "The burden of proof is still on the proponents of gold therapy to demonstrate that a

significant effect is exerted on the course of rheumatoid arthritis."

Peebles Brown and Currie do not claim that their failure to demonstrate any beneficial effect thereby establishes the fact that gold is of no value, and they draw attention to the fact that there is a good deal of contrary evidence already published—evidence which is not, however, entirely satisfactory. Moreover, most (though not all) clinicians of wide experience in the treatment of rheumatoid arthritis still believe that gold therapy is beneficial, and this cannot be ignored. What is certainly important is that this paper provides a sharp reminder that gold, in common with all other drugs, affords no short cut to the treatment of rheumatoid arthritis and that it is no substitute for the proper management of these patients. Treatment must include, in particular, the prevention of deformity and the maintenance of muscle power and joint range. Gold therapy must not divert our attention from these fundamental principles. Whatever the final outcome of this problem, the role of gold therapy in rheumatoid arthritis can be no more than a subsidiary one at present.

LIFE AND HEALTH OF DOCTORS

What became of them all, our student contemporaries at school and hospital, after they qualified and went out into the world? Did the wild boys settle down, the clever ones become professors, the literary ones forsake medicine? Did all the predicted futures come true? For ancient friendship or for curiosity, for the chance to see which of our prognoses were right, the biographies of all those now lost to sight would be interesting; and, taken as a group for planned study, they have a sociological value and can guide administration, for they represent a kind of follow-up to show whether a medical school's initial selection of students had the right results and whether its training has fitted doctors for all branches of medicine. In a different direction they show the nurse's chances of marrying a doctor, and the doctor's chance of practising on his native heath—and whether these chances are changing. They can reflect the evolving customs and structure of our whole society and the professional man's shifting place in it.

Dr. A. Meiklejohn and his colleagues at Glasgow took the opportunity of the University's quincentenary celebrations there in 1951 to ask all their Glaswegian fellow students of 1923–6 twenty-five searching questions on their life and opinions. The results are published on p. 930, and represent replies from almost half of the 800 still alive, and information about the 99 who were dead. If it be assumed that the replies are representative for the whole 800, they throw light on two subjects—the doctor's health and the Scots doctors' contribution to medical practice. Three-fifths of the doctors were in general practice and another fifth had become consultants. In the years 1923–6 two out of every five new doctors put on the *Medical Register* were Scots.

³ Hood, W. D., *Hlth Bull. (Edinb.)*, 1953, **11**, 19.

Scotland has long been known as a country producing doctors for export, and in 1926, with a population of about 4.8 million—representing only one-ninth of all the people in Britain—she was contributing nearly half the doctors. Nor has this position greatly changed. A recent analysis¹ shows that at present she produces about 550 new doctors annually, over half of whom must cross the border to find employment. In proportion to population this is a production three times that of England and Wales. Why this should be so requires further fact-finding, though the tradition maintained by the large and highly esteemed Scottish medical schools since the eighteenth century may provide a partial explanation.

Dr. Meiklejohn's paper has some interesting sidelights on the health of his group. Half the doctors who replied said they had never been seriously ill since they graduated. Among the 99 deaths were the expected excess due to coronary thrombosis, and also a surprisingly large number of drownings and poisonings, which seems to point to a suicide rate above that of the general population. Again it is surprising that one-quarter of all graduates were still unmarried ten years after qualification, though it must be remembered that, partly because of the 1931 economic slump, it was the custom to marry later than it is to-day. After twenty-five years 90% of the graduates had married. It would be interesting if other medical schools made similar investigations among their old students, for in this way there could gradually be built up a real picture, both sociological and psychological, of the doctor as a man and as a member of the community.

INTRINSIC FACTOR IN THE TREATMENT OF PERNICIOUS ANAEMIA

Despite the fact that the blood counts of patients suffering from pernicious anaemia can be restored to normal by the parenteral administration of vitamin B₁₂, the precise pathogenesis of the disease is still not entirely clear. It is generally believed that the fundamental defect is simply a failure of the upper alimentary tract to absorb vitamin B₁₂ (extrinsic factor), and that this is due to lack of a substance (intrinsic factor) which is normally present in gastric juice.¹ Some progress in the identification of intrinsic factor has been made in recent years. Evidence put forward by Glass^{2,3} in the U.S.A. and by Latner and Ungley⁴ in this country shows that a gastric mucoprotein or mucopolysaccharide has great intrinsic-factor activity, but whether the mucoprotein is intrinsic factor itself or is merely a carrier of it has not yet been established.⁵ Gastric juice from normal subjects or gastric extracts containing intrinsic factor unquestionably facilitate in some way the absorption of small amounts of B₁₂ when given by mouth.

Exactly how intrinsic factor brings about this absorption remains to be discovered. It is a conceivable but unproved hypothesis that combination with intrinsic factor may assist the passage of B₁₂ through the cell

membranes of the intestinal epithelium.⁶ A quite different explanation was indicated by the work of Ternberg and Eakin,⁷ who showed that certain bacteria which required B₁₂ for growth failed to grow if gastric preparations were added to the medium—a possible reason for this being that the B₁₂ was "bound" and in some way made unavailable to the bacteria. It was therefore suggested that in a healthy man the binding of vitamin B₁₂ by some component of gastric juice might prevent the utilization or destruction of B₁₂ by bacteria within the upper intestine. But it was later shown that bacteria which could not grow in the absence of the vitamin constituted only a very small part of the intestinal flora, and also that proteins other than intrinsic-factor-containing material had the property of making B₁₂ unavailable.

On the other hand, it is now known that certain bacteria, including some strains of *Bact. coli*, take up large amounts of B₁₂, although not actually requiring it for growth.⁸ The presence of bacteria in the upper intestine in patients with pernicious anaemia may therefore still be of importance. Moreover, it has been claimed^{9,10} that the very large uptake of B₁₂ by *Bact. coli* could be prevented by giving small amounts of gastric preparations, and that this did not happen with other protein and organ extracts.¹¹ Hoff-Jørgensen, Skouby, and Andresen¹² concluded that the "coli factor" and intrinsic factor were probably identical. Following up this idea, they have carried out some preliminary clinical trials with gastric extracts previously assayed for their ability to inhibit the adsorption of B₁₂ by *Bact. coli*.

This work is clearly of importance, since a convenient method of assaying intrinsic factor is badly needed, not only as an aid to the purification of intrinsic factor itself but also as an essential step in the preparation of gastric preparations intended to be used therapeutically in pernicious anaemia. Whether or not oral treatment with gastric extracts combined with vitamin B₁₂ can compete in effectiveness with parenteral treatment with the vitamin alone would seem to depend upon the reliability of the preparations intended for oral administration, the regularity with which patients absorb and respond to oral preparations, and their cheapness. It is hoped that oral preparations will not be used in the routine treatment of pernicious anaemia until they have been thoroughly tested under carefully controlled conditions. In any case it would be regrettable if their use led to a lessening of the personal supervision of the patient that the use of parenteral preparations at present entails.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

INJURIES TO THE BACK—II

BY

E. A. NICOLL, C.B.E., M.D., F.R.C.S.Ed.

Surgical Director of Orthopaedic and Accident Services, Chesterfield Royal Hospital and Mansfield General Hospital; Surgeon, Harlow Wood Orthopaedic Hospital

Simple compression fractures are produced by hyperflexion of the spine, which may be caused by direct violence such as a weight falling on the back or by indirect violence such as falling on the feet from a height. The former is by far the more common, and two-thirds of the resulting fractures are in the dorso-lumbar region. They are often called "wedge fractures," because they produce a characteristic wedge-shaped deformity of the vertebral body. The deformity is never great, however, and in many cases cannot be recognized clinically. If the vertebral body is crushed by more than one-third of its height anteriorly, the ligaments posterior to the fulcrum (see Part I of this article, printed in our last issue) are almost certainly ruptured. Subluxation then occurs with separation of the spinous processes and the condition is no longer a simple compression fracture but a fracture-dislocation. The differentiation is very important, because, whereas a simple compression fracture is stable and relatively innocuous, a fracture-dislocation is extremely dangerous and associated with a high incidence of damage to the spinal cord or nerve roots.

Management of Simple Compression Fractures

It used to be taught that all compression fractures, however slight the deformity, should be corrected by hyperextending the spine and immobilizing it in plaster-of-Paris for three to four months. There are still many adherents of this view, but it is becoming increasingly accepted that most of these fractures can be treated as soft-tissue injuries with much less trouble to the patient, a quicker return to work, and a better functional result. This view is based on the fact that if the fracture is stable—that is, if the fulcrum and the ligaments posterior to it have remained intact—the deformity is necessarily slight and will not increase even if the spine is not immobilized. The fracture is a crushing of the cancellous bone and will therefore heal readily and rapidly even without fixation.

It has also been established that in a series of functionally perfect results there is the same proportion of patients with residual deformity as in a series of poor results. Deformity in itself is therefore not the crucial factor, nor can it be prevented in certain cases, even if the fracture is reduced and immobilized for a prolonged period. In many of these cases the intervertebral disk has been irretrievably damaged, and, since it is a structure devoid of blood supply, it is incapable of repair and will inevitably collapse once the supporting plaster is removed. It is such considerations as these that have led to a modification of our views about the treatment of simple compression fractures, though it cannot be stressed too strongly that the decision rests on an appreciation of the stability of the fracture and its differentiation from fracture-dislocation or fracture-subluxation. This calls for considerable experience in the interpretation of x-ray films and the films must be of very high quality.

Fig. 1 illustrates a stable compression fracture which was treated on these lines. The patient was kept at rest in bed for three weeks. He was then transferred to a rehabilitation centre, where he proceeded through the normal course of progressive remedial exercises for spine cases. Treatment was completed in eight weeks and he returned to light work.

In three months he was back at his ordinary work as a miner and x-ray films at that time showed that the fracture had consolidated without any increase in the amount of wedging. In other words, he was back at full work at a time when under the older method of treatment he would still have been in plaster.

However, the above regime may seem to be such a departure from orthodoxy that it is permissible to digress for a moment and consider the basic principles underlying the use of plaster or other immobilizing agents in the treatment of fractures, lest it become a ritual rather than a scientific procedure. There are only two reasons for immobilizing a fracture: one is to place it at complete rest in order to promote union, the other is to maintain reduction until union has occurred. There are many fractures, however, that will unite whether immobilized or not (fractures of the ribs, for example, which cannot be immobilized). There are other fractures—for example, of the clavicle—in which deformity within certain limits does not affect function. Simple compression fractures of the spine fall into both categories, so there is no scientific basis for reduction and prolonged immobilization. If plaster is used in such fractures it should be recognized for what it is—namely, a method of resting damaged soft tissues during the initial stages of healing—and as such it may be entirely justified. While I subscribe to these views, however, it must be stressed that there are still many authorities who adhere to the methods advocated by Böhler and Watson-Jones that all compression fractures of the spine should be immobilized in hyperextension for three to four months.

Fractures of the Laminae

These injuries are comparatively rare, but their importance lies in the fact that they are difficult to detect, yet because of their instability they may result in the condition known as spondylolisthesis. The lesion occurs in the lowest part of the lumbar spine and is caused by a combination of flexion and rotation. It is often associated with fractures of the transverse processes. The laminae fracture near their junction with the pedicles and this allows the upper vertebra to slide forwards on the lower one, particularly at the lumbo-sacral junction, where the force of gravity alone will produce progressive displacement if the fracture is undetected and the patient is allowed to walk about. High-

FIG. 1.—Radiograph of simple compression fracture.

quality x-ray pictures, including lateral and oblique views, are needed to reveal these fractures. If they are detected before forward displacement has occurred they should be immobilized in a full plaster-jacket, including both thighs so as to fix the lumbo-sacral junction. Once displacement has occurred, reduction by manipulative methods is impossible and fusion of the affected spinal segment should be carried out to prevent further displacement.

Spondylolisthesis also occurs as the result of a congenital defect in the laminae. It is a gradual process which often does not produce symptoms until adult life. These symptoms may be precipitated by an injury to the lower part of the spine, so that the congenital variety may be revealed for the first time following trauma. There is no doubt, however, that traumatic spondylolisthesis resulting from actual fracture of the laminae is a real entity. The spinal cord is not endangered to the same extent as in fracture-dislocations, because the neural arch posterior to the fracture or congenital defect is not displaced forwards. The nerve roots can, however, be involved in this displacement, causing a radiating type of pain. The roots affected are usually the fifth lumbar or first sacral, so that spondylolisthesis is one of the conditions apt to be confused with a prolapsed intervertebral disk.

Fracture-dislocations

Fracture-dislocations are the result of direct violence causing hyperflexion, and they are the most dangerous of all spinal injuries because of their tendency to cause damage to the spinal cord or cauda equina. The supraspinous, interspinous, and capsular ligaments, which stabilize the spine in flexion, are all ruptured, allowing the spinous processes to separate and the posterior intervertebral joints to dislocate. The flexion force causes a forward displacement of the upper vertebra and a compression fracture of the lower one (Fig. 2). At least 50% of these fracture-dislocations are associated with damage to the spinal cord or cauda equina, causing varying degrees of paraplegia or quadriplegia according to the level of the injury. They are among the most difficult of all first-aid problems, particularly as most of them occur in mining accidents and the patient may have to be extricated from a very confined space. Any movement of the patient which increases the

flexion deformity may damage the cord irretrievably, therefore the handling and transport of these men is of the utmost importance. The angular deformity can always be felt, as can the large gap between the spinous processes.

Some years ago it was advocated that all back injuries should be transported in the prone position to avoid any possible flexion of the spine, and this is no doubt the safest procedure if it is practicable. There are often circumstances, however,

FIG. 2.—Radiograph of fracture dislocation.

which make it impracticable, and then the main concern of the first-aid worker should be to ensure that at all times the spine is supported and not allowed to flex. The same precautions must be observed during the reception of the case into hospital and during the x-ray examination.

Some fracture-dislocations can be reduced by manipulative means, but in others the dislocated facets become locked and reduction cannot be achieved except by operation. Locked facets can usually be demonstrated on x-ray examination, although once again it must be stressed that high quality x-ray films are needed to disclose these details.

All fracture-dislocations are highly unstable and a great danger to the spinal cord. They should always be reduced at the earliest possible moment either by manipulative or by operative methods, depending on whether the facets are locked or not. If manipulative reduction is possible and there is no paraplegia, fixation in plaster should be carried out for four months with frequent x-ray checks to ensure that reduction is maintained. If operative reduction has to be carried out, it is usual to supplement it by applying a bone graft to the spinous processes as an additional safeguard against late redisplacement. In either case a period of four months' fixation in plaster is necessary, but during most of this time the patient may be ambulant. On removing the plaster, progressive remedial exercises are carried out, together with other forms of rehabilitation such as recreational and occupational therapy. It may be eight months before the patient is fit to resume work, but if sound union is obtained and the injured segments of the spine are securely stabilized there is no reason why these cases should not eventually achieve the same degree of fitness as those with simple compression fractures.

Traumatic Paraplegia

The system of treatment outlined above for fracture-dislocations of the spine does not apply to cases complicated by paraplegia. In these the use of plaster inevitably leads to pressure sores and thence to a vicious circle of complications ending in renal failure. The treatment of traumatic paraplegia would demand an article in itself, so the present review must necessarily be confined to a brief survey in very general terms.

Paraplegia following spinal injuries was first described about 5,000 years ago in the Edwin Smith Papyrus, and the author of that remarkable document summed up treatment in the words "an ailment not to be treated." His view, no doubt, was that the physician should not try to prolong a state of misery which he was powerless to alleviate, and any doctor who has worked long enough in a mining community to become familiar with the distressing spectacle presented by these unfortunate patients might well be forgiven for agreeing with him. Unable to move, incontinent of urine and faeces, with large stinking pressure sores getting larger as the patient becomes more emaciated, painful involuntary spasms, contractures, urinary sepsis, renal calculi, and finally uraemia—this is the distressing sequence of events that is often dragged out for four or even five years.

The change that has been brought about in the past 10 years is almost unbelievable, and the story of its accomplishment is one of the most remarkable "combined operations" of surgery and social medicine. It demands a degree of special knowledge, skill, nursing attention, and social welfare that can be achieved only in special units, but that it can be done has been proved beyond all doubt by the work of such centres as Stoke Mandeville and Wharncliffe in this country and by many others in America. There can surely be no middle course with a condition capable of causing such prolonged misery and suffering: it must be treated either superbly well or not at all. The worst thing that can happen to these unfortunate patients—and there is no doubt it is still happening—is that they should be treated well enough to prevent them from dying but not well enough to make life worth living.

Next Refresher Course Article.—"Anticoagulant Therapy," by Dr. H. Payling Wright.

TWENTY-FIVE YEARS IN MEDICINE

A RETROSPECT

BY

A. MEIKLEJOHN, M.D., F.R.F.P.S., M.R.C.P.

Senior Lecturer in Industrial Health, University of Glasgow

"Dear Fellow-Student,—Nearly 25 years or more have passed since we graduated in the years 1923, 1924, 1925, and 1926. In the intervening period we have become dispersed all over the globe and into every branch of the profession. Some, no doubt, have been more fortunate than others; not a few have died long ere their prime. The experience of the goodly company must form a most interesting and not insignificant chapter in medical annals."

These were the opening lines of a letter which a group of doctors* addressed in 1950 to their companions of undergraduate days.

Origin of the Inquiry

In June, 1951, the University of Glasgow was due to celebrate the quinqucentenary of its foundation. Many graduates, it was anticipated, would make the pilgrimage to join in the ceremonies and to pay tribute to their Alma Mater. A small group of medical graduates foresaw in this occasion a unique opportunity for a reunion with their fellow students, in which it might be possible to discover something of the collective story of the years between.

The men involved were the graduates in medicine in the four years 1923–6, which means that by 1951 each had achieved at least 25 years of practice. In the course of their lifetime they had endured two world wars and the economic slump of the early 'thirties; they had lived in a golden age of advance in medicine and had been involved in the inception of the National Health Service on July 5, 1948. As undergraduates they had studied under such renowned teachers as Macewen, Muir, Cathcart, and Carl Browning, and from these teachers they had shared in the continuing glory and inspiration of Lister, Hector Cameron, and Gairdner. As medical men, over a quarter of a century as rich and varied as any in the medical and social history of Great Britain, they had experience of three generations of practice and teaching, as exemplified by their teachers, their contemporaries, and their assistants, who in some instances were their own sons and daughters.

Method of Inquiry

The only means of contacting each individual was by a questionnaire distributed by post. All the names were available in the graduation lists. Information enabling us to trace those still alive was available in the current *Medical Register*. In the case of those deceased the Registrar of the University was able to provide certain particulars.

The committee was fully aware of the defects of this type of survey, and that the response might not exceed 30%. The purpose of the inquiry was explained in a covering letter, of which the opening lines have been quoted, and it is worthy of record that not only did 48% complete the form but many expressed their gratitude for this link with the past. There were 25 questions, occupying four foolscap pages, and these required much time and thought. The questions were divisible into two main groups: (a) facts and (b) opinions. The nature of these appears from what follows.

Population at Issue

The graduates numbered 899, and at June 30, 1951—a minimum interval of 25 years since graduation—800 were alive and 99 dead (Table I). Of the 800 survivors, 385 (48.1%) completed and returned the questionnaire.

The Registrar of the Medical Council has provided the details, shown in Table II, of new medical registrations

for the same years. Scotland therefore provided 40.8% of the total new medical registrations in Great Britain, while the present group represented no less than 11.9%.

In the relative number of replies and in the analysis of the data which follows there emerged a remarkable identity in the individual years. While this is not proof that the respondents constitute a fair sample of the total population, it is at least suggestive that the findings may be representative of the whole group.

TABLE I.—Follow-up of Graduates, 1923–6, as at June 30, 1951 (899 Graduates)

Year of Graduation	No. of Graduates	Replies		Deceased	
		No.	%	No.	%
1923	263	109	41.4	31	11.8
1924	290	130	44.8	29	10.0
1925	195	80	41.0	22	11.3
1926	151	66	43.7	17	11.3
1923–6	899	385	42.8	99	11.0

TABLE II.—Medical Registrations (Male and Female) 1923–6

Year	Great Britain	Scotland
1923	1,853	878
1924	2,125	935
1925	1,982	736
1926	1,586	527
1923–6	7,546	3,076

Present Practice

Dr. Johnson's dictum that the fairest prospect for a Scot is the broad highway to England (single ticket) is not altogether supported by the present location of these 800 doctors: 52% are in England and Wales, 40% in Scotland, mainly in the south-west, and 8% abroad. Rather more than half held house appointments, and they are now distributed as follows: general practice, 59%; consultant practice, 18%; appointments, 21%; others, 2%. Many of the consultants of this period graduated through general practice, and almost unanimously they commend the benefit of this experience. Indeed, it is generally urged that all doctors should spend some time in general practice. The period need not be long; many thought it should be one year.

Marriage (385 Replies)

Only three were already married before graduation, but by the date of the inquiry 91% had married. The marriage state in relation to graduation year of the 385 graduates was as follows:

Married at end of 5 years	..	42.7%
" " " " 10 "	..	75.5%
" " " " 15 "	..	86.7%
" " " " 20 "	..	89.3%
" " " " 25 "	..	90.9%
Unmarried	..	9.1%

General practitioners married early; consultants and others were more tardy: immunity seems to increase with the years, but it is doubtful if it ever becomes complete. Remarriages were rare.

The occupation of the spouse is of some interest; thus 7% of the 385 graduates married doctors, 19% nurses, and the remainder "other occupations." If this pattern of marriage selection is general to the profession, then, having regard to the relative proportion of male to female graduates, an interesting deduction follows—namely, that between 30 and 40% of women graduates marry doctors.

The 350 marriages resulted in 295 (84%) families, numbering 703 children, of whom all but 32 (4.6%) survive. The number of children in family ranged from 1 to 10, with an average of 2.4. According to "Census 1951, Great Britain, One Per Cent. Sample Tables" (H.M.S.O., 1952) at April, 1951, the average size of families in Scotland was 2.03, compared with 1.69 in England and Wales and 1.72 over the whole of Great Britain. The most appropri-

ate comparative figure, however, may be that for Scots-women aged 45–49 years and married for 15–19 years, whose average size of family (including children who have since died) is 1.87. In the professional classes the figure was 1.41 (18% below the figure for all classes combined).

Analysis according to the occupation of the spouse revealed no difference between the groups—doctor, nurse, and "other occupations."

Social Pattern of Marriage and Family

The preceding facts raise certain serious considerations for the profession under present-day circumstances. It seems reasonable to assert that this social pattern of marriage and the family is unlikely to change radically in the near future, if indeed ever.

Medical studies now begin at the age of 18 years and extend over a minimum period of six years. Thereafter one year must be spent in hospital appointments and a further two years in National Service. This means that the young doctor will have attained the minimum age of 27 years before he is free to begin his career. During the next 10 years the prospect is marriage and a family of two or three children. Other considerations apart, this represents a heavy financial load for a further 20 years—indeed, until the parents are approaching ages between 50 and 55 years. This involves serious implications concerning the remuneration and social status of all future doctors and their families. Distant prospects and rewards of hard practice thus assume relatively less importance than the assurance of an adequate income in the early and middle years. The satisfaction of vocation, no matter how complete, will not suffice; indeed, it is not likely to be attained unless supported by a reasonable freedom from economic pressure. These are not insignificant matters, because from them must derive the whole quality of the National Health Service.

In recent controversies it has often been asserted that in future medical men will not enter their children for medicine. This would seem to ignore the well-founded observation of a family trend in certain occupations, and it is not altogether supported by recent applications to the medical schools. From the present group 136 (20%) among 671 children have already graduated or are studying for a medical degree. Moreover, these 136 children derived from 295 families, signifying that approximately one family in every two maintains continuity in the profession. Many of the girls have entered nursing and associated professions in hospitals. Furthermore, many are still at school and too young to have chosen their future career.

As a supplement to the foregoing, inquiry has been made into the broad occupational groups which provide new entrants to the study of medicine (Table III). This is of interest in so far that educational grants for study at a university are now more generally available than heretofore. There are many factors which could influence this pattern, and it is not possible from the figures to make any precise deduction. This notwithstanding, it does not seem that as yet in the West of Scotland there is any alteration in the number of students from the artisan and labouring groups. Scholarships and grants, however, may be of real assistance to all classes where the father is deceased.

TABLE III.—Pattern of Applicants (Male Students) to Faculty of Medicine According to Occupation of Father (University of Glasgow)

Category	1918–22		1950–3	
	No.	%	No.	%
Medical practitioners	65	7.2	136	14.2
Other professions	221	24.7	213	22.2
Business	378	42.2	303	31.6
Artisans and others	203	22.7	201	21.0
Not stated or Deceased	29	3.2	29	3.0
Total	896	100.0	958	100.0

Health and Sickness

A specific question was asked about major illnesses since graduation, with special reference to dates, duration, and residual disability. No less than one-half of the total, all now aged about 50 years, stated with gratitude that they had not suffered any serious sickness.

An analysis of the illnesses recorded revealed the pre-dominance of gastro-intestinal affections, appendicitis, cholecystitis, peptic ulcer, and dysentery. In relation to these the interesting fact emerged that almost invariably these conditions were treated surgically, and that cholecystectomy was usually supplemented by appendicectomy. Respiratory diseases, pneumonia, and tuberculosis were next in order of frequency. Altogether nine cases of coronary thrombosis were recorded. The acute infectious diseases usually associated with childhood were not infrequent, and there were several cases of acute poliomyelitis.

A matter of vital concern to the profession arises from these answers—one which, so far, has received all too little emphasis. It concerns those doctors who, through chronic disabling sickness or accident, become handicapped for their work, particularly general practice in industrial areas. Hitherto such persons could seek alternative work in appointments in the public health service, in laboratory work, in some specialty, or in transfer to a less arduous general practice. Nowadays, under the National Health Service, there is neither freedom of entry nor of transfer in the various branches of the profession. Medical boards would appear to be their only refuge, and a place on these is not easy of attainment. Meanwhile the profession is continually being enjoined to increase its concern with the rehabilitation and resettlement of disabled and aged workmen. This is right, but at the same time there is urgent need to ensure adequate arrangements for disabled and aged members of our own profession.

It may also not be without relevance to remark that this observation has an important bearing on the health of students. Each year a number of students with a history of tuberculous disease, at the time regarded as closed or quiescent, and other disabling conditions are admitted—and rightly so—to medical schools. For these there is a need for regular medical supervision and vocational guidance. Such interest should not be opposed or be regarded as an infringement of individual freedom.

Deaths

Of the original 899 graduates, 99 died during the intervening period, and the detailed certified cause of death was obtained in 90 cases; this information was not available in the others, who died abroad.

The incidence of deaths in individual years varied between one and eight, and no fewer than four deaths occurred within one year of graduation. The principal causes of death are shown in Table IV.

TABLE IV.—Causes of Death

Cause	No.	Remarks
Unnatural (violence, 12; drowning, 5; poisoning, 8)	25	5, war
Pulmonary tuberculosis	10	
Pneumonia	10	
Bronchiectasis	2	
Cancer	9	5, lung
Coronary thrombosis	3	
Other heart disease	4	
Nephritis	4	
Furuncle of nose	4	
Miscellaneous	14	Of each 1 case
All causes	90	

Mortality in Glasgow Medical Graduates

By courtesy of Dr. W. P. D. Logan, of the General Register Office, Mr. B. Benjamin examined these causes of death. Assuming—quite reasonably—that the graduates were all aged 20–24 and uniformly distributed over that

*J. Black, A. M. Campbell, A. S. Henderson, J. A. Imrie, A. G. Mearns, and A. Meiklejohn.

age group, he found it was possible to apply life-table factors to calculate the expected deaths in successive periods of time. Thereby he was enabled to compare the expected number of deaths with those actually experienced and to determine whether or not the mortality among the graduates was greater or less than that of the body of lives from which the table was derived. For this comparison the Scottish Life Table, 1931, was most appropriate.

It emerged that the mortality experienced by the graduates was a good deal lighter than the mortality of the Scottish population as a whole (urban and rural mixed).

When the distribution of causes of death was compared with that expected it was found that deaths from tuberculosis were much fewer than would be expected on a general-population basis. Deaths from heart disease in total were not significantly greater than expected, but the number certified as from coronary thrombosis was excessive.

The four deaths from "furuncle of the nose," which at first sight seemed unusual, were found to conform to previous experience of mortality of doctors from septicaemia, carbuncles, and boils.

The only significant excess of deaths was from violence. Excluding the five war injuries, 20 graduate deaths resulted from violence. On the basis of statistics for England and Wales the expected number from drowning should have been one, and from poisoning two—the actual figures were five and eight respectively, greatly in excess of expectation. Mr. Benjamin summed up: "The general impression (and the data do not justify more than an impression) is that the mortality of these Glasgow graduates differed from that of the general population in so far as there was (a) an excessive incidence of violent deaths (drowning and poisoning), and (b) an excess mortality at ages 30–34 followed by lighter than average mortality. Whether (a) and (b) are the same depends on the provision of data of age and cause together. It looks as though, but for excessive violent deaths, the graduates' mortality might have been below average." (Note the ages at death by drowning were 24, 25, 32, 42, and 45; and by poisoning 36, 37, 39, 39, 42, 45, 48, and 61.)

Activities and Outlook

The remaining questions were directed to discovering something of the general activities and outlook, and the impressions formed in 25 years of practice. Higher qualifications obtained by examination were very common, but the M.D. degree, which at Glasgow University requires the presentation of a written thesis based on original work, had been conferred on only 14% of the group (800). A few had engaged in local government, but activities outside professional work were almost entirely confined to meetings of medical organizations and societies.

Almost all had found medicine a satisfying way of life, but there was much condemnation of conditions of practice following the introduction of the Health Service. In this matter, however, it was rather disappointing to note that the criticisms were expressed in the trite phrases of the medical press—frustration, loss of status, excessive demands of the public, too much work and too little time, book-keeping and form-filling, and the wife the unpaid drudge of the Health Service.

Medical Education

There was a very consistent demand for a general course comparable to the old *studium generale*, as an introduction and background to the subjects of professional study. While it was recognized that new discoveries and developments in all branches of medicine had greatly increased the amount of knowledge to be acquired, the need for the extension of the period of undergraduate study to six years was not generally acknowledged. On the contrary, many submitted that a five-year period was adequate if teachers made more effective use of the time. Thus there was ample scope for the diminution in the number and length of systematic lectures, particularly of those which were largely a recapitulation of textbook material. Similar criticisms were directed against ward rounds and demonstrations of patients suffering from advanced and rare diseases. More of the avail-

able time, it was urged, should be devoted to clinics, with the focus on everyday ailments and the beginnings of disease.

As to individual class subjects, a demand appeared for the co-ordination of the primary scientific studies in a course on biology. While many condemned the emphasis on the minute details of anatomical dissection, they recommended a more continuous and thorough teaching of anatomy and physiology as part of clinical instruction. Materia medica and therapeutics attracted adverse comment, in which there was a demand for more intensive instruction in the proper use of medicaments, particularly those which had established their worth.

As to what they recognized as recent advances in medicine, individual opinions were obviously influenced by the sphere of practice. It was, however, abundantly clear that the general practitioners attached chief importance to those measures which assisted in the management of chronic disease—for example, insulin and liver therapy. Diphtheria immunization was generally acclaimed.

Finally, what present as the challenges of our age? The answer is, the care of the aged and infirm and the chronic sick, the control and management of tuberculosis, and the need to link general and hospital practice more effectively towards the fulfilment of the Health Service.

This story, and it pretends to be nothing more, was made possible only by the co-operation and encouragement of our fellow-students, and to them the members of the team wish to convey their sincere gratitude and greetings for the future. They also wish to record their thanks to Dr. W. P. D. Logan and Mr. B. Benjamin, of the General Register Office; to Mr. C. Weston, Registrar of the General Medical Council; to Mr. T. H. Graham, of the Branch Medical Council Office for Scotland; to Dr. R. T. Hutcheson, Registrar of Glasgow University; to Dr. R. A. Robb; and to Miss Meikle, who undertook the secretarial work. We are also indebted to the University Court, who defrayed the cost of the inquiry.

THE PROBLEMS OF CONVALESCENCE

A two-day conference in London, attended chiefly by almoners, matrons, and superintendents of convalescent homes, was held, under the auspices of King Edward's Hospital Fund, on April 10 and 11. The questions of quicker turnover of hospital beds, the needs of the early convalescent, and the psychology of recovery were discussed. Professor Alan Moncrieff said that one unfortunate circumstance, elicited by a King's Fund survey not long ago, was that over a quarter of the patients recommended for convalescent homes had to wait in hospital an average of eight days before transfer—a sheer waste of hospital bed-time. One reason for delay was that the placing of convalescent homes had no strict relation to the regional organization of the National Health Service or even to the situation of the hospital. Convalescent homes had also various restrictions and regulations which tended to prevent early transfer. It would not be a great exaggeration to say that some of them took patients only when the patients had so far recovered that they could go home. Some of them, for example, would not take a child who had had chorea until all choreic movements had ceased; they feared that other children might catch the movements by imitation. Professor Moncrieff thought that convalescent homes should be prepared to undertake simple nursing duties, such as the giving of enemas, syringing of cavities, application of strappings and dressings and the like, and they should make provision for physiotherapy and occupational therapy.

The point of view of the convalescent home was put forward by Dr. J. O. Reid, of Princess Mary's Hospital (Rehabilitation), Margate. He envisaged a convalescent hospital in every region which should take and treat all kinds of patients. Every convalescent home, he said, should have a doctor of wide clinical experience and a "restoration minded" nursing staff. Treatment, especially simple physiotherapy, must come first, but as much freedom should be allowed as possible, for freedom restored the sense of self-reliance and responsibility. The patient must,

however, be controlled and guided throughout the whole period. Given proper facilities at the convalescent home, patients should be sent there earlier; application for admission should be made earlier by the general hospital, not on the day of the patient's discharge.

He had letters from almoners saying that the transfer must be postponed because the wound had not healed, but in convalescent homes they should welcome wounds that were not healed. In his own hospital they carried out 5,000–6,000 major dressings a year. Not all patients would fully recover, and these must be taught in the convalescent home to live with their disabilities. Dr. Reid also referred to the amount of drugs which patients brought with them from hospital—"whole winchesters of medicines." It seemed to be thought that convalescent homes had no doctor who could prescribe for patients.

Finally, Dr. J. S. Richardson, of St. Thomas's, considered the psychology of convalescence under the three heads of childishness, anxiety, and depression. He felt that a point to be remembered in dealing with convalescents was that the majority of them were gregarious and resented too much solitude. But there was also the quiet person, to whom mixing with a crowd was an ordeal. He quoted a psychiatrist colleague as saying that people with depression of the endogenous type should not be sent to convalescent homes at all, and that not a few cases of suicide had resulted from sending them. The physical expressions of depression were severe headaches, possibly constipation, slow movement, and aches and pains of the "dragging" type. Dr. Richardson was insistent that patients should not be kept too long in a convalescent home. There was an optimum period when they should be discharged, and in this last statement he was supported by Sir Henry Tidy, from his experience of Red Cross convalescent hospitals during the war, who said that, while it could not be laid down as an invariable rule that patients should be discharged at the end of two or three weeks, it was important to keep in mind some general limit of that kind.

Nova et Vetera

JOHN ABERNETHY

John Abernethy: A Biography. By John L. Thornton, A.L.A. Librarian of St. Bartholomew's Hospital Medical School. (Pp. 184. £1 5s.) London: Simpkin Marshall. 1953.

Of such as Abernethy it has been said that "they enjoyed their immortality in their lifetimes" and, by implication, not after. Abernethy takes no important place in the history of surgery, but he was an extremely popular teacher, a remarkably successful practitioner, and, above all, the effective founder of St. Bartholomew's Hospital Medical College. Locally, at the school that he founded, his reputation remains immense. The matter is well summed up by Sir Arthur Keith, whom Mr. Thornton quotes: "There is one side of a man's nature which can never grow old—never pass out of date or fashion. That is his character. Abernethy as a man will never be out of date."

John Abernethy (1764–1831) was born in London, well educated, and early attracted to surgery. He was apprenticed to a surgeon, as the manner then was. His master was a surgeon at St. Bartholomew's, and there he learned much of his art from the lectures on the subject by that admirable exponent, Percivall Pott (1714–89). Meanwhile he attended anatomical lectures at the London Hospital. In 1787 he was elected assistant surgeon to Bartholomew's, but had to wait 28 years before reaching the full staff. As assistant surgeon he began to teach anatomy at his private house until in 1791 he succeeded in persuading the governors to build a lecture theatre. There he lectured for many years to very large audiences on anatomy, physiology, and surgery. He was a devoted admirer of John Hunter (1728–93) and a supporter of William Clift, Hunter's secretary, in his gallant, devoted, and successful stand to keep his great

master's collection intact. Thus Abernethy should be remembered for his share in developing the scientific idea of a museum.

But when it is asked what were Abernethy's positive achievements, no adequate answer can be given. His contributions to anatomy and physiology are insignificant. True he was the first to ligate the external iliac artery successfully for aneurysm, but he disliked operating, and his best professional claim is that in those days of heroic surgery he adopted and constantly inculcated reasonably conservative and expectant tactics, combined with cleanliness which, however, could not in those days be aseptic. But he was a judge of men, and his greatest discovery was Richard Owen (1804–92), the most eminent comparative anatomist that Britain has produced. He promoted the student Owen to be his prosector and later recommended him for the museum of the College of Surgeons. Thus the spirit of Abernethy stands as that of a sort of elder statesman at the back of much of modern medical and scientific education. His life was well worthy of the pleasant and beautifully illustrated account which Mr. Thornton here provides, for it was a good life, well and fully lived.

CHARLES SINGER.

Preparations and Appliances

LIGHT ATTACHMENT FOR DOTT'S GAG

Mr. W. G. HOLDSWORTH, F.R.C.S., of the Plastic and Jaw Unit, Rooksdown House, Basingstoke, writes: Two methods of illumination are available for palate surgery. One is a headlight and the other a scialytic lamp near the surgeon's head. Neither of these is altogether satisfactory, and with the idea of having the light actually within the mouth the device illustrated was made. This is a tongue-piece

carrying two lamps, the rays of which are directed on to the palate (A) through columns of "perspex" (B) bent as required and sheathed in metal. The danger of sparking is virtually eliminated by having the lights at a distance from the mouth (D) and enclosed by screw attachments (C) to the metal sheaths. Even with prolonged use there is no rise in temperature of any part. Illumination is by a 4½-volt battery. The whole appliance, including the flexible leads, can be boiled. The lighting system was devised by Messrs. Vann Brothers, Ltd., after prolonged and persistent experiments, and the tongue-piece was constructed by Chas. F. Thackray, Ltd. As shown, the appliance fits on to the Dott's gag, which is used by most British surgeons when operating on the palate.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Neonatal Intestinal Obstruction

SIR,—Dr. W. P. Sweetnam and his colleagues (*Journal*, April 4, p. 765) are to be congratulated on their successful case of intestinal atresia in the newborn. In their discussion they refer to an article published by one of us (Rickham)¹ in which the development of regional neonatal surgical centres was strongly advocated. They mention that the delay and disturbance involved in transferring these babies to a centre would be harmful, and they also argue that operations for intestinal obstruction in the newborn should remain within the province of the general surgeon. These statements prompt us to reply.

Neonatal surgery has made great strides during the last dozen years; so rapid has been the advance that many recent developments and figures have, as yet, not been reported in the literature. The figures published by Ladd and Gross² (quoted by Dr. Sweetnam) were collected in the 'twenties and 'thirties and are completely out of date. One of us has recently visited Boston and learnt that the operative mortality in intestinal obstruction of the newborn (excluding meconium ileus) is now in the neighbourhood of 10% in the Children's Hospital. Even in this country, where we have been backward in recognizing the value of paediatric surgical centres, the results have improved considerably. In the previously mentioned article (Rickham¹), 23 cases of neonatal intestinal obstruction were reviewed; the mortality was 78.3%. These cases occurred in the Liverpool region during 1949, and a large proportion were operated upon in peripheral hospitals. This contrasts sharply with the mortality rate of 26.1% in 23 similar cases operated upon during 1952 in our neonatal surgical centre. Our last seven consecutive cases of ileal and colonic atresia have survived operation.

There is no doubt that occasional successes will occur in general surgical clinics, but, unless these cases are concentrated, the operative mortality of neonatal intestinal obstruction will remain high throughout the country as a whole. The improvement in the mortality has been mainly brought about by advances in the pre- and post-operative care and a better understanding of the biochemical changes which are involved. Improvement in the actual surgical technique has been of less importance. Continuously high recovery rates are impossible without the work of a team of surgeons, anaesthetists, pathologists, biochemists, and nurses specialized in this type of surgery. Such a team can only be formed in a centre. The general surgeon, unless he is trained to undertake the pre- and post-operative treatment, will always work at a disadvantage, he will have to depend on paediatricians who are inexperienced in these special surgical problems. If we are to improve the mortality associated with these conditions we will have to establish more regional centres in this country. This has long been recognized in those North American and Scandinavian countries which have left us behind in this type of surgery. Luckily, our distances are comparatively small, and three to four hours' travel would take a child from the remotest area to a regional centre, a delay which is insignificant. Babies are sent to us from distances up to 100 miles. These children travel well, provided an experienced nurse is sent with them. Delay in treatment due to distance is, in our experience, insignificant compared with the delay due to late diagnosis.

In our view the greatest advance in this type of work has been the appointment of paediatricians to outlying hospitals. This has resulted in early diagnosis and rapid transit to the appropriate centre.—We are, etc.,

ISABELLA FORSHALL.

- ¹ *Lancet*, 1952, 1, 332.
- ² *Abdominal Surgery of Infancy and Childhood*, 1941. Saunders, Philadelphia.

SIR,—Dr. W. P. Sweetnam, Mr. F. W. Shepherd, and Dr. E. F. Murphy (*Journal*, April 4, p. 765) advocate that cases of congenital deformity of the digestive tract occurring in

the abdomen should be treated by general surgeons: in other words that the system which now obtains in most parts of this country should persist. They recommend, however, that similar deformities occurring in the thoracic part of the tract should be treated in special centres; and they do not mention the very varied and difficult ones occurring in the lowest part, the rectum and anus.

In support of their argument the authors present a series of two cases, neither of which I find very convincing. The case of intestinal anastomosis survives with the grave handicap of a blind length of bowel leading off the caecum, and, as congenital defects of the bowel are often multiple, many authorities would not agree with the omission to examine the whole digestive tract. The other case was allowed to develop obstruction under the eye of the surgeon. In their references they quote Wangenstein,¹ who has been preaching for many years against delays of this kind. They also quote Ladd and Gross,² whose classical and most valuable work would have been impossible under the system they recommend. If the authors of the paper would investigate precisely what has happened to all the cases of deformities of the digestive tract in a definite district surrounding them over a definite space of time we should have some really valuable information, of the kind gathered by P. P. Rickham.³ It would then be possible to compare these results with those gained in centres of paediatric surgery in Boston and Stockholm, not to mention Liverpool and London.

This is, of course, not to suggest that the authors of this paper are wrong to treat such cases; but I do think they are wrong in encouraging the average general surgeon to take on their care, and in discouraging the formation of those units of paediatric surgery which have brought the treatment of all congenital deformities to an efficiency that is far from realized by the profession at large. What I would like to see would be purely paediatric surgical units set up in centres such as Huddersfield, with young surgeons in charge of them who would take the work of these difficult and fascinating cases to a higher pitch of efficiency than is to be found anywhere at present. They would find plenty to do, and it is only by concentrating such relatively rare conditions in large numbers that a real body of knowledge of pathology, diagnosis, and treatment can be built up.—I am, etc.,

London, W.1.

DENIS BROWNE.

- ³ *Lancet*, 1952, 1, 332.

SIR,—Dr. W. P. Sweetnam, Mr. F. W. Shepherd, and Dr. E. F. Murphy (*Journal*, April 4, p. 765) with the anaesthetist and nurses concerned must be congratulated on the successful surgical treatment of two premature infants with intestinal obstruction. They raise the question of who should operate on the newborn, and take a proper view that much neonatal abdominal surgery is within the competence of the general surgeon. The thoracic, the plastic, and the neurosurgeon can also play their appropriate parts, provided that the particular surgeon, anaesthetist, and staff (like the paediatrician) will acquaint themselves with the latest developments in the special field.

Clearly there is room for one or two units for intensive study of surgery of the newborn as such, even though they may not have the monopoly of valuable results. The modern trend is to demand the complete range of "extra-specialists" everywhere, on the principle that everyone must have the best. This leads to rather elaborate and possibly wasteful staffing. There is still a limit to the number of outstanding men. Let us give them full opportunity when we recognize them and learn from them what we can. And let us remember that multiplication of departments does not automatically multiply talents.—I am, etc.,

London, W.1.

ALFRED WHITE FRANKLIN.

The Judet Operation

SIR.—The Judet operation is probably at the height of its popularity at the moment. Furthermore, the stimulus which it seems to have given to the marketing of newer and even more formidable prostheses may have exceeded the bounds of reason. At this stage, then, it may be fruitful to record some impressions arising from a personal series of about 50 cases. These are qualified by the fact that there must be few indeed in the country with sufficient long-term experience of the operation to draw precise conclusions about its lasting efficacy. Indeed, the only worth-while follow-up yet published is that of Judet himself, and naturally he is enthusiastic about his own operation.

The results of some 25 cases of subcapital fracture of the femoral neck treated by acrylic replacement have been at least encouraging. Apart from one death in the sixth post-operative week from bronchopneumonia, all the patients have been able to walk well (albeit with one stick), have regained full, or nearly full, movement, and have been free from pain—this in substantially less time than one usually considers a "nailing" fit to bear weight. The osteoarthritis, however, have given less cause for satisfaction. In some 28 cases, four have had a return of hip-joint pain within two years of their operation. Return of symptoms has recurred in cases where a technically satisfactory operation has been performed, and one has been at a loss for an explanation. Certain facts, however, appear to become more significant when meditating upon these indifferent results. No prosthesis can ever accurately match the head which is removed, and, as a sequel, where two bearing surfaces are not exactly congruous mechanical wear is absolutely inevitable.

With these figures and deductions in mind I now find myself, perhaps unconsciously, leaning towards the older established procedures such as arthrodesis and displacement operations of the MacMurray type. Space forbids discussion of the merits of each. Suffice it to say that, apart from its own intrinsic merits (and these are considerable), a MacMurray's osteotomy has never yet given me an ungrateful patient, and it may even become a standard method of dealing with the "failed" acrylic head. In conclusion, let us become a little less prosthetically minded and indulge in some critical thinking about this widespread joint "re-bushing."—I am, etc.,

West Hartlepool.

A. WEBB-JONES.

Nicotinic-acid Deficiency

SIR,—I am very interested in the case note published by Dr. G. H. Collins in his letter (March 28, p. 731), for it corroborates observations of my own¹ regarding the importance of high blood concentrations of vitamins in various clinical conditions. In such instances vitamins are no longer used as dietary supplements, nor can they be adequately regarded as catalysts. It is tempting to consider them as metabolic reagents having metabolic cycles of their own which, however, have not so far been described.

There is a further comment I would wish to make regarding the use of nicotinic acid in the dose of 1,500 mg. mentioned by Dr. Collins. In my experience, even as little as 50 mg. intravenously may produce intense abdominal pains, and furthermore subjective discomfort may be most severe owing to vasodilatation. Quite marked blood pressure alterations and other signs of autonomic disturbance may occur if large doses of any single vitamin are given directly into the blood stream. In so far as Dr. Collins's case showed a syndrome highly suggestive of nicotinic-acid deficiency, it is almost certain that the other members of the "B-complex" were insufficiently present. My own experience has led me to prefer a mixed barrage of vitamins, and always to use nicotinamide rather than nicotinic acid where possible. Although I have not treated a case exactly comparable to Dr. Collins's, results obtained by a colleague and myself in the treatment of acute alcoholic and toxic-infective psychoses are in preparation for publication. We have successfully used variations of the mixture of vitamins mentioned in the paper quoted—namely, dextrose, 10 g. (10% solution):

aneurin hydrochloride, 1,000 mg.; nicotinamide, 200 mg.; pyridoxin, 200 mg.; and ascorbic acid, 1,500 mg.

Of course, in the presence of clinical signs suggestive of a marked single vitamin deficiency, the corresponding agents should be given in greater amounts.—I am, etc.,

London, W.1.

JONATHAN GOULD.

Intravenous Detoxication of Drunkenness

SIR,—Dr. Peter Nobes (*Journal*, April 11, p. 836) is of course quite right in stating that the quelling of a drunken patient by intravenous barbiturates (as recommended by Dr. A. H. Bartley (*Journal*, January 17, p. 163)) is potentially dangerous, but, where intravenous injection is feasible, why not detoxicate instead of appease? It is not generally known that high-dosage multiple-vitamin intravenous injection not only gets rid of the excitement but of every other symptom of intoxication, and will even dispose of delirium tremens in a matter of hours. This method, which also applies to other "toxic" psychoses, was first used in 1942, and (like convulsive treatment) gradually improved. It is fully described and documented in Dr. J. Gould's recent article.¹

Detoxication does not of course cure the alcoholic, but helps to bring it home to him that subsequent curative treatment is possible.—I am, etc.,

Isleworth, Middlesex.

H. PULLAR-STRECKER.

REFERENCE

- ¹ *Lancet*, 1953, 1, 570.

SIR,—When a casualty officer I was not infrequently faced with the problem of the acute alcoholic. I had heard that those of my colleagues who prescribed vitamin B₆ for post-radiation sickness swore to its effectiveness as an antidote to the alcoholic hangover. I therefore tried an intravenous injection of 50–100 mg. The results were far more dramatic than I had anticipated, and of the same order as the giving of intravenous glucose to a patient in the aggressive phase of hypoglycaemia. A typical case was a woman of 45 brought in singing, swearing, and staggering. Three minutes after an intravenous injection of 100 mg. of vitamin B₆ ("benadon") she became quiet, apologized for the trouble she had caused us, and asserted she felt quite sober. She was able to walk across the room perfectly steadily.

My series was only about six cases in all, but the results were uniform, and it does appear to me that vitamin B₆ is a specific antidote to alcohol. As an anaesthetic to general anaesthetics, at any rate in the dose of 100 mg., it appears to have little effect. I feel that this treatment is more physiological than the use of sedatives, and may possibly be of some use in making the diagnosis between drunkenness and head injury. I should be interested to hear if others have had experience of this method of treatment.—I am, etc.,

Thornton Heath, Surrey.

V. P. WORDSWORTH.

Banishment of Bromides

SIR,—I feel that those doctors who have had years of experience of the great value of bromides should not let the banishers have things all their own way just because of lack of time, or lethargy in putting pen to paper. I refer especially to the article (*Journal*, March 28, p. 694) in which Professor D. M. Dunlop and his colleagues give a survey of prescribing in Scotland in 1951 and state: (1) "Bromides seldom prove more effective than phenobarbitone either as sedatives or as anticonvulsants. Their frequent side-effects and the undesirable cumulative toxic effects which result from their prolonged administration relegate bromides to the group of drugs which should largely be discarded in modern therapeutics," and (2) "Bromides are sedatives which have to be administered frequently before there is a sufficient replacement of chloride by bromide ion to exert a depressant effect on the central nervous system, and their occasional administration with a hypnotic such as chloral has no more effect than a dose of salt water."

There is undoubtedly truth in the first part of the first statement, but the conclusion is hardly justified. The effect of sedatives is extraordinarily individualized, as one realizes more and more the longer one has experience of them. One patient of nervous type with disseminated sclerosis went through seas of trouble on various daytime sedatives until I went back to a bromide and chloral mixture, of which a small or medium dose was taken as required. The patient had previously been doing reasonably well on it, but an exacerbation of the disease occurred, and in deference to modern views I decided to try without the mixture. We persevered for a long time with various barbiturates, etc., during and after the exacerbation, but a return to the bromide and chloral mixture made it quite clear that it was the best daytime sedative for the case. The second statement I can only regard as incorrect. Doubtless some neglected factor in the experiments will be found, as happened with the contention that ergot by the mouth was ineffective. I can cite other patients who get exactly the mild daytime sedation they may require from a small dose of bromide alone, either occasionally or repeated for a few days; it has always worked so well that there has been no justification for change.

The late Dr. Alfred Parsons, a well-known Dublin teacher, gave outstanding credit to the value of small doses of sodium bromide in many, if not most, of the ills that flesh is heir to. The late Sir Maurice Craig, of London, held, I believe, a similar opinion. It would seem a pity for young doctors to fight shy of old and most helpful remedies because of modern pronouncements perhaps not based on a thorough personal experience with the drugs condemned. It is relevant to recall that quite a number of patients are intolerant to phenobarbitone, and that it is slowly excreted and can also accumulate in the system.—I am, etc.,

Portadown, Co. Armagh.

ROBERT E. HADDEN.

The Backward Child

SIR,—Having worked in the Fountain Hospital in 1948, and at that time having been impressed by Dr. B. H. Kirman's open-minded approach to the problem of mental deficiency, I greatly enjoyed his letter (*Journal*, February 7, p. 334).

Like Dr. D. Jackson (*Journal*, March 7, p. 559), I agree with Dr. Kirman that a final diagnosis regarding educability should be postponed as long as possible. To Dr. Jackson's statement that educability will largely depend on "advances in psychology and education" I want to add "and on advances in medicine." By this I mean on new findings in brain pathology which have to be combined and synthesized with findings of brain anatomy and of brain physiology to bear upon the concept of mind. Medical research should lead the way in demonstrating what different integrative actions of the brain are involved in solving various intelligence tests. Analysing a great number of such tests, I found every single one resting basically on integrations of the visual or the auditory sense with either proprioceptive or interoceptive impulses.

It is a well-known fact that visual and auditory nerve fibres are integrated with proprioceptive fibres in the superior and inferior corpus quadrigeminum. It is at present only a well-founded hypothesis that visual and auditory impulses are integrated with interoceptive impulses from the hypothalamus in the corpus geniculata laterale and mediale.

In a report for the Ministry of Health, published in 1922 by H.M. Stationery Office, Eardley Holland described his findings in the brains of almost 100 stillborn children. He found in every case a massive haemorrhage, which "could be pinned down within narrow limits . . . and corresponds to the course of the vein of Galen." The blood coagulum pressed on the lamina quadrigemina and against the caudal end of the thalamus—that is, against the corpora geniculata and the pulvinar. A number of other researchers have since confirmed the correctness of Holland's findings and the enormous frequency of these haemorrhages in stillborn children and in young infants who died from intercurrent diseases during the first year of life. Holland posed the question: "As these injuries are so frequent and probably in most cases not fatal, what happens to the children who survive?" Strangely enough, nobody has tried to answer this

question by investigating the brain stem in diseased aments. The explanation is probably that nobody considered the likelihood of an intellectual defect originating in the lowest brain region, a region which is almost identical in all vertebrates from fish to man.

Clinical and brain pathological studies in the field of mental deficiency during the last eight years have enabled me to collect a large amount of clinical data and a lesser amount of pathological data which might help to answer Holland's question. My findings and observations strongly support the theory that pathological changes in the above-mentioned ganglia and in their afferent and efferent tracts may play one of the most important roles in the causation of mental defect. Organic disturbances in one or several of these structures will—according to their severity—disturb more or less severely a child's visual or auditory reflex activity, either somatic or autonomic. At the same time, these disturbances will deprive the cortex of necessary sensory-somatic or sensory-autonomic impulses. This loss will create more or less distorted concepts of reality in the mind of an afflicted child.

Analysis of the individual scoring patterns in intelligence tests makes it possible to gain a fairly good impression of the special functional disabilities of a mentally handicapped individual. Neurological examination designed to reveal disturbed visual and auditory reflexes have to supplement the diagnosis of visuo-somatic, auditory-somatic, visuo-autonomic, and auditory-autonomic impairment. We often find a combination of two, sometimes even of three or four, disorders. On the basis of such a diagnosis educational treatment can be instituted. Following the example set by the development of blind and deaf teaching, new educational procedures and new educational tools have to be devised. These have to be designed to make use of intact pathways into the cortex so as to supply the mind with undistorted information. Adequate stimulation, mentioned by Dr. Jackson, originates in this undistorted information.

At Columbus State School in Ohio we are presently engaged in a research project based on the above considerations and designed to develop the dormant intellectual potentialities of 20 ineducable children, aged 6 to 8 years, with I.Q.s between 30 and 50. In contrast to English usage, Americans regard an institution for backward children as— to use Dr. Jackson's words again—"an educational establishment, that is, school."—I am, etc.,

Columbus, Ohio.

LISE GELLNER.

Pilonidal Sinus of the Suprapubic Region

SIR,—We have read with interest the medical memorandum by Mr. Roderick G. MacLeod (*Journal*, March 28, p. 710) entitled "Pilonidal Sinus of the Suprapubic Region." In this he states that pilonidal sinuses have been previously described in the axilla, the sacro-coccygeal region, the perineum, barbers' hands, the sole of the foot, and the umbilicus, and adds a seventh site, the suprapubic region.

As we have seen several cases of sinuses in barbers' hands within recent months and intend to publish a review of this condition shortly, we are interested not only in hair-bearing sinuses in any situation but also in the nomenclature presently in use. The term pilonidal sinus, which is descriptive only and has no histiogenetic or aetiological basis, was used first by Hodges¹ and applied by him to the post-sacral type. It is of interest that he was aware of the lesions occurring in barbers' hands and did not apply the term pilonidal to these. Patey and Scarff² have recently drawn attention to this occupational disease of barbers, and have suggested that the mechanism of formation of the post-anal pilonidal sinus may be similar to that of the barbers' lesion. Although we feel that there is much to be said in favour of the congenital theory in the production of the post-anal sinus, it is suggested that the purely descriptive term of post-anal pilonidal sinus be used and not that of post-sacral dermoid, as its real nature is still in doubt. In cases where a sinus has arisen as a result of rupture of an infected dermoid cyst—one of us has recently seen one on the nose—it is surely unnecessary and wrong to give it a name which is only descriptive, when the true pathology is known.

Finally, in the case of the sinuses of barbers' hands, it is well established that the lesion is produced by the tissue reaction to extraneous hairs and not to the hairs of the

host. There are no hair follicles in the sinus wall, and the lesion arises as a result of penetration of the epidermis by short sharp hairs from the heads of males, the setting up of a foreign-body reaction to them, and secondary infection. It is therefore again preferable to name such lesions "interdigital sinuses of barbers' hands," rather than use the confusing term "pilonidal sinuses."—We are, etc.,

SIR,—Neither history nor histology supports Mr. R. G. MacLeod (*Journal*, March 28, p. 710) in applying the term pilonidal sinus to a suppurating and discharging dermoid cyst. The term pilonidal sinus was coined by R. M. Hodges¹ in 1880, and he described the condition in the following words: "On exposing its interior by an incision, a certain quantity of pus is evacuated, and a lock of loose hair is found occupying the space, more or less matted and curled, and of varying size and amount. The hairs of which it is made up are always short, without bulbs, and correspond in colour to those of the patient. The cavity containing them has no cyst or lining membrane, or other characteristic suggestive of a congenital dermoid wen; merely the granulating walls of an ordinary suppurating sinus, with no trace or suspicion of hairs growing from its surface, or of isolated spots of cuticle from which they might have been shed."

It is remarkable that in the face of such evidence as this the developmental or endogenous theory of a pilonidal sinus should have become widespread. The champions of this theory have been hard put to it to explain the conspicuous absence of an epithelial lining from the main cavity of a pilonidal sinus and have had to fall back on the argument that the epithelium is destroyed by the suppuration. Mr. MacLeod's interesting case has spiked this gun by showing that when there really is an epithelial lining it can withstand the repeated suppuration for as long as two years. It is time the endogenists surrendered.—I am, etc.,

Myxomatosis in Control of Rabbits

SIR,—I was interested to see in the *Journal* (March 21, p. 639) the brief note about the satisfactory effects of myxomatosis in the destruction of rabbits in Australia. I think there should have been included some reference to Dr. H. de B. Aragão, of the Instituto Oswaldo Cruz in Rio de Janeiro, who first suggested its use for rabbit control in 1928. His work and the parts played by American and British workers are briefly summarized in an article by Liversidge in *Discovery*.—I am, etc.,

Cancer and Organic Content of Soil

SIR,—Dr. E. H. Eason (October 25, 1952, p. 941) considered it misleading to mention organic manure in relation to plant copper deficiency. I can find no substantiation for this, since it appears from the literature that the factor involved is simply the power of organic matter to fix copper in a form unavailable to plants. The other soil conditions mentioned by Dr. Eason are not relevant here, important though they are in agriculture. On the other hand, Dr. E. D. Allen-Price (October 11, 1952, p. 831) finds excessive gastric cancer mortality in an area of intensive cultivation in his region.

I have therefore examined data¹ for one area where exceptionally heavy organic manuring has long been practised—the Biggleswade and Sandy area of Bedfordshire. It has been observed that this area "seemed conspicuous for

the malignancy of cancers of all sorts."² Total cancer mortality, standardized for the experience of all Bedfordshire (age, sex, type of district), is given below.

District	Expected	Actual	Ratio %
Biggleswade R.D.	175	199	113
U.D.	64	63	99
Sandy U.D.	31	43	139
Aggregate	270	305	113

Soil samples from cultivated land in the area gave an ignition-loss figure of 8.2% ; from heaths and woods, 6.0%. From this it would seem that heavy organic manuring does induce the "total cancer factor," despite rapid humus turnover. From other evidence too lengthy to give here I suspect that a protective factor exists in normal vegetables, which is depressed by copper deficiency. It may be a product of tyrosine oxidation, though this is problematic. If this deduction is correct, then a simple agricultural operation can increase human resistance to carcinogenesis. Indeed, in areas where micronutrient fertilization is essential for adequate crops, farmers may now be preventing cancer. How true to historical form!

So long as the malignant mutation remains irreversible, active prevention is the best hope.—I am, etc.,

London, S.W.17.

Agriculture (Poisonous Substances) Regulations

SIR,—I would refer to your annotation in the *Journal* of March 28 (p. 717) on Agriculture (Poisonous Substances) Regulations, S.I. 1953, No. 358. The last paragraph of the annotation contained the following comment. "They [the regulations] are open to criticism for the reliance they place on the wearing of face-shields rather than full face respirators. The main route of absorption is through the lungs, and face-shields do not prevent absorption by this route during spraying operations. They are likely to be particularly ineffectual when organo-phosphorus compounds are used in an enclosed space such as a greenhouse."

This criticism is hardly justified, and suggests misinterpretation of the regulations. The regulations rightly distinguish between the dangers from the specified substances when they are suspended in the atmosphere in an enclosed space and likely to be absorbed in the lungs, and when in the form of coarser droplets which are rapidly deposited. In the former case the use of a full-face respirator is specified in the regulations (see First Schedule, Part II, item 7, and Regulations 4 (2)), in the latter a face-shield only is required.—I am, etc.,

W. A. WILLIAMS,

Secretary.

Attempted Suicide by Burning

SIR,—Mr. R. J. V. Battle and Dr. H. E. S. Marshall's case record of an attempted suicide by burning (*Journal*, December 27, 1952, p. 1397) recalls a patient who is at present undergoing treatment for a like condition.

Two years ago a 15-year-old girl poured paraffin over her clothes and set them alight. She suffered severe burns of the right side of face, neck, front and back of chest, axillae, right forearm, and hand. On healing, severe contractures were formed on the neck and axillae. She is one of eight daughters; and, according to a local attitude to which her family adheres, this is considered a misfortune. She was denied any parental affection, and besides the scolding by her father she was often beaten. She has had limited schooling. Following the healing of the burns, she has attended a psychiatric centre in Jerusalem, but at all times, according to their records, she maintained a reticence about her deeds.

While under plastic surgical treatment, which is of necessity a lengthy one, she is proving very co-operative. The abdominal flap is already in position on the neck, and the favourable result

thereof seems to have produced a marked psychological improvement in the patient. Suicide by burning among the peoples of the Middle East is apparently not infrequent.

I wish to thank Mr. Jack Penn for his advice in planning the plastic procedures on this patient.—I am, etc.,

Haifa.

B. HIRSHOWITZ.

Liver Injury by Antibiotics

SIR,—Attention has been drawn in your annotation (*Journal*, April 4, p. 777) to reports of changes seen in liver tissue associated with a large dosage of antibiotics. The comment has been made that "this evidence from human and animal studies shows that aureomycin, and probably terramycin, are mildly injurious to the liver when given in large doses, especially parenterally."

Among the references given, as regards terramycin, Lepper *et al.*¹ reported the effects of large doses of antibiotics on the livers of mice. They found that "the effect of terramycin was similar to that of aureomycin, although less marked." They also emphasized that the dosages of both antibiotics were much higher than those which are recommended for the treatment of human infections. Nevertheless, the very mildness of the possible liver injury subsequent to excessive antibiotic therapy is summed up in the first article quoted in the annotation²: "Excessive amounts administered therapeutically, for instance, may act in a manner analogous to that of excessive amounts of dextrose given by the intravenous route." Again, in the same article, the authors considered that the liver damage would seem to be reversible if administration of the drug was stopped soon enough. The seven patients in this article are reported as having shown definite clinical signs of liver damage after aureomycin, but the authors emphasize that six of them, from whom they had obtained liver tissue for examination, had evidence of potential or demonstrable liver damage prior to any treatment.

Lastly, the discovery of the structural formula of terramycin has shown it to be both unique and devoid of dangerous chemical radicals which are known to provoke serious toxic reactions. This new knowledge helps to explain the high degree of safety of the drug, an experience which has been amply confirmed by many thousands of clinical trials in which terramycin is shown to be free of toxic effects in blood and blood-forming organs, liver, heart, and other vital organs.—I am, etc.,

- ² *Ibid.*, 1951, **88**, 271.

SIR,—In your annotation on "Liver Injury by Antibiotics" (April 4, p. 777) you state that the evidence from human and animal studies shows that aureomycin and probably terramycin are mildly injurious to the liver when given in large doses parenterally, and that there is a remarkable absence of such toxicity when given orally in the usual dosage.

Lepper and his associates in the paper which you quote¹ mention that the dosages of aureomycin which produced evidence of liver dysfunction in patients were excessive. Lepper further states that intravenous doses of aureomycin totalling less than 2 g. a day were not accompanied by evidence of liver dysfunction or injury. In more than 1,300 patients to whom they administered aureomycin orally, no evidence of liver injury was noted.

Kalz and his co-workers² and Knight *et al.*³ have found aureomycin useful in chronic liver diseases and particularly in the chronic residua of acute hepatitis. It appears also to be of definite value in hepatic failure and in the fulminating type of acute hepatitis (Kimbrough⁴).

Long⁵ states that every year since its introduction the dosage requirements of aureomycin have been decreased and are now about 50% less than those suggested two years ago. The present recommended dosage of aureomycin of

12 mg. per kilo of body weight, or 1 g. daily for the average adult, does not produce injury to the liver.

However, your annotation emphasizes the possible ill-effects of administering doses of antibiotics parenterally in excess of therapeutic requirements, and is a timely warning on the misuse of these substances.—I am, etc.,

"Efocaine" and the Relief of Pain

SIR,—Referring to Dr. T. H. Howell's note (*Journal*, April 4, p. 785) giving his results with "efocaine" for the relief of pain in fibrositis, my personal experience is that the chemical constitution of the solution injected is quite immaterial, provided that all the myalgic spots where the pain originates are successfully located. The relief then given should last for months.

In a recently published series¹ I described a carefully controlled experiment in which the objective effect of injecting normal saline was the same as that of injecting procaine. The advantage that normal saline has over any of the anaesthetic solutions of which procaine is the prototype lies in the fact that there is never any reaction. For the last two years I have used nothing else.—I am, etc.,

London, W.1.

The Metric System

SIR,—I have read with great interest the correspondence on the metric system. I have been working in Zurich for two years, and therefore have had ample experience of the practical side of this question. I can wholeheartedly agree with the opinions expressed by Dr. C. Langton Hewer in his letters (*Journal*, February 21, p. 450, and April 4, p. 782), and Dr. John Primrose (*Journal*, April 4, p. 782) seems to have arrived at the happy compromise. My personal experience is that in practice it is by no means the excellent system that theory would lead one to expect.

When the dosage is in grammes the metric system works well, but when it is in milligrams or fractions of milligrams then it is often corrupted and becomes confusing. For example, when I wish to order 1/150 gr. I must say to the sister the equivalent of: "Please give nought comma nought nought five" (this is an approximation, 1/150 gr. = 0.00044 g.). For some reason of habitual usage I cannot say the equivalent of, "Please give half, or 0.5 mg.," or confusion might be worse confused. 1/100 gr. is 0.0006 g., but who would argue that the mental picture of the difference between 1/150 gr. and 1/100 gr. is not more quickly appreciated than the metric 0.00044 g. and 0.0006 g.?

The difficulty is largely overcome here by the simple but very undesirable system of ordering drugs in "whole ampoule" or "half ampoule." Apparently this is a local expedient to overcome the practical difficulties, adopted by those who have been brought up on the metric system all their educational lives. The disadvantages and, indeed, dangers of such an expedient are self-evident.

Touches of the magic wand of mathematical nicety cannot change human mental processes. Ever since the days when we were little boys and girls and gave our playmate half an apple (and gave or kept the "bigger half" for ourselves) fractions will have a clearer mental picture for the average adult than a metric system. So far I have never heard my small son come in and say: "Daddy, Hans gave me 0.5 of his apple." And in our hospitals we must work with the average practical individual who gets on with the work, rather than the adherents of a beautifully correct mathematical system.—I am, etc.,

Zurich.

R. A. C. HERRON.

The Medical Practitioner and the Law

SIR,—The time has come for the medical profession to recognize the double threat inherent in the growing tendency for dissatisfied patients to bring an accusation of negligence against a doctor and/or his hospital. The present tendency is due partly to the impersonal element introduced by the National Health Service, and partly to the financial immunity of certain claimants because of the legal aid system.

The first part of the threat is against the faith of the public in their doctor. Obviously the more often doctors are declared to have been negligent the less faith the public may reasonably put in them. The second threat challenges to some extent the freedom of the practice of medicine. It is again obvious that, if the doctor is gradually forced to give only such treatment as can be defended safely in a court of law should any unforeseen or unavoidable complication arise, then progress in medicine will be deterred.

Although it is the public who ultimately stand to lose by these processes, it is nevertheless our duty to counter them. It seems to me that it is desirable for members of our profession to take particular care that they do not yield to the temptation to support slender grounds a claim of negligence against a fellow practitioner. Where a medical man finds himself faced with the invidious duty of saying whether a colleague has been negligent, he should not shrink from that duty. He may feel that he has a responsibility to assist the course of justice and he must discharge it. The medical profession does not wish, even were it possible, to set itself above judicial criticism or beyond reproach. But the doctor who has to give his opinion as to negligence should be satisfied that there are facts on which he can base his opinion. He must remember that medicine is not an exact science, that assumption and conjecture about patients whom he has not seen and about whom the facts are uncertain are completely unreliable. Conjectures, assumptions, and hypotheses are not sufficient grounds on which to give a responsible and honest opinion that a colleague has been negligent.

One hears that a doctor giving evidence as an expert witness in one of these cases said "there must have been" such and such a sign: "there would obviously be" such and such a symptom. What nonsense! Human reactions are not so consistent as that. I have myself heard a medical witness in such a case base his allegation of his colleague's negligence on a series of three postulates, the second of which was impossible, the third highly unlikely, and the first, on which his case rested, was contrary to the evidence that his colleague had given on oath. And I have seen the same witness feed his counsel assiduously with material intended to trip, to confound, and to discredit medical witnesses for the defence, even including sisters and nurses. I felt ashamed when I saw it. If one holds views it is obviously reasonable occasionally to pass a note or a suggestion to the counsel who is putting those views, but to keep up a continuous stream of suggestions in which every possible attempt is made "by hook or by crook" to catch out a fellow practitioner is really carrying zeal too far. And it is all eventually to the discredit of the profession and to the public harm.

I suggest, Sir, that not only should the Ethical Committee of the British Medical Association peruse a full and complete transcript of the evidence in these cases, but also that the pertinent parts should be printed in your *Journal*.—I am, etc.,

Liverpool, 1.

BRYAN MCFARLAND.

SIR,—Mr. G. A. Craig (*Journal*, March 14, p. 618) deserves credit for his comments on the current spate of anti-medical litigation, and particularly the alarming measure of success with which these efforts have been attended.

There would appear to be an unpleasant current tendency for the patient to regard his doctor with a mixture of suspicion and hostility, so that when something goes wrong recourse to the Courts for retribution follows naturally. While no one is immune from the attacks of these factious malcontents, it is clear that both eminence and experience afford considerable protection, and so it is that the more vulnerable younger practitioners must bear the brunt of the assault. Hospital residents appear to be popular targets, and, while some are sheltered by their consultants, the

unfortunate casualty officer, who is constantly exposed to difficult and dangerous decisions, is often unowned and unsupported. He is in fact a "sitting duck," and entirely at the mercy of the aggrieved bereaved. No sane practitioner could claim that mistakes are entirely unavoidable, and it is obvious that the less experienced a man the more often will he be in error. Casualty posts offer the type of experience and remuneration that will appeal mainly to the recently qualified practitioner, whose judgment will of necessity be immature.

We were taught that, provided we exercised reasonable care and a degree of skill compatible with our experience, we were not generally responsible for unfortunate sequelae. However, it is apparent that the exercise of care and skill is no longer a safeguard; and a combination of free law and free medicine is breeding an insupportable doctrine that because someone dies someone must, therefore, have been negligent. A startling illustration of the development of this new concept of negligence is afforded by the outrageous Payne case, which appeared to the majority of the medical profession to be a travesty of moral justice.

While it is undoubtedly comforting to be in a position to face litigation secure in the knowledge that our expenses will be met by our Defence Society, there are few who are satisfied with this purely defensive strategy. Further mischievous and malignant actions must be met with vigorous and uncompromising resistance by the bodies concerned with the legal protection of the profession, so that our safeguard against the consequences of natural and ungovernable phenomena is restored.—I am, etc.,

Northampton.

T. T. E. MICHAEL.

Vitamins

SIR,—Professor D. M. Dunlop and his colleagues in the "Survey of Prescribing in Scotland in 1951" (*Journal*, March 28, p. 694) estimate that in the United Kingdom about two million pounds are spent in the prescribing of vitamins by general practitioners.

This practice is merely an emulation of the widespread use of vitamins in hospital. In the wards of a teaching hospital wherein I worked recently vitamin tablets and iron tablets were issued routinely with each meal, irrespective of whether any specific deficiency was thought to exist.

This costly custom in practice and in hospital assumes that our food is devitalized and deficient. The increasing incidence of diseases of degeneration, viewed in the light of the pioneer work of Sir Robert McCarrison, surely indicates that this assumption is correct. But to attempt to supplement a deficient diet by using the torrent of synthetic products poured out by enterprising chemists is futile, costly, and illogical.

As long as a large proportion of our food is processed, desiccated, and canned our tissues will continue to degenerate, our hospital waiting-lists will be long, and our consulting-rooms full. Those who doubt this statement should study the Cantor Lectures delivered by McCarrison in 1936 and now published under the title *Nutrition and National Health* (London, 1953).

Only a complete reform of our food production and manufacture, beginning with the abolition of the milling of low extraction wheat flour, will restore the health and vitality of the population and make unnecessary the wasting of millions of pounds in worthless prescribing.—I am, etc.,

Aberfeldy, Perthshire.

W. W. YELLOWLEES.

SIR,—It is very difficult to be strictly scientific in our approach to medicine, though the modern tendency seems to be that way. I assume that Dr. A. Lewis (*Journal*, March 28, p. 729) never gives penicillin without first ascertaining that the organism responsible for the illness he is treating is penicillin-sensitive, and never uses any of the still commonly prescribed "expectorants" because clever scientific doctors say they serve no useful purpose. It happens, though, and not infrequently, that experience is a

better guide than the test-tube or microscope, and experience has shown that in early childhood and in pregnancy, as Dr. Lewis admits, and in soldiers on active service, vitamin supplements are of value. Such supplements have been regularly used for many years as part of the routine training diet of undergraduates undergoing the very severe physical training necessary before rowing in the Boat Race. There are no statistically significant figures available, but it seems that the incidence of coughs, colds, influenza, and minor infections generally is lower among the selected few who undergo Boat Race training at Cambridge than among the common undergraduate population. Of course, all sorts of other factors are involved, and the conclusion that vitamin supplements "help" is grossly unscientific. However, it is likely that Cambridge Boat Race crews will continue to use these extra accessory food factors.—I am, etc.,

Cambridge.

E. V. BEVAN.

SIR,—It is astonishing that Dr. A. Lewis, who is so ready to challenge (*Journal*, August 23, 1952, p. 445) statements in the daily press, should be unfamiliar with scientific advances in the study of vitamins during the last two decades. The point of view made in his letter (*Journal*, March 28, p. 729) represents opinions current at least 20 years ago, when little was known of the exact physiological needs for vitamins. The situation is different to-day. While recognizing that requirements vary from individual to individual, we can now make estimates within relatively narrow limits of human daily needs, and can with a good measure of accuracy assess the intake from food.

From the Ministry of Food publication (1952) *Domestic Food Consumption and Expenditure, 1950*, we learn that the average intake of vitamins for all households was above the standard set by the B.M.A., but average values are misleading unless we recognize that they are obtained by the combination of levels below with levels above. It would be reassuring to think that food provided in our universities could always be depended upon to give students protective nutrients up to or above their estimated needs. But can we be sure of this? In a college where special studies are made of nutritional problems 20% of a group of students were found in 1948 to be deficient in vitamin A (Miss Stella Doraiswami and Professor John Yudkin, *British Medical Journal*, 1948, 2, 708).

Cambridge at any rate has decided to err on the side of safety. Dr. Lewis says "vitamins . . . are especially valuable where there is fear of vitamin deficiency." This surely is a justifiable fear. The problem could be settled by an analysis of the food eaten before and during training, when the extent of supplementation by vitamins could be determined with some measure of accuracy. This is, in fact, done by members of the Oxford University Exploration Club, who also take care that they are not short of vitamins.

Dr. Lewis asks for an official statement on the limitations of vitamins. The Report of the B.M.A. Committee on Nutrition, 1950, gives the most recent estimates of needs, and the Ministry of Food's recent new edition of the *Manual of Nutrition* aptly mentions on p. 38 that "shortage of water-soluble vitamins B₁, C, and riboflavin will also take some time to become evident. Then slothfulness, malaise, and minor skin troubles may arise." It would surely be folly on the part of a trainer to wait until these become manifest in his crew before taking steps to prevent such an occurrence.—I am, etc.,

Medical Research Department,
Vitamins Ltd., London, W.6.

AUDREY Z. BAKER.

Crohn's Disease Involving the Stomach

SIR,—The literature in Crohn's disease is extensive, but case reports of the lesion involving the stomach are rare, which gives added interest and importance to the two cases of Mr. F. R. R. Martin and Dr. R. J. Carr (*Journal*, March 28, p. 700). In claiming priority of proof of gastric occurrence I think they must be unaware of the short series of Comfort *et al.*¹ that included "the first case report of a lesion in the stomach identical with regional enteritis and confirmed by pathological examination." The present authors

emphasize the diagnostic role of anorexia and vomiting, regarding these symptoms as pointers to the involvement of the stomach in the absence of stenosis of the intestine. Some clinical experience of the disease finds one at variance with this interpretation. In the first place, anorexia and vomiting do occur in typical Crohn's disease apart from obstruction, and are usually accompanied by pain in the epigastrium or lower abdomen. Indeed, it is often pain which is responsible for the development of anorexia, because the patient is afraid to eat. Aggravation of the pain by food is a characteristic and very real feature, so much so that one man remarked that he preferred "aspirins and brandy" to a meal.

Further, it is hard to follow the authors in their view that there is danger of a gastric lesion being overlooked through lack of attention. Surely the routine barium meal x-ray examination of the gastro-intestinal tract should suffice to reveal any morbid changes in the stomach wall. That they are rarely described is due, I believe, to the fact that they are rarely present, and not to oversight. A comment on the radiological appearances in these two cases may not be amiss. If we accept the consensus of opinion that an infection—slow, chronic, and as yet unproven—is an aetiological factor then it would seem a fair assumption that an acute (allergic) gastro-duodenitis has flared up in this segment previously sensitized to the infective agent—that is to say, an acute-on-chronic reaction. The effect on the mucous membrane would be a necrotizing one, and the necrosis of the mucosa would account for the disappearance of the mucosal folds, even as the inflammatory reaction causes an arrest of peristalsis. With the subsidence of the inflammatory attack peristalsis returns, and regeneration of the epithelium restores the normal mucosal pattern. Some support for this allergic theory is derived at laparotomy when one has seen spasm of the pylorus and of segments of the colon, a characteristic of sensitized plain muscle. A similar explanation can be applied to the phase of the lesion commonly described as "acute ileitis," which represents an allergic exacerbation in a segment of intestine already sensitized to an infection of unknown origin.—I am, etc.,

Ashton-under-Lyne.

F. G. RALPHS.

Sympathetic Nerves and Eclampsia

SIR,—Obstetricians generally must welcome Mr. G. W. Theobald's article (*Journal*, February 21, p. 422), especially as it detailed the successful outcome of pregnancy in three patients who hitherto had failed to secure a live child. Even making allowances for the fact that recurrent toxæmia does on occasion fail to repeat itself in a pregnancy, or proves itself milder, the significance of his therapeutics in the survival of the foetus is manifest.

It is unlikely, however, that the reasons he has advanced for the effectiveness of his procedure will remain unchallenged. Although preliminarily he emphasizes the fact that toxæmia of pregnancy is a non-recurrent condition, he subsequently includes under this broad designation three cases (A, B, and C), on which his conclusions have been founded, which should have been more specifically classified as two cases of toxæmia complicating essential hypertension and one case of toxæmia associated with chronic nephritis. The absence of cardiovascular and of renal signs must be viewed against the genetic background and the reasonably predictable after-history of this group of patients. Pickering¹ states: "Essential hypertension . . . probably represents an inherited abnormality. . . . The beginning and middle part of the course are still largely hidden; it is during this period that pregnancies may occur as a series of events which may or may not influence permanently the hypertension." Browne² in reviewing his experience regards 25% of all toxæmias as belonging to this group. Mr. Theobald's three cases cannot be classified outside it either.

Further, it will be observed that Cases A, B, and C all had certain afferent nerves arising from the uterus interrupted when

the internal iliac vessels were injected with phenol. Cunningham³ states that all blood vessels "are accompanied by nerve fibres both medullated and non-medullated, some of which are afferent and some motor." Such injection must have helped to effect a degree of uterine denervation which, in Cases B and C, was well-nigh completed by presacral neurectomy. The result of practically complete denervation in Cases B and C was in marked contrast to that of the incomplete in Case A. The latter patient gained 3 stones (18.9 kg.) by the 37th week, and her blood pressure of 120/74 mm. Hg had risen to 150/90 in the same period. The water retention reflected in her weight gain and the raised level of her blood pressure proclaimed the toxæmic process, which had not advanced sufficiently, however—for example, to systolic level of 160 mm. Hg—to provoke albuminuria or to injure the foetus. Case B, whose uterus had been largely denervated, appeared to be free from toxæmic stigmata. Case C—of severe chronic nephritis—whose kidney function was perilously perched indeed, escaped disaster and thereby helped to prove the value of uterine denervation. Although Mr. Theobald omits to mention the specific gravity of her urine, the mechanism of dilute and copious urine production in this type of case was fully explained by Platt in his Lumsden Lectures (1952). So profound are the processes responsible for diuresis here that any degree of moderate glomerular shutdown, if it had occurred, would have been entirely masked by them.

Denervation in the fourth case was incomplete, inasmuch as presacral neurectomy had not been performed and the effectiveness of the phenol injection of the vessel had not had time to develop. Emphasis is thus once again provided indirectly on the value of uterine denervation in this method of therapeutics, and Mr. Theobald has unwittingly gone far to prove that interruption of nervous stimuli originating in the uterus prevents the toxæmic process. The utero-renal reflex offers an explanation of the pathway of these stimuli, and if interpolated suffices to explain the renal changes of toxæmia. Although the tension of the multiparous uterus is not as high as the primiparous, the renal soil has been so prepared in the essential hypertensive as to react to weaker stimulation (Sophian⁴). It is these stimuli which internal iliac denervation and presacral sympathectomy interrupt, and therefore toxæmia fails to develop.

Mr. Theobald attempts to discount the thesis of a nervously integrated renal shutdown arising from the uterus because of its tension by certain invalid arguments. For instance, he has failed to appreciate Poiseuille's law by constant tension of the uterine wall with a raised intrauterine pressure in his experiment of filling the distensible post-partum uterus in the hope of highly accentuating its tension. There is no proof that he had succeeded in effecting the latter, and it is therefore wrong for him to expect evidence of a utero-renal reflex acutely evoked thereby. In certain experiments of which I have knowledge, the intact (not the denervated) artery of supply to one horn of the rabbit's uterus was electrically stimulated and resulted in renal shutdown. In his experiments both the site of application of the stimulus and the fact that the internal iliac was sympathectomized serve to destroy any analogy.

It is apparent that readers of the article must interpret the data quite differently from Mr. Theobald.—I am, etc.,

JOHN SOPHIAN.

Incidence of Scabies

SIR,—I wonder whether any of your readers have noticed an increase in the number of cases of scabies occurring in their practices recently? I notice that in the out-patient clinics attended by the dermatological unit in this area we had only four cases of scabies in 1951, and six cases in 1952; whereas in the first 10 weeks of this year we have had 19 cases.

I believe I am correct in saying that a marked increase in scabies arose just before the 1914–18 war, and some 18 months before the 1939–45 war, the significance of this being that in both cases the increase was pre-war. I am not trying to spread alarm and despondency, but would be inter-

ested to hear if there is now an increase in scabies after the marked drop we had at the end of the last war.—I am, etc.,

Bradford.

ALLAN BIGHAM.

Cricket

SIR,—You very kindly published a letter of mine in the *Journal* of June 7, 1952 (p. 1251), in which information was given that a cricket match had been arranged between the B.M.A. and the Law Society at Hurlingham, London, on Sunday, July 5, 1953, at 11.30 a.m. The response to this letter was encouraging. The replies were often informative, not infrequently amusing, and without exception couched in humble terms in regard to the prowess of the writers.

The approach of another cricket season prompts me to put out this reminder in the hope that other members of the Association who are interested in cricket may be encouraged to get in touch with me as soon as possible, so that the best possible available side is obtained. At the moment the most urgent need is a wicket-keeper and a slow left-hand bowler.—I am, etc.,

The Little House,
Broadwater Down,
Tunbridge Wells.

Life of Hugh Owen Thomas

SIR,—I am writing a new *Life of Hugh Owen Thomas*, together with a revised edition of his collected works. Any assistance in this task would be welcomed; in particular I am anxious to have access to previously unpublished material. Letters or documents relating to any aspect of Thomas's private or professional life, or to the history of the family, will be carefully handled and returned to the owners as soon as possible.—I am, etc.,

10, Harley Street,
London, W.1.

DAVID LE VAY.

POINTS FROM LETTERS

Research in General Practice

Dr. B. BARNETT (Birmingham) writes: Professor Robert Platt's article (*Journal*, March 14, p. 577) has to be welcomed, since it highlights some of the problems of general practice as it operates at present and the richly rewarding work which would incidentally appear from a reorganization of such work. Facility for research can arise only when facility for adequate work has been provided. Records, ancillary workers, fuller examination, adequate facilities, liaison with other doctors, some form of group practice—these are the prime requisites, and until they are met we can expect little. We yet have to be thankful to Professor Platt for showing us a beacon ahead.

Recurrent Boils

Dr. E. McKERROW (Workington, Cumberland) writes: With reference to the Refresher Course article on boils (*Journal*, March 28, p. 721), within the past few years I have had two cases of recurrent boils in elderly couples. In both cases the husband was the first patient, and in both cases the focus of infection was eventually proved to be the umbilicus of the wife. Soon after this was discovered and cleared up there was an end to boils in both cases.

Patients as Individuals

Dr. J. M. MACLENNAN (Vancouver) writes: Dr. R. R. Bomford's "discursive and eclectic review of some changing concepts in medicine" (*Journal*, March 21, p. 633) is perhaps deliberately provocative. Certainly the medicine he was taught nearly 25 years ago is strangely different from that which I was taught at the very same period. Our teachers insisted on the study of the patients as individuals. That there was a personality factor in peptic ulceration, rheumatoid arthritis, asthma, etc., was made very clear to us. We were urged to study people's faces as well as the domestic and industrial environment of our patients. Did Dr. Bomford not hear those things 25 years ago? His Bradshaw Lecture sends one back with renewed appreciation to Professor C. F. W. Illingworth's Refresher Course article on peptic ulcer (*Journal*, July 26, 1952, p. 206), so brief, so clear, so firmly based, and so closely related to the patients and their experiences.

Obituary

ALEXANDER MILES, M.D., LL.D., F.R.C.S.Ed.

Mr. Alexander Miles, who died at his home in Edinburgh on April 9 at the age of 87, was one of the leading surgeons of his day. He will be remembered also for his outstanding work on behalf of the Edinburgh medical school.

Alexander Miles was born at Leith on May 21, 1865, and was educated at George Watson's College and at the University of Edinburgh, where he graduated M.B., C.M. in 1888. He was elected F.R.C.S.Ed. in 1890 and proceeded to the M.D. in the

Swan Watson, Edinburgh

following year, winning the gold medal and the Symes Surgical Fellowship for his thesis. After holding the appointments of clinical assistant in the observation wards and resident surgeon at Edinburgh Royal Infirmary, he became lecturer in anatomy in the University, assistant surgeon to the Royal Infirmary, and surgeon to Leith Hospital. He was also appointed lecturer in surgery in the school of medicine of the Edinburgh Royal Colleges. In 1909 he was promoted to full surgeon at the Infirmary, retiring in 1924. Mr. Miles succeeded the late Sir James Hodsdon as the representative of the Royal College of Surgeons of Edinburgh on the General Medical Council in 1928, and he continued to serve in that capacity until 1943. He was a member of the executive committee of the Council for 10 years; of the penal cases committee and the finance committee for 12 years; the public health committee in 1928-9; the examination committee from 1929 to 1939; and of the education committee from 1940 to 1943. In addition he was appointed a member of the Dental Education and Examination Committee, a committee set up for the purpose of the revision of the dental curriculum in 1931. On Miles's retirement from the G.M.C. the President paid tribute to his sober judgment and wise counsel, especially as a member of the penal cases committee. When the British Medical Association held its Annual Meeting at Aberdeen in 1914 Mr. Miles acted as a vice-president of the Section of Surgery, and from 1926 to 1930 he was a member of the Arrangements Committee. For a time Mr. Miles was joint editor of the *Edinburgh Medical Journal*, and he was a past president of the Royal Medical Society of Edinburgh.

We are indebted to Mr. W. J. STUART for the following appreciation: Despite the fact that Mr. Miles had reached his 88th year he had, until the comparatively recent onset of ill-health, so maintained his active interest in the Edinburgh medical school and all that concerned it that his death means much more than the passing of a half-forgotten figure. He gave the qualifying lecture courses in surgery and in operative surgery in the extramural school of medicine of the Royal Colleges of Edinburgh, and his classes were always large. According to custom he discontinued the classes on his appointment as surgeon to the Infirmary,

a post which he held for the routine period of 15 years till 1924, and during that time and thereafter his work for the university became increasingly important. He was a member of the University Court, and was also one of the Curators of Patronage, in whose hands lie the appointments to certain university chairs in Edinburgh. In 1925 his university deservedly honoured him by conferring upon him the degree of LL.D. His connexion with the Royal College of Surgeons of Edinburgh was also close. He was a most efficient secretary and treasurer for seven years, president for the usual two years, and its representative on the General Medical Council for 15 years. In later life one of his greatest interests lay in the Astley-Ainslie Hospital for occupational therapy, of whose board he was the first chairman, and his constant interest was a significant factor in its success.

The most important of his numerous contributions to medical literature was undoubtedly the *Manual of Surgery*, written jointly with Alexis Thomson, which was first published in 1904. It became an immediate favourite among students and young graduates, and its continued popularity was indicated by the publication in 1939 of the ninth edition, for which, owing to the death of Alexis Thomson, Miles had obtained the collaboration of the late Sir David Wilkie. For the last edition of his textbook on *Operative Surgery*, published in 1950, he had Sir James Learmonth as joint editor: it must be exceptional that any man at the age of 84 should be capable of such work and, moreover, of writing the chapter on amputations contained in that volume.

Miles was one of the prominent surgeons of his time in the Edinburgh school, and it is difficult to realize that it is almost 30 years since the close of his active hospital life. His increased leisure in later years enabled more use to be made of his great administrative and organizing gifts by the university and other institutions, to which he freely gave his services. He is survived by his wife, formerly Miss Helen J. Greig, and a daughter.

We are indebted to Dr. HARLEY WILLIAMS for the following appreciation: Having to choose my first surgical clinic, I consulted an older man, who said, "You will learn a lot from Sandy Miles." He was indeed considered the best all-round surgeon in the Royal Infirmary: from him I learnt all I was capable of learning. He was slight, fresh, and sandy, and he operated without gloves, with his sleeves loosely rolled up. His hands were small but very capable, and in teaching he was neither reticent nor talkative. To watch him handle a patient was in itself a perfect process of learning. Students used to smile at the frequent use he made of his self-invented instrument, the Miles "dissector," which was a very ordinary tool such as we felt anyone might have devised. That was typical of Miles's approach to an operation. Technique for him meant the simplest, most fundamental way of doing a thing. He had a tepid sense of humour, but only once do I remember his throwing an instrument upon the floor—not the beloved dissector, but a pair of forceps that would not grip. His surgical results were the justification of his craftsmanship. Alexander Miles was known at Edinburgh as the conscientious partner in that team of extraordinary opposites—Thomson and Miles. Each was everything the other was not. Alexis Thomson, brilliant, eccentric, reckless: Miles, cautious, careful, conscientious. They hung together over many years with enormous mutual respect. Yet it always seemed amazing that their jointly written textbook could have so successfully emerged from this incongruous association. At the final examinations many students would encounter that strange partnership for the last time. Alexis Thomson was impetuous, impatient, and then bored. The ever-kindly Miles ran the show, calmed the alarmed examinee, and supplied the proper efficiency and fairness.

Under his conventional exterior there must have been a secret poet, for he called his house in Perthshire by a Gaelic name meaning "hill of the fairies" or something of that kind. His only son, Hamish Miles, who died many years

ago, was becoming well known in literature and wrote a life of Arthur Machen. Miles the surgeon lived on for more than 20 years after his retirement, still nimble, young-looking, kindly, a monument to the influence of an equable temperament and the virtues of moderation.

Sir EDWARD WORTHINGTON, K.C.V.O.
C.B., C.M.G., C.I.E., M.R.C.S.

Sir Edward Worthington, who entered the R.A.M.C. in 1900 and was at one time physician to the late Duke of Connaught, died on April 5 at the age of 76.

Edward Scott Worthington was born on October 15, 1876, and was educated privately and at Trinity University, Toronto. Soon after qualifying M.R.C.S., L.R.C.P. in 1899 he volunteered for service as a civil surgeon in the war in South Africa, and in November, 1900, he entered the R.A.M.C. as a lieutenant, having been recommended for a commission by the commander-in-chief. For his services in South Africa he was awarded the Queen's medal, with four clasps, and the King's medal, with two clasps. After a brief period in the United Kingdom in 1902-3 he served in India for five years before returning to England in 1908. Two years later he was present, as medical officer on the staff of the Duke of Connaught, at the opening of the first Parliament of the Union of South Africa, and he later went to Canada when the Duke was appointed Governor-General of the Dominion. When war broke out in 1914 Worthington was recalled to England, and he was with the British Expeditionary Force in France until October, 1916, when he returned to England. Towards the end of the war he was deputy assistant director-general of medical services at the War Office for a short time, and he also became an Honorary Physician to the King. He retired in 1926. Worthington was the recipient of many Crown honours. He was appointed M.V.O. in 1911 and created a knight in 1913. For his war services he was awarded the C.M.G. in 1915 and the C.B. in 1918, in which year he was also promoted K.C.V.O. His appointment as C.I.E. was the reward for his services as medical officer on the staff of the Duke of Connaught in India when the Princes' Council was opened in 1920. Other awards he received were the Belgian Croix de Guerre and the American Distinguished Service Medal, and he was appointed an Officer of the Order of Leopold of Belgium and of the Sacred Elephant of Siam. He was also appointed a Knight of Grace of the Venerable Order of St. John of Jerusalem in 1913. Worthington married Miss Winifred J. Wallace in 1914 and had one son and one daughter.

R. PATERSON SMITH, M.D., D.P.H.

Dr. R. Paterson Smith, who was professor of pathology and bacteriology at Dalhousie University, Halifax, Nova Scotia, for more than 20 years, died in Newcastle-upon-Tyne on April 7. He was 57 years of age.

Ralph Paterson Smith was a native of Greenock and was educated at Greenock Academy and Glasgow University, where he graduated M.B., Ch.B. with honours in 1918. After a period of service in the R.A.M.C., during which he was in Egypt for a time, he returned to Glasgow as assistant to the professor of pathology. In 1922 he took the D.P.H., and in the following year he went to Newcastle—his wife's home town—as lecturer in pathology at Durham University and assistant pathologist to the Royal Infirmary. It was in 1927 that he was appointed to the professorship of pathology at

Dalhousie University, but before he left for Canada he had submitted a thesis for the M.D. degree of Glasgow University on the subject of enteric fever, and for this he was awarded the Bellahouston gold medal.

From 1927 to 1950 Professor Paterson Smith, who was a born teacher, played a prominent part in the medical affairs of the Maritime Provinces of Canada, and his advice was widely sought on medico-legal and educational matters. He examined in pathology for the Dominion Medical Council of Canada and for the Canadian College of Physicians and Surgeons. A Founder Fellow of the College of American Pathologists, he was also a member of several other learned societies in North America. His writings covered a wide range of subjects, including bacteriology, parasitology, and toxicology, but his main interest was in neoplastic diseases, and in this branch of study he left his mark on medical teaching. An important paper on "Lobular Hyperplasia of the Breast" was published in the *Canadian Medical Association Journal* in 1940.

Genial and courteous in manner, Paterson Smith was a most energetic worker, and when three years ago he returned to this country as consultant pathologist to the Newcastle General Hospital he put all his heart into the organization of his department. He leaves a widow and five sons, of whom three have settled abroad and one is a medical student at the University of Durham.

After a prolonged illness contracted on service and borne with great cheerfulness and fortitude, Colonel R. W. VINT died on March 2 at the age of 65. Robert Washington Vint was born at Carrickfergus, Co. Antrim, on July 4, 1887, a twin son of the late Mr. John Vint, and was educated at the Royal Belfast Academical Institution, matriculating at the former Royal University of Ireland, and later studying medicine at the old Queen's College, Belfast, where he was a keen player of Rugby football. After graduating M.B., B.Ch. in 1910 he served as house-surgeon at the Maternity Hospital, Belfast, and later as house-surgeon and house-physician at the Royal Victoria Hospital. He entered the R.A.M.C. by competitive examination in 1912, and was in India when war broke out in 1914. He then served with a field ambulance in Mesopotamia and Persia, gaining considerable surgical experience. After the war he served in the United Kingdom, Malta, and India, chiefly as a surgical specialist, and wherever he went he was universally popular. During the last war he was in command of a large hospital in India, and later became A.D.M.S., Waziristan District, North-west Frontier Province, and an Honorary Surgeon to the Viceroy of India. On reaching the age of retirement he was re-employed to command a large tuberculosis hospital in the Indian hills, and he finally retired in 1947. Colonel Vint is survived by his wife and one son. His death will be deeply felt by a multitude of friends in many parts of the world.

Dr. WILLIAM WHITE, who died at his home at Cappoquin, Co. Waterford, on March 7 in his 80th year, was the son of the late Dr. Thomas Kyran White, of Kilsheelan, Co. Tipperary. William White was educated at Blackrock College and the old Queen's College, Cork, graduating M.B., B.Ch. from the former Royal University of Ireland in 1898. After graduation he held the post of house-surgeon at the County and City Infirmary, Waterford, and afterwards acted as assistant resident medical superintendent at the mental hospital there. During the war in South Africa he served as civil surgeon, and was attached to the 13th Lancers and the 9th Hussars. After the war he entered general practice and worked successively in Liverpool, in Mullinavat, Co. Kilkenny, and in Whitechurch, Co. Waterford, until, in 1914, he was appointed medical officer of health for the Cappoquin

district, where he practised until his death. Dr. White was an all-round athlete. He was a keen horseman from his early days and rode with the Tipperary hounds. Besides being an amateur boxer of some skill, he played Rugby at Black-rock College and at Queen's College, Cork, and gained an inter-provincial Rugby cap for Munster in 1892 and again in 1893. He also represented County Tipperary in the Gaelic Field and was captain of the Shandon Rowing Club, Cork, for some years. The achievements of his youth he recollected pleasantly, but it will be as a general practitioner of the highest order that he will be remembered by his colleagues and his patients. Dr. White kept well abreast of the times, and excelled as a diagnostician, using a happy combination of old and new methods. His punctuality was a by-word in the neighbourhood, his attention to his patients never failed, while his good humour and quiet manner endeared him to all. Dr. White is survived by his son and four daughters, Mrs. White having died in 1944. His son, Thomas Kyran White, was formerly a colonel in the Indian Medical Service, and one of his daughters, Dr. Winifred A. White, is in practice at Cappoquin.—M. O'F.

Dr. E. C. BRADFORD, who was in practice at Horsham, in Sussex, for many years, died in hospital at Durban, South Africa, on March 24, aged 63. Ernest Cordley Bradford was born on August 13, 1889, the son of the late Dr. Cordley Bradford, a well-known general practitioner of Acock's Green, Birmingham, and was educated at Rugby, Pembroke College, Cambridge, and at St. Bartholomew's Hospital, qualifying M.R.C.S., L.R.C.P. in 1914, and taking the degrees of M.B., B.Chir. in the following year. He was a house-surgeon at the Birmingham General Hospital before entering the R.A.M.C. to serve in the war of 1914-18. After the war he settled in general practice at Horsham, retiring because of illness in 1943. An enthusiastic member of the British Medical Association, he was honorary secretary of the Horsham Division from 1925 to 1933, and chairman of the West Sussex Division from 1934 to 1937. After his retirement Dr. Bradford fought against ill-health with such great courage that in 1951 he was able to take a post as ship surgeon and make several trips round Africa. His new appointment brought with it a return of his old zest for life and enjoyment in work, but unfortunately his health again deteriorated. Although he was really unfit for his last trip, he made light of his symptoms and rejoined his ship. But he had to be put ashore at Durban, and there he died, in harness, as did his father before him. Dr. Bradford was bred in the old tradition of medical practice, and had ingrained in him all the attributes which go to make the ideal general practitioner. First and foremost a family man, he had a wide range of interests, including all kinds of sport. He served the Horsham Hospital with a strong sense of duty, and many local societies and institutions also received his support. A real friend to the families whom he attended, he was quite unsparing of himself and always ready to do acts of kindness which many people would consider unnecessary for a busy man to undertake. So, as with many of the best general practitioners, the strain began to tell, and his last few years in general practice were an increasing struggle against failing health. He leaves a widow and three sons, two of whom are following their father's profession.—J. W. D.

We record with regret the death on March 28 of Mr. KENNETH TURNBULL at the early age of 33. He and his wife were killed in a motoring accident in Southern Rhodesia when their car ran into the back of a stationary lorry. Kenneth Turnbull was born on January 20, 1920, and had a distinguished career at the medical school of the University of Durham, where he graduated M.B., B.S., with second-class honours, in 1942. After holding the appointment of house-surgeon at the Royal Victoria Infirmary, Newcastle-upon-Tyne, he entered the Royal Navy for service in the last war, and was seconded to the Fleet Air Arm in 1943. On his release from the Royal Navy in 1946 he returned to the Royal Victoria Infirmary and was subsequently

appointed surgical registrar. He took the Fellowship of the Royal College of Surgeons of England in 1948. Two years later he went out to Salisbury, in Southern Rhodesia, where he soon built up a large and successful surgical practice. Last year he and his wife and small son returned to this country on holiday for a few months, and they had not been long back in Southern Rhodesia when the tragedy happened.

We are indebted to Professor J. HAMILTON BARCLAY for the following appreciation: Kenneth Turnbull was an outstanding man in every way, and the cutting short of such a promising career is hard to understand. While a student at Newcastle-upon-Tyne he was a noted athlete, and he played for the University of Durham at both Association and Rugby football, and was president of the Durham University Athletic Union, winning the 100 yards two years running. In addition he was also "capped" at Rugby for Durham County. On the surgical side he showed ability much above the average and gave promise of becoming a first-class surgeon. He was a most charming and unassuming man, and was liked by everyone with whom he came in contact. His wife, formerly Miss Jean C. Gossage, whom he met during the war when she was an officer in the W.R.N.S., had also a most delightful and pleasing personality. They leave a little son, aged 3. Our sincere sympathy goes out to the parents of Mr. and Mrs. Turnbull and to their son.

Medical Notes in Parliament

Hospital Medical Staff

Mr. A. BLENKINSOP asked the Minister of Health on April 16 what total reduction in the medical staffs of teaching and non-teaching hospitals he anticipated during the current financial year.

Mr. IAIN MACLEOD replied that he could not predict the results of the special review of medical staff which he had asked hospital authorities to make.

Mr. BLENKINSOP asked how many of the registrars, of which the Minister must know the number, were likely to go out of practice during the next 12 months.

Mr. MACLEOD said there was no particular pressure being put on the department in that matter, although it was a difficult one.

Dr. BARNET STROSS said that many hospitals were finding difficulty in obtaining junior registrars. Had the Minister considered what he could do to help them, so that men in senior appointments had the necessary help to carry on their work?

Mr. MACLEOD replied that the figures for junior registrars had been for some time closely in accord with the planned schedule laid down by the Socialist Government. There were difficulties there, but the total number of specialist posts becoming available was unhappily not as high as was hoped when it was laid down.

Mr. BLENKINSOP asked him to explain how it was that there had been a big drop in the provision made in the estimates for medical staff of the teaching and non-teaching hospitals.

Mr. MACLEOD said that Mr. Blenkinsop was fallaciously comparing this year's estimates with last year's estimates, instead of last year's outlay. There had been, in fact, no change.

Mr. BLENKINSOP also asked the Minister if he would give the number of senior registrars whose appointments were being terminated and for whom there were not likely to be vacancies in hospitals, and what action he proposed to take.

Mr. MACLEOD replied that this information was not available, as the number of hospital vacancies could not be predicted with any accuracy. He was, however, reviewing the position in consultation with representatives of the profession.

Dangerous Drugs

Dr. BARNET STROSS asked the Minister of Health on April 14 if he would list the drugs that were known to cause malignant neutropenia, agranulocytosis, and acute leukaemia; what statistics he had showing the incidence of these conditions during the past two years, as compared with the year 1930; and whether he would withdraw from the official pharmacopoeia any of these drugs known to carry this danger.

Miss PAT HORNSBY-SMITH, the Parliamentary Secretary, replied that any list would be misleading. Many valuable drugs had on occasion been suspected of being the toxic factor in these diseases, but any particular drug had relatively seldom been incriminated; moreover, many patients had taken such drugs without any disorder of the blood resulting. The figures asked for were not available. The contents of the *British Pharmacopoeia* were a matter for the Pharmacopoeia Commission.

Central Purchasing

Mr. A. BLENKINSOP asked the Minister of Health on April 16 why he was proposing to reduce the amount of central purchasing of general medical and surgical stores and appliances and drugs and vaccines in the current financial year, in view of the economies that had been effected by central purchasing in the past.

Mr. IAIN MACLEOD replied that the reduction in estimated expenditure on these supplies in 1953-4 was due mainly to revision of the estimated amount of direct purchases for other Government departments. The amount of central purchasing and contracting for the National Health Service had not been reduced.

Tuberculosis Treatment Abroad

Mrs. JEAN MANN asked the Secretary of State for Scotland how many Scottish tuberculous patients were receiving treatment outside Scotland, where the sanatoria concerned were situated, what was the cost per patient in these sanatoria, and what was the corresponding cost in Scottish sanatoria.

Mr. J. STUART informed her that the present number receiving such treatment under National Health Service arrangements was 195, in three sanatoria in Switzerland. The average daily cost of treatment was about 30s., or 34s. 4d. allowing for transport and incidentals such as dental treatment. The average daily cost in Scottish sanatoria was about 23s. 6d.

Cremation Certificates

Mr. J. REEVES asked the Home Secretary on April 16 whether his attention had been drawn to the high fees charged by medical practitioners for certificates required under the Cremation Acts, and whether he would expedite the negotiations with the appropriate medical professional bodies so that a maximum fee might be fixed within the reach of the ordinary wage-earner.

Sir HUGH LUCAS-TOOTH, the Under-Secretary, said that the Home Secretary hoped to make a statement in the near future.

Industrial Diseases Inquiry

Mr. OSBERT PEAKE, in reply to a question on April 16, stated that the committee to consider the cover for diseases under the Industrial Injuries Act had been appointed, and Mr. F. W. Beney, Q.C., had accepted the chairmanship. The terms of reference of the committee were: "To review the present provisions of the Industrial Injuries Act under which benefit is paid for diseases and for personal injuries not caused by accident, and to make recommendations." The membership was: Mr. J. W. Berry, Sir Ernest Rock, Mr. C. R. Dale, Sir Wilfrid Garrett, Mr. R. Kean, Sir William Laythorpe, Dr. L. G. Norman, Mr. A. Roberts, Dr. Alice Mary Stewart, Mrs. Gertrude Williams. One other member was to be appointed after consultation with the nationalized industries.

Medico-Legal

NEGLIGENCE

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

There has in recent years been a large increase in the number of actions which have come before the courts in which allegations of professional negligence have been made against doctors. Sometimes it is the doctors themselves, sometimes the hospital authorities which employ them, that the actions are brought against. This situation is causing concern in the profession, and there is a widespread feeling that the results of such actions show that the courts are not properly distinguishing between the sort of mistakes which are inevitable in the practice of medicine and have to be accepted as the price to be paid for the advance of medical science, and the sort of mistakes which properly deserve the stigma of negligence and for which compensation should properly be awarded.

It has first to be said that in all the recent cases there has been no change whatsoever in the law. In common with all those who hold themselves out as carrying on any skilled activity, the doctor is under a duty in law to use "due care, diligence, and skill" towards his patient. Failure to do so which results in damage to the patient renders him liable to pay damages for negligence. The degree of care, diligence, and skill which he must exercise to fulfil his duty is the degree which would be expected of him by the general consensus of opinion in the profession, his experience and qualifications being taken into consideration, together with what he has set out to do, and the conditions in which he set out to do it. A less exacting standard will be required of the newly qualified surgeon carrying out an emergency operation in a man's home which could not wait until he could be got to hospital than would be required of a specialist carrying out the same operation with all the resources of a hospital at his disposal. This is not only sound law, but, like most sound law, good common sense.

The Importance of Expert Witnesses

Moreover, since it is only by means of the expert evidence of medical witnesses that the law can be applied to each particular set of facts which is brought before the courts, it is the doctors themselves who in the ultimate analysis set the standard of care which dictates whether a mistake is negligent or simply one of those which must be accepted.

No action involving allegations of negligence against a doctor can be won unless the plaintiff can support his case by calling as an expert witness a doctor who will swear that what was done fell short of the degree of care, diligence, and skill which would have been expected in the circumstances by the general consensus of opinion in the profession. If, after hearing that expert witness cross-examined, and after hearing the experts called by the defence to prove the contrary examined and cross-examined, the Court prefers the evidence of the expert witness called for the plaintiff, there will be a finding of negligence against the doctor. But a finding of negligence against a doctor can be reached by no other road.

Accordingly, where the Court in finding negligence against a doctor reaches a wrong conclusion, the most that can be said is that it has preferred the evidence of the wrong expert, and has been misled by a doctor who took the wrong view of the general consensus of professional opinion on the facts of the particular case. There is no other basis upon which a wrong conclusion can be reached.

Effect of Free Legal Aid

If statistics were available they should therefore show that, while there has been a great increase in the number of actions brought involving allegations of negligence against doctors, there has been no significant increase in the propor-

tion of such actions which have been successful. The reason for the increase in the number of actions brought does not lie in any change in the law; nor is it to be found in the institution of the National Health Service, which has in no way altered either the legal concept of the duty of the doctor towards his patients or the test of "general consensus of opinion in the profession" by which the legal concept is applied. The increase in actions has largely occurred since 1949, and is undoubtedly the result of the Legal Aid and Advice Act passed in that year.

Since the 1949 Act it has become financially practicable for any plaintiff, however poor, who can satisfy a committee set up under the Act that on his own version of what happened he has a *prima facie* case of negligence against a doctor or hospital, to litigate his case in the High Court. Before the 1949 Act, unless he had substantial means of his own or from some other source to support him, he had in practice no hope of litigating such an action, owing to the very heavy expense necessarily involved. Now, provided he has a *prima facie* case, the State will make up the deficit which previously would have prevented him from bringing the action, even though he may well lose it in the end.

Like many others who were largely protected before 1949 by the cost of litigation, doctors are now exposed in practice as they have always been in theory to the actions of any patients who consider that they have been injured by a breach of the doctor's duty towards them. The standard of duty is set by the medical profession itself, so that it lies in the doctor's own hands to see that, although occasionally a case will have the wrong result, substantially no injustice either to patient or to doctor will be done.

Universities and Colleges

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a meeting of the Council of the College, held on March 12, with Sir Cecil Wakeley, President, in the chair, a report of the death of Professor Johan Holst, of Oslo, an Honorary Fellow of the College, was received with deep regret.

The Hallett Prize was presented to A. T. Matheson (Cape-town) and the Handcock Prize to A. H. Tooley (King's College Hospital). The Council received reports of the renewal of the Mackenzie Mackinnon Research Fellowship of Dr. I. K. R. McMillan (St. Thomas's) and the Streatfeild Research Scholarship of Mr. A. T. Andreasen.

A Diploma of Membership was awarded to D. B. Fox (University College).

At a meeting of the Council of the College held on April 9, with Sir Cecil Wakeley, President, in the chair, Professor Reynaldo dos Santos, of Lisbon, was admitted to the Honorary Fellowship.

The following were elected Fellows of the College without examination as being medical practitioners of at least 20 years' standing: Mr. W. E. Tucker (Bermuda), Professor F. Davies (Sheffield), Mr. J. Dobson (Wigan), Mr. R. Scot Skirving (Sydney), Mr. A. E. Coates (Melbourne).

The Jacksonian Prize for 1952 was awarded to Mr. John Borrie (New Zealand), and a certificate of honourable mention was awarded to Mr. Rodney Smith (St. George's) for their essays on the surgical treatment of carcinoma of the stomach. The Council selected "Melanomas and Melanosis" as the subject for the Jacksonian Prize for 1954.

The Council received a gift of the *Conquest of Ceylon*, in three volumes, by P. de Queyroz, from the Faculty of Medicine, University of Ceylon.

Diplomas in Physical Medicine, in Ophthalmology, in Tropical Medicine and Hygiene, in Laryngology and Otolaryngology, in Industrial Health, and in Medical Radiotherapy were granted, jointly with the Royal College of Physicians of London, to the following successful candidates:

DIPLOMA IN PHYSICAL MEDICINE.—L. S. Bain, E. E. Bullock, A. B. Coyer, J. A. M. Joyce, S. Mattingly, A. P. H. Randle, Dorothy J. Roth, R. A. Shaddick, G. O. Storey.

DIPLOMA IN OPHTHALMOLOGY.—Judith MacA. Brown, R. U. Chowdhary, K. J. Dastur, J. M. Heaton, S. Itchhaporia, B. R. Jones, Mary A. C. Jones, A. T. Karsgaard, M. K. Mehra, J. Moss, M. Nawaz, C. I. Phillips, A. Samad, J. Singh, J. R. van der Merwe, Billie I. Williams, T. Wilson.

DIPLOMA IN TROPICAL MEDICINE AND HYGIENE.—I. Ahmad, Anwar-ul-Islam, T. Awuku-Asabre, A. R. O. Bakare, S. A. Biggart, E. B. Bright, G. H. Burgess, Carmel Cachia, J. E. Cranswick, R. A. Davis, S. R. A. Dodu, P. F. Doherty, I. M. Grant, C. H. Gurd, S. M. M. Haque, H. G. Hendow, C. S. Heymann, Jasmine R. Jacob, V. V. Kalbian, W. N. Laing, A. R. T. Lundie, A. D. A. Maconochie, D. E. Marmion, S. Nadesan, M. C. Peterside, Irene Rajaratnam, D. Ramadwar, S. Paul, A. W. Senft, P. Sirivorasarn, H. G. Skinner, G. J. Stott, Gladys M. Vanniasingham, A. V. A. Vethanayagam, S. Vyas, M. C. Williams, W. Williams, R. Woodward.

DIPLOMA IN LARYNGOLOGY AND OTOLARYNGOLOGY.—P. J. Damato.

DIPLOMA IN INDUSTRIAL HEALTH.—P. H. Nash.

DIPLOMA IN MEDICAL RADIOTHERAPY.—R. Finney.

Hospitals were recognized under paragraph 23 of the F.R.C.S. regulations as follows: Albert Dock Hospital, London, orthopaedic registrar, for six months; house-surgeon, for six months; from January, 1954, casualty and receiving-room officer. Paddington Hospital, surgical registrar; two house-surgeons, for six months. Jersey General Hospital, St. Helier, resident surgical officer, for six months (until March, 1956). Pontypool Hospital, house-surgeon, for six months. Griffithstown County Hospital, senior house officer (general surgery), for six months. Kingston Hospital, *decennial revision*, two senior house officers (orthopaedic and casualty); two senior house officers (general surgery); two house officers (general surgery), all for six months. Ipswich Borough General Hospital, *additional recognition*, junior orthopaedic registrar, for six months. Pembroke County War Memorial Hospital, Haverfordwest, *confirmation of temporary recognition*, resident surgical officer, for one year; house-surgeon, for six months. Bridge of Earn Hospital, *additional recognition*, registrar (general surgery), for six months. Birmingham Accident Hospital, *revision from January, 1954*, four resident surgical officers; six house-surgeons. Royal Hampshire County Hospital, Winchester, *additional recognition*, two house-surgeons (general surgery and ear, nose, and throat); house-surgeon (general surgery and ophthalmology), all for six months, from January, 1954, casualty officer, to be recognized for casualty work and not, as hitherto, for general surgery. Royal Victoria Hospital, Bournemouth, from January, 1954, casualty officer; orthopaedic house-surgeon. Bridgend General Hospital, from January, 1954, casualty house-surgeon. Chase Farm Hospital, Enfield, from January, 1954, casualty officer, to be recognized for casualty work and not, as hitherto, for general surgery. Dulwich Hospital, *redesignation*, "surgical registrar" to be replaced by "resident surgical officer"; from January, 1954, casualty officer. St. Giles's Hospital, London, from January, 1954, casualty officer. St. Andrew's Hospital, Bow, from January 1954, casualty officer. Woolwich Memorial Hospital, *redesignation*, "senior resident surgical officer" now becomes "registrar general surgery"; from January, 1954, casualty officer (senior house officer). Mansfield and District Hospital, *alteration to existing recognition*, omit senior house-surgeon; from January, 1954, two senior house officers to casualty and orthopaedic department. Royal Gwent Hospital, Newport, from January, 1954, two senior house officers (casualty). Northampton General Hospital, from January, 1954, casualty officer; *additional recognition*, fourth house-surgeon, for six months; *redesignation*, "resident surgical officer" now becomes "senior surgical registrar." Perth Royal Infirmary, from January, 1954, house-surgeon (casualty). Queen Mary's Hospital, Sidcup, from January, 1954, casualty officer. St. Nicholas Hospital, Plumstead, from January, 1954, first and second casualty officers. Merthyr General Hospital, resident surgical officer, house-surgeon, both for six months. St. Albans City Hospital, *confirmation of temporary recognition*, two surgical registrars, both for 12 months; two house-surgeons, both for six months. From January, 1954, casualty officer. Bolton Royal Infirmary, paragraph 23c, ear, nose, and throat, registrar. Royal Hospital, Richmond, *decennial revision*, house-surgeon, for six months. Royal Salop Infirmary, Shrewsbury, *additional recognition*, orthopaedic house-surgeon, for six months. From January, 1954, casualty house-surgeon. Portsmouth and Southern Counties Eye and Ear Hospital, paragraph 23c, ear, nose, and throat registrar; senior house officer (otolaryngology). St. Richard's Hospital, Chichester, from January, 1954, casualty officer. Epsom District Hospital, *revision*, increased period of recognition of resident surgical officer (surgical registrar) from six to twelve months. From January, 1954, casualty officer. Queen Mary's Hospital for the East End, *decennial revision*, resident surgical officer, deputy resident surgical officer, both for twelve months; two house-surgeons, each for six months. Poplar Hospital, *decennial revision*, two house-surgeons, for six months. From January, 1954, casualty house-surgeon. Clare Hall Hospital, Barnet, *redesignation*, registrar has now become

"senior registrar." Blackburn Royal Infirmary, *revision*, surgical registrar, for twelve months; senior house officer (general), three house officers, all for six months. From January, 1954, two senior house officers (orthopaedics and casualty). Queen's Park Hospital, Blackburn, *revision*, surgical registrar for twelve months; house officer (general), for six months. Dryburn Hospital, Durham, *additional recognition*, surgical registrar, for six months. City General Hospital, Gloucester, *revision*, orthopaedic registrar; orthopaedic house-surgeon, both for six months. Ballochmyle Hospital, Mauchline, *additional recognition*, two junior house officers, for six months. Birkenhead General Hospital, from January, 1954, two casualty officers. Reduction of period of recognition of posts already recognized from twelve to six months: two surgical registrars; orthopaedic registrar; senior house-surgeon. Chester Royal Infirmary, from January, 1954, casualty officer. *Redesignation*, orthopaedic registrar has been replaced by assistant orthopaedic surgeon (S.H.M.O.). Bootle Hospital, from January, 1954, casualty officer. Ashford County Hospital, *redesignation*, three surgical registrars become one senior registrar and two registrars (12 months); two house officers, for six months, in place of three resident junior house-surgeons, for twelve months. From January, 1954, third house officer to be recognized for casualty work and not, as hitherto, for general surgery. Bedford General Hospital, *revision*, period of recognition of two house-surgeons to be reduced from twelve to six months. From January, 1954, house-surgeon (casualty to six months. Dudley Road Hospital, Birmingham, *revision*, department). Dudley Road Hospital, Birmingham, *revision*, senior surgical registrar and surgical registrar, both for twelve months; three house-surgeons, for six months. From January, 1954, two casualty officers. Gloucestershire Royal Hospital, from January, 1954, casualty officer. *Revision*, period of recognition of first and second house-surgeons to be reduced from twelve to six months. Royal Surrey County Hospital, Guildford, from January, 1954, two casualty officers. Edgware General Hospital, from January, 1954, two casualty officers. Leicester Royal Infirmary, *revision*, omit one (of five) general house-surgeons. From January, 1954, two registrars (casualty and general surgery); senior house officer (casualty department). Bethnal Green Hospital, from January, 1954, casualty officer. Miller General Hospital, London, from January, 1954, casualty officer. Prince of Wales's General Hospital, London, from January, 1954, senior casualty officer. St. Alfege's Hospital, London, from January, 1954, casualty officer. St. James' Hospital, Balham, from January, 1954, two casualty officers. St. Mary Abbots Hospital, London, from January, 1954, casualty officer. Luton and Dunstable Hospital, *redesignation*, senior surgical registrar becomes "registrar" (12 months); senior orthopaedic registrar becomes "orthopaedic registrar," for six months. From January, 1954, house officer (casualty). Poole General Hospital, from January, 1954, casualty officer. Southlands Hospital, Shoreham-by-Sea, from January, 1954, orthopaedic registrar; orthopaedic house-surgeon. *Redesignation*, resident surgical officer now becomes surgical registrar (twelve months); reduction of period of recognition of house-surgeon from twelve to six months. Upton Hospital, Slough, from January, 1954, senior house officer (casualty). Leigh Infirmary, Wigan, from January, 1954, casualty officer to be recognized for casualty work and not, as hitherto, for general surgery. Royal Albert Edward Infirmary, Wigan, from January, 1954, casualty officer to be recognized for casualty work and not, as hitherto, for general surgery.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

At a meeting of the Council of the College, held on January 31, with the President, Mr. A. A. Gemmell, in the chair, D. C. A. Bevis, I. Donald, and I. Macdonald were awarded Leverhulme Research Scholarships for 1953.

The following were elected to the Membership of the College: D. M. Brodie, P. Bruce-Lockhart, D. S. Burris, K. G. Cockburn, S. B. Cooper, Janet G. Cowie, H. J. G. De Villiers, H. G. Dixon, Margaret M. Downes, E. M. Edwards, J. R. Elliott, A. H. Foate, G. S. Foster, A. E. Fyfe, G. H. Garfield, J. M. Gate, G. L. Gleeson, L. Goldman, N. G. Gourlay, M. Grant, R. W. Grayburn, J. M. Holmes, G. C. S. Hunter, Valentine M. Husband, Sarah I. Jacob, R. A. Kenihan, K. Khadenga, H. H. Kirk, B. V. Kyle, J. C. McCawley, J. Macpherson, J. S. McVeigh, Jean Murray-Jones, T. J. M. Myles, L. M. Norburn, E. M. O'Dwyer, S. Panchalingam, R. M. McK. Pratt, M. J. M. Solomons, W. K. Sutton, T. A. Thompson, R. S. Wurm.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

The following were admitted to the Membership of the College on February 6: G. T. L. Archer, V. T. B. Doyle, T. M. Gregg, Elinor D. U. Powell.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending April 4 (No. 13) and corresponding week 1952.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1953					1952				
	Eng. & Wales	Land.	Scot.	N. Ire.	Eire	Eng. & Wales	Land.	Scot.	N. Ire.	Eire

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenza pneumonia.

‡ Includes puerperal pyrexia.

Vital Statistics

Smallpox in the North Country

Up to noon, April 21, there had been 25 confirmed cases of smallpox, including 6 deaths. Since last week's report there have been 1 death, 1 new case, and 1 suspected case. The patient who died was a man aged 61, probably vaccinated in infancy. The new case was a boy aged 16, unvaccinated. The suspected new case was a woman aged 69, vaccinated in infancy. The boy aged 8 whose death was reported in this column last week is now known to have died from haemorrhagic smallpox.

Infectious Diseases in the First Quarter

The chief features of the returns of infectious diseases during the first quarter of this year were the trends of measles and diphtheria. The notifications of measles reached the highest level since this disease was made notifiable, 32,890 cases being notified during the seventh week. The notifications of diphtheria reached the lowest level ever recorded, only 11 cases being notified during the thirteenth week. The incidence of scarlet fever and acute pneumonia was relatively high during the quarter. A comparison of the number of notifications for the first quarters of the past five years is as follows:

England and Wales	1949	1950	1951	1952	1953
Scarlet fever	16,087	24,802	12,088	18,013	20,550
Diphtheria	1,523	955	572	456	264
Whooping-cough	37,221	23,619	66,865	35,042	34,207
Measles	201,140	54,568	311,709	64,596	350,836
Acute pneumonia	17,147	13,720	26,536	12,960	20,005
Meningococcal infections	474	536	662	562	595
Acute poliomyelitis	245	512	339	238	345
Dysentery	886	3,938	13,995	6,936	4,449
Enteric fevers (typhoid and paratyphoid)	100	154	149	126	123
Great Towns:					
Influenza deaths			7,448	496	2,995

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1944-52 are shown thus -----, the figures for 1953 thus ————. Except for the curves showing notifications in 1953, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

Infectious diseases were less prevalent in England and Wales during the week ending April 4. Falls in the number of notifications included 4,625 for measles, from 25,791 to 21,166; 694 for whooping-cough, from 3,202 to 2,508; and 336 for scarlet fever, from 1,739 to 1,403.

The largest decreases in the incidence of measles were 617 in Yorkshire West Riding, from 1,998 to 1,381; 357 in Kent, from 1,149 to 792; 336 in Bedfordshire, from 616 to 280; 268 in Hertfordshire, from 715 to 447; 256 in Middlesex, from 1,098 to 842; 235 in Leicestershire, from 614 to 379; and 222 in Staffordshire, from 1,272 to 1,050. The largest falls in the number of notifications of whooping-cough were 157 in Lancashire, from 585 to 428; 112 in London, from 260 to 148; 83 in Yorkshire West Riding, from 251 to 168; and 45 in Durham, from 133 to 88. The only large fluctuation in the trends of scarlet fever was a fall of 79 in the number of notifications in Lancashire.

11 cases of diphtheria were notified, 9 fewer than in the preceding week. This total was the smallest ever recorded. The chief feature of the returns of diphtheria was a fall from 10 to 2 in the number of cases notified in Lancashire.

6 cases of typhoid fever were notified, 3 in South Shields C.B., 2 in Wigan C.B., and 1 in Moseley M.B.

38 cases of acute poliomyelitis were notified. These were 11 fewer for paralytic and 3 more for non-paralytic cases than in the preceding week. The largest returns were Yorkshire West Riding 6 (Rotherham C.B. 2), Surrey 5 (Wimbledon M.B. 2), Essex 4 (Brentwood U.D. 2), and Middlesex 4.

The notifications of dysentery fell from 463 to 423. A rise was recorded in Lancashire from 60 to 109, due mainly

to an outbreak in Lancaster M.B. with 31 notifications. The other large returns in this county were Liverpool C.B. 39 and Manchester C.B. 28. The other large centres of infection were London 60 (Bethnal Green 15, Islington 17), Yorkshire West Riding 41 (Leeds C.B. 13, Barnsley C.B. 10), Leicestershire 38 (Leicester C.B. 38), and Middlesex 26 (Edmonton M.B. 16).

52 deaths were attributed to influenza in the great towns, 48 fewer than in the preceding week.

Northern Ireland's Health in 1952

The Registrar-General for Northern Ireland states that the general death rate, the infant mortality rate, and the death rate from tuberculosis for 1952 were the lowest ever recorded. For the first time since records have been maintained no deaths were reported from diphtheria.

The birth rate for 1952 was 20.9 per thousand of the population, as against 20.7 for the previous year. Although this rate is below the average for the five years 1947-51 it is above the 1939 level of 19.5.

The death rate was 10.8 per 1,000 population. This was a decrease of 2.0 as compared with the rate for 1951, but the rate for 1951 was exceptionally high because of the severe epidemic of influenza which occurred early in that year. The death rate from tuberculosis continued to fall, and now stands at 30 per 100,000 of the population. This rate is about one-third of what it was 20 years ago.

During the same period the infant mortality rate fell from 83 deaths per 1,000 live births to 39. For the past three years the maternal mortality rate has remained unchanged at 1.1 per 1,000 live births, this being the lowest rate ever recorded for Northern Ireland. In 1932 this rate was 5.3 deaths per 1,000 births. Only four cases of diphtheria were notified during the year.

Week Ending April 11

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,266, whooping-cough 2,618, diphtheria 19, measles 23,388, acute poliomyelitis 38, dysentery 325, paratyphoid fever 9, and typhoid fever 2.

Medical News

Regius Chair of Medicine, Glasgow.—The Queen has appointed Professor E. J. Wayne to the Regius Chair of Practice of Medicine at Glasgow University in succession to Sir John McNee, who is retiring on October 1. Professor Wayne, who is 50 years of age, is professor of pharmacology and therapeutics at Sheffield University. He is also physician to the Sheffield Royal Infirmary and the Sheffield Hospital for Children.

Association of British Pharmaceutical Industry.—The Minister of Health was the chief speaker at the annual dinner of the Association of British Pharmaceutical Industry on April 15. Discussing the financial problems that concern the Ministry and the pharmaceutical industry, Mr. Macleod said that the Government, as other Governments had been, was deeply concerned with the size of the drug bill. The total bill that had to be met from Part 4 and Part 2 of the Health Service in England and Wales and Scotland came to about £60 million, of which seven or eight million was paid by the patients. The greatest possible value must be obtained for that large sum, which was a little short of that needed to take sixpence off the income tax. The contribution of the pharmaceutical industry to the export trade was very important, and the industry also had to develop and continue the research which had brought such benefits to mankind. After mentioning the "perfect bill of health" which insulin had been given by

the Monopolies Commission on Insulin, Mr. Macleod referred briefly to the efforts of the A.B.P.I. to get the metric system officially adopted, and concluded with a tribute to the pharmaceutical industry's contribution to the National Health Service. In reply the president of the A.B.P.I., Mr. C. L. Saul, said that if the industry made a present of the drugs dispensed by chemists under the N.H.S. the total cost of the Service would still be over £400 million. "The industry," he said, "had to listen to two voices—the Board of Trade and the Ministry of Health." If there were one central body which at the highest level could look at any problems from the domestic and export angle at one and the same time, the industry would give it full co-operation. After Mr. Saul had proposed the health of the guests, Mr. Richard Law, M.P., made a brief reply.

Local Medical Societies.—Recent meetings have included the following: On March 4 there was a joint meeting of the *Liverpool Medical Institution* and the *Manchester Medical Society*, at which Dr. E. N. Chamberlain read a paper on rheumatic carditis and Mr. J. Howell Hughes reviewed the usefulness of gastroscopy. *Manchester Medical Society.*—On February 11 Dr. M. C. G. Israëls dealt with the classification of the reticuloses in his presidential address to the Section of Pathology. On March 10 Mr. Robert Cooke spoke to the Section of Surgery on "Abdominal Exploration and Re-exploration." He stressed the dangers of delaying laparotomy too long in cases of non-penetrating abdominal injury, the need to explore when in doubt—"We talk of paralytic ileus, when we should be operating for mechanical obstruction"—and the value of surgery in advanced malignant disease. On March 11 Professor R. E. Glover, F.R.C.V.S., read a paper to the Section of Pathology on "The Significance of Mutation in Virus Diseases in Animals," using foot-and-mouth disease and influenza for illustration. On March 19 Dr. Maurice Campbell, addressing the Society on "The Selection of Patients for Mitral Valvotomy and the Results," said that the operation should be considered in all patients with mitral stenosis who were progressively disabled. Orthopnoea, cardiac asthma, pulmonary hypertension, and recurrent pulmonary oedema were special indications; active rheumatic carditis, gross mitral regurgitation, and unrelievable congestive heart failure were the main contraindications. On March 23 Dr. E. Howard Kitching read a paper to the Section of General Practice entitled "Some Psychiatric Disorders of Childhood." He discussed behaviour disorders, "tics, tricks, and habits in children," which he said were almost always determined by innate factors and were usually early manifestations of an obsessional character likely to persist throughout life, and juvenile delinquency. *North of England Obstetrical and Gynaecological Society.*—At a meeting in Leeds on March 27 Dr. A. V. G. Bibby described "Two Cases of Ruptured Uterus in Accidental Haemorrhage"; Mr. G. Manley described a case of "Advanced Epithelioma of the Vulva"; Mr. D. C. Racker read a paper on "The Management of Post-maturity"; and Dr. J. C. W. Somerville read a paper on "Cerebral Vascular Accident in Labour."

B.M.S.A. Regional Clinical Conference.—The clinical conference of the midland region of the British Medical Students' Association was held in Oxford from April 15 to 17 under the presidency of the Regius Professor of Medicine, Professor A. D. Gardner. The conference was organized by the Oxford University Medical Society and attended by 80 students from medical schools throughout the country. The programme included lectures, ward rounds, and visits to departments engaged in research.

The May "Family Doctor."—Two articles in the May issue of *Family Doctor*, which appears on Tuesday, aim at relieving the natural fears of those who must face major surgery: "Challenge to a Woman," by Dr. T. Traherne, offers encouragement for the woman whose breast must be amputated, while "I Had My Throat Cut" will hearten those booked for thyroidectomy. Sex education is represented by an illustrated feature, "The Moment of Concep-

tion," which is the first instalment of a new series by Dr. Roger Pilkington, Ph.D., and by Dr. Winifred de Kok's suggestions on how to tell children about the father's part in procreation. On the more strictly medical side there are articles on migraine, vitamin C, and infant feeding. In "Little Thief," Dr. John Brandon sympathetically examines the reasons why children steal and the ways to cure them. A topical note is provided by "First-aid on the Cricket Field" and "Close-up of Science."

International Medical Art Exhibition.—The Royal Netherlands Medical Association is sponsoring an international exhibition of paintings, drawings, and sculpture by doctors, which will be held at The Hague at the time of the Seventh General Assembly of the W.M.A. in September. The exhibition will be run by the Union of Physician-Painters ("Pincettes et Pinceaux") of the Netherlands. Associations of medical artists or individuals who wish to exhibit are invited to write without delay to the Royal Netherlands Medical Association, Keizersgracht 327, Amsterdam C., Netherlands.

National Film Theatre.—The British Film Institute has decided to end the scheme for free associate membership announced in the *Journal* of December 27, 1952 (p. 1429). This is because the response was so great that the National Film Theatre's bona fides as a private theatre has been cast in doubt. Members of the B.M.A. who joined the scheme are being notified by the B.F.I., and are being offered the alternative of paid individual membership.

Blood Donor Record.—Blood donations in England and Wales last year numbered 647,009, the highest total in any year since the 1944 record of 669,000. The total strength of the blood donor panel at the end of the year was 487,660, but 135,000 more donors are still required.

COMING EVENTS

Hastings Lecture, 1953.—Professor F. A. E. Crew, F.R.S., professor of public health and social medicine in the University of Edinburgh, is to give this year's Hastings Lecture of the British Medical Association on May 6 at 6.30 p.m. in the Great Hall of B.M.A. House. His subject is, "Medicine and Social Policy." Mr. Walter Elliott, C.H., F.R.S., will be in the chair. The Hastings Lecture is expressly intended for the lay public, and it is hoped that doctors will bring this function to the notice of lay people who might be able to attend. Admission is free by ticket obtained in advance on application to the Public Relations Department, B.M.A. House, Tavistock Square, London, W.C.1.

The Irish Medical Schools and Graduates Association are holding their annual spring dinner dance at the Rembrandt Hotel on May 7. The president, Dr. W. R. F. Collis (Dublin), will present the Arnott Memorial Medal to Mr. Terence Millin, and will invest Mr. Ian Fraser (Belfast) with the badge of presidency for the coming year. Those Irish graduates interested in this association are invited to write to the honorary secretaries at 149, Harley Street, London, W.1.

Society of Chiropodists.—The 1953 annual convention of the Society of Chiropodists will be held at the Royal Hotel, Woburn Place, London, W.C.1, from May 7 to 9. The convention will include lectures and demonstrations, and will be officially opened by Sir Heneage Ogilvie at 2.30 p.m. on May 7. The annual general meeting of the Society will be held at 10 a.m. on May 9, and the annual dinner will be at the Park Lane Hotel on May 7.

Occupational Therapy Conference.—The Association of Occupational Therapists is holding a conference in the Hoare Memorial Hall, Church House, Westminster, from April 30 to May 2 inclusive. The conference will be opened by the president, Lord Webb-Johnson, at 11 a.m. on April 30, and at 2 p.m. on that day Sir Russell Brain will speak on "A Neurologist Looks at Occupational Therapy." The ordinary general meeting of the association will be held at 2.30 p.m. on May 2.

Contraceptive Technique.—A lecture and demonstration on contraceptive technique will be given by Marie Stopes, Ph.D., at the Mothers' Clinic, 108, Whitfield Street, London, W.1, on May 7 at 2.30 p.m. No fee is charged, but tickets must be obtained in advance, as space is very limited.

Royal Dental Hospital.—The annual clinical "At Home" will be held at the Royal Dental Hospital of London on Saturday, May 9, at 2 p.m.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, April 27

- INSTITUTE OF OPHTHALMOLOGY.—5.30 p.m., Dr. Alan Woods (Baltimore): American Approach to the Cataract Operation.
- INSTITUTE OF PSYCHIATRY.—5.30 p.m., lecture-demonstration by Dr. E. Stengel.
- POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. Sheila Sherlock: Portal Hypertension.
- ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. N. R. Barrett: Hiatus Hernia; 6.30 p.m., Mr. Denis Browne: Hypospadias, Epispadias, and Hermaphroditism.
- UNIVERSITY COLLEGE.—At Physiology Theatre, 4.45 p.m., Sir Rudolph Peters, F.R.S.: Inhibitors and Intracellular Chemical Dissection.

Tuesday, April 28

- DUBLIN UNIVERSITY.—At Physiology Theatre, 4.30 p.m., John Mallet Purser Lecture by Professor A. Brodal (Oslo): Pyramidal Tract in the Light of Recent Anatomical Research.
- INSTITUTE OF OPHTHALMOLOGY.—5.30 p.m., Dr. Alan Woods (Baltimore): Recent Studies on the Pathogenesis of Diabetic Retinopathy.
- ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. A. Dickson Wright: Colostomy; 6.30 p.m., Sir Zachary Cope: Actinomycosis.
- SOUTH-WEST LONDON MEDICAL SOCIETY.—At Bolingbroke Hospital, 8.30 p.m., Mr. W. A. Hervey: Some Recent Advances in Ear, Nose, and Throat Therapy.

Wednesday, April 29

- BIRMINGHAM MEDICAL INSTITUTE: SECTION OF PSYCHIATRY.—At Department of Experimental Psychiatry, Medical School, Birmingham, 8 p.m., Professor J. Elkes: Pharmacological Method in Psychiatric Research.
- CAMBRIDGE MEDICAL SOCIETY.—At Addenbrooke's Hospital, 8.15 p.m., films: (1) Thrombosis and Embolism; (2) Haemorrhagic Diseases. Discussion to be opened by Dr. J. Marks.
- POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. H. A. Sissons: Growth and Repair in the Pathology of Bone and Muscle.
- ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Sir Clement Price Thomas: Some Aspects of the Surgical Treatment of Pulmonary Tuberculosis; 6.30 p.m., Sir Geoffrey Jefferson, F.R.S.: Stupor—Traumatic and Otherwise.
- ROYAL EYE HOSPITAL.—5.30 p.m., Dr. A. A. Guild: Symptomatology and Treatment of Cerebello-pontine Angle Tumours.
- UNIVERSITY COLLEGE.—At Physiology Theatre, 4.45 p.m., Professor George Wald (Harvard): Molecular Basis of Vision.

Thursday, April 30

- CHADWICK TRUST.—At Walker Art Gallery, Liverpool, 7.30 p.m., Professor S. E. Finer: Public Health—A Comparison Between the Age of Chadwick and Our Own.
- LONDON UNIVERSITY.—(1) At Anatomy Lecture Theatre, University College, 5.30 p.m., Professor Wayne Dennis, Ph.D. (New York): Productivity of Scientists. (2) At University College Hospital Medical School, 5.30 p.m., Professor R. Nicolaysen (Oslo): Some Dynamic and Quantitative Aspects of Calcium Metabolism.
- NUFFIELD ORTHOPAEDIC CENTRE, Wingfield-Morris Orthopaedic Hospital.—8.30 p.m., Mr. E. W. Somerville: Congenital Dislocation of the Hip.
- POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., two films by Dr. Ian McMillan: (1) Movements of Normal and Pathological Aortic and Mitral Valves; (2) High-Speed Cinematography of the Dog's Heart with Simultaneous Pressure Recording.
- RENAL ASSOCIATION.—At 41, Portland Place, W., 4.30 p.m., annual general meeting. Dr. H. Wirz (Basle): The Osmotic Work of the Mammalian Kidney.
- ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.30 p.m., Otolaryngology Lecture by Mr. Norman Barrett: Cardiospasm.
- ROYAL COLLEGE OF SURGEONS OF ENGLAND.—6.30 p.m., Mr. R. J. McNeill Love: Gall-bladder and Bile Ducts.
- ROYAL EYE HOSPITAL.—5.30 p.m., Miss M. Savory: Conjunctivitis and its Modern Treatment.
- ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Dr. G. S. Dawes: Changes in the Circulation at Birth.
- ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. D. Williams: postgraduate demonstration in neurology.
- WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—At London Airport, 7.30 for 8 p.m., dinner meeting. Sir Harold Whittingham: Some Medical Problems of Air Transport.

Friday, May 1

- INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. M. B. MacKenna: Eczema.
- LONDON UNIVERSITY.—At University College Hospital Medical School, 5 p.m., Professor J. Chassar Moir: Use of Radiology in Forecasting the Course of Labour.
- POSTGRADUATE MEDICAL SCHOOL OF LONDON.—12 noon, Professor R. A. McCance, F.R.S.: Renal Function Before and After Birth; 4 p.m., Dr. J. Goodwin: Cardiac Arrhythmias.
- ROYAL EYE HOSPITAL.—4.30 p.m., Mr. A. J. Cameron: Virus Diseases of the Eye.
- ST. MARY'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Obstetric and Gynaecological Conference, Tuberculosis in Pregnancy. Speakers, Dr. Raymond Cohen and Dr. W. D. W. Brooks.

Saturday, May 2

- MIDLAND TUBERCULOSIS SOCIETY.—At Yardley Green Hospital, clinical meeting.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Toxicity of Detergents

Q.—What is known about the toxicity of detergents in common domestic use? Are there risks from external contact or ingestion? G. S. Wilson¹ has raised the question of their carcinogenic activity. Is this likely?

A.—In their concentrated form some of the modern detergents are acutely poisonous when given by mouth to animals. A single human fatality has been described.²

They are normally handled in very dilute form for washing and cleaning. Animal experiments have shown that quantities larger than any expected to remain as residues on food from ordinary use can be ingested for long periods without causing toxic effects. There are, however, many different preparations in use, and by no means all have been tested in this way. The possibility that some of these detergents may be carcinogenic is being investigated experimentally at the present time.

Because detergents degrease the skin, are commonly alkaline, and may provoke a sensitization reaction they may sometimes do provoke a severe type of dermatitis from which recovery is slow. It is not easy to protect against these dangers, but there is some prospect of success from the use of acid-buffered creams.³

Hay-fever Desensitization

Q.—(1) An adult male suffers from very severe hay-fever every year. In any year he can be prevented completely from having symptoms by a graduated course of 20 injections of the appropriate pollen extract. These injections are quite painful and cause considerable local reaction, especially at the beginning of the course. How can this be prevented? (2) Alternatively, if after a full course had been completed the patient was given only maintenance treatment in the form of the maximum dose once every two months, would this be likely to prevent his hay-fever?

A.—(1) The discomfort attached to starting each new course could be avoided by starting the initial dose at a much weaker strength—approximately one-tenth of the pre-much weaker strength. Excessively large local swellings should be avoided, not only because they are painful, but because they indicate a nearness to a dose which may cause a severe and even dangerous constitutional reaction. If, following an injection, an excessive swelling occurs the dose should be reduced by one-tenth; if a medium swelling occurs the subsequent dose should not be increased but repeated. It would appear that if the present 20 injections were increased to 25 or 30 injections—a more usual scheme—no reactions might occur, and the course would certainly be safer. The maximum dose is correct as the result is satisfactory.

(2) The perennial treatment suggested is a well-accepted method, but the interval between successive maximum doses (or perhaps, preferably, a submaximum dose) should not exceed one month, for a longer interval gives a definite risk of a constitutional reaction. A few patients tend to have constitutional reactions if the interval is more than 10 to 14 days, even on submaximum doses. It is important to remember that solutions of pollen gradually deteriorate in strength, and, when fresh solutions are obtained in the early months of the year, then the dose must be reduced to about 10% of that used with the old extract. The

maximum dose should then be built up again by weekly injections. About four weeks before the onset of the hay-fever season the injections should again be given weekly.

Moniliasis Following Treatment with Antibiotics

Q.—What is the incidence of generalized moniliasis after antibiotic therapy? After which antibiotic is its occurrence most frequent? What are the symptoms, and what is the treatment?

A.—The exact incidence of moniliasis occurring during the course of treatment with antibiotics is not known. That it is not high is suggested by the fact that the report of a single case still warrants publication. Earlier in this issue two fatal cases are recorded: in the first there was widely disseminated moniliasis and aspergillosis associated with agranulocytosis and antibiotic therapy (p. 918); in the second a monilial peritonitis followed perforation of a duodenal ulcer (p. 919).

The causal organism, the fungus *Candida albicans*, usually behaves as a harmless commensal in the upper respiratory tract, but its potential pathogenicity is shown by its ability to cause thrush, and, much less commonly, to invade the lungs, meninges, endocardium, and the blood stream. The administration of the newer "wide-spectrum" antibiotics (aureomycin, terramycin, and chloramphenicol) in high dosage, and especially when two or more are used simultaneously or in combination with streptomycin or penicillin, can destroy the entire bacterial flora of the respiratory and intestinal tracts; in these circumstances the fungi, which are not sensitive to the drugs, proliferate rapidly and may spread widely. As a rule they cause lesions no more serious than the glossitis and stomatitis which are so familiar and annoying in association with aureomycin therapy, but invasion of the lungs gives rise to a serious illness, with fever, wasting, haemoptysis, and cavitation, which may be mistaken for tuberculosis or, alternatively, may be regarded as an indication for still more energetic chemotherapy. No more specific treatment of the established disease is available than stopping the administration of all antibiotics. This relatively rare complication would be still more rare if it were the rule to give an antibiotic for not more than four days in the absence of a favourable clinical response.

Bathing and Urticaria

Q.—What investigations and treatment are advised for a man who regularly develops an urticarial eruption almost immediately after bathing, both in fresh and salt water? The patient is keen to continue bathing. Can any likely causes be suggested?

A.—The treatment of urticaria due to cold water is unsatisfactory. I presume that this reaction to bathing has come on only recently, so it is probable that some new factor in the patient's make-up has become important. Some cases have been cured after search for and removal of septic foci in teeth, tonsils, or elimination of intestinal parasites, and in many cases a very definite psychological stress has appeared to be the cause. If the urticaria is related only to very cold water, repeated baths gradually decreasing the temperature from day to day have been suggested. If none of these causes is present, the only thing to do is to use one of the antihistaminic drugs before bathing takes place. The patient must, of course, be warned of the possible unpleasant side-effects of such drugs, and a drug should be chosen which does not give unpleasant reactions in the particular patient.

Treatment of Congenital Dislocation of the Hip

Q.—What is the best age for the treatment of congenital dislocation of the hip? What is the prognosis for the development of the acetabulum after reduction? Will any dietary or hormone treatment assist this?

A.—The best age for the treatment of congenital dislocation is unquestionably as early as possible; the difficulty

of treating the condition early enough arises from the difficulty of diagnosis before the child walks. This is largely because the mother does not notice anything wrong with the hip until that time. However, there is a great deal of evidence that treatment in the early months of life is both simple and satisfactory. Shortening of the leg and alteration of the creases of the thigh are the more obvious signs of this condition, and would warrant x-ray examination.

The reformation of the acetabulum after reduction is on the whole satisfactory, and the earlier the reduction the more likely it is to occur. A small percentage of reductions fail to develop a satisfactory roof. Present-day opinion is that these will become subluxated and that a shelf operation is indicated if there is a failure of development of the acetabular roof. No dietary or hormonal treatment is effective.

Oiling Floors and Blankets in Boarding Schools

Q.—Is the oiling of floors and blankets likely to reduce the incidence of upper respiratory infections in boarding schools?

A.—Experience of the use of oiling to prevent the dispersal of dust from floors and bedclothes has been largely confined to hospitals and Army barracks. The results obtained there certainly suggested that the treatment often reduced the spread, at least, of infections due to haemolytic streptococci, but except in one instance the reduction was not great. The treatment might well be expected to help also in controlling the spread of similar infections in schools, but it could not of course alone prevent such spread. The technique of oiling bedclothes¹ and floors² has been described in this *Journal*.

Immobilization in Spinal Tuberculosis

Q.—What is the best way of immobilizing cases of spinal tuberculosis?

A.—Cases of spinal tuberculosis can be immobilized either in a plaster bed or on a spinal frame of the Robert Jones type. The latter is a more efficient method, and such frames can be obtained from most appliance-makers. Immobilization is usually required for not less than two years.

NOTES AND COMMENTS

Dangers of Aluminium Welding.—Dr. H. G. TAYLOR, D.Sc., M.I.E.E., F.Inst.P. (Director of Research, British Welding Research Association), and Dr. E. G. WEST, Ph.D., F.I.M. (Technical Director, The Aluminium Development Association), write: Your issue of March 14 (p. 631) contained an answer to a request for information on the health of welders of aluminium. Experience with this process now extends over some 50 years, so that its health hazards are well understood, and we should be obliged if you would publish our comments on the reply referred to above. The principal risks are the same as in the welding of other metals—for instance, electric shock and injuries to the eyes and skin as indicated in *The Health of Welders*, by A. T. Doig and L. N. Duguid.¹ Reporting a clinical survey of 247 industrial welders engaged on steel welding, these authors state that the abnormal physical signs sometimes found indicate "a mild form of bronchial irritation and are not associated with evidence of pulmonary fibrosis or of impaired exercise tolerance." Although some abnormal x-ray appearances were observed, these were believed to be due to the deposition of fume, which lies inertly in the lungs and disappears when exposure to fume ceases. The x-ray picture was stated, therefore, to be of little significance in itself, which conforms with the suggestions made in your journal about x-ray pictures taken after 10 years of aluminium welding. Hunter, Milton, Perry, and Thompson² found no evidence that the dust of aluminium or of aluminium oxide produced any disease of the trachea, bronchi, or lungs of 92 men engaged in grinding aluminium-alloy aircraft propellers.

An analysis given in the published reply may perhaps give a misleading impression of the nature of fumes produced in welding

aluminium. Fluorine and chlorine in the free, uncombine condition are certainly never present, although there might conceivably be fluorides and chlorides from the fluxes or electrode coatings used. The modern inert-gas shielded welding arc, however, requires no flux or coating, so that such compounds will be absent. In our view it is highly doubtful whether there are any grave risks associated with the production of ozone or oxide of nitrogen in welding, but good ventilation is essential when working in a confined space if for no other reason than to help dissipate the heat generated. Lastly, we must correct the statement that lead is present in aluminium. No commercial aluminium alloy contains more than 0.05% lead, and the alloy which are welded contain much less than this.

REFERENCES

- ¹ *The Health of Welders*, 1951. Factory Department, Ministry of Labour and National Service.
² *Brit. J. Industr. Med.*, 1944, 1, 159.

OUR EXPERT writes: No doubt aluminium welding was tried about 50 years ago, but my information is that a really satisfactory method of doing it was developed about 1938 and that it has only been done on an appreciable scale during the last eight years. The health risks of the welding of steel are well known, but this was not the subject of the question. The remarks by Doig on the clinical and x-ray features of welders apply only to the welding of steel, and he was able to find only one reference to aluminium welding¹ in the medical literature reviewed.

There is no space to review the many articles on the effects of aluminium on the lungs, but the fact is that some writers say that it damages the lungs, while others say that it is harmless. In quoting analyses of fumes, one can only give the results as stated by the investigators, and admittedly such information might be misleading if it is not interpreted correctly by the reader. It should be pointed out, however, that the soluble fluorides as well as free fluorine are toxic. In correcting the statement that lead might be present in aluminium alloys, the writers admit that my statement is correct, by saying that no commercial alloy contains more than 0.05% lead. It is true that Thrysin, Gerhardtsson, and Forssman² found only small amounts of lead in the fume from aluminium welding. But they did find some, and it would be better from the health point of view if there were no lead at all. It is a matter of opinion whether or not "there are any grave risks associated with the production of ozone or oxides of nitrogen in welding." Medical opinion would certainly classify such a risk as grave when many deaths have been reported as a result of welding in confined spaces. The risk is greater with oxyacetylene than with electric arc welding, and less when the shielded arcs are used. Thrysin *et al.*² also point out that the amount of nitrogen oxides developed depends primarily on the length of the arc, on the voltage, and also on the amperage used. The heat generated constitutes, by comparison, a minor risk.

Spinach.—Dr. H. LEHMANN (Tunbridge Wells) writes: Spinach is not richer in iron than other plants. If anything it is poorer in that respect than most vegetables (Hill, R., and Lehmann, H., *Biochem. J.*, 1941, 35, 1190). The widespread misconception is probably based on the fact that its peculiar preparation for the table involves a degree of concentration not applied to any other greens. Cooked spinach corresponds to about ten times its volume as a raw vegetable. One lb. (0.45 kg.) of fresh spinach occupies, after cooking, a volume of 12 fl. oz. (336 ml.); this is three times less than the space taken up by the equivalent amount of cabbage (1½ pints—994 ml.).

COMBINED CHEMOTHERAPY IN BACTERIAL INFECTIONS*

BY

L. P. GARROD, M.D., F.R.C.P.

Bacteriologist, St. Bartholomew's Hospital; Professor of Bacteriology in the University of London

The practice of combining two or even more chemotherapeutic drugs in the treatment of patients is growing commoner, and its merits demand examination. Inquiry soon reveals that the subject is one of great complexity, and that for various reasons these combinations may often be useful, sometimes may be no better than one of the pair used alone, and at least occasionally may be contraindicated because a diminished instead of an enhanced effect results. The laboratory work sometimes required for the intelligent direction of such treatment is perhaps more elaborate and time-consuming than anything previously undertaken in routine clinical bacteriology.

Some Indications for Combined Therapy

The Urgent Undiagnosed Case.—An acutely ill patient evidently suffering from some infection, in whom no bacteriological (and perhaps even no clinical) diagnosis has been made, may require treatment with one antibiotic or another, and it is perhaps tempting to give him both until the situation is clarified. This is often done, but genuine necessity for it should be very exceptional. Premature and blindly directed treatment may obscure the diagnosis, and should not be begun until any specimens have been obtained the examination of which is likely to be helpful.

Mixed and Double Infections.—There are some infections, notably those originating in the bowel, but also including some involving the lungs, the flora of which is so varied that no single drug may be expected to combat the whole of it. In peritonitis due to perforation of the lower part of the bowel treatment with both penicillin and streptomycin has been common practice and is theoretically sound, although I know of no statistical proof of its efficacy. It may well be superseded by the use of the newer antibiotics with their wider range of activity: terramycin, given at first intravenously, has in my experience been particularly effective.

A patient may, on the other hand, have two separate conditions, due to entirely different bacteria: perhaps the commonest of such pairs is a lung infection complicating one of the urinary tract or vice versa. If it should be thought necessary to treat both together no single drug may serve for both, and two may therefore be needed.

Prevention of Toxic Effects.—Another possible indication for using two drugs is the danger of toxic effects from only one. In this category comes the use of sulphonamide combinations—for example, "sulphatriad"—an advantage of which is that each component

*Based on a Holme Lecture delivered at University College Hospital on February 12, 1953.

retains its individual solubility in the urine, with the result that the risk of heavy crystalline deposition and consequent tubular or ureteric blockage is minimized. Among antibiotics, streptomycin is that most liable to produce toxic effects, and any effective combination with it which enabled the dose of streptomycin to be reduced from a risky to a safe level might have this type of advantage.

These three indications are of much less significance than the prevention of acquired resistance and the achievement of synergism.

Prevention of Acquired Resistance

Acquired bacterial resistance is a change which threatens ultimately to extinguish the usefulness of all the present major antibiotics except penicillin. Its gradual development in communities where these drugs are freely available can be delayed in only two ways. One is more discriminating and restricted use, and, to judge by experience hitherto, much cannot be hoped from this direction. The second is to combine with the main drug another with an adjuvant effect. The other may not only exert its own independent effect but prevent acquisition of resistance to the first. Precisely how this is achieved we cannot pretend to say until more is known of the mode of action of antibiotics, but in general terms the mechanism is almost certainly this. Sulphonamides act by blocking a stage in an essential synthesis, and antibiotics probably act similarly. The acquisition of resistance results from a circumvention of this chemical process, another being substituted for it having the same ultimate effect, with which the antibiotic cannot interfere. If the second drug used blocks this second process the alternative metabolic route cannot be established, and the organism therefore remains sensitive.

If this explanation is true, it is perhaps remarkable that so many combinations do act in this way, and it encourages the belief that by this means itself more may be discovered about the points of attack of individual drugs. In practice it may even prove advantageous to use more than two drugs together: Carpenter *et al.* (1945) found that gonococci could be entirely prevented from acquiring resistance to sulphathiazole, rivanol, promanide, and penicillin only by exposing them to all four together, a combination of the first three not being fully effective. Similar *in vitro* studies with antibiotics have been made by Kaipainen (1951, 1952), who has shown that a mutual resistance-preventing relationship exists between streptomycin on the one hand and aureomycin, chloramphenicol, or terramycin on the other. (It does not follow that

these actual combinations will be therapeutically effective, and indeed there is at least a theoretical objection to them on other grounds.) Streptomycin, as the antibiotic to which high resistance is most readily acquired, stands most in need of a partner to prevent this, particularly when it has to be given for long periods, as in the treatment of tuberculosis. Its combination with *p*-aminosalicylic acid, now regarded as obligatory for the treatment of this disease, has been clearly shown to have this effect, provided that the dose of P.A.S. is adequate (Report, 1949; Daniels and Hill, 1952), as well as securing an improved therapeutic response. The combination of streptomycin with isoniazid also militates against the acquisition of resistance to either (Report, 1953).

Synergism

Another notable advantage of combined therapy can be (but by no means always is) the achievement of a synergic effect. This is one of three possible results of combining two drugs, and the terms describing them require definition. In the simplest terms, an additive effect is the sum of those of the same dose of each drug given separately; a synergic effect is something more than this, and an antagonistic effect something less. If these effects can be observed in the form of clinical therapeutic results they are undeniable: if, on the other hand, we are referring to something capable of assessment in the laboratory the definition must be extended by an explanation of what effect is meant. The most easily observed effect is simple inhibition of visible growth, and it is not surprising that so many workers have studied both single and combined effects by this standard only. Unfortunately it is inadequate and misleading for certain combined effects, and a true picture of them can be obtained only by studying bactericidal instead of merely bacteriostatic action, and preferably by following its progress in a series of observations. The definition of synergism proposed by Jawetz and Gunnison (1952a), whose studies of combined drug effects have contributed so largely to our present knowledge, is: "A large increase in the rate of early bactericidal action and the rate of cure of infections beyond that obtainable by simple additive effects of the agents."

An ultimately fatal case of *Str. faecalis* endocarditis was the incentive for Jawetz's (1952) work, and it is in this disease that we find the clearest example of antibiotic synergism yet known. Jawetz and his colleagues showed that when *Str. faecalis* is exposed to an optimal concentration of penicillin the initial bactericidal effect is incomplete and is followed eventually by growth; if, on the other hand, streptomycin is added, even in a concentration quite ineffective acting alone, the initial rate of killing is accelerated and continues to the point of total sterilization (Jawetz and Gunnison, 1950). That this combination of drugs offers the only hope of cure in this infection is now fairly well recognized, and is evident from the extensive series of cases described by Robbins and Tompsett (1951). We have treated four cases of this infection at St. Bartholomew's Hospital: three were included in the four cases of penicillin-resistant bacterial endocarditis reported by Cates, Christie, and Garrod (1951), and the fourth is more recent. The antibiotic sensitivities of the organisms from these patients,

stated in the Table, are strikingly uniform, and would seem to demand some other treatment than that which in fact was required. All four strains were highly sensitive to aureomycin, yet a six-weeks course of this drug was ineffective in Case 1, and an eight-weeks course, during the latter half of which the dose was 8 g. daily, was equally so in Case 2. Case 3 had a 10-weeks course of chloramphenicol, and Case 4 shorter courses of several drugs without effect (most of all this treatment was given elsewhere). The infection was controlled in all four patients by penicillin and streptomycin, although two of the patients died from heart failure, Case 1 after and Case 3 during treatment.

In relation to the task which chemotherapy has to perform, bacterial endocarditis is certainly an exceptional disease and possibly unique. It is not enough, as in most other infections, to prevent further bacterial growth and leave the disposal of survivors to the body defences; this is a disease in which those defences are powerless. It is probably true to say that chemotherapy must eliminate the last surviving streptococcus in the vegetations if relapse is not to occur. That a bactericidal drug (penicillin) should be necessary, or in this particular infection a highly bactericidal combination, is not surprising. There are few reports of cures of this disease by any of the newer antibiotics.

In treating *Str. faecalis* endocarditis we have hitherto assumed that the higher the concentration of each drug that can be maintained in the blood the better, and our patients have accordingly been given large doses of both. The two survivors in the earlier series (Cates, Christie, and Garrod, 1951) both suffered severe vestibular damage from having received 4 g. of streptomycin daily for six and seven weeks, and in our recent case the dose was limited to 2 g. daily in the hope of obviating this effect. There is another possible reason for limiting the dose not of streptomycin but of penicillin. It has been shown by Eagle and Musselman (1948) that *Str. faecalis* is one of the species subject to the zone phenomenon in the bactericidal action of penicillin: the optimum concentration is about 6 µg. (10 units) per ml., and concentrations higher than this kill the organism more slowly. Whether this paradoxical effect operates when streptomycin is also present is of some interest: according to Gunnison, Jawetz, and Coleman (1950) it does not. Strains of *Str. faecalis* from two of our cases were tested to verify this. Both exhibited the zone phenomenon when exposed to penicillin only, a concentration of 10 µg. per ml. killing more rapidly than 500 µg. per ml. When 10 or 20 µg. per ml. of streptomycin was combined with these and intermediate concentrations of penicillin, the much accelerated death rate varied little with the latter, the higher concentrations sometimes giving a slightly faster kill and sometimes not. It appears from these results that little is either gained or lost by massive penicillin dosage in this combination, but there is some suggestion in results obtained by Martin, Chabbert, and Sureau (1953, Table I) by a rather different method that intermediate concentrations are the most effective.

Str. faecalis endocarditis is an exceptional disease, and it may well be asked whether the drug combination required for its treatment is indicated in any other condition. It may be indicated in other exceptional cases which can be identified as requiring it only by elaborate *in vitro* tests: the need for it in mixed infections such as peritonitis has to a large extent been removed by the advent of the new "broad spectrum" antibiotics. The indiscriminate use of penicillin-streptomycin combinations is certainly to be deplored, and it may be thought unfortunate that proprietary mixtures of these two antibiotics, having flourished on the American market for some time, have now been introduced in this country. That these are commercially successful is due to two ideas about them—that they are generally more potent than penicillin itself, and that they afford wider cover in the undiagnosed case. The logical outcome of the latter standpoint would be a chemotherapeutic cocktail supposedly capable of dealing with any microbial infection, and given automatically to any patient with fever. Apart from the general

undesirability of "shot-gun" therapy, the use of streptomycin in patients of whom at least nine-tenths will probably get no benefit from it is to be deprecated on three grounds—the possibility of either toxic effects or sensitization, and the likelihood of evoking bacterial resistance. These and other weighty reasons for discouraging the use of these combinations have been formulated by Jawetz and Gunnison (1952b) in a report published by the Council on Pharmacy and Chemistry of the American Medical Association.

Laboratory Tests of Combined Action

Repeated viable counts in various mixtures and the plotting of death curves constitute a major operation in any laboratory and are almost beyond the capacity of some. A simpler method of determining combined effects must consequently be found if laboratory guidance for such treatment is to be provided. Unfortunately, simple tests of growth inhibition, at least by pairs of antibiotics, seem to be worthless. A few examples from many studies made in this way will show how misleading their results can be. Richter (1952), in a long series of such tests, found that there was not even an additive effect between streptomycin and penicillin acting on *Str. faecalis*, although this is perhaps the clearest example of a synergic combination that we know. Reid, Jones, and Bryce (1952) found that most combinations of five antibiotics acting on four species of Gram-negative bacilli gave an enhanced effect, although one of their combinations, penicillin+chloramphenicol, has been proved by more appropriate methods, including therapeutic tests, to be antagonistic. In some experiments by Bigger (1950) P.A.S. and streptomycin were made under certain conditions to appear antagonistic. Price, Randall, Welch, and Chandler (1949) tested various combinations not only in this way but therapeutically in mice, and obtained agreement between the two methods in only 50% of their results, some being frankly contradictory.

These authors used liquid media; others have hoped to demonstrate synergism even more simply by an agar diffusion method. That this hope is vain may be concluded from the findings of Peyré and Velu (1952), who tested combinations both in plates and in agar columns in tubes, and found that the width or depth of the inhibition zone differed little from that given by the more rapidly diffusing and active of the pair acting alone. It has also been suggested, and found impracticable, to determine combined effect in a plate in which two antibiotics diffuse from paper strips or gutters meeting at a right angle. I have been unable to obtain true or even consistent results in trials of this method. The fact undoubtedly is that mere inhibition of growth, as judged by naked-eye appearance, affords no true reflection of what a combination of drugs does to bacteria. What matters therapeutically is whether the combination kills them, and in a culture showing no visible growth the bacteria may either have been killed within an hour or may even be slowly multiplying.

There is thus no alternative to a method involving the enumeration of survivors after a period of exposure to the drugs. That proposed by Martin, Sureau, and Chabbert (1952) is not unduly complex, and in their hands has afforded a guide to successful treatment. If four antibiotics—for example, penicillin, streptomycin, chloramphenicol, and terramycin—are to be tested singly and in every possible combination, only ten tubes of broth are required, provided that only a single concentration of each antibiotic is to be tested. After incubation for 24 hours or less a measured inoculum from each is spread over a segment of a plate: decimal dilutions of the culture used for inoculation are plated similarly, only four plates being required in all. By comparison with this control it can be seen whether the inoculum in the tubes has multiplied or diminished in numbers: if the latter, the result can be stated as a very approximate percentage surviving.

The difficulty with such a simplified method is to choose appropriate single concentrations of the antibiotics, since to vary them would immediately complicate it: even two con-

centrations instead of one would mean 36 tubes instead of 10. They can evidently be chosen on either of two principles: in relation to the sensitivity of the organism to each used singly or in relation to the concentrations attained in the body by the dosage it is proposed to use. Arbitrary amounts chosen on the latter basis are preferable for routine use. The test is certainly worthy of extended trial as a guide to treatment in difficult cases.

We have recently applied a simple three-tube form of this test to determining whether the penicillin-streptomycin synergy against *Str. faecalis* which can be demonstrated by this as well as by more elaborate methods is also exerted against other species. Some strains of *Bact. coli*, *Proteus*, and penicillin-resistant *Staph. pyogenes* reacted similarly, suggesting that this combination may have uses other than the treatment of bacterial endocarditis.

Sulphonamide-Antibiotic Combinations

I was responsible eight years ago (Garrod, 1945) for a misleading although correct observation—namely, that, as observed by viable counts over an eight-hour period, sulphathiazole reduces the rate at which penicillin kills staphylococci. An explanation of this was not far to seek: penicillin is active only against multiplying bacteria, and another agent which prevents multiplication therefore removes a condition necessary for at least its full effect. The defect of this experiment was that it was terminated too early. Others who have prolonged such experiments have shown that the initial rapid decline produced by penicillin alone may be succeeded by bacterial recovery and actual growth, whereas the slower decline caused by penicillin and a sulphonamide continues and proceeds to ultimate extinction. The explanation for this suggested by Hobby and Dawson (1946) and by Klein and Kalter (1946) is that penicillin reduces the number of living bacteria to a level at which a sulphonamide can exert its full effect: the dependence of sulphonamide activity on bacterial numbers is well known. This is therefore not so much synergy in the ordinary sense as two successive and complementary effects. It is evident from the work of the authors quoted that the result is conditioned by various factors, and, among these, time relationships between the introduction of the two drugs have been particularly studied by Gunnison, Speck, Jawetz, and Bruff (1951), who draw an interesting distinction between the apparent interfering effects of sulphonamides and the newer antibiotics with the bactericidal action of penicillin.

Simple tests of growth inhibition have consistently shown that an enhanced effect is obtained by combining penicillin and a sulphonamide: in this connexion Bigger's (1946) work on *Salm. typhi* may be recalled; Thomas and Hayes (1947) and Stewart (1947) obtained similar results with the same organism, and Bigger (1944) previously showed that they were obtainable with *Staph. pyogenes*. Most authors who have tested penicillin-sulphonamide combinations therapeutically in mice (Ungar, 1943; Soo-Hoo and Schnitzer, 1944; Nitti, Boyer, and Faguet, 1946; Kolmer, 1948; Domagk, 1952) have observed synergic effects. There have been fewer studies of the combined action of sulphonamides and streptomycin, but Klein and Kimmelman (1947) and Knapp (1950) report mutual reinforcement by such combinations, and the former emphasize particularly that the presence of a sulphonamide tends to prevent the development of bacterial resistance to streptomycin.

Clinical experience confirms the general tenor of these findings in two particulars. Waring and Smith (1944) are emphatic that sulphadiazine must be given in addition to penicillin for the treatment of pneumococcal meningitis; 11 out of 12 patients so treated recovered, whereas penicillin alone was less successful. Smith, Duthie, and Cairns (1946) base the same conclusion on a study of 38 cases. The second clear example is provided by the action of streptomycin and sulphadiazine in brucellosis, which was the only effective treatment for this disease until the discovery of aureomycin and chloramphenicol (Spink, Hall, Shaffer, and Braude, 1948; Scowen and Garrod, 1948).

Antibiotic Sensitivities of Four Strains of *Str. faecalis* Isolated from Cases of Endocarditis; St. Bartholomew's Hospital, 1950-2

Sex	Age	Inhibitory Concentrations (µg./ml.)			
		Penicillin	Streptomycin	Aureomycin	Chloramphenicol
F	36	2.5	30	0.15	20
M	57	1.8	30	0.1	6
M	63	2.5	125	0.15	2.5
F	25	2.5	10	0.3	0.6

Antagonistic Effects

Although interference by sulphonamides with the action of penicillin is only apparent, interference by other antibiotics due to a similar mechanism is not merely demonstrable in a similar way *in vitro*, but verifiable by therapeutic tests. That aureomycin may interfere with the action of penicillin or streptomycin was first shown by Lankford and Lacy (1949), but most of our now extensive knowledge of this subject is due to the work of Jawetz and his colleagues, which has been summarized in recent reviews (Jawetz, 1952; Jawetz and Gunnison, 1953). The stages in the development of this work were as follows. It was first shown that chloramphenicol interferes with the bactericidal action of penicillin *in vitro* (Jawetz, Gunnison, and Coleman, 1950), and later that aureomycin and terramycin have a similar interfering effect (Gunnison, Coleman, and Jawetz, 1950). The interfering action of chloramphenicol had meanwhile been confirmed therapeutically (Jawetz and Speck, 1950): mice infected with *Str. pyogenes* and treated with both chloramphenicol and penicillin had a lower survival rate than those treated with the same dose of either drug alone. The objection that such acute experiments, in which only a single dose of the drug or drugs is given, are far removed from the conditions of clinical use appears to be answered by later studies (Speck and Jawetz, 1952) of a subacute streptococcal infection produced by intramuscular inoculation, of which control mice died in five to eight days. Although treatment was continued for five days, the same type of effect was observed, chloramphenicol and particularly terramycin reducing survivors to as low as 45% when combined with a dose of penicillin which alone saved 100%. In another series of experiments, both *in vitro* and *in vivo*, it was shown that the newer antibiotics also interfere with the action of streptomycin, chloramphenicol having the most pronounced effect (Jawetz, Gunnison, and Speck, 1951a).

The explanation of these findings is as follows (Jawetz and Gunnison, 1952a). Antibiotics are divisible into two classes:—Group 1 (bactericidal): penicillin, streptomycin, bacitracin, neomycin. Group 2 (bacteriostatic): aureomycin, chloramphenicol, terramycin.

Combinations within group 1 are often synergic. Within group 2 they are no more than additive. Combinations of the two groups are apt to be antagonistic, the group 2 drug interfering with the bactericidal action of the other. Such antagonism is observed only when the organism is fully sensitive to the bactericidal component: if it is more resistant (although naturally not if completely so) the combination may actually be synergic. Instances of this paradoxical effect are cited by Jawetz, Gunnison, and Speck (1951b), and by Spies *et al.* (1951); both patients had staphylococcal endocarditis, and the successful combinations were terramycin-streptomycin and penicillin-aureomycin respectively.

These patients afford striking confirmation of one aspect of the Jawetz theory. What evidence is there of the clinical reality of antagonism? Certainly the clearest is the experience of Lepper and Dowling (1951) in the treatment of pneumococcal meningitis. Alternate cases were treated with penicillin alone and with penicillin + aureomycin, the penicillin being given intramuscularly only in a dose of 1,000,000 units two-hourly. Of 14 patients given penicillin only 3 died (21%), and in a total of 43 patients so treated 13 died (30%), whereas only 3 out of 14 receiving combined treatment recovered, a mortality of 79%. A similar though less emphatic conclusion may be drawn from the findings of Lepper *et al.* (1952) in meningococcal meningitis: here there was almost no mortality, but the duration of fever and of "mental abnormality" seems definitely to have been prolonged by combining aureomycin with penicillin. It has been remarked by several authors that conditions in the meninges are ideal for antagonism, critical concentrations for this effect being maintained fairly constantly in an area where efficient bactericidal action is probably imperative. Whether antagonism occurs in other situations it is the task of future clinical observation to decide.

Complexity of the Problem

We have seen that there are several specific instances in which drug combinations are clearly indicated either because they delay the acquisition of bacterial resistance or because they exert a synergic effect. In pyogenic meningitis we have a disease in which certain combinations are contraindicated because their effect is antagonistic, and future clinical appraisal may possibly decide that these combinations are either contraindicated or at least without advantage in other conditions. But these conclusions refer to only a few specific and (except tuberculosis) uncommon infections, and leave the general question of the usefulness of combined therapy in everyday medicine unanswered.

It is strongly emphasized by Jawetz and Gunnison (1952b) that no general rules about synergism and antagonism can be laid down. The same pair of antibiotics may exhibit either effect against different organisms, according to their degrees of sensitivity. Other authors have found that the same pair may be either synergic or antagonistic against the same organism according to the concentrations used. The whole of this account of this subject has in fact been oversimplified, for the sake of brevity, by omitting mention of many factors which have been shown to determine the results of combined action.

In any serious case an *ad hoc* effort to provide a rational basis for treatment should be made by laboratory experiment, and the simplified test of bactericidal action proposed by Martin, Sureau, and Chabbert (1952) may afford useful indications with little delay. On the other hand, more elaborate proceedings may be very advisable, and I calculate that various studies in connexion with our last case of enterococcal endocarditis occupied well over 100 hours of laboratory time. I have contended for many years that the action of chemicals, whether simple germicides or chemotherapeutic agents, on bacteria can be determined in the laboratory in such a way as to provide a reliable guide to their use. I still adhere to this view, but I begin to doubt whether such determinations in connexion with combined antibacterial action are practicable. The feasibility of attaining a significant result from a reasonable amount of any such work depends on the number of variables involved. It might be supposed that the introduction of a second drug merely adds one more variable, and this is true in a sense, but drug interactions are so complex that it does no justice to the result. The bacteriologist who tackles individual problems of this kind seriously is facing what I believe to be the most complicated task in the whole of routine laboratory medicine.

I am indebted to Dr. Bernard Sureau and Dr. Ernest Jawetz for the privilege of reading their papers before publication, and for helpful discussions with both and with colleagues of the former, and to my clinical colleagues, particularly Professor R. V. Christie, for permission to cite their cases.

CLINICAL TRIAL OF A NEW
ORAL DIURETIC

BY

A. G. SPENCER, M.D., M.R.C.P.

Assistant, Medical Unit,
University College Hospital Medical School, London

AND

H. G. LLOYD-THOMAS, M.B., B.Chir., M.R.C.P.
Assistant Registrar, University College Hospital, London

In a search for a potent non-toxic oral diuretic, Kattus, Newman, and Franklin (1951) tested for diuretic activity in dogs a series of compounds derived from the uracil nucleus. One compound, 1-propyl-3-ethyl-6-aminouracil, was found to be an effective diuretic, and produced only a minor degree of gastro-intestinal disturbance. Papesch and Schroeder (1950) had previously synthesized this substance, and for convenience it is referred to by their serial number, S.C.2614. The structural formula is:

Kattus, Arrington, and Newman (1952) subsequently reported that compound S.C.2614 was an effective diuretic when given by mouth to dogs, to normal human subjects, and to patients with oedema. No serious toxic reactions were noted in their studies.

The present report describes an investigation into the effectiveness of compound S.C.2614 as an oral diuretic when given to normal human subjects and to patients with renal or cardiac disease.

Chemical Methods.—The daily renal excretion of protein was determined by micro-Kjeldahl estimation of the protein precipitate obtained from centrifuged aliquots of the 24-hour urine. The other chemical methods have been described previously (Spencer and Franglen, 1952).

Effect on Normal Subjects

Observations on the diuretic effect of S.C.2614 were made during ten tests on nine normal males aged 21–35 years.

These subjects were ambulant and took their normal diet. Urine was collected over two 24-hour periods; the first period being the control day, and the second the test day on which 1,250 mg. of S.C.2614 was taken by mouth in 125-mg. tablets over a period of six hours. The renal excretion of water, sodium, chloride, and potassium was measured on each day, and the results are summarized in Tables I and II.

TABLE I.—Effect of Compound S.C.2614 on Normal Subjects. The 24-hour Renal Excretion of Water and Sodium on a Control Day Compared with that on a Day when 1,250 mg. of S.C.2614 was Taken by Mouth. Ten Tests on Normal Subjects

Subject	Renal Excretion in 24 Hours			
	Water (ml.)		Sodium (mEq)

TABLE II.—Effect of Compound S.C.2614 on Normal Subjects. The 24-hour Renal Excretion of Water and Sodium on a Control Day Compared with that on a Day when 1,250 mg. of S.C.2614 was Taken by Mouth. Means and Standard Deviations of the Data from Ten Tests on Nine Normal Subjects

	Water (ml.)	Sodium (mEq)	Chloride (mEq)	Potassium (mEq)
Control day . .	1,573 S.D.=460	153 S.D.=29	166 S.D.=32	71 S.D.=9
S.C.2614 day . .	2,631 S.D.=530	341 S.D.=28	378 S.D.=66	97 S.D.=28
Mean difference	+1,058	+188	+212	+26
Mean diuresis as % of control	161	222	227	136
Level of significance	P=0.01	P=0.01	P=0.01	P=0.02

In nine of the ten tests there was a considerable increase in the urine volume and excretion of sodium and chloride on the test day. One subject did not show a significant water diuresis, although his excretion of sodium on the test day was 178% of that on the control day. For all the ten tests the mean excretions on the test day compared with the control day were: water, 161%; sodium, 222%; chloride, 227%; potassium 136%. In these tests the water diuresis in response to oral S.C.2614 was equivalent to that reported by Blumgart *et al.* (1934) for mercurial diuretics when given by intramuscular injection to normal subjects. The effect of oral S.C.2614 on sodium excretion also compared favourably with that reported by Kattus *et al.* (1952) for a 2-ml. injection of a mercurial diuretic in a comparable series of normal subjects, and was much greater than that which was produced by 1.2 g. of aminophylline by mouth.

Toxic Reactions.—Two subjects complained of epigastric pain and abdominal discomfort, one of anorexia, and two of tinnitus. During the administration of S.C.2614 there was no significant change in the low normal rate of daily excretion of protein in the urine, and in no case did urine microscopy show any abnormality.

Effect on Patients: Method of Investigation

The patients were not deliberately selected, and included those with every degree of fluid retention, from little or no pitting oedema to gross anasarca. Fifty tests were completed on 30 patients, 22 with cardiovascular and 8 with renal disease. All patients were confined to bed and, except when otherwise stated, were given a standard hospital low-salt diet (10–25 mEq) of sodium and a measured fluid intake of 30–50 oz. (850–1,420 ml.). There was a preliminary period of observation of at least six days in which to

detect and exclude those patients who were undergoing a spontaneous diuresis in response to rest in bed and the low-salt diet. Patients treated with digitalis were observed for a longer period, usually one to three weeks, so as to avoid confusion with the diuretic effect of this drug.

TABLE III.—Effect of Oral S.C.2614 on Patients with Cardio-vascular or Renal Disease

The daily renal excretion of water, sodium, potassium, and chloride ions was measured for three to eight days before the test, on the test day, and for a variable time afterwards. On the test day, starting at 9 a.m., compound S.C.2614 was given by mouth in 125-mg. tablets, two every three hours until 1,250 mg. had been taken. The deposits from the centrifuged urine were examined microscopically in the control period and on the test day. The 24-hour excretion of protein in the urine of 26 patients was also measured.

An approximate comparison of the effectiveness of oral S.C.2614 with a 2-ml. intramuscular injection of mersalyl B.P. was obtained by testing both diuretics in 22 patients. There was an interval of at least four days between the two tests, and nine of the patients received the mersalyl injection before the S.C.2614 tablets, while the others were given the S.C.2614 tablets first.

Two tests were invalidated by errors in urine collection, and three patients were given a diet containing approximately 40 mEq of sodium a day, instead of the standard diet containing 10–25 mEq of sodium. The main results of 47 tests, together with a summary of the clinical condition of the patients, are given in Table III.

Assessment of Diuresis

There were formidable difficulties in the assessment of a diuretic response. The test patients differed in the nature of their disease, in the causation of their oedema, in renal function, and in many other variable factors important in the differential distribution of body fluids, such as the concentration of the serum albumin and that of the plasma sodium. Not only did the patients necessarily differ among themselves but there was a considerable variation from day to day in the same patient of the renal excretion of water and electrolytes. This was still the case when the input was constant within the limits of a standard low-salt diet. The prolonged period of observation, necessary to detect and exclude those patients undergoing a diuresis in response to rest and other forms of treatment, produced two further difficulties. First, many patients lost their pitting oedema before the test; and, secondly, the remaining patients with oedema were no longer a representative series, and in fact many were particularly resistant to all forms of treatment. This selection of patients reduced the chance of a successful diuresis in response to compound S.C.2614; but when such a diuresis occurred it could be attributed with more confidence to the drug.

A successful diuretic response has been defined as one in which all the following standards were exceeded on the test day: a urine volume of 70 oz. (1,990 ml.) containing 75 mEq sodium; an excess renal excretion over the intake of 30 oz. (850 ml.) of water and 50 mEq sodium; an excretion of 150% of the mean control values for both water and sodium, with increments greater than four times the mean deviations.

Results in Patients with Heart Disease

Thirty-four tests were completed on 20 patients with heart disease: four with chronic rheumatic carditis and valvular disease, one with constrictive pericarditis, and fifteen with hypertension or disease of the coronary arteries (Table III). The mean results for all the tests on cardiac patients are given in Table IV.

However, these average figures do not represent the true clinical response to compound S.C.2614. The data are abnormally distributed within the series, so that the average figures are misleading. On applying the strict criteria of a

TABLE IV

No. of Patients	No. of Tests	Water Excretion		Sodium Excretion

10	22	19	1,070 ml.	2,530 ml.	23 mEq	121 mEq

successful diuretic response which we have previously defined, it is apparent that of the 34 tests 20 were successful; but these 20 successful tests occurred in only 10 patients. This series has therefore been subdivided into three groups:

(a) *Oedematous Patients Without Evidence of Sodium Depletion* (Table V).—The diuretic response to S.C.2614 in this group of patients was very satisfactory, and, as will be shown later, the results were comparable with those obtained from intramuscular mersalyl. An example of a successful series of diuretic responses is given in the accompanying Chart.

The effect of oral S.C.2614 and of intramuscular mersalyl (2 ml.) on an oedematous patient with congestive cardiac failure. The daily balances of water, sodium, potassium, and chloride ions. Intake 20 mEq sodium and 1,000–1,200 ml. of water a day. Input plotted upwards from the base lines and output downwards from the level of the input, so that the black columns represent the daily negative balances.

(b) *Oedematous Patients with Sodium Depletion.* (Plasma sodium below 132 mEq, or a recent large abdominal paracentesis.) (Table VI).—There was no successful diuretic

response in this small group of patients. One subsequently had a good diuresis following an injection of mersalyl.

(c) *Patients Without Pitting Oedema* (Table VII).—Although none of this group of patients had a good diuresis in response to oral S.C.2614, there was a noticeable effect on water and sodium excretion. This was approximately half of that obtained in those patients with oedema and no evidence of sodium depletion.

Comparative Efficiency of Oral S.C.2614 with Intramuscular Mersalyl

Because patients differed widely in their response to a single diuretic, and as the response of the same patient also varied from day to day, it was extremely difficult to obtain a reliable comparison of the relative effectiveness of two different diuretics. In the twin tests of oral S.C.2614 and intramuscular mersalyl (2 ml.) the order in which the diuretics were tested obviously affected the result (Table VIII).

TABLE VIII.—Efficiency of Oral S.C.2614 Compared with a 2-ml. Intramuscular Injection of Mersalyl in Patients with Cardiac Disease

	No. of Tests	S.C.2614 Mean Diuresis			Mersalyl Mean Diuresis		
		Water (ml.)	Sodium (mEq)	Successes	Water (ml.)	Sodium (mEq)	Successes
Mersalyl first..	9	1,760	43	4	2,353	97	8
S.C.2614 first..	13	2,146	81	8	2,173	63	5

When mersalyl was given first it produced twice as many successful diuretic responses as did the subsequent tests of S.C.2614, and the mean excretion of water and of sodium in response to mersalyl was much greater. When compound S.C.2614 was tested first it produced eight successful diuretic responses compared with five by mersalyl, but the mean excretion of water and of sodium was of the same order for both diuretics. For both groups of tests the mean excretion of water and of sodium was, for mersalyl 2,260 ml. of water and 80 mEq of sodium; for S.C.2614 1,950 ml. of water and 62 mEq of sodium. It appeared, therefore, that although compound S.C.2614 was an effective diuretic in the oedematous patients it was not generally such a potent diuretic as a 2-ml. intramuscular injection of mersalyl.

This conclusion is supported by a comparison of the data available for compound S.C.2614 with those published for mercurial diuretics in patients with heart disease (Table IX). The approximate relative efficiency of various diuretics compared with intramuscular mercurials (100%) appears to be: intravenous mersalyl, 120–140%; mersalyl suppositories, 40%; "novurit" suppositories, 80%; oral "unephral"

TABLE IX.—A Comparison of the Response to Various Diuretics in Patients with Heart Disease. Urine Volumes (ml.) on the Test Day

Oral S.C.2614	Oral Mercurials	Mercurial Suppository	Intramuscular Mercurials	Intravenous Mersalyl

³ Present series, all cases. ⁴ Thomson (1937).
⁵ Present series, oedematous cases. ⁶ Approximate efficiency compared with intramuscular mercurial diuretics used with theophylline and ammonium chloride.

(formerly "neptal"), 70%; oral mersalyl, 60%; oral S.C.2614, 70-110%. The mercurial diuretics contained theophylline and were given in conjunction with ammonium chloride.

Results in Patients with Renal Disease

There were 13 tests of compound S.C.2614 on seven patients, and in only two was there a successful diuretic response (Table III). Two successful responses were obtained from a patient with diabetic nephrosclerosis, and four from a patient with chronic nephritis, but the oedema in the latter case was probably produced in part by congestive heart failure.

Toxic Reactions to Oral Compound S.C.2614

Gastro-intestinal disturbances were reported by 9 of the 39 subjects who were given compound S.C.2614. The complaints were: epigastric discomfort, 9; anorexia, 8; nausea, 7; vomiting, 4. Apart from the four patients who each vomited on a single occasion, the symptoms were mild and did not interfere with the administration of the tablets.

Two normal subjects complained of tinnitus. One patient had a transient sparse urticarial eruption.

Routine microscopy of the urine did not show any alteration in the pattern of the organized deposit following the administration of S.C.2614.

Patients with gross albuminuria often showed a pronounced increase in the 24-hour excretion of urinary protein on the day in which S.C.2614 was given.

Comment

The therapeutic value of a new drug, and its toxic effects, can be assessed only by a prolonged study of its action on a large number of patients. Such a large-scale clinical trial would be justified by the unqualified success of the drug in a pilot experiment. The present trial of S.C.2614 appeared to show that, in a divided dose of 1.25 g., it was an effective oral diuretic in 70% of patients with cardiovascular disease, provided there was definite oedema and no evidence of sodium depletion. In this group of patients oral S.C.2614 was usually about 80% as effective as a 2-ml. intramuscular injection of mersalyl, preceded by ammonium chloride. There was seldom a useful diuretic response to S.C.2614 in the absence of oedema or in patients who had a low plasma sodium, a serum albumin below 2 g. per 100 ml., or a blood urea over 150 mg. per 100 ml. Intramuscular mersalyl was also generally less effective in these patients, but usually more successful than S.C.2614. There was not enough evidence to assess the value of S.C.2614 in patients with renal disease, but there were some good diuretic responses.

This useful diuretic action of S.C.2614 was seriously offset by the high incidence of gastro-intestinal disturbance following the ingestion of the tablets. Although these symptoms were rarely severe, they were sufficient to elicit a spontaneous complaint from 23% of the test subjects. We have therefore begun a pilot trial of a related aminouracil compound which is believed to be less toxic than compound S.C.2614 (Winter, personal communication). For these reasons it is thought that extensive trials of compound S.C.2614 are not justified at the present time.

An effective non-toxic diuretic would undoubtedly be useful in domiciliary practice and when the mercurial diuretics are contraindicated. Further studies of the aminouracil compounds may therefore be profitable, either by themselves or in conjunction with other diuretics.

Summary

A new oral diuretic, an aminouracil compound designated S.C.2614, was tested 57 times in 36 subjects in a divided dosage of 1.25 g.

In normal subjects there was a satisfactory diuresis in nine out of ten tests. Expressed in relation to the

mean excretion on the control days the mean diuresis was: of water, 161%; sodium, 222%; chloride, 227%; and potassium, 136%.

In 22 tests on 10 oedematous patients with heart disease there was a good diuretic response in 19, with a mean urine volume of 2,530 ml. containing 121 mEq of sodium; water excretion 236%, and sodium 520% of the control days. This was 80% of the diuretic effect of a 2-ml. intramuscular injection of mersalyl B.P. in the same group of patients.

Compound S.C.2614 usually failed to produce a satisfactory diuresis in any other group of patients. There were 19 failures in 25 tests on 17 patients. No useful diuresis occurred in cardiac patients without pitting oedema, in patients with a low plasma sodium, a serum albumin below 2 g. per 100 ml., or a blood urea over 150 mg. per 100 ml.

There was not enough evidence to assess the effect of S.C.2614 in patients with renal disease, but there were a few useful diuretic responses.

The high incidence (23%) of gastro-intestinal disturbance provoked by S.C.2614 was regarded as a serious disadvantage, although such symptoms were usually mild.

Further studies are in progress with a related aminouracil compound which may prove to be less toxic than S.C.2614.

We gratefully acknowledge the help given by Professor M. L. Rosenheim and the physicians of University College Hospital; by the nursing staff, the normal test subjects; by Mr. G. T. Franglen, who did some of the earlier chemical estimations; and by Dr. Irwin C. Winter, of G. D. Searle and Co., for information and supplies of the aminouracil diuretics.

Since the publication of the Curtis Report (1946) and the carrying out of its recommendations for children "taken into care," increasing attention has been given to children neglected or ill-treated in their own homes. The National Association for Maternity and Child Welfare, in collaboration with other bodies, has issued a short report, *Child Neglect and the Social Services*, on the present position and future possibilities for dealing with child neglect or ill-treatment in the home. It is estimated that the 80,000 problem families in England and Wales contain upwards of 250,000 children. A joint circular issued by the Home Office and the Ministries of Health and Education in 1950 drew attention to the powers of local authorities under the Children Act, the National Assistance Act, and the Education Acts. The circular suggested that officers should be designated to be responsible for enlisting the interest and co-operation of local services concerned with the welfare of children in their homes, that these officials should meet regularly officers of local authorities and other responsible organizations, and that cases of child neglect and ill-treatment should be reported to the designated officer. The report is obtainable from the National Association for Maternity and Child Welfare, at Tavistock House North, Tavistock Square, London, W.C.1, price 2s.

CONTROLLED HYPOTENSION IN NEUROSURGERY WITH HEXAMETHONIUM AND PROCAINE AMIDE

BY

DAVID ASERMAN, M.D., D.A.

Anaesthetist, the National Hospital, Queen Square, London

The two greatest difficulties with which the neurosurgeon has to contend are haemorrhage and increased intracranial tension. It is now becoming possible for the anaesthetist to give him the great advantage of working in an almost bloodless field and with a brain shrunken to an easily manageable size; but these benefits are bought at the price of certain dangers. This paper attempts to outline the methods of lowering the blood pressure, to give a list of the main dangers that may be encountered, and to suggest measures for countering them.

Methods of Controlling Blood Pressure

Hexamethonium Bromide (or Iodide).—This is the drug in common use for the induction of hypotension. Its great disadvantage is that it has a failure (or partial failure) rate of some 40%.

Procaine Amide.—This is used extensively in cardiac and thoracic surgery for the elimination of cardiac irregularities. A common side-effect is to cause a slight lowering of the blood pressure, and W. D. M. Paton (personal communication) has suggested that this may be due to a weak ganglion-blocking effect. There often follows a small decrease in the pulse rate, which connotes possibly a decrease in cardiac output. When a case fails to respond satisfactorily to hexamethonium a suitable dose of procaine amide will with a high degree of probability convert it into a successful case of hypotension. The reason for this a potentiation is not clearly understood. It may be due to a simple synergistic action or to the effect of a reduced cardiac output, or to a combination of these factors.

Posture.—This plays an important part in the management of the case. Before the administration of the hypotensive drug the patient is placed in an anti-Trendelenburg tilt of 25 to 30 degrees. This will usually reduce the blood pressure by about 10 mm. Hg. The tilt is decreased during the course of the operation if the blood pressure falls too low. Post-operatively the blood pressure is prevented from rising too rapidly or from falling too low by altering the position of the patient. As an example of the delicacy of blood-pressure control by means of posture, we operated on a few cases on a table which did not have a foot-rest (to prevent the patient sliding down the table). The patients were arranged with the head slightly raised, the body almost horizontal, and the legs hanging over the end of the table. In each case when it became necessary at the end of the operation to increase the blood pressure the mere act of raising the legs to the horizontal position caused a rise of 15 to 20 mm. Hg within a few minutes. In only two cases has it been necessary to resort to methylamphetamine hydrochloride to raise the blood pressure post-operatively.

Dangers of Hypotensive Anaesthesia

1. Allowing the Pressure to Drop too Low

It cannot be said with certainty how low the pressure may be dropped with safety. Pressures below 60 mm. may result in liver damage. Still lower pressures may be associated with anoxia, thrombosis, or even death. One

fatal case probably falls into this category, but with the added results of "retractor anaemia," under which heading it is described.

2. Anoxia

Although there is no supporting evidence, it is possible that a slight degree of cerebral anoxia may be present during hypotension because of the reduced amount of blood passing through the brain. The colour of the brain and blood does not suggest that this is so. Siguier *et al.* (1951) state that the electroencephalogram shows no evidence of anoxia. During direct electroencephalographic recordings of the cortex I have deliberately produced a slight degree of anoxia (without hypotension), and the tracings have shown no changes from the normal. The claim of Siguier *et al.* would therefore seem to be valueless. Nor do tracings under hypotension show variations from the normal. There is evidence to suggest that the blood flow through the brain is less than is indicated by the brachial blood pressure, and that therefore the danger of anoxia may be greater than would appear on the surface.

A man of 20 was having his frontal lobe amputated for epilepsy. His blood pressure before operation was 126/84. An inexplicable rise to 160/120 after induction was lowered to 154 by 50 mg. of hexamethonium, and to 134 by a further dose of 50 mg. All this time, as was to be expected, a good deal of bleeding was going on and the dura was tense. At this stage 400 mg. of procaine amide was given intravenously, and within a few minutes the bleeding had stopped and the brain had retracted from the dura. Yet the blood pressure was 118.

It is hoped to obtain further knowledge on this point by taking blood pressure readings from a cerebral artery. No definite evidence of anoxia has appeared in any cases in the present series, yet its results may possibly have been masked by surgical trauma.

3. Thrombosis

This is an ever-present danger and may occur with even a small drop in blood pressure. Many cases have been reported under this form of anaesthesia. There were no cases of thrombosis in the present series.

4. Reactionary Haemorrhage

In general surgery, under hypotension, reactionary haemorrhage has been one of the most frequent complications. In neurosurgery it is apt to occur under any type of anaesthesia. It has occurred in only one case in this series.

A woman of 54 had an angioma removed in the morning. After an early recovery she became drowsy towards evening and showed signs of intracranial bleeding. On reopening the flap a small subdural clot, together with a quantity of blood-stained fluid, was evacuated. The surgeon felt doubtful whether this was a true haemorrhage. The patient had no further trouble and made a good recovery.

5. "Retractor Anaemia"

So far as I know this condition has not up to the present been recognized, and for that reason and because of its importance it is dealt with at some length. In the series there were three deaths attributable directly or indirectly to the anaesthetic. All three showed evidence of "retractor anaemia," two of them to a marked degree.

When hypotension is induced the brain retracts within the cranial cavity, leaving a clear space between it and the cut edge of the dura. At the same time its consistency is completely altered. It has lost all tone and behaves like soft dough. When pressure is applied it is easily compressed, and on release is slow to regain its normal conformity. Blood is forced out of those parts of the brain on which the pressure is exerted, and because of the small blood flow the vessels are only slowly replenished on removal of the pressure. It can be seen that pressure by a brain retractor may be transmitted even to comparatively

distant parts of the brain, thereby depriving those areas of their blood supply and thus causing irreversible and possibly widespread damage.

A man of 35 had a pituitary adenoma removed. He recovered well from the operation and anaesthetic and was responding within a few minutes of the end of the operation. His condition continued to be satisfactory, giving no cause whatsoever for anxiety, when suddenly, eight hours later, he died. The post-mortem findings were: "Cranium and contents: Haemorrhage had taken place around the bone-flap and no haemorrhage was present under the dura. The convolutions of the cerebral hemisphere were flattened and there was some herniation of the right hemisphere under the falx. A marked degree of tonsillar herniation through the foramen magnum had occurred. . . . Haemorrhage had taken place into the remaining portions of the tumour and into the right frontal lobe. The right frontal lobe was soft in consistency. The right cerebral hemisphere was greatly enlarged, particularly anteriorly, and herniated under the falx. . . ."

The striking part of this report is the great enlargement of the right hemisphere, particularly the anterior part of it—so great, in fact, that part of the lobe had to be accommodated under the falx. (The craniotomy was of course performed on the right side.) The enlargement is undoubtedly due to acute oedema, which, in its turn, is caused by vascular damage. Had vascular damage been caused by hypotension and anoxia due to the anaesthetic one would have expected enlargement of both hemispheres. There seems, therefore, little room for doubt that the damage was caused by retractor pressure. A second death occurred in the following case.

A man of 42 with a right frontal glioma had had his frontal lobe amputated. Post-operatively he did not regain consciousness, and died the following morning. His blood pressure, by an unfortunate chain of circumstances, had been allowed to remain too low, and at the time we attributed his death to this cause. The post-mortem examination showed: "Cranium and contents: no evidence of thrombosis was seen in the venous sinuses. The convolutions of both cerebral hemispheres were flattened and the sulci shallow. The right hemisphere was much larger than the left and had herniated under the falx cerebri. It filled the cranium, although the frontal lobe had been amputated for the removal of a calcified glioma. On the right the hippocampus herniated through the tentorium cerebelli, pushing the right communicating artery downwards, and portions of the hippocampus lay on either side of the vessel. There was no marked degree of tonsillar herniation. A large amount of blood had collected in the cisterna magna. The right frontal lobe had been amputated, but the right hemisphere filled the cranial cavity on this side and herniated to a very marked degree under the falx. . . ."

Here we have a picture very similar to the previous case. Amputation of the frontal lobe is a comparatively innocuous procedure which as a rule causes little or no upset to the patient. A persistent low blood pressure would be expected to cause more generalized changes in the brain. The pronounced changes on the right point once again to the extreme vulnerability of the brain in the hypotensive state, to retractor pressure. A third death occurred in the following case.

A man of 39, with a pituitary adenoma, was one of the early cases in the series; we were then not seriously concerned if the blood pressure fell to below 60. In this case it dropped to 40, and, in spite of reducing the tilt, did not rise more than a few points. He failed to come round after the operation, developed decerebrate rigidity, and died the following day. A post-mortem examination revealed the following: "On removing the skull vault the dura was under marked tension and the underlying brain obviously swollen. . . . On cutting the brain there was marked oedema throughout both hemispheres. . . . Pathological report: " . . . Examination revealed a haemorrhage 2 cm. in diameter situated at a low level in the right cerebral peduncle. . . ."

Bilateral enlargement of the hemisphere suggests generalized brain damage by too low blood pressure. The haemorrhage into the peduncle may have been caused by retractor pressure. Several of the earlier cases were operated on under very low pressure without obvious ill effects, and, while this is no argument that the patient did not die as a result of the damage due solely to low blood pressure, retractor pressure cannot be entirely dissociated as an additional factor.

An interesting comparison with the preceding examples is provided by a case which terminated fatally, a result for which the anaesthetic could in no way be held responsible.

A woman of 56 was being operated on for removal of a phenoid wing meningioma. In the course of the operation the surgeon accidentally opened a big vessel, causing a profuse and rapid loss of blood. In due course the haemorrhage was arrested by clipping two large arteries. During this period the condition of the patient had been fairly satisfactorily maintained by rapid replacement of blood and, of course, by levelling the table. By the end of the operation she was responding well and her general condition was quite good. However, she gradually deteriorated, and died the same day. The necropsy report was as follows: "The cerebral convolutions of both hemispheres were flattened. The right cerebral hemisphere was enormously enlarged and had herniated under the falx cerebri. The adjacent sides of the fronto-temporal lobes had been removed. The fronto-parietal part of the hemisphere was very soft in consistency. Clips were present on the right middle and right anterior cerebral arteries. A considerable degree of hippocampal herniation had taken place on the right side. . . . An extensive infarction was present in the region supplied by the right middle cerebral artery. . . . The hypothalamus on the right side did not appear to be infarcted. . . ."

This picture is strikingly reminiscent of the previously described cases. Each shows the result of widespread ischaemia of the brain, in one case by clipping arteries, in the other cases by retractor pressure on the brain.

Two cases of pituitary adenoma show post-operative signs which may have been due to retractor pressure. As a rule these patients proceed to an uneventful recovery.

A man of 49 made a good immediate recovery, but had a stormy convalescence. On discharge the final note read: "This man has made an excellent recovery following aspiration of a cystic chromophobe adenoma; however, he remains retarded and still has pathological extensor plantar responses. Post-operatively he has some ataxia of his gait and left arm."

A man of 64 was in coma for two hours after operation. He remained drowsy and incontinent after initial improvement. The final note said: "He is alert, fully orientated as regards time, place, and person. He remains, however, quite still, a little sleepy, more than normal."

Technique

Premedication consists of atropine only, given half an hour to an hour before operation. The patient is induced with thiopentone, 0.5 to 1 g., followed by a short-acting relaxant and 50 to 100 mg. of pethidine intravenously. An endotracheal tube is then introduced and anaesthesia is maintained on a nitrous oxide and oxygen mixture with periodic injections of 15 to 20 mg. of pethidine. Rarely, very small quantities of trichlorethylene are added.

Of the relaxants I prefer gallamine triethiodide to succinylcholine chloride, as the duration of action of the latter is so short that introduction of the endotracheal tube will often start a bout of coughing. Gallamine triethiodide allows time for the pethidine to come into action, so that one is rarely bothered by this disturbance. Succinylcholine chloride has the advantage so far as relaxation of the cords is concerned.

In all craniotomies an intravenous drip is put up; in cases in which excessive haemorrhage is anticipated the drip is duplicated. The patient is placed on the operating table, which is then put into an anti-Trendelenburg tilt of 25 to 30 degrees. The head is cleaned and draped, and at this point the hexamethonium compound is injected. If a local analgesic is used, adrenaline must of course be omitted, as it antagonizes the action of hexamethonium.

In certain operations—namely, hemispherectomy or excision of an epileptic focus—the actual operation of ablation is preceded by direct electrical stimulation of the motor cortex and electroencephalographic tracings. Since these investigations involve a considerable amount of time the hexamethonium is withheld until these procedures have been completed.

Neither pethidine nor hexamethonium has any effect on the electroencephalogram, in contradistinction to thiopen-

tone, which, in small doses, potentiates epileptic waves and is given when it is desired to produce this effect.

Enderby and Pelmore (1951) suggest initial doses of 40 to 50 mg. of hexamethonium. Guiot and Damoiseau (1952) postulate a maximum of 50 mg. I have found these doses to be on the low side, and originally my practice was to start with at least 100 mg. in a robust patient, and I have at times increased this to as much as 250 mg. When using procaine amide in addition for resistant cases I am now giving rather smaller initial doses of hexamethonium—40–75 mg. for an elderly patient, 50–100 mg. for a young adult.

Within a few minutes of the injection the blood pressure will begin to fall and in a favourable case will reach a point between 60 and 70 mm. Hg, where it will remain. At the same time the pulse pressure shows a considerable decrease with only a few points marking the difference between the systolic and the diastolic pressure.

As a general rule bleeding is minimal when the pressure is dropped to 70 or lower. This is surprising, as one would expect that in order to obtain what would appear to be this critical point in bleeding it would be necessary to produce a lower blood pressure in a patient with an initial low pressure than in a patient with an initial high pressure. A blood pressure below 60, we now know, may result in liver degeneration. Our aim should therefore be to keep the pressure between 60 and 70.

Frequently, following the injection of hexamethonium, the initial fall in blood pressure, which may reach a point well below 60, is quickly followed by a rise which, favourably, will be held below 70. If the pressure should remain below 60 for more than a few minutes the foot-down tilt must be decreased until this pressure is attained. If, on the other hand, the pressure should continue to rise beyond 70, increasing the tilt will not check the rise. Nor will an additional dose of hexamethonium as a rule have the desired effect. Yet again hexamethonium may fail to give a satisfactory response in the first place, and the pressure may drop by only a few points.

The cases in which hexamethonium fails to give an adequate reaction or in which the action is of extremely short duration constitute a fairly high proportion of the total number—in the neighbourhood of 40%—and until recently they were therefore written off as failures. With procaine amide at our disposal we are now able to "rescue" the majority of them.

The dose of procaine amide is judged according to the previous effect of the hexamethonium and the age and condition of the patient, and varies between 200 and 500 mg. A poor result of hexamethonium demands a high dosage of procaine amide, as does a young and robust adult.

Assuming the hexamethonium has been given, one should be able to decide within five to seven minutes whether a successful reaction is to be anticipated. If after this time the blood pressure fails to reach a satisfactory level, or, having dropped to a suitable level, immediately begins to rise and continues to do so, procaine amide should be given. The injection is made intravenously and slowly, taking ten to twenty seconds for each 100 mg. From now on there is no further tendency for the blood pressure to rise. It will remain stationary for ten minutes or so and then gradually fall. At the same time there will usually be a decrease in the pulse rate.

One cannot predict the duration of action of these compounds. A single dose will often suffice for the complete operation. On the other hand, if the blood pressure rises, causing increased bleeding, the drug will have to be given again. The second dose should be much smaller than the first.

At the conclusion of the operation Siguier *et al.* raise the blood pressure by rapidly returning the patient to horizontal, and all bleeding is then stopped. Our policy from the beginning has been to allow a slow return of blood pressure over several hours. This is carried out entirely by

means of posture. The nursing staff have clear instructions that the blood pressure must, so far as possible, be kept below 100 for several hours.

Recovery

Recovery from the anaesthetic is usually extremely good and very similar to recovery after pethidine anaesthesia. Hexamethonium, in fact, seems to have little added effect. Provided the blood pressure is over 70, consciousness is regained within a few minutes after the end of the operation and the patient will respond to simple commands and answer simple questions, albeit drowsily.

Post-operative restlessness is uncommon, owing, no doubt, to the action of pethidine, which allows a prolonged period of freedom from pain and headache and thus eliminates to a great extent the need for post-operative sedative drugs.

The patient can easily be roused, and there is no danger of confusing this drowsiness with that due to post-operative bleeding.

Contraindications

As thrombosis is one of the chief dangers with this form of anaesthesia, any pre-existing liability to thrombosis would be a contraindication to its use. Unfortunately we are unable to assess this liability, particularly in the case of coronary disease. A previous coronary thrombosis is, of course, an absolute contraindication.

Guiot and Damoiseau give hypertension and arteriosclerosis as contraindications. I should be very chary of employing the method in an advanced case of arteriosclerosis, but early cases, as one would expect, react well to the drugs and do not appear to come to harm.

I have used the method in a number of children, most of whom have reacted favourably. A child of 3 failed to give a satisfactory response, whereas a perfect result was obtained in a 7-years-old child. Comparatively large doses are required in children. The oldest patient was a man of 70.

With the danger of "retractor anaemia" in mind, it follows that this method of anaesthesia is absolutely contraindicated in any operation in which pressure is applied to a portion of the brain that is not to be excised in the course of the operation. There are occasions when it is impossible to decide in advance whether such pressure will be necessary, and in these cases it is advisable to defer the induction of hypotension until the bone flap is turned and the surgeon is quite clear about the condition he has to deal with. In this respect it is the surgeon's responsibility to decide whether hypotension is suitable or not.

When operations in the posterior fossa are carried out with patients in the prone position the same rule will apply. In this unit, however, these operations are performed in the sitting-up position, in which operating conditions are as a rule satisfactory, as regards both haemorrhage and intracranial tension. It would, of course, be foolhardy to use a hypotensive drug with a patient in this position.

Descriptive Cases

A few unusual cases are of interest.

A woman of 50 had a cerebrospinal leak from the anterior fossa. Before the opening was successfully sealed off, three operations were performed at intervals of six weeks and fourteen weeks. In each of the first two operations 150 mg. of hexamethonium produced a perfect result. In the third operation 80 mg. sufficed. The blood-pressure charts were almost identical in the three operations.

A woman of 43 with an angioma had two operations within 11 days. In the first an initial drop in blood pressure with 80 mg. of hexamethonium was followed by a slow rise which necessitated the injection of 300 mg. of procaine amide. The blood pressure fell to 66, where it remained throughout operation. At the second operation 100 mg. of hexamethonium reduced the pressure

to 50, but it rose steadily throughout the operation, which lasted only half an hour. There was a steady blood loss towards the end of the operation.

Two points emerge from these cases. First, it would seem that a patient who once responds satisfactorily to these drugs may be expected to respond in the same way on any future occasion. That being so, the converse is of course true. Secondly, hexamethonium alone may at times suffice for a short operation. If the operation is more prolonged additional hexamethonium may be given, but probably procaine amide will have the more lasting effect.

A man of 70 was being operated on for removal of a meningioma. Thirty-seven minutes after induction with thiopentone, gallamine triethiodide, and pethidine he developed an attack of asthma. Some 10 minutes previously he had been given an injection of hexamethonium, which had reduced his blood pressure to 66. Surprisingly the supervention of bronchospasm failed to cause an appreciable increase in blood pressure and the bleeding remained negligible and the colour good; but movements of the head due to laboured breathing and bulging of the brain during expiration were an annoyance to the surgeon. The condition persisted throughout the operation, clearing up within a few minutes after withdrawal of the endotracheal tube. The patient made a good recovery.

Results

The series consists of 90 cases. I have divided these into two groups, which happen to be equal in number; the first includes all those cases up to the time when procaine amide was first used, the second the remainder. The criteria of success were a negligible amount of bleeding and a good reduction in intracranial tension. Many cases, while not completely fulfilling these criteria, gave unquestionably improved operating conditions, and these I have classified as "partially successful."

In the first group of 45 cases 26 (58%) were successful, 9 (20%) were partially successful, and 10 (22%) were failures. In the second group 38 (85%) were successful, 5 (11%) were partially successful, 2 (4%) were failures.

It will be seen from these figures that procaine amide is a useful adjunct to this form of anaesthesia, as it converts many of the potentially failed and partially failed hexamethonium cases into successful ones.

Three deaths due directly or indirectly to the anaesthetic have occurred. In the light of our experience two at least of these cases are considered to have been unsuitable for this type of anaesthesia.

There was one case of reactionary haemorrhage.

Summary

The advantages of controlled hypotension in neurosurgery are listed.

The dangers of the method are discussed, with special reference to "retractor anaemia."

A method is described of reducing the failure rate of hexamethonium by potentiating with procaine amide.

The results of a series of 90 cases are given.

AN OUTBREAK OF DIPHTHERIA: INFLUENCE OF IMMUNIZATION

BY

C. D. L. LYCETT, M.D., D.P.H.

Deputy County Medical Officer of Health and Deputy
School Medical Officer, Staffordshire

AND

J. T. A. GEORGE, M.B., Ch.B., D.P.H.

Medical Officer of Health, Coseley Urban District

During 1951 an outbreak of diphtheria of unusual size for the present time occurred in and around Coseley. Coseley, with a population of 34,414 at the 1951 Census, is an urban district in the Administrative County of Stafford between the county boroughs of Wolverhampton and Dudley and almost surrounded by other industrial districts. Wolverhampton and Dudley were not included in the investigation here considered, but it is understood that Wolverhampton had five cases of diphtheria during the year and that Dudley had 11 (all during the first two quarters). The total population of the seven surrounding districts included in this report was 232,836, and together they had 50 confirmed cases during the year, while Coseley had 58. These 108 cases were 15.5% of the 699 (provisional) corrected notifications for England and Wales in 1951. There has in the past been a steady and at times surprisingly high incidence of diphtheria in the neighbourhood. In Fig. 1, the figures for which were obtained from the annual reports of the medical officers of health of Coseley, the number of notifications and deaths and the population for the years 1908-51 are given.

The incidence of diphtheria in Coseley in recent years compares unfavourably with the national incidence and that of non-county boroughs and urban districts (England only, excluding London), as is shown by Fig. 2, which is based on figures published in the Registrar-General's statistical reviews 1912-49.

Bacteriology

The bacteriology of diphtheria in the Administrative County of Stafford is of interest.

Menton *et al.* (1935) reported the results of 500 swabs from 500 individual patients classified according to the type of diphtheria organism; their figures showed a marked predominance of mitis diphtheria. For 1941-4 the published data of the Stafford Public Health Laboratory showed a change to the gravis and, to a lesser extent, to the intermedius types. Comparable figures for 1946-50 show that the intermedius type exceeded the gravis type, which, however, still almost equalled the mitis type in number. In 1951 the outbreak was due to gravis diphtheria. The data are set out in Table I.

TABLE I.—Relative Incidence of Types of *C. diphtheriae*—Administrative County of Stafford (Based on the Number of Cases Shown in Parentheses)

	Reported in 1935	1941-4	1946-50	1951
Gravis ..	3.8% (19)	56.9% (1,230)	27.0% (98)	98.7% (78)
Mitis ..	68.6% (343)	6.7% (144)	27.5% (100)	1.3% (1)
Intermedius ..	19.8% (99)	36.4% (787)	45.5% (165)	0% (0)
Irregular ..	7.8% (39)	—	—	—

FIG. 1.—Number of cases of and deaths from diphtheria, and population in Coseley for 1908-51.

Logan (1952) considers that the general rapid downward trend in diphtheria cases and deaths in England and Wales may be partly due to the fact that the proportion of mitis strains recovered between 1945 and 1948 almost doubled, whereas the proportions of intermedius and gravis strains substantially declined. Although this change of type occurred in Staffordshire between 1945 and 1948, it was not accompanied by a marked reduction in the incidence of diphtheria, and over the longer period 1935-51 the change in type has been the opposite.

In Coseley, in 1951, swabs from 77 persons (not all confirmed clinical cases of the disease) were positive on culture for the diphtheria organism, and they were all of gravis type with the exception of one of intermedius type. The corresponding figure for the surrounding districts was 28 corresponding figure for the surrounding districts was 28 corresponding figure for the surrounding districts was 28—all gravis. Comprehensive records of swab results obtained in the years 1936-40 are unfortunately not available; therefore the precise period during which the change of type occurred is not known, nor can a hypothetical reason for the change be offered. Fig. 1 shows that the present wave of diphtheria was already well established in 1935, 1936, 1937, and 1938, and that the death rate was as high in 1936 as at any time since.

FIG. 2.—Incidence of diphtheria in England and Wales, in non-county borough and urban districts (England only, excluding London), and in Coseley.

1951 Outbreak

During 1951, 108 confirmed cases of diphtheria occurred in the whole area under review, of which 58 were in the Urban District of Coseley. Table II shows the ratio of notifications to confirmed cases and deaths.

Of the 34 unconfirmed notifications in Coseley, 12 (35.3%) had nasal or throat swabs positive for *C. diphtheriae* at some time and 22 (64.7%) never had a positive swab. Of the 44 unconfirmed notifications in the surrounding districts, 4 (9.1%) had positive swabs and 40 (90.9%) had not. These patients had initial signs and symptoms suspicious enough to prompt the action taken by their doctors, but the signs were transient, as no evidence of clinical diphtheria was found after admission to hospital. Those cases with early positive swabs may have been carriers, but this is not thought likely, as there was no previous history of diphtheria or chronic nasal discharge, nor were any positive swabs obtained subsequently. It is

much more likely that they were, in fact, minimal clinical cases which rapidly overcame the disease after contracting it. They form an appreciable percentage of the unconfirmed notifications.

TABLE II.—Diphtheria Cases and Deaths, 1951

Area	1951 Census Population	Notifications	Confirmed Cases	Deaths
Coseley U.D.	34,414	92	58	1
* Surrounding districts	232,836	94	50	5
Total ..	267,250	186	108	6

* Bilston M.B., Darlaston U.D., Rowley Regis M.B., Sedgley U.D., Wednesbury M.B., Willenhall U.D., Tipton M.B.

Of the surrounding districts the one most affected in the outbreak was Bilston M.B., which borders on Coseley and had a population at the 1951 Census of 33,464. There were 18 cases with 3 deaths. Four cases were in one family and 15 were in schoolchildren. Reference is made below to the action taken in Bilston. In the remainder of the surrounding districts 32 sporadic cases occurred.

Seasonal Incidence.—In Coseley, cases occurred steadily throughout the year, but this was not so in the surrounding districts, where the outbreak did not gather momentum until the late summer, reaching a peak in November.

Age and Sex Incidence.—The age incidence of confirmed cases only is shown in Table III. Children of school age formed 65.5% of the total cases in Coseley and 65.7% of all cases.

The confirmed cases are classified according to age group and sex in Table IV. The sexes were attacked in approximately equal numbers in pre-school- and school-children.

TABLE III.—Age Incidence of Confirmed Cases of Diphtheria, 1951

All cases	11	10	21	37	34	71	4	12	16	52	56	108

Clinical Features

Of the 108 confirmed cases, 61 (56.5%) were classed as mild, 25 (23.1%) as of moderate severity, and 22 (20.4%) as severe, including the 6 fatal cases. In 74 the nose and/or throat swabs were positive for the gravis type of organism, but 34, although diagnosed clinically as diphtheria cases, did not have positive swabs. The exclusive occurrence of the gravis type of diphtheria has not resulted in a generally severe clinical form of the disease. The case fatality of 5.6% compares with 8.1% in the 11,492 gravis cases reviewed by McLeod (1943).

Of the 108 patients, 106 were admitted to hospital, the mean stay being 53 days; the longest stay was 152 days for a boy of 6 whose illness was of moderate severity but whose tonsils were removed for persistently positive swabs.

The complications were those commonly associated with gravis diphtheria. Of the 16 patients who were severely ill but recovered, 15 had paralyses, as did 8 of the 25 moderate cases and 3 of the 61 mild cases. One patient who died showed paralysis; the others did not live long enough to show it. Nine patients, including all the fatal cases, had bull-neck. Only three patients had a laryngeal membrane, and these were all mild cases; 27 had a pharyngeal, palatopharyngeal, or nasopharyngeal membrane, and these included the 6 fatal cases and 13 of the 16 other severe cases.

Of the six patients who died five were children between the ages of 7 and 11 years, all of whom died within seven days of admission to hospital. The other was a male school-teacher, aged 31, who died after 28 days in hospital. The cause of death in each case was myocarditis.

Spread of the Disease

In spite of the majority of cases being in schoolchildren there was little evidence that the infection was spread in school. The occurrence of cases was not affected by the school holidays, nor could a series of cases be found in the same school or class in circumstances suggesting transmission from one child to another by any of the classical and recognized methods, such as the sharing of pencils, contiguous position in class, and so on.

While in most cases there was little or no evidence to show how or from whom the infection was obtained, some of the confirmed cases were concerned in multiple infections in the same household. Nine families in Coseley between them had 23 individuals with positive swabs. Eighteen of these were later confirmed as having clinical diphtheria, this number being 31% of all confirmed cases in Coseley. The occurrence of the first case in each household was as difficult to explain as was the spread within the household easy. These first cases and the 69% of cases arising singly occurred sporadically and irregularly without traceable cause in the great majority of cases.

The location of the cases in Coseley, particularly in relation to the distribution of population, was most interesting. Coseley is not an isolated industrial town with a central business and shopping area, an inner industrial ring, and an outer suburban residential area in the usual way. It is rather a group of a dozen or so villages of varying size spaced throughout the 3,300 acres of the district, the villages being separated by stretches of waste and agricultural land interspersed with factories. During 1951, 59 (76.6%) of the total of 77 individuals found to have positive swabs lived in only five of these relatively sharply defined areas, the

remaining areas either escaping completely or having only the odd scattered case. The cases were punched in a striking manner. In one of these localities, the worst affected, there were 13 confirmed cases and 11 other persons with positive swabs living within an area of about 12 acres.

In the other four areas those with the infection were similarly clustered, though in smaller numbers. In spite of this, interrogation of contacts, neighbours, friends, etc., failed to show any connexion between the cases. Chronologically the cases in these areas did not link up, as they occurred often at widely spaced intervals of time. Inquiries failed to establish connexions between the cases except in one or two instances. It was unlikely, for example, that pre-school children would be in the habit of playing with children aged 12 years or more living near by. The weight of the evidence suggests that the infection was spread at home rather than at school, yet little specific evidence of home spread in individual cases was elicited except for those in the same family.

While these five areas are well defined, they have services common to other areas in Coseley and the surrounding districts. The same public transport, places of entertainment, main shopping centres, and so on are used by people of the affected and unaffected areas and of the surrounding districts. No explanation can be offered of why the cases should be so sharply confined for so many months to the affected areas.

The experience in previous years of the various areas in Coseley is of some interest. Records show that the incidence has been greatest in different areas at different times. Those suffering heavily ten years before escaped entirely in 1951, and vice versa. The irregular movement of the infection from one year to the next resembles that described by Grant (1951) during the years 1936-46 in Gateshead, and by Newsholme (1898) in his report on the 1888-96 epidemic of diphtheria in London.

The possibility that milk might be the vehicle of infection was investigated, but there was no evidence to support this.

The fact that the incidence was highest in schoolchildren led to a search for carriers in the schools and to an inquiry into the immunization state of the child population.

Search for Carriers in Schools

Between June 11 and 22 nose and throat swabs were taken from every child in eight school departments in Coseley. Five of these departments were those in which the greatest number of cases had occurred, and the other three, having only one case between them, were used as controls. The results are summarized in Table V.

Thus in school departments A to E, where the incidence of notified and confirmed cases of gravis diphtheria was 1.5%, a further 1% of the children were found to be harbouring *C. diphtheriae gravis* in the nose or throat, while in Departments F, G, and H, where the incidence of confirmed cases was 0.16%, no further children were found to be harbouring the organism. It must be emphasized that these figures are small and that they are based upon swabbing carried out on one occasion only.

The 15 children with positive swabs were free of symptoms, but nevertheless the evidence seems in favour of their being subclinical cases of diphtheria rather than carriers; none had any history of diphtheria or chronic nasal discharge, and their infection cleared up rapidly upon isolation in hospital; only five had any history at all of adequate immunization within the previous three years. If this is accepted, the investigation showed no evidence of a higher carrier rate in those schools with a number of cases of diphtheria than in those where none or only one case had occurred. As is mentioned above, there was an association in their home surroundings also between the children who were confirmed cases and those found to be harbouring the organism on swabbing, so that these bacteriological findings do not particularly indicate spread of the infection at school.

TABLE V.—Results of Nose and Throat Swabs of Coseley School-children

	School Departments with Highest Incidence of Diphtheria					All Departments
	A	B	C	D	E	
Confirmed cases of diphtheria January 1-June 11, 1951	9	4	3	3	2	21
No. of children on roll	449	371	155	183	242	1,400

Immunization State

The percentage of the child population who had completed a course of immunization at any time before December 31, 1950, according to the annual returns, is shown in Table VI. It is seen that 73% of the school population of Coseley were shown in the return for 1950 as having been immunized.

This method of estimating the immunization state of the child population has, however, obvious disadvantages. It takes no account of the recency or otherwise of the immunization, nor, in the case of schoolchildren, whether they have had a reinforcement dose preceded by adequate primary immunization. It was thought that, in estimating whether or not a child could be regarded as probably adequately protected by immunization, stricter criteria were

TABLE VI.—Percentage of Child Population Immunized Before 1951

	Age Group		Age Group	
	0-4	5-14	0-4	5-14
Coseley	32	73	24	96
Bilston	33	81	37	95
Wednesbury	47	89	51	93
Willenhall	42	86	26	79

TABLE VII.—Immunization Record of Children Swabbed

Presumably adequately protected:	152
With complete primary course within previous 3 years	388
With complete primary course followed by a reinforcement dose, the latter within previous 3 years	540
Total	540
Unprotected or inadequately protected:	764
No record of immunization	589
Primary course more than 3 years previously; no reinforcement dose	32
Record of incomplete primary course only	68
Record of "reinforcement" dose only	15
Complete primary course with reinforcement more than 3 years previously	1,468
Total	1,468

Proportion of 2,008 children investigated whose immunization records showed evidence of adequate protection within previous 3 years 26.9%

needed, and for the purpose of this investigation an admittedly arbitrary standard of complete immunization within the preceding three years was adopted. For all those children swabbed in the schools mentioned in Table V, a detailed survey of the immunization records was made and the result is shown in Table VII.

This result must be qualified by stating that the County Council's immunization records in their present form date only from April, 1949, when they were collated from the previous unstandardized records and a new system of supervision of immunization was introduced. It is probable that the percentage adequately protected, on the rather strict criteria set out above, was appreciably higher than 26.9%; this supposition is strengthened by the results of the inquiry made into the immunization state of those who were confirmed cases of diphtheria, in a number of whom a history of immunization was obtained from relatives or patient, although not entered in the records.

The criticism may also be made that estimation of the antitoxin content of the blood, or even the Schick test, would have been a better method of assessing the probable immunity or susceptibility of these schoolchildren than a scrutiny of the available records of their immunization. Unfortunately it was impracticable to carry out these tests for the 2,008 children.

The total school population of Coseley U.D. in June, 1951, was approximately 4,403, and, although the sample of 2,008 was not entirely unselected (especially as regards age and economic status), the results given above certainly indicated a much lower state of protection against diphtheria of the school population of Coseley than would appear from the official returns or would generally be regarded as necessary to prevent an outbreak of diphtheria.

Reference must here be made to the conclusion of the Tyneside and Dundee investigators (Hartley *et al.*, 1950) that a person inoculated as a child can expect to secure for himself early and adequate protection should he be exposed to infection in later life, because even in the absence of a reinforcing dose the infection itself serves as a secondary stimulus so that antitoxin is rapidly produced, and the disease is mild. Thomson (1951) also concludes, from statistics available to the Ministry of Health, that the prognosis for those who contract the disease, but who at some time have been immunized, is much better than that of those who have never had any such protection.

Nevertheless, the importance of the reinforcing dose of antigen in causing a rise in antitoxin titre, thus protecting the individual against an attack of diphtheria, and the community against an outbreak, remains unchallenged. It is possible that the present standard form of immunization return to the Ministry of Health may give an unduly optimistic impression, especially with regard to schoolchildren, and that further analysis of immunization records of local

TABLE VIII.—Immunization Records of Confirmed Cases

Severity	Age (Years)	Presumably Adequately Protected*	Inadequately Protected†	No Record of Immunization
Mild	0-4	1 (3)	— (—)	10 (8)
	5-14	4 (6)	6 (22)	27 (9)
	15+	— (—)	— (6)	13 (7)
Moderate	0-4	— (2)	— (1)	7 (4)
	5-14	1 (1)	2 (6)	13 (9)
	15+	— (—)	— (—)	2 (2)
Severe	0-4	— (—)	1 (—)	2 (3)
	5-14	1 (1)	1 (5)	16 (12)
	15+	— (—)	— (—)	1 (1)
		7 (13)	10 (40)	91 (55)
		6.5% (12%)	9.2% (37.1%)	84.3% (50.9%)

In parentheses is shown the immunization state based upon the history obtained from relatives and (where possible) from the patient.

* Complete primary course within previous 3 years or complete primary course followed by a reinforcement dose—the latter within previous 3 years.

† Primary course more than 3 years previously—no reinforcement dose, record of incomplete primary course only, record of "reinforcement" dose only or complete primary course with reinforcement more than 3 years previously.

health authorities might show a less favourable state of affairs than is believed to exist. The immunization records of the 108 confirmed cases are shown in Table VIII.

Thus, although 49.1% of all the confirmed cases had some history of immunization, only 12% had been protected adequately within the preceding three years. Of the 22 severe cases, however, only 7 (31.8%) had any history of immunization at all, and of the six patients who died five had never been immunized, while the sixth, a girl of 8, had only a doubtful history of immunization in infancy. Two of the children who died had, however, received one dose of antigen—one about 24 days and the other about 11 days before the onset of the illness.

Of the 31 individuals whose swabs were positive (30 for gravis and 1 for intermedius diphtheria), although they were not clinically confirmed cases, 11 appeared never to have been immunized, while not more than seven were adequately protected.

Action Taken

By the end of September, 31 cases had occurred in Coseley schoolchildren, and it was also plain that the level of immunity of the child population was too low. A special letter was distributed through the teachers to the parents of each child attending the Coseley schools, urging the need for immunization and including a form of consent. Immunization was offered in this way for all the children, irrespective of their immunization history, and consent was obtained for 87%. A full primary course was given to each child, A.P.T. being used for all infants (aged 5-7), and T.A.F. for all secondary-school children (aged 11-15); the intermediate group (aged 8-10) were given A.P.T. or T.A.F. at the discretion of the medical officer performing the immunization. About 3,500 children were thus immunized; the operation began on October 22, and the great majority were completed by December 7.

In the meantime seven Bilston schoolchildren contracted the disease during November, and one died. A schoolmaster in a Bilston school who lived in Coseley also had diphtheria (and died later). A similar immunization campaign was therefore undertaken for the Bilston schoolchildren. Here 79% consents were obtained and about 4,000 children were given a primary course between December 10, 1951, and February 28, 1952, out of a school population of approximately 6,089, leaving a further 800 to be completed after that date.

Both at Coseley and at Bilston the proportion of consents obtained from parents was higher in the presence of the outbreak of diphtheria than had been customary. At the same time the ordinary measures to secure the immunization of pre-school children were intensified.

It was not expected that the special campaigns would produce enough immunity in Coseley and Bilston schoolchildren to control the outbreak of diphtheria until two to three months after their conclusion, but in fact the incidence fell markedly in Coseley at the end of 1951, and in Bilston in February, 1952, especially in schoolchildren. Whether the fall was wholly due to the immunization is uncertain.

From January 1 to November 3, 1952, 17 confirmed cases of gravis diphtheria occurred in Coseley, and 11 in the surrounding districts, but six of these were in Bilston in January and February, before the immunization campaign could have been effective.

Of the other 22 patients, 11 were schoolchildren and 6 pre-school children, but only five had ever been immunized. Of these five three were brothers and sisters who became ill within a few days of each other at the end of October, together with three other sibs, two of whom were unimmunized confirmed cases and the other a symptomless carrier or subclinical case.

Summary and Conclusions

A report is made on an outbreak of gravis diphtheria in Coseley and the surrounding districts in which 108 cases with six deaths occurred during 1951 in a popula-

tion of 267,250 and a further 31 persons were found to be harbouring the organism.

In Coseley there had been for some years an incidence of diphtheria unusual in this country since immunization became general, and the change in the prevalent types of *C. diphtheriae* had been opposite to that in England and Wales as a whole—namely, from mitis to gravis and intermedius. The outbreak was provided with a fertile soil by the low level of immunity of the child population, and was not, so far as can be said, the result of the development of a strain of *C. diphtheriae gravis* more than usually capable of overcoming the immunity produced by the ordinary diphtheria antigens.

Long-term carriers appeared to play no part in the spread, and the large number of persons found to be harbouring the organism with slight or no symptom were probably subclinical cases or transient carriers—that is, the result and not the cause of the outbreak.

The infection was probably spread mainly at home rather than at school, although most of the cases were in schoolchildren. No explanation can be offered of the remarkable grouping of confirmed cases and other found to be harbouring the germ in certain areas in Coseley.

In the two districts most affected the incidence fell immediately after mass immunization of the school population.

The outbreak emphasized the importance of a constant watch upon the proportion of children receiving reinforcement doses of diphtheria antigen, and showed that reliance upon the figures prepared for the annual immunization return may be misleading, especially where schoolchildren are concerned. It occurred in an area in every district of which at least 73% of the school population had completed a course of immunization at some previous time. Nevertheless, the outbreak provided further evidence for the belief that the risk of severe illness or death is reduced for those who have at any time been immunized. It also demonstrated the greater willingness of the public to accept immunization when they are confronted with an outbreak of diphtheria.

We gratefully acknowledge the facilities for the investigation afforded by Dr. G. Ramage, County Medical Officer of Health for Staffordshire. We wish to express our thanks to Dr. B. C. Haller, Medical Officer of Health, Bilston M.B., for information concerning diphtheria in Bilston; to Dr. R. N. Phease, Director of the Stafford Public Health Laboratory, for swabbing 2,000 Coseley schoolchildren and for collating information on the type of diphtheria organism found at the laboratory in the year 1946-50; and to Dr. C. Simpson Smith for kindly supplying clinical details of the hospital patients.

PIGMENTED SCARS

BY

B. S. CRAWFORD, M.B., F.R.C.S.

Registrar, Plastic and Jaw Department, United Sheffield Hospitals

This communication is concerned with those scars, usually of the face, which follow injuries in which pigmented material becomes embedded in the skin and often in the subcutaneous tissues. Those which follow road accidents are the most common, and they are considered in some detail; reference is also made to pigmented scars following injury in coal-miners. Although scars are inevitable after such injuries, most of them would be inconspicuous, and some almost invisible, but for their contained pigment. It is not appreciated by many of those responsible for the initial treatment of these patients that the pigmentation of scars can be prevented by methods which do not require special experience for their application.

There are few references to the methods of preventing the pigmentation of scars, but short accounts are given by Matthews (1946) and Straith and Pilling (1947). In the American literature Iverson (1947) and Sheehan and Swanker (1950) refer to the treatment of established pigmented scars, but I have been unable to trace any work on this subject in the British literature.

Cases of injury in which pigmented material has been forced into the tissues can be divided into two groups—a large one in which the injuries are abrasive in type, and a small group in which the injuries follow an explosion.

Abrasive Injuries

Most of the cases in this group are the result of injury to exposed skin when the subject is flung forward along a road surface as the result of an accident. Motor-cyclists, cyclists, and pedestrians who are poorly protected—especially about the face—are most likely to sustain this type of injury. The skin is lacerated and abraded as it slides over the rough surface of the road, and loose particles of road grit become embedded in the wounds. Those parts of the face which are rendered prominent by the underlying bony skeleton—namely, the upper part of the nose, upper lip, chin, malar and supraorbital regions—usually sustain the severest damage, the lacerations running in various directions owing to the fact that the skin, which is stretched over the bony prominences, is split by impact with the irregular road surface. In these areas the lacerations usually penetrate as far as the subcutaneous fat and may reach the underlying bone, but in areas less firmly supported—for example, the cheek below the level of the malar prominence, and the neck—they take the form of multiple parallel abrasions of the skin which run in the direction in which the patient was travelling during the injury.

Immediately adjacent to these lacerations and abrasions there may be little or no evidence of damage to the skin, although foreign particles are embedded in it in large numbers. Lesions of the lower half of the nose, other than trivial ones, are uncommon, because this portion has a cartilaginous framework which allows it to be thrust aside at the moment of impact; this exposes the upper lip, which, no longer protected by the nose, is injured with unexpected frequency. The lower lip becomes everted as the head slides in a forward direction during the accident, exposing the buccal aspect to direct injury by the road surface, and in many cases the mucosa is split transversely just above the floor of the buccal sulcus. After a severe injury all the areas mentioned above may be damaged; in most cases, however, only one or two of them are found to be involved,

but in practically all cases the lesions are confined to one side of the face.

Exposed skin surfaces other than those of the face—for example, the hands and knees—may also be affected; the knuckle regions of the hands are commonly involved, and in addition similar lesions of the anterior aspect of the knees may be seen in women and children.

In coal-miners lesions almost identical with those due to road accidents are seen as a result of coal falling from the "roof." Sometimes the face is directly damaged, but more often the back receives the force of the impact; the face is then injured if the miner is thrown forward on to it.

Explosive Injuries

In civilian practice pigment-contaminated wounds due to injury by high explosives are rare, and are most likely to be encountered as a result of accidents in industry.

In coal-mining, barriers of stone or coal are sometimes removed by shot-firing, in which a charge of T.N.T. or nitroglycerin is placed in a prepared hole, which is then filled or "stemmed" with a mixture of clay and sand. If the charge explodes before the worker takes cover the skin of exposed areas is tattooed by coal, shale, and stone fragments, with the addition of the materials used in "stemming." Identical injuries may follow the explosion of a compressed-air cylinder in a coal-mine.

Clinical Features of Pigmented Scars

The patients complain of conspicuous scars which excite unwelcome attention, particularly if they are on the face; those with pigmented scars on the upper lip, for example, complain of the frequency with which they are told that their nasal toilet is incomplete. The pigmented scars which follow injuries of the abrasive type are found in one or more of those areas which sustain damage in the way described, their depth and direction varying, like those of the original wounds, with the site of injury. Pigmented scars overlying bony prominences are almost invariably deep and run in various directions; scars in other situations are usually superficial, the pigmentation lying in parallel lines which are generally vertical in direction. The colour varies from light grey to black, depending on the concentration of pigment in the skin.

Multiple blue-black scars in exposed areas (scalp, back, and extremities) are extremely common in coal-miners, who rarely complain of them; indeed, they are usually proud of these marks of their trade. Those of the face which may follow explosive injuries, however, are most disfiguring (Fig. 1). They present a blotchy appearance, as most of the pigmented material lies in scattered pockets of deep damage.

During the first few months after injury many pigmented scars are raised, indurated, and erythematous, and it is remarkable that after this period the scars gradually become flat and supple, in spite of the fact that they still contain a great deal of foreign material.

Pathology

Examination of a wound or abrasion of the skin within a few hours of the injury will reveal an exudate of serous fluid which soon dries to form a surface coagulum. In the case of wounds or abrasions impregnated with pigmented foreign particles, the coagulum is found, on naked-eye and microscopical examination, to contain large numbers of foreign particles. These have also been found to be present in cases in which the surface had previously been freed of contaminants by swabbing and irrigation. It is therefore inferred that pigmented scars contain only those foreign particles which have remained embedded in spite of this natural attempt at extrusion.

A number of pigmented scars removed from a variety of cases were sectioned and examined by Dr. J. L. Edwards, who reported the presence of three types of foreign body: (1) doubly refractile material with sharp edges—possibly

arteritis were conspicuously absent; there were no cases of peripheral emboli, with the possible exception of the patient who showed aphasia. Only three patients had red cells in the urine, but several showed evidence of pulmonary emboli. The rarity of peripheral emboli when infection of a ductus occurs is a result of the direction of the blood flow, which is from aorta to pulmonary artery—that is, from high to low pressure. Consequently, blood clot tends to be carried into the lungs. Peripheral emboli may, however, occur under two conditions: (1) when spread of the infection has occurred to the mitral and aortic valves; and (2) when there is reversal of the shunt as a result of pressure changes in the aorta and pulmonary artery. This occurs when congestive failure supervenes.

Blood Pressure.—As would be expected, a high pulse pressure was found (average 64 mm. Hg, highest 90 mm. Hg, lowest 25 mm. Hg). No correlation was found between pulse pressure and the size of the ductus. The exercise test (Bohn, 1938) was carried out in 11 instances only, and produced a diastolic fall in eight and a rise in two. In one case the response was variable. This suggests that, although the test is not infallible, it is a useful means of confirming the diagnosis. Again no clear correlation could be found between the response to exercise and the type of ductus.

Signs.—All the patients had the classical machinery murmur. One patient had been known to have a ductus murmur for many years; when the ductus became infected there were periods when the murmur could not be heard. This could be due to one of two causes—either the ductus was becoming blocked by vegetations (this seems to have happened in the boy previously mentioned) or it might have been due to equalization of pressures as the left ventricle began to fail. There would then be little flow of blood through the ductus. This seems the more likely explanation, since it was observed that shortly before operation the murmur again became difficult to hear, and during that time the patient was cyanosed, suggesting a reversal of the shunt. On the other hand, a machinery murmur was heard in the second patient who was in failure. Although the machinery murmur is a very constant sign in persistent ductus arteriosus, it may be absent in very young children and during cardiac failure; it disappears when the ductus becomes obliterated or blocked by blood clot or vegetations, and, of course, following ligation. On the other hand a machinery murmur may rarely be present in the absence of a persistent ductus arteriosus. It may be heard in unusual sites in a persistent truncus arteriosus or aneurysm of the sinus of Valsalva. A case in which such a murmur was heard is reported by Björck and Crafoord (1947); it was due to an aneurysmal communication of an anomalous branch of the left coronary artery and a pulmonary artery. In 32 patients a thrill was felt.

X-ray Appearance.—Nineteen patients were thought to have had cardiac enlargement as judged from a simple postero-anterior film. Three of these had associated cardiac defects, leaving 16 cases of pure persistent ductus arteriosus with cardiac enlargement. Of these, five were infected and four probably infected. On the other hand, three infected cases showed no cardiac enlargement. This suggests that cardiac enlargement should make one suspect the presence of infection. Gross enlargement was present in both cases of failure; of these, the patient who was also infected presented the typical picture described by Gilchrist (1945), with a prominent pulmonary artery and patchy consolidation of the lung fields.

Incapacity.—Of the 50 cases of persistent ductus arteriosus, 33 were never incapacitated in any way. One was incapacitated by heart failure, one by palpitations, and nine when they became infected (of these, one developed congestive failure as a result of infection). One woman with an infected ductus had had a child a short time before the diagnosis was made. It is of importance to note that in addition six children had their activities unnecessarily curtailed by their parents. One child of 11, in particular,

had never been allowed to go to school. It would seem that parental overanxiety is the second common incapacitating factor in persistent ductus arteriosus.

Congenital Abnormalities.—The following congenital abnormalities were found in association: one case each of spina bifida, left-sided vena cava and arachnoidactyly, interventricular septal defect, subaortic stenosis, narrowed aorta not amounting to coarctation, and possibly a second case of left superior vena cava.

Complications

Seven cases were with certainty infected, and five were probably infected. The following case is of interest in this connexion.

Case 1.—A woman of 25 had been known to have had a ductus arteriosus since childhood. In April, 1951, she began to complain of sweating, chills, and breathlessness. Blood culture produced a growth of *Streptococcus viridans*, and a diagnosis of infected persistent ductus arteriosus was made. Treatment with penicillin brought initial improvement, but she relapsed when that was stopped after six weeks. She was then treated with aureomycin without response. It was found that so long as she was given 600,000 units of procaine penicillin daily she would keep well, except for occasional chills and joint pains. There were no peripheral signs of the infection. Anxiety was occasioned by the intermittent disappearance of her murmur. She began to accumulate oedema and was intermittently cyanosed. It was decided to ligate her ductus in spite of the smouldering infection, and operation was carried out five months after the onset of infection. The ductus was large and friable, but ligation was carried out without any great difficulty. After operation the patient's condition gave rise to anxiety, as her oedema increased and she developed multiple ventricular extrasystoles. She was treated with digitalis and diuretics with steady improvement. For the first time in three months it was possible to stop penicillin without a recurrence of symptoms and elevation of her temperature.

Cardiac failure as the first manifestation is illustrated by the following case.

Case 2.—A woman aged 40 presented with congestive cardiac failure. She was not hypertensive, and gave no history of rheumatic fever. On examination there was a typical machinery murmur, and x-ray examination showed marked cardiac enlargement, a prominent pulmonary artery, and congestive changes at both lung bases. There was calcification in the aortic knuckle. At operation the ductus was found to be calcified, and it was tied with tape, as it was feared that a silk ligature would break it. After operation there was rapid improvement in her condition and she was able to lead an unrestricted life.

Operation

The postero-lateral approach was used in all cases. Ligation with heavy silk was carried out in most of them, two ligatures being used in two grooves. Where possible, a few drops of 50% glucose solution were injected between ligatures to promote fibrosis of the ductus. In no case was division attempted. In most instances no difficulty was experienced. In three cases bleeding occurred from the ductus; two of these were infected, and once there was considerable bleeding from a large pulmonary artery. Excessive oozing occurred in three cases. On every occasion bleeding was fairly easily controlled.

Controversy exists regarding the merits of simple ligation as compared with division of the ductus. As early as 1939 Gross stated his belief that division would be preferable, but at that time thought it would not be feasible. He points out that ligation in continuity of a vessel is against all accepted principles of vascular surgery. Shapiro (quoted by Potts *et al.*, 1949) collected 643 cases of persistent ductus arteriosus operated on by 46 surgeons; of these, 8.7% recurred. Wangenstein *et al.* (1949) report two recanalizations out of 16 ligations. In view of these figures many surgeons now prefer to divide and suture the ductus. That recanalization is not impossible even then is shown by a case of Crafoord's (1948). Ligation is still the operation carried out by many surgeons, including Blalock (1946). It is preferred in this unit, as it would appear to be a safer

procedure. So far there have been no recurrences among the 50 cases operated upon. Naturally the number of recurrences will depend on the criteria accepted in diagnosing such an event, and a minimal leak may produce marked signs. Hence the figures quoted above may exaggerate the incidence of recanalization following simple ligation. It should be noted that a systolic pulmonary murmur often persists for some time after ligation, presumably as a result of dilatation of the pulmonary artery.

Although on the whole no particular anxiety was felt during most operations, the dramatic and serious events in the following case make it worth recording.

Case 3.—The patient, a girl aged 13, had suffered no symptoms, though she was mentally rather backward. Operation was carried out under thiopentone, followed by nitrous oxide and oxygen and out under thiopentone, followed by nitrous oxide and oxygen and out under thiopentone. Immediately the chest had been opened it was noticed that there was practically no bleeding. The heart was inspected. The auricles were seen to be contracting irregularly, while the ventricles were at a standstill. Cardiac massage was begun at once, followed by intracardiac adrenaline. The ventricles resumed beating immediately, and continued to do so strongly and regularly. It was estimated that they had been standing still for two to three minutes. It was decided to proceed with the operation, and this was carried out without further difficulty. After operation the patient was given cytochrome C, 2 pints (1.1 litres) of quadruple-strength plasma, and sodium succinate. She continued unconscious for two days in an attitude resembling decerebrate rigidity. A hopeless prognosis was given to her parents; nevertheless she regained consciousness and entered a period of restlessness lasting about ten days. Henceforth her mentality improved slowly, though it was many weeks before she could feed herself and had regained continence. Six months after operation she returned to school, though she has difficulty in coping. Nevertheless she appears to be improving.

An exactly similar case is described by Wangenstein *et al.* (1949). One must conclude that it is well worth while to persevere in the treatment of such cases, which in the early stages would appear to be utterly hopeless.

Post-operative Course

One boy aged 6 died two days after operation. He was a typical case of persistent ductus arteriosus, and operation was straightforward. On his way to the ward he was allowed to become cyanosed, and this was not discovered for some time. Although he eventually recovered consciousness he died of cerebral anoxaemia after two days. This death is directly attributable to a shortage of trained nursing staff. One patient had a mild wound infection which cleared rapidly. Four patients developed pleural effusions which cleared completely. One patient had a pulmonary infarct; this was one of the infected cases. Two patients required bronchoscopy for post-operative lung collapse, and one patient produced four or five tracheal casts.

Follow-up Period

This has been up to four years, and there have been no recurrences. The woman aged 40 who was in failure recurred completely—this being one of the few types of cardiac failure in which complete recovery is possible. The infected cases all recovered completely, irrespective of the use of antibiotics. In most cases, however, an attempt was made to cure the infection first by the use of large doses of penicillin. The children who were handicapped by the knowledge of heart disease have all returned to a normal life.

Summary and Conclusion

Fifty cases of ligation of persistent ductus arteriosus, with one death, are analysed. Ten physically handicapped patients made a complete recovery, and six who were held back by the knowledge of heart disease were allowed to return to normal life.

No certain knowledge is available to show how many of the asymptomatic cases, had they been left alone, would have gone on to obliteration of the ductus. It is well known that persistent ductus arteriosus is un-

common in the elderly, and this is sometimes taken as proof of the poor prognosis of the condition. On the other hand, it may mean that obliteration does occur more often at a later age than is at present recognized. Nevertheless, operation seems well justified in view of its low mortality as compared with the dangers of a persistent ductus—mainly subacute bacterial endarteritis and cardiac failure. In some cases the accelerated growth and development following operation are striking. For these reasons operation should not be too long delayed, and about 7 years probably represents a good age to operate.

My thanks are due to Mr. G. L. Cruickshank, who carried out the operations, for permission to publish this series.

REDUCTION OF POST-OPERATIVE PAIN

BY

D. LINCOLN LEWIS, M.C., M.Chir., F.R.C.S.

AND

W. A. L. THOMPSON, M.B., Ch.B.

(From the Royal Salop Infirmary)

The object of this communication is to present a simple way of diminishing post-operative pain in abdominal incisions. Briefly, analgesia is obtained by injecting procaine every three hours into the rectus sheath through polythene tubes for a period of three days. The method was first used by Blades and Ford (1950) in chest operations, and they suggested that it might prove successful in abdominal surgery. It was subsequently employed by Gerwig, Thompson, and Blades (1951) in 24 patients undergoing cholecystectomy. These writers came to the conclusion that it guaranteed satisfactory analgesia in upper paramedian incisions.

Pain is the chief factor preventing full respiratory excursions and adequate coughing after abdominal operations. Pain can be diminished by morphine, but morphine has an inhibitory effect on the cough reflex, and this may cause pulmonary complications sufficient to endanger a patient who has had an operation such as partial gastrectomy. Pooler (1949) found that pulmonary complications occurred in 19% of patients after upper abdominal operations. Using a spirometer, he found that there was a great diminution in vital capacity. He came to the conclusion that reflex muscle spasm was the chief cause of this reduction, and something more than the abolition of conscious pain was required. This could be accomplished only by interrupting the reflex arc on the afferent side.

Present Investigation

We were led to try the method of local infiltration with procaine, with a few modifications, after observing the reactions of a healthy young man who developed pulmonary collapse following a simple laparotomy through an upper paramedian incision. He had a great deal of pain in the

wound and needed five injections of morphine and pethidine during the first three post-operative days. He would not cough even with persistent encouragement. His temperature rose to 103° F. (39.4° C.) on the second day and remained at over 100° F. (37.8° C.) for three days. It was felt that this complication could have been avoided by the use of some method which reduced wound pain locally.

In this investigation polythene tubes were used in a consecutive series of 30 upper abdominal operations (see Table). The method adds less than 30 seconds to the operative time.

Summary of Cases

All the cases had considerable relief from pain a few minutes after the injections were given. This in itself should make it a valuable addition to post-operative treatment, since a sense of well-being improves morale. Patients were able to carry out their breathing exercises unhampered by pain, movement in bed was facilitated, and ambulation was made more comfortable. Another point of interest was that some patients found that the passage of urine and flatus was much easier after the injections of procaine. There was no delay in healing or any evidence of wound infection. It is obvious that great care should be taken not to introduce infection at the time of injection.

It was found, however, that many patients did not sleep during the first night, though pain was relieved. They did not complain of pain, but remained wide awake because cerebation was active. To combat this sleeplessness, an injection of soluble phenobarbitone, 3 gr. (0.2 g.), and pethidine, 100 mg., was given on the first night. In anxious patients this was repeated on the second night. The procaine injections were used only for the first three days after operation, as after this time wound pain was not severe enough to call for continuation of the treatment. A degree of euphoria was noted in some cases, possibly due to a central effect of procaine.

The method was also found to be successful in midline incisions, the tubes being placed between the peritoneum and the linea alba.

Anatomy

The rectus sheath is formed in its upper three-quarters by the aponeurosis of the internal oblique muscle, which splits at the lateral border of the rectus muscle into an anterior and a posterior layer. These layers fuse with each other and with those of the other side at the linea alba. The aponeurosis of the external oblique muscle fuses with this anterior layer and the transversus muscle with the posterior

layer. In the lower quarter all three aponeurotic layers pass in front of the rectus muscle, leaving behind it only the fascia transversalis and the peritoneum.

The nerve supply of the rectus muscle, its sheath, and the subjacent peritoneum is derived segmentally from the lower intercostal nerves. T.7 supplies the upper part, T.10 the level of the umbilicus, and L.1 the lower part above the pubis. The terminal part of a typical lower intercostal nerve enters the posterior aspect of the rectus sheath near its lateral border. It supplies branches to the sheath and to the subjacent peritoneum. It then passes forwards, through the rectus muscle which it supplies, and terminates in the overlying skin.

Technique

After closure of the peritoneum a No. 16 B.W.G. needle is inserted through the skin 4 cm. lateral to the lower third of a paramedian incision, and continued obliquely upwards and inwards, passing through the anterior rectus sheath and the rectus muscle. Along the bore of this needle a size 1 polythene cannula is introduced into the space between the posterior rectus sheath and the rectus muscle. The needle is withdrawn and the polythene tube pulled upwards towards the costal margin. It is most important to be sure that this tube is as high up in the sheath as possible. Failure to ensure this will result in the patient's complaining of pain over the seventh and eighth costal cartilages. The pain is probably due to bruising of the cartilages by retraction at the time of operation.

A second tube is introduced into the upper third of the rectus sheath in the same way and passed downwards towards the lower end of the sheath. This method of placing the tubes lessens the chance of accidental removal before the end of three days. Further fixation of the tubes is obtained with elastic adhesive bandage in the form of a modified watershed dressing after closure of the wound.

Before the patient leaves the theatre 4 ml. of 2% procaine is injected into each tube. A further 3-5 ml. is injected every three hours into each tube for the next three days. The amount injected depends on the thickness of the abdominal wall. If only 2 ml. is injected the period of analgesia is very short. Penicillin, 300,000 units every four hours, is given the night before operation and continued for five days.

Conclusions

Procaine injected through polythene tubes into upper abdominal incisions satisfactorily controls post-operative pain.

The necessity for post-operative narcotics is greatly diminished.

Breathing and coughing are facilitated, with consequent diminution in pulmonary morbidity.

The staffing of many small homes for old people which are being opened throughout the country is an acute problem, and in an attempt to meet this need the National Old People's Welfare Committee has initiated a training course for matrons and assistant matrons. The fourth of these courses, which are supported by the Ministry of Health, begins in October; it will last for four months and comprise theoretical teaching and practical training in the geriatrics units of London hospitals and in old people's homes. Local education authorities are encouraged to assist students from their areas with grants towards the cost of tuition. Further information about these courses may be obtained from the National Old People's Welfare Committee, 26, Bedford Square, London, W.C.1.

A "NEW" Rh ANTIBODY, ANTI-f

BY

R. E. ROSENFELD, M.D.

P. VOGEL, M.D.

NATALIE GIBBEL, A.B.

Mount Sinai Hospital, New York, N.Y., and Bureau of Laboratories, Department of Health, New York, N.Y.

RUTH SANGER, Ph.D.

AND

R. R. RACE, Ph.D., M.R.C.S., F.R.S.

Medical Research Council, Blood Group Research Unit, the Lister Institute, Chelsea Bridge Road, London, S.W.1

A "new" Rh antibody, which we propose to call anti-f, has been found in the serum of a man, Mr. Cl., aged 30, who suffers from haemophilia.

Since childhood Mr. Cl. has received about 35 transfusions of blood, the last of which, in December, 1951, was followed by a shaking chill. He was seen by us, for the first time, in March, 1952,* when three blood-group antibodies were found in his serum—anti-B, anti-K, and anti-S. In addition there was at least one other unidentified antibody. In the hope of clarifying the reactions of this antibody 0.25 ml. of O, NsNs, cDe/cde, kk blood was injected on two occasions; following this, the presence of anti-N was disclosed and, in addition, the antibody anti-f, which is the main reason for this publication.

The blood groups of Mr. Cl. are: A₁, MsMs, P+, CDe/cDE, Lu(a-), K-, Le(a+b-), Fy(a+), Jk(a+b+).

The serum of Mr. Cl. can be absorbed free of the other antibodies, leaving anti-f alone. This absorbed serum has been used to test the blood of 276 unrelated white people and 114 of their relatives. From the results it is clear that the antigen recognized by anti-f is part of the Rh complex of antigens; it is also clear that the antigen is not associated with any other of the known blood-group antigens, with sex, or with the ability to taste phenylthiocarbamide.

Properties

In brief, the antibody reacts with a product of the chromosomes cde and cDe, which may consequently be distinguished by the addition of f. We have been able to classify all the important chromosomes save the rare cD^ue (which we expect to have f).

If the absence of f is indicated by the letter F the chromosomes are:

cdef, cDef, CDeF, cDEF, C^wDeF, CdeF, cdEF, CD^ueF, cD^uEF, CDEF, CD^uEF, C^wdeF, and CdeF.

These are the usual Caucasian chromosomes. For reasons which will be given in a later communication, we expect certain less common combinations to exist—namely, cDeF, cdeF, CDeF, and cDEF. We have found a sample of blood giving the reactions expected of cDeF/cdeF and one giving the reactions expected of cdeF/cdef. If the genes are arranged in a linear order on the chromosome then the order CDEF fits best with the observed facts.

If anti-F exists, as we presume it does, it will be difficult to identify with the test cells commonly available: it will give the reactions of a mixture of anti-C and anti-E, and, furthermore, it may be combined also with anti-D.

*Referred by the Hemophilia Foundation, Inc.

Anti-f agglutinates red cells suspended in albumin, and the results can be confirmed by absorption tests. The reaction of homozygous, ff, cells is stronger than that of heterozygous, Ff, cells. The antiglobulin test is not particularly useful with this example of this antibody.

Anti-f does not promise to be of any great practical importance in routine Rh blood-group work. Certainly it splits off CDe/cde and CDe/cDe from CDe/cDE, CDe/cdE, and Cde/cDE; it also separates Cde/cde from Cde/cdE. But these are hardly day-to-day problems. There is evidence that anti-f may be present in some anti-e and anti-c sera, and so these sera are laid open to investigation from this angle.

From a theoretical point of view anti-f is obviously of the first importance and must be taken into account in any thought about the Rh groups. Many interpretations of this new antibody have been considered, but the reactions can be most simply and conservatively explained by the postulation of a fourth allelomorph pair of Rh antigens, f and F.

A detailed account of the serological and genetical work on anti-f will be published soon, together with acknowledgment to many people who have helped us by collecting samples of blood of rare Rh genotypes.

THREE CASES OF SUPPURATION DUE TO FUSIFORMIS INFECTION

BY

W. M. R. HENDERSON, M.D.

Pathologist, Pembury Hospital, Tunbridge Wells, Kent

A number of non-sporing, non-motile, anaerobic bacilli have been isolated by different workers from necrotic lesions in man and animals. They represent an ill-defined group of organisms classified at the moment as the genus *Fusiformis* (Topley, Wilson, and Miles, 1948). The term "necrobacillosis" has been given to the disease they cause in man.

These organisms have been demonstrated in the normal flora of the mouth, intestines, and genito-urinary tract by Beveridge (1934) and others, and in a variety of human pathological lesions, including ulcerative colitis (Dack, Dragstedt, and Heinz, 1936), in osteomyelitis and mastoiditis (Chandler and Breaks, 1941), in infected wounds (Forbes and Goligher, 1944), in post-abortive fever (Jones, 1944), in puerperal fever (Harris and Brown, 1927), and in appendicitis (Veillon and Zuber, quoted by Topley *et al.*, 1948). These organisms have also been isolated from various necrotic conditions in animals, such as calf diphtheria and labial necrosis of rabbits. A fuller description of these organisms is given by Beveridge (1934), Lemierre (1936), and Schwabacher and Mitchison (1947).

Organisms of the *Fusiformis* group were isolated from the following cases of peritonitis (two cases) and ischio-rectal abscess (one case), and the characteristics of the organisms were substantially the same in all.

Case Reports

Case 1.—A married woman aged 45 was admitted to hospital on March 14, 1950, complaining of pain and tenderness in the right groin for the past eight days. On examination the abdomen was distended and shifting dullness was present. A large ill-defined mass was felt in the right loin and the overlying skin was red and oedematous. Laparotomy was performed next day and general peritonitis was

found with many adhesions. Gentle exploration of the upper right abdominal quadrant liberated a gush of foul-smelling pus, and 2 pints (1.1 litres) was removed by suction, a drain was inserted, and the abdomen was closed. A provisional diagnosis of appendix abscess was made at this time. A course of penicillin, 250,000 units twice a day, and streptomycin, 0.5 g. once a day, was started. In spite of this her temperature did not settle and a further operation was performed on March 23. At this a further 2 pints (1.1 litres) of pus was evacuated through a right subcostal incision, presumably coming from a subphrenic abscess. The patient slowly improved after this, although foul-smelling pus continued to be discharged from her wound for several days. The streptomycin was discontinued after nine days and the penicillin after two weeks, when a total of 6,250,000 units had been given. The patient made a slow but satisfactory recovery, and was discharged a few weeks later.

Case 2.—A man aged 64 came to the out-patients' department complaining of a painful lump on his buttock. On examination an ischio-rectal abscess was discovered. This was incised and about 4 oz. (114 ml.) of foul-smelling pus was evacuated. A drain was inserted, an injection of 1 ml. of "prolophen" was given, and the patient was sent home to rest. A further injection of prolophen was given next day, and the dressing was changed. Two days later he was feeling well and comfortable, and his abscess was discharging through the incision. A week later the wound was healed and the patient was completely cured.

Case 3.—A man aged 43 complained of sudden onset of pain in the lower abdomen. On examination he was pyrexial and there was generalized abdominal rigidity with tenderness in the right iliac fossa. A diagnosis of perforated abdominal viscus was made, and a laparotomy was performed the same day. Free pus was found in the peritoneal cavity, and the appendix was acutely inflamed and had perforated. The appendix was removed and a suitable drain inserted. Penicillin, 500,000 units a day, was given for seven days (a total of 3,900,000 units). Eleven days after admission he began to have rigors and a mass could be felt in the right loin. A second operation was performed, at which $\frac{1}{2}$ pint (285 ml.) of foul-smelling pus was released under pressure from the right paracolic gutter. Two drainage tubes were put in, and a course of chloramphenicol was begun, 8.5 g. being given in five days. The patient made an uneventful recovery.

Bacteriology

In all three cases foul-smelling dirty-brown pus was obtained from the abscesses. Films stained by Gram's method showed pus ++, necrotic debris, and some small Gram-negative bacilli. In addition, in Case 2 some Gram-positive cocci and in Case 3 both Gram-positive cocci and large Gram-negative bacilli were also seen. The material was inoculated on to blood-agar plates and incubated aerobically and anaerobically.

The aerobic plates in Case 1 were sterile, in Case 2 they grew a few colonies of *Staph. saprophyticus* and *Bact. coli*, and in Case 3 *Bact. coli* only. After 24 hours' incubation the anaerobic plates in all cases showed some very small pin-point colonies resembling those of *Haemophilus influenzae*. After 48 hours the colonies measured 0.5–1 mm. in diameter, were smooth and convex, and were slightly opaque like drops of milky water. Stained films showed them to be composed of slender pleomorphic Gram-negative cocco-bacilli, some the size of *H. influenzae* and others as large as coliforms. There were also a few slender filamentous forms. A small zone of haemolysis was now apparent surrounding the colonies. The organisms were subcultured on to blood agar, plain nutrient agar, and into Robertson's meat broth and incubated aerobically and anaerobically. All aerobic plates remained sterile, but the organism grew satisfactorily on blood agar and plain agar under anaerobic conditions, and it also grew in Robertson's broth, from which it was again subcultured on to blood agar and grown anaerobically. At no time was the organism grown under aerobic conditions. The addition of a few

drops of laked horse cells (to supply the X factor) or streaking the plate with *Staph. pyogenes* (to supply the Y factor) did not enable the organism to grow aerobically, but the growth on the anaerobic plates appeared to be improved by their addition, and "satellitism" around the staphylococcal colonies occurred.

In Case 3 an anaerobic streptococcus was grown as well as the fusiformis. The association of anaerobic streptococci with these organisms has already been quoted by Lemierre (1936). The organisms were kept going quite easily by subculturing every two or three days on to fresh blood-agar plates. Acid but no gas was produced in lactose, glucose, maltose, and saccharose, though not in dulcitol or mannite. Two or three days' incubation in an anaerobic jar was required to produce a satisfactory growth in the sugars. The addition of serum to the sugar media did not appear to be necessary. Indole was produced by Case 3 but not by the other two. Gelatin was not liquefied by any of the organisms, and the reaction in milk was neutral. The organism from Case 3 was found to be sensitive to penicillin, streptomycin, and chloramphenicol; the others were not tested.

Broth cultures of the organisms from Cases 1 and 2 were inoculated subcutaneously into guinea-pigs with no apparent ill effect. The animals were killed four weeks later and no abnormality was discovered at the post-mortem examination. Unfortunately no rabbits were available at this time.

Discussion

The organisms from these three cases had very similar cultural and biochemical characteristics, which, so far as they went, also agreed with the descriptions by Schwabacher and Mitchison (1947) for two strains of the genus *Fusiformis* and by Topley *et al.* (1948) for *Fusiformis fragilis*. The organism from Case 3 differed from the others by producing indole, but Chandler and Breaks (1941), Forbes and Goligher (1944), and Owen and Spink (1948) all described indole production in their cases.

There is no doubt that there must be many strains in this group, as various individuals have reported different characteristics, but it is thought that the organisms described in this paper can reasonably be included in the genus *Fusiformis*—the main characteristics of the group being that they are non-spore, non-motile, anaerobic Gram-negative cocco-bacilli which show a variable amount of pleomorphism and filamentous forms. The material from which they are originally obtained is usually foul-smelling pus. Colonial and morphological appearances resemble the *Haemophilus* group, but their ability to grow without X and Y factors, and their dependence on strict anaerobic conditions, exclude them from this group.

In dealing with material from the female genital tract it is important not to confuse fusiformis organisms with morphologically similar Gram-negative cocco-bacilli, which can often be grown from the normal vagina. These latter organisms are not true anaerobes and will grow aerobically as long as X and Y factors are present, but will not grow on plain agar. Moreover, the colonies are smaller and do not show the "milky water" appearance of fusiformis. As they can be found in the flora of the normal vagina of healthy adults and young girls, they are not regarded as pathogenic, and their dependence on X and Y factors for growth suggests that they may be members of the *Haemophilus* group, possibly related to *H. ducreyi*.

The three cases of necrobacillosis described in this paper all recovered, and the one organism tested was found to be sensitive to penicillin, streptomycin, and chloramphenicol. It therefore seems that with modern antibiotics, and surgical drainage where indicated, the prognosis in these cases is good.

Summary

Three cases of suppuration due to infection by fusiformis organisms are described. All made satisfactory recoveries.

The morphological and cultural characteristics of the organism are described, and are compared with those reported by other workers.

A morphologically similar organism found in the normal vagina, which must not be mistaken for fusiformis, is briefly mentioned.

With suitable antibiotic treatment, and surgical drainage where indicated, the prognosis in infection with these organisms is regarded as good.

I wish to thank both Dr. J. L. Pinniger, of St. Thomas's Hospital, London, in whose laboratory this work was done, and Dr. Mary Barber, of the Department of Bacteriology, St. Thomas's Hospital Medical School, for their helpful criticism and advice.

D.T.M.&H.

(From the Division of Insect-borne Diseases, Medical Research Laboratory, Nairobi)

This experiment was undertaken to find out if a proguanil-resistant strain of malaria also showed partial or absolute resistance to pyrimethamine ("daraprim"). I was both subject and experimenter. By the co-operation of Dr. G. I. Robertson, of the I.C.I. laboratory, Nairobi, I received 10 bites by five mosquitoes (*A. gambiae*) infected with a proguanil-resistant strain of malaria parasite imported from the Tampin area in Malaya.

The biting took place on August 21, 1952. All mosquitoes showed sporozoites on dissection. Parasites appeared in the blood on September 1 (Day No. 1) (see Table).

Course of the Infection

Day No.	Maximum Parasitaemia	Ring/Leucocyte Ratio	Treatment	Time of Treatment
1	38/50 leucocytes	0.7:1	50 mg. pyrimethamine	Noon
2	53/50 "	1:1	50 " "	"
3	94/50 "	2:1	100 " "	2 p.m.
			100 " "	10 "
4	625/50 "	12:1	50 " " i.v., 7 tab. chloroquine in divided doses	1 "
5	763/50 "	15:1	10 gr. quinine i.v. and 10 gr. by mouth, 6 tab. chloroquine in divided doses	1 "
6	58/50 "	1:1	4 tab. chloroquine and 20 gr. quinine in divided doses	

REFERENCE

- Wilson, T., and Edeson, J. F. B. (1953). *British Medical Journal*, 1, 253.

This year the number of students applying for admission to American medical schools has again declined, according to a survey by the director of studies for the Association of American Medical Colleges. 3,150 fewer students applied this year than in 1951–2, 7,600 less than three years ago. Of the 16,763 persons applying last autumn only 7,778 were accepted. The survey also shows that the average pre-medical student applies to three or four medical schools, and that the geographical distribution of students is uneven, half the candidates coming from only seven States. One cautious student applied to 45 medical schools and was accepted by one.

On the third and fourth days the white blood cell counts were 4,100 and 4,500 per c.mm. respectively. After the sixth day recovery was rapid, and I was able to leave hospital on the tenth day feeling fit. At no time was toxæmia profound, and mental clarity was retained throughout, though headache became very severe on the fourth day.

Discussion

I had not previously had malaria, so immunity played no part in the infection. The experiment proved that a strain of malaria resistant to proguanil can show absolute resistance to pyrimethamine. This is hardly surprising when it is realized that pyrimethamine resulted from research on the antimalarial properties of diaminopyrimidines undertaken because these compounds showed a structural analogy with proguanil and similarities of microbiological behaviour. It is probable that both drugs act upon the same enzyme system of the malaria parasite.

It is evident that medical policy in Kenya has been wise, in that the African population has not been subjected to treatment with proguanil on a large scale. Because of dispensing difficulties in Reserves this might have been given in doses small enough to allow the widespread rise of resistant strains. The same applies, in theory, to pyrimethamine, though the drug is effective in such small doses that this danger seems unlikely to occur. The sale of 5 mg. tablets for prophylaxis would be dangerous, as adult Africans would use them for treatment, with the certainty of underdosage. Perhaps only tablets of not less than 25 mg. should be allowed for sale. These are readily divisible for treating infants, and, as the drug has a very low toxicity, there seems little to fear from overdosage. Generally speaking, it is probable that the majority of people taking pyrimethamine will do so in doses that, though harmless, are far more than actually required to eradicate infection. The fact that the drug is tasteless and cheap should ensure this.

In a recent paper Wilson and Edeson (1953), as a result of work in Malaya, report no difference in response to pyrimethamine between unselected strains of malaria and those resistant to proguanil. East African strains of malaria parasites are extremely sensitive to pyrimethamine, though recently a case of subtertian malaria which did not respond to pyrimethamine has been encountered, the resistance of the infecting parasite being confirmed by subinoculation. It would be a tragedy if other resistant strains were imported. The presence of men of the King's African Rifles in Malaya creates a hazard, and it is hoped that special care will be taken that none return to East Africa with the gametocytes of Malayan strains of malaria in the blood.

I thank the Director of Medical Services, Kenya, for permission to publish this paper and Dr. B. P. Harris for undertaking treatment at the conclusion of the experiment, when intervention became necessary; thanks are also due to the senior parasitologist, Dr. R. B. Heisch, who watched the parasite rate when I was unable to do so, and to Dr. G. I. Robertson for the great help and interest shown by him in the experiment. The nursing skill and attention were beyond praise.

Medical Memoranda

Persistent Ductus Arteriosus and Pregnancy

The following case is reported because of the current interest in congenital heart disease and on account of the rarity of a second confinement in a woman with persistent ductus arteriosus.

CASE REPORT

A woman aged 31, who withstood one previous confinement surprisingly well, and who had given birth to a healthy full-term infant in June, 1948, after a normal labour lasting 11 hours 40 minutes, was referred to hospital in March, 1951.

There was no history of rheumatic fever, chorea, or recurrent sore throats. She did not suffer from dyspnoea and had never noticed any oedema of the ankles. She had become pregnant for the second time, and the expected date of confinement was in June, 1951. On physical examination there was no clinical evidence of cardiac enlargement; the maximal impulse, which was normal in character, was situated in the fifth intercostal space, just inside the mid-clavicular line. A thrill and a loud clanging murmur were audible to the left of the manubrium. The murmur was maximal at the end of systole and continued through the second sound into diastole. The blood pressure was 125/70. The electrocardiogram was within normal limits. A skiagram of the chest revealed slight left ventricular enlargement and dilatation of the pulmonary artery. Pregnancy pursued its usual course, a normal confinement occurred in June, and the puerperium was uneventful.

COMMENT

Congenital heart disease comprises about 1% of all organic heart disease, so that it is a rare finding in pregnant women. Donovan (1936) expresses the opinion that congenital lesions constitute a contraindication to pregnancy. Most authorities entirely disagree with this opinion. In 1905 Pouliot stated that marriage was contraindicated in congenital heart disease only in the presence of cyanosis, and in 1912 Couderc concluded that if the condition was compatible with adult life the prognosis depended less upon the form of the lesion than upon the state of compensation, the size of the heart, the degree of cyanosis and polycythaemia, parity, and the advent of complications, especially tuberculosis and endocarditis.

Mendelson and Pardee (1941) review a series of 20 cases of congenital heart disease admitted to the New York Lying-in Hospital over a period of nine years. The total number of obstetrical patients in this period was approximately 31,000. In their series there were two cases of persistent ductus arteriosus, the average age being 24, and the average parity 0.5. There was no dyspnoea, cyanosis, polycythaemia, or any cardiac difficulty during pregnancy, labour, or the puerperium. Including the series of Couderc (1912) and Jensen (1938) there are 31 other reported cases of persistent ductus arteriosus complicating pregnancy. Jensen found the average age to be 27.2 and the average parity 2.2. There are six recorded deaths, only two of which can be attributed to the lesion—one patient died of congestive failure at five months' gestation (Von Schulz, 1928) and the other died of congestive failure following caesarean section at term. There is no mention of any cardiac difficulty during pregnancy, labour, or the puerperium in the other cases.

In persistent ductus arteriosus the danger of a veno-arterial shunt developing during labour or the puerperium has been stressed in the literature. Alarming symptoms may unexpectedly develop immediately after delivery. The symptoms are dyspnoea and tachycardia without venous congestion. Carr and Hamilton (1933) suggest that these symptoms are due to a sudden fall in peripheral resistance following emptying of the uterus, and state that they are more apt to occur after caesarean section than after normal delivery. Certain precautions should be taken to avoid this possibility. Arterial blood pressure should be maintained by

avoiding traumatic procedures and post-partum haemorrhage, or by promptly instituting appropriate measures in the event of such occurrences. Judicious use of forceps will obviate undue bearing-down pains, with resulting increased pressure in the pulmonary circuit. Particular attention should be paid to the avoidance of infection. Binding the limbs and abdomen after delivery has also been recommended.

My thanks are due to Dr. M. W. Bailie, who referred the patient to hospital. He conducted the second confinement and provided the details of her first pregnancy.

Aberrant Branch of the Splenic Artery

In the course of dissection of museum specimens at Guntur, Madras State, the following variation has been noted. From the splenic artery a fairly large branch is seen to enter the spleen near the medial end (see Diagram). This is in addition to the usual branches that enter the spleen near the hilum. This branch is given off from the splenic artery before the left gastro-epiploic.

It is unusual to encounter branches from the splenic artery entering the spleen except at its hilum. Though it

Diagram showing the aberrant branch of the splenic artery.

is a rare type of anomaly, this finding is described, as it has to be borne in mind by surgeons when performing a splenectomy. This arterial branch has to be separately ligated from the splenic artery, as this is given off proximal to the left gastro-epiploic artery. Failure to ligate arteries like this, when present, may account for some of the haemorrhages that result from splenectomy.

My thanks are due to the Principal of Guntur Medical College for the specimen.

Reviews

SCIENTIFIC BASIS OF MEDICINE

Lectures on the Scientific Basis of Medicine. Volume I. 1951-2. British Postgraduate Medical Federation. (Pp. 396; illustrated. £1 10s.) London: The Athlone Press. 1953.

This is described as the first of a series of annual volumes to be based on the series of lectures under this title which are arranged each winter by the British Postgraduate Medical Federation. Of the 39 lectures delivered during the winter of 1951-2, 18 are included in this first annual volume. The range of topics is wide, and it is not possible to summarize them in a few words. Most of the articles are transcripts of the lectures and run to 6,000-8,000 words. Two of them, however, have been expanded to over 20,000 words—"Studies of Normal and Pathological Physiology of the Kidney," by Van Slyke, and "Growth of the Human at the Time of Adolescence," by J. M. Tanner—and must therefore be regarded as reviews rather than lectures.

In previous book reviews I have expressed doubts about the value of collecting series of lectures into annual volumes unless they are of the nature of a symposium. The proper place for lectures on the scientific basis of medicine is in the weekly journals, despite recent suggestions that many members of our profession are interested only in reading a strictly practical journal for general practitioners. Leaving this question on one side, I believe that most doctors who have preserved the habit of reading would enjoy each and any of the 18 lectures printed in this volume, whatever branch of medicine they are pursuing, and the British Postgraduate Medical Federation is to be congratulated on having stimulated the production of these interesting lectures.

B.C.G. VACCINATION

B.C.G. Vaccination. Studies by the WHO Tuberculosis Research Office, Copenhagen. Report prepared under the direction of Lydia B. Edwards, M.D., and Carroll E. Palmer, M.D., Ph.D., with the assistance of Knut Magnus. Monograph Series, No. 12. (Pp. 307. 15s., \$3, French francs 960, or Swiss francs 12.) Geneva: World Health Organization.

This monograph consists of a series of reports on work carried out by the World Health Organization's Tuberculosis Research Office at Copenhagen. The substance of many of the reports has already been published in British and American journals. The present volume, however, contains not only 150 pages of descriptive text but also a further 150 pages of appendices setting out the original observations in tabular form.

The chief aim of the inquiry was to study the numerous variables that affect vaccination with B.C.G. For this purpose the quantitative response of children to tuberculin was used as the main tool. Observations were made on a total of over 40,000 schoolchildren, most of them in Denmark, but some in Egypt, India, and Mexico. Instead of taking an arbitrary figure, such as 6 mm. of induration and over, as a positive reaction, the authors measured the transverse diameter of the reactions and plotted them as histograms. In this way surprising differences were revealed between the behaviour of unvaccinated children in different countries. In Denmark, for example, a high proportion of all children were insensitive to the intradermal injection of 10 T.U. In Egypt and Mexico, on the other hand, some of the children were insensitive or practically so and others reacted strongly, thus giving a bimodal histogram. An increase in dose to 100 T.U. had little effect on the non-reactors in Denmark, but converted many of the non-reactors in Egypt to weak reactors. The authors therefore recognize a high-grade type of sensitivity characterized by a strong reaction

to a small dose of tuberculin, and a low-grade type characterized by a weak reaction to a small dose and a stronger reaction to a large dose. They bring evidence to suggest that the high-grade type of sensitivity is alone indicative of specific infection with the tubercle bacillus.

Other studies lead to the conclusion that there is no simple relationship between the severity of the local reaction after B.C.G. vaccination and the strength of the subsequent allergic response; that B.C.G. vaccine retains its full potency for at least four weeks when stored at 2-4° C., but falls off rapidly at temperatures over 30° C.; that sunlight has a most damaging effect on the vaccine, five minutes' exposure to Egyptian sunshine destroying 99% of the organisms; and that the degree of allergy produced by a given batch of vaccine depends to some extent on the proportions of living and dead bacilli present.

This work, it need hardly be said, is of absorbing interest to the immunologist, and has important practical applications to the attempted control of tuberculosis by vaccination. It is pioneer work carried out by visionaries in the international field, raising more problems than it has solved, and emphasizing once more the danger of assuming that epidemiological conclusions reached in one country are necessarily valid for other countries. The World Health Organization is to be congratulated on its wisdom in fostering this inquiry, and Dr. Carroll Palmer with his associates for their imagination and skill in undertaking a task of such magnitude.

G. S. WILSON.

THE WHITE PLAGUE

The White Plague: Tuberculosis, Man, and Society. By René and Jean Dubos. (Pp. 277. 15s.) London: Victor Gollancz. 1953.

This book is written for laymen as well as for scientists. The reconciling of the language of medicine with presentation to the non-medical reader is always a difficult task. The writer is apt to be too technical and prosy for the layman, or too simple and trite for the pundit. The authors here have skilfully avoided either extreme, and the result is a book of equal interest to both classes of readers.

Part I is devoted to the "White Plague" in the greater part of the nineteenth century, when it was rife, favoured by overcrowding, treated in overheated, ill-ventilated rooms, believed not to be contagious, and the cause was unknown. It often assumed epidemic proportions when introduced into schools, convents, barracks, and among primitive races. To adorn the tale, accounts are given of famous sufferers from the disease—for instance, Keats, Shelley, Paganini, Chopin, and the Brontës. With regard to the Brontës, the usual view is adopted that the Reverend Patrick Brontë was a chronic consumptive and infected his children. It seems more probable that the tuberculosis which destroyed one by one all the members of that gifted family was contracted primarily at Cowan Bridge School, the "Lowood" which Charlotte pilloried in *Jane Eyre*. Two sisters, Maria and Elizabeth, were infected there and, presumably, Charlotte and Emily also. Maria and Elizabeth died after being brought home, and they or Emily transmitted the infection to their brother Branwell and sister Anne. Tuberculosis was endemic in the school. The authors consider there may be some basis for the statement that consumption fosters and nourishes genius, but, as Dr. Andrew Morland has pointed out, creative artists and writers, engrossed in their work and often exposed to privation in their early years, are a likely prey to the tubercle bacillus.

Part II is on the causes, Part III on the prevention and cure of tuberculosis, and Part IV on tuberculosis and society. The book thus ranges over a wide field in the discussion of a complex subject. The authors seem sceptical about therapeutic and surgical treatment and put more faith in public health measures, common sense, and individual and social conscience than in B.C.G. and chemotherapy. Prevention

has achieved much in lowering the incidence and mortality of tuberculosis, and it is highly important in Britain that the treatment of tuberculosis under the National Health Service shall be closely co-ordinated with the preventive work of the local authorities.

Epidemiologists are unlikely to agree with the contention on p. 185 that a study of mortality curves over 150 years shows that tuberculosis began to decrease before any specific measures had been taken against the disease. Reliable figures of the mortality from all forms of tuberculosis in England and Wales first became available since the decennium 1851-60, and do show a marked decline. Since 1848, however, environmental hygiene has greatly improved, especially for the poor. There has been a higher standard of living, more institutional segregation of the highly infective patient, cessation of indiscriminate expectoration, and, as a consequence of these things, less exposure of the public to massive infection. Furthermore, the direct attack on tuberculosis must have exerted a beneficial effect. Yet tuberculosis is still a killing disease, and this book should help to stimulate further endeavour, especially as regards co-operation of the public in preventive measures.

ARTHUR S. MACNALLY.

BRITISH PSYCHOLOGY TO-DAY

Current Trends in British Psychology. Edited by Professor C. A. Mace, M.A., D.Litt., and Professor P. E. Vernon, M.A., D.Sc., Ph.D. (Pp. 262. 15s.) London: Methuen and Co. 1953.

In 1951 the psychology section of the British Association for the Advancement of Science decided in the Festival year to devote their annual meeting to presenting a survey of the work of psychologists in this country. This book contains 20 papers by senior representatives of the different fields of work written for the intelligent layman or the scientist of another discipline, and is therefore ideal for the suspicious medical reader who is doubtful of the credentials of this relatively youthful science.

The first ten papers are devoted to the application of psychology to practical problems. Industrial psychology, arising from the inquiry into the health of munition workers in the first world war, is now concerned with such subjects as working conditions, incentives, and joint consultation, while clinical psychology, which began with the testing of backward children, has now become a valuable aid to psychiatric diagnosis and treatment. Vocational guidance and educational selection are seen recovering from the enthusiasm for test procedures which invaded the Army and the educational system in the war years and after. It is interesting to learn that the interview, the general knowledge test, and even the examination paper are returning to favour, and that the Civil Service Selection Board has moved from the house at Stoke d'Abernon where candidates were subjected to ordeal by house-party.

The second ten papers are concerned with the fundamental concepts and methods of psychology, and particular interest attaches to the work of Professor O. L. Zangwill on the application of psychology to brain function in neurological disease. The studies of defects at the higher levels of integration carried out at the National Hospital, Queen Square, offer the hope of partially quantifying the neurological examination and of extending the work of Goldstein to the problems created by hemispherectomy and other ablations now surgically feasible.

These short papers are for the most part free of technical jargon and give the medical reader the opportunity to judge for himself which workers are contributing something to knowledge or to human welfare and which are suspect of producing a verbal soufflé rather than something more nourishing. On the whole this picture of British psychology shows that its place is established and that its feet are on the ground.

ALEXANDER KENNEDY.

X-RAY SIEVE THERAPY

X-ray Sieve Therapy in Cancer: A Connective Tissue Problem. By Benjamin Jolles, M.D., D.M.R. Foreword by Professor Sidney Russ, C.B.E., D.Sc., F.Inst.P. (Pp. 192; 51 illustrations. £1 5s.) London: H. K. Lewis and Co. 1953.

This work bears the stamp of individuality. The author has devoted most of his professional career to radiotherapy, and throughout his radiotherapeutic work has focused his interest on the connective tissue in its relationship to tumours and to radiotherapy. With some justification he deplores the apparent view of many of his colleagues, including cancer research workers, that the malignant cell is all-important, and he considers that the tissues in which they grow are neglected. He tries first to show the nature of the connective tissue from a discussion of a great deal of literature, emphasizing its highly organized, sensitive, and specific features. The impression made on me was that the connective tissue is important and complex, but the significance of many of the experimental and morphological facts quoted is still obscure. In discussing the importance of the connective tissue in its relationship to cancer he gives the reader increasingly more insight, but it is when he begins to discuss his own work on skin reactions and the development of the "sieve" or "chequer board" type of treatment field that he develops the authority which, even though one might criticize, most impresses the reader. His account of the importance of the periphery of a treated area or volume is original, well done, and of the highest importance. The use of the sieve is pioneer work in Britain, although parallel work has been done in other countries with less scientific basis. The criticisms I would make of this part are that he should have considered the differences between the chequer board and the sieve in which irradiated areas are not contiguous. He should also have discussed the significance of the very much larger doses apparently tolerated through a sieve of this type than any radiotherapist of experience has any right to expect; although such doses have been given in the U.S.A., and, following that experience, in Britain, though more cautiously.

The book is well documented, well printed, and well illustrated, and is to be commended, even though it has shortcomings, for its thought-provoking viewpoint. It should prove of interest to biologists and research workers as well as to those engaged clinically in cancer work.

FRANK ELLIS.

RADIODIAGNOSIS

Lehrbuch der Röntgendiagnostik. By H. R. Schinz et al. Part 8: Innere Organe. Fifth edition. (Pp. 454; 559 figures. M. 96.) Stuttgart: Georg Thieme. 1952.

This volume completes the new edition of the greatest Swiss work on radiodiagnosis, and it maintains the very high standard set by the earlier volumes. The authors discuss the radiography of all the abdominal organs and describe in elaborate detail the precise technique required in each individual case. In every instance we are offered the results of vast experience and of superb technical achievement, so admirably presented as to be of real practical value.

The illustrations throughout are of a very high order, both in execution and in production, and they are worthy of close study quite apart from the text. A special feature of the volume is the attention devoted to normal anatomy, and it is indeed a revelation to learn of the importance of anatomy as revealed by x-ray examination. Of special beauty are the illustrations of the gall-bladder and gall-stones, and of the genito-urinary system.

We are glad to hear that an edition in English will soon be brought out. It should have a wide appeal to all who are interested in the study of the human body in both health and disease.

HENRY SOUTTAR.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MAY 2 1953

THE EXTRAORDINARY GENERAL MEETING

The Extraordinary General Meeting to take place on May 5 at B.M.A. House is being held on the signed requisition of more than a hundred members of the Association. The requisitionists have put forward for consideration a resolution¹ which "requires the Council forthwith to approach the Minister of Health with proposals for the better protection (financial and otherwise) of the small-list doctor and of the doctor newly seeking entry into practice." They request that the implementation of the Working Party's scheme should be postponed until new proposals have been considered. The requisitionists are clearly dissatisfied with the present scheme, believing that the small-list doctors are being adversely affected, thus reviving the objections that were voiced about ten months ago. The requisitionists have a right to use the constitutional machinery of the Association to bring to the fore, even at this late date, their doubts about the distribution of the Danckwerts award. It is odd to criticize this as undemocratic, as an attempt by a minority to overthrow the wishes of the majority. It is surely essential to democracy that the minority voice should be heard; and, if it fails to convince the majority, then, properly, the majority will have its way. But surely the proper mechanism for this purpose would have been a special Representative Meeting requisitioned by the aggrieved through their Divisions, for the Representative Body is the final court of appeal and the arbiter of policy. It is unrealistic to propose that the Working Party's report should not be implemented, for its implementation has already been carried out. It is hoped, therefore, that the Extraordinary General Meeting will adopt Lord Horder's amendment² that this part of the requisitionists' resolution should be deleted. The meeting will then be able to debate the proposition that the small-list doctor and the new entrant to practice may not be receiving a fair deal.

It is as well to recall that in June and July last year the Special Conference of Local Medical Committees

and the Representative Body accepted all the Working Party's recommendations for the distribution of money to general practitioners in the N.H.S., and accepted them with enthusiasm. In a letter to this journal in August last year Mr. Hilary Marquand³ threw doubts on the scheme and considered it did not adequately improve the lot of the young and poorer-paid doctors. It appeared that he and the discontented wanted to load the capitation fee for the first thousand of a doctor's list. But in 1951 Mr. Marquand's own department, in its plans for a new distribution of the pool, referred to "improving the position of practitioners with lists of the order of 1,000 to 2,500." The Working Party's loading was, and is, on the thousand persons on a list after the first 500, giving a capitation fee of 27s. for numbers 501 to 1,500 on a list. It was suggested in these columns⁴ that, as the average number of patients per doctor in England and Wales was about 2,200, it could be argued that the loading should be on the second thousand of a list. With the loading now in force, the initial practice allowance, and the notional list, it is logically difficult to see how the young and the new entrant should be hard hit. And, as we observed subsequently⁵: "A sound practice is not static, and to rob the Peter of the good established practice to subsidize the Paul of the unestablished practice would be to deprive general practice and its future practitioners of much healthy enterprise." The young man and the new entrant to general practice now have to put up with much less hardship than did their elders when they were young. It is good that it is so. But it would also be good if there were wider recognition of this fact.

It should, too, be recognized that provision was made for cases of hardship that might arise, as they must arise in any scheme of distribution however perfect—and who has ever yet devised a scheme that would satisfy everyone? The G.M.S. Committee has already set up an *ad hoc* committee of the medical members of the Working Party, of the Assistants and Young Practitioners Subcommittee, of the Medical Practitioners Union, and of the Amending Acts Committee of the B.M.A. to consider allocating a proportion of "the final settlement moneys for the purpose of remedying any obvious defects in the distribution scheme." In the terms of the rider to the Working Party's report,⁶ such possible defects relate to "certain groups of practitioners who under the terms of reference of the Working Party might have expected to have benefited [but] have in fact not done so." In its recent report⁶ the G.M.S. Committee observes that "its preliminary work was hampered by lack of reliable information as to the extent of the problem."

¹ See *British Medical Journal Supplement*, March 21, p. 76.

² *Ibid.*, April 25, p. 152.

³ *Ibid.*, 1952, 2, 93.

⁴ *British Medical Journal*, 1952, 2, 327.

⁵ *British Medical Journal Supplement*, 1952, 2, 141.

⁶ See *Supplement*, April 4, p. 99.

It argues that there is no case for altering the scheme to give additional help, for example, to the small-list doctors who are, or may become, junior partners, or to those eligible for the initial practice allowances. It admits that "there may remain a proportion of small-list practitioners devoting their whole professional time and ability to the running and the building-up of their practices for whom modifications may need to be sought."

What is now needed is the ascertainment of the number of doctors so affected. The full Working Party has already met, and has decided how best to obtain this necessary information. The number of hard cases cannot be large, but, however small, everything must and will be done to see that justice is done to them. This will best be accomplished if the Extraordinary General Meeting next Tuesday afternoon tackles the problem in a sober fashion with the aim of getting things done rather than of giving expression to grievances, some of which may turn out to be imaginary.

CONSTRUCTIVE PERICARDITIS

Constrictive pericarditis, sometimes called Pick's disease, is perhaps badly named, since the thickened pericardium does not constrict the heart but restricts the action of the cardiac muscle. Surgical decompression is the only effective treatment. Although not a common disease, it presents a typical picture. Early diagnosis can prevent chronic invalidism by allowing operative treatment before irreversible cirrhotic changes have occurred in the liver. Evans and Jackson¹ have recently reviewed 30 cases treated by operation in England, and Chambliss and others² 61 cases so treated in America. Their conclusions are similar. The disease is four times more common in men than in women, and most often seen in the fourth decade. Dyspnoea on exertion is the commonest symptom, typically disappearing at the moment of halting; it is unusual at rest. Swelling of the abdomen is often the symptom which leads the patient to seek advice; swelling of the ankles is almost as frequent, but usually occurs later. Fatigue may be marked. The onset is usually gradual, except when the disease follows acute pericarditis. Many of the physical signs resemble those of right heart failure, but bear a different emphasis. All patients with constrictive pericarditis have raised venous pressure, shown by distension of the veins of the neck and elsewhere, and all have an enlarged liver, which is firm and smooth but not tender. Pulsation of the engorged veins is a useful sign. The pulse is small, never slow, and seldom paradoxical, and the blood

pressure low; about one-third of the patients have auricular fibrillation. Cyanosis may be seen; it is an unfavourable sign. Ascites or oedema is usually present, often both, the former generally more conspicuous, and paracentesis is often necessary. Pleural effusions may also occur. Features unlike those of heart failure are that the apex beat is seldom displaced and often difficult to palpate; significant murmurs are unusual, but an adventitious diastolic sound is often present, either a third heart sound or a split second sound. Further investigation assists diagnosis. The most informative radiographic sign is calcification, but this is absent in at least one-third of the patients. When present it is usually most conspicuous behind the heart or on the left border; the left anterior oblique view often demonstrates a convincing crescent. The cardiac silhouette is normal or somewhat enlarged in size, sometimes altered in shape to triangular or globular; the right border is prominent, partly from a raised diaphragm, and the superior vena cava may appear distended; there may be pleural effusion or thickening. On screening, diminished or altered pulsation is usually seen. The electrocardiogram will confirm an arrhythmia. The curve is often of low voltage, the T-wave usually low or inverted, and the P-wave often notched or broad. The circulation time is increased and the cardiac output diminished. Liver biopsy shows congestive cirrhosis with central fibrosis, which, if severe, suggests a poor prognosis after operation. If oedema is present the serum proteins are reduced.

Differential diagnosis must be made from valvular heart disease by the findings described, especially the relatively high venous pressure compared with the moderate dyspnoea and the small quiet heart without murmurs. Conditions to be considered include cirrhosis of the liver, in which the venous pressure is normal even when ascites and oedema are present; polyserositis, an inflammatory lesion involving more than one body cavity, of acute onset with fever, usually tuberculous in origin (if the pericardium is involved, constrictive pericarditis may follow, so that the effusions are perpetuated); and malignant ascites due to multiple metastases.

It is likely that constrictive pericarditis is usually of tuberculous origin. (Sound evidence has been brought forward by Andrews, Pickering, and Sellors³ that there are other forms of chronic adherent pericarditis which do not give the usual clinical picture.) Sometimes tubercle bacilli can be cultured from operative specimens; many cases have progressed from acute

¹ *Brit. Heart J.*, 1952, 14, 53.

² *Circulation*, 1951, 4, 816.

³ *Quart. J. Med.*, 1948, 17, 291.

⁴ *Arch. Surg.*, 1950, 61, 266.

pericarditis known to be tuberculous, which, as it heals, restricts the heart; occasionally miliary dissemination has followed operation; other patients have had active tuberculosis elsewhere. The pathological findings in these patients are no different from those who present no direct evidence of tuberculosis, and in all cases it is unusual to find specific features on histological examination, which shows chronic inflammation with much fibrosis and few cells. The disease never follows rheumatic fever, but may occasionally be a sequel to acute non-specific pericarditis and rarely to trauma. It has been suggested that it is often due to the rupture of a caseous tuberculous mediastinal gland into the pericardial sac. Grossly, the pericardium is dense, fibrous, and thickened; both layers are affected and are adherent to the heart, which is encased and compressed; calcification is common and caseation occasionally present. The scar is seldom uniform but may involve any part of the heart, often invading the myocardium, which may even contain cold abscesses. Sometimes the scar is most marked in the atrio-ventricular groove.

The main effect of the constriction is reduction of cardiac output, both filling and ejection being limited, and this can be corrected only by removal of the encasing scar. In most cases it is the scar over the ventricles which is responsible for the disability. As fluid in the pericardium tends to gravitate to the back, the scar is often thickest over the posterior and inferior part of the heart, involving especially the left ventricle. A left-sided approach is therefore the most generally used, with either an anterior or more usually an extensive lateral thoracotomy, passing across the pleural cavity, which may itself be obliterated by adhesions. The relative immobility of the encased heart is striking; the surgeon should not be satisfied until normal action of the heart muscle is restored, and to allow this both parietal and visceral layers must be stripped. It is usually possible to do this by blunt dissection, but sometimes invasion of the myocardium makes it difficult. As much as possible of the heart is freed, avoiding only the region of the coronary vessels; their exact identification may be impossible, since they are often embedded in scar. Arrhythmias or cardiac arrest may occur, but are less likely if pauses are made in the dissection. Haemorrhage can usually be controlled by sutures or by replacing a small flap of the thickened pericardium.

In general the ideal time for operation is as soon as there is evidence of cardiac compression. In cases of insidious onset this will be indicated by the symptoms and signs mentioned, especially the raised venous pressure. In cases of recent acute pericarditis Evans and Jackson advise operating as soon as there

is evidence of fluid retention in the body. Holman⁴ also advises early operation and claims good results, although it was formerly considered that operation is dangerous until the disease is completely quiescent. If the patient has tuberculosis elsewhere, operation should be delayed. The operation is never an emergency, and the patient should be prepared by freeing him so far as possible from excess fluid, which may be evident as oedema or effusions, by restricting salt and fluid intake, by mercurial diuretics, and by aspiration. Many patients improve immediately after operation; in others improvement may be gradual or follow a delay, sometimes of many months. A second operation may be indicated, possibly using a right-sided approach to clear this side of the heart. To complete the decompression at one stage some surgeons use a midline incision, dividing the sternum completely either vertically or horizontally and spreading it widely to give access to the front and both sides of the heart.

Of Evans and Jackson's 30 patients, 18 have been relieved of symptoms for at least five years, and 5 others are improved. Of the 61 patients of Chambliss and others, 38 had excellent results, and 6 others were improved. Of about 500 cases reviewed in the literature and summarized by these authors, satisfactory results have been obtained in nearly 65%. Even in patients completely relieved of symptoms, the venous pressure often remains high, and residual calcification can be seen on a radiograph. A hospital mortality rate of about 15% is still to be expected; but without treatment, although the course may extend over years, natural cure does not occur, the symptoms are severely disabling, and in the end usually fatal.

ANTICHOLINESTERASES

There is a large and diverse group of chemical compounds showing the property of inhibiting those enzymes in the body which hydrolyse the esters of choline. They have gained the generic title of "anticholinesterase." This ugly name includes compounds developed for an ugly purpose, such as the newer war gases produced by the Germans during the last war. Other anticholinesterases more familiar to our readers include eserine and neostigmine and di-isopropyl fluorophosphonate (D.F.P.) used in clinical medicine, and organophosphorus compounds used as insecticides.

Probably the most important of the choline esters in the body is acetylcholine, on whose transitory presence at vital points depends the proper functioning of our brain, nerves, muscles, and glands. By its persistence, however, acetylcholine will undo all the good effects achieved by its passing, hence the importance of cholinesterase to ensure that it does not linger too long upon the scene. Neostigmine has been used successfully for

many years to treat myasthenia gravis, though we are still in the dark about the exact nature of this disease. Such new organo-phosphorus compounds as tetraethyl pyrophosphate and octamethyl pyrophosphoramidate have been tried on a limited scale for this purpose but are so toxic that errors in dosage may have serious consequences. D.F.P. has been used to stimulate peristalsis in paralytic ileus and to contract the pupil in glaucoma.

The ever-growing knowledge about the toxic properties of the new organo-phosphorus anticholinesterases confirms the classical work of Loewi, Dale, and others, who first discovered the importance of acetylcholine and its attendant hydrolysing enzymes. In their work much use was made of the older inhibitor eserine. But a closer study of the action of the new and more toxic compounds has suggested new problems about the role of acetylcholine and cholinesterase. The scale of interest in these problems was reflected in an audience of 200 that attended a two-day symposium organized recently by the British Pharmacological Society and the Society of Chemical Industry. There were a dozen major papers and twice as many shorter contributions, as well as expert introductions and summaries of the four sessions. The interest of the symposium was not centred on medical problems but rather on the physiological and biochemical processes that are disturbed by the anticholinesterases. The action of the highly toxic war gases was described in detail by workers from Porton. This provided a welcome lifting on the ban of secrecy so long applied to work of this kind. The contribution gave an excellent illustration of how defence research can advance general scientific knowledge.

A number of papers posed new problems, though sometimes in a manner difficult to follow. There were two outstandingly clear papers on the use of these compounds as tools in research. One described a study on the nervous control of renal function. The other analysed the mechanism by which enzymes become inhibited. This may well lead to more knowledge of how enzymes work. The unexpected side-effects of some of these compounds which result in serious neurological lesions in both man and some experimental animals aroused considerable interest. The clinical picture of poisoning and the nervous lesions are the same as those known for many years to follow poisoning by tri-ortho-cresyl-phosphate (T.O.C.P.), itself an organo-phosphorus compound. A hypothesis that T.O.C.P. owed its action to its power to inhibit for long periods the cholinesterase associated with the white matter of the central nervous system has suffered the fate of the majority of hypotheses. Nevertheless it has served the purpose of all sensible hypotheses in stimulating research into the mode of action of this interesting compound which, as well as paralysing thousands of bootleggers' customers 20 years ago, has continued to injure those exposed to it during manufacture or from accidental contamination of food. From these beginnings new information may soon be acquired on the metabolism of the nervous tissues about the diseases of which we know so little.

The mysteries and problems discussed in this symposium were not confined to the action of anticholin-

esterases in the body. The biochemists studying the enzymes called cholinesterases have been forced to subdivide them still further according to their properties, thus raising new questions about their real function and the possibility that other esters of choline may have important roles in physiology. Even in the chemical field, where the biologist is inclined to think that everything is much more cut-and-dried, there seems to be no clear basis for deciding what will and what will not make a good inhibitor of cholinesterase or a good poison. The chemists' task is complicated by the fact that some of the compounds produced, having no apparent interest for the biochemist studying their activity against cholinesterase in the test-tube, prove extremely poisonous when injected into the body. The chemist must therefore be prepared for his own handiwork to be unexpectedly improved in a manner he does not yet clearly understand by the metabolic processes of the body. Such possibilities make it seem ever more unlikely that a clear relationship between chemical structure and biological action will become established.

The search for new and more unpleasant poisons will probably not be abandoned, but the medical man may draw a measure of satisfaction from the possibility that the study of them may increase our knowledge of how the body works, and hence our chances of understanding and correcting such disorders of its mechanism as are seen in disease.

TRAINING IN FORENSIC MEDICINE

The most vivid memories of student days are probably of the great teachers rather than of the great subjects in medicine—whichever they may later be thought to be. But forensic medicine, shot with its arresting criminal colours, is perhaps the one department of teaching where lecturer and subject may, in happy symbiosis, provide lasting instruction in a form so easily assimilable that what is being taught may not always be apparent. It is a common misconception among even enlightened academic planners that forensic medicine consists of stabbing, strangling, rape, and the homicidal *causes célèbres* in poisoning. This is far from the truth.

How much forensic medicine—and what sort of teaching—does the medical practitioner need? How much should he be taught as a student, and how much might reasonably be left for experience and postgraduate training should he later wish to practise this branch of pathology? The average doctor need know little of ballistics as a science, of the technical details of reconstruction of human remains, or of serological paternity tests, though he should know enough about them to enable him to co-operate usefully with a consultant called in to deal with a case. Forensic medicine has in the past been somewhat overweighted with tuition in matters best left to the expert. But every doctor must know what to do with a dead body, how to certify death and for cremation, when to ask for the assistance of the coroner or police, and how to collaborate with the law in the best interests of the public. He cannot afford to be ignorant of the law on poisons, abortion, or infanticide or of his own legal and moral obligations in practice.

These are things on which he must have detailed instruction—as much for his own as for general security. The numerous inquiries received from practising doctors by departments of forensic medicine on medico-legal problems, and the increasing recourse to litigation by members of the public, give ample proof of the necessity for such instruction.

The universities have an important task in fostering both undergraduate and postgraduate training—so admirably fulfilled for long in Edinburgh and Glasgow, and now more recently in Leeds and, if only in one medical school, in London. Yet it has so happened that, just when a university department of forensic medicine has been established in one of the London medical schools, the decision has been made to eliminate forensic medicine as a separate subject from the final examination. The student may well overlook the significance of the subject and devote less interest to its teaching—a possibility that carries dangers both for himself and for his patients. The remonstrances of teachers in the subject were apparently overwhelmed by the claims made for the numerous other subjects to be represented in the final examinations.

While undergraduate teaching continues—as indeed it must—and is directed to the needs of future medical practitioners in their contact with the law, postgraduate instruction is being expanded, notably in Glasgow, Edinburgh, and London. In the last city about 8,000 bodies every year come within the jurisdiction of the coroners, and also available for instructional purposes are several school departments of pathology, one department of forensic medicine (with ancillary toxicological and physical laboratories), the public mortuary service, police surgeons' work, and the courts. The ideal arrangements are undoubtedly easier to achieve in a small city, for the population of London provides too many dead over too vast an area to make transport to one central institute of all types of dead a practical proposition. Nor is it necessary. Of 10,000 coroners' cases analysed for a Ministry of Health report towards the end of 1945, no fewer than 5,510 were ordinary natural deaths in which there had been no medical attention, a further 1,388 had some trivial injury, and 120 were "returned by the Registrar." The remainder lay in more forensic fields: 592 were "anaesthetic deaths," and 1,554 were due to accidents; 836 suicidal, poisoning, or criminal fatalities completed the total. What are required are good mortuary facilities with ancillary laboratory accommodation, and the services of specially trained forensic pathologists, and part-time university posts for the senior among these, who, on the basis of their practical daily experience of special material, could devote part of their time to postgraduate teaching in the subject.

Forensic medicine strives to satisfy the growing need for preventing crime at its roots. It teaches practising doctors as well as more specialized pathologists to be ever watchful for "grounds for suspicion," wary of unsatisfactory certification, jealous of the moral and litigious security of the public whom it serves, and able to serve the law before the uniformed man is at the door. The doctor's work may only incidentally include criminal cases, but much of it is of a medico-legal

character which demands skill and proper training, as much for the security of the doctor himself as for the public. It would be unfortunate if the training for this branch of medicine fell behind the needs of those who must practise it, whether as consultants or general practitioners.

TUBERCULOSIS AFTER PARTIAL GASTRECTOMY

The great advantage of surgical over medical treatment for peptic ulcer is that the risk of relapse is much reduced; even if the surgeon needs to qualify his assurance somewhat to the patient with a duodenal ulcer, he can confidently assert that a gastric ulcer will be permanently cured. The immediate mortality from surgical treatment is extremely low in the uncomplicated case, so that it is only the occurrence of a number of undesirable end-results, unrelated to the original disease from which the patient was suffering, that prevents partial gastrectomy from being adopted on a far wider scale than it is at present. Much has been written about the occurrence of anaemia and of the dumping syndrome after partial gastrectomy. The former can always be treated successfully, though it is sometimes not easy to do so. The latter, if it occurs, may be both persistent and unpleasant, and a number of new surgical techniques have been devised with the object of eliminating it—for example, Capper and Butler's¹ proposal to give anatomical support at the time of operation to the remnant of the stomach and to the afferent loop of the jejunum. Less interest has been shown in the loss of weight which occurs after radical gastrectomy in some 50% of patients, though it stands to reason that a lowered standard of nutrition might often adversely affect the patient's subsequent health. Pulvertaft² has reported that 8 patients out of 23 who died two to seven years after partial gastrectomy died of tuberculosis (7 of pulmonary and 1 of meningeal tuberculosis). Only 2 of the patients who died were known to have had the disease before the operation, and it is possible that the development of active disease in the others was brought about by impaired nutrition. Certainly the proportion of deaths due to tuberculosis is far greater than could be expected among a normal population of the age and sex distribution of Pulvertaft's series.

This is the most striking experience that has been reported, but other workers have also noted a disproportionately great number of deaths from tuberculosis. Bruusgaard³ found 4 such deaths out of the 14 which occurred among patients discharged from hospital; and Drablos, Linden, and Skjelbred⁴ found 3 among 30 deaths. Yet others have reported no deaths from tuberculosis, so that before any association can be accepted it will be necessary to ensure that the group of patients studied are properly representative of all patients who have been subjected to the operation. It may be,

³ *Acta chir. scand.*, 1946, 94, Suppl. 117.

⁴ *Acta med. scand.*, 1951, 140, 327.

⁵ *Lancet*, 1948, 1, 505, 551.

for example, that the extensive resection advocated by Visick,⁵ and which had been performed on most of the patients referred to by Pulvertaft, is more conducive to the development of tuberculosis than the limited two-thirds to three-quarters gastrectomy performed by some other surgeons. It is also possible that the fundamental association is with poor economic status—which is known to be independently linked with both gastric ulcer and pulmonary tuberculosis. Nevertheless, enough evidence is available to make it clear that the final effects of partial gastrectomy cannot be assessed one or two years after the operation. Before it can be confidently recommended as the treatment of choice for young patients it is necessary to know what effect it may have on their lives 10 and even 20 years later—and about that there is, as yet, not enough information.

SMOKING AND CANCER OF THE LUNG IN DOCTORS

Further evidence of a causal connexion of some sort between smoking and cancer of the lung is reported in a recent issue of the *New England Journal of Medicine*. There Dr. E. L. Wynder and Mr. J. Cornfield describe¹ an investigation they have conducted into cancer of the lung in physicians, and the main conclusion of it is that they found a "highly significant association between the use of tobacco and the development of pulmonary cancer."

Their investigation was of a kind that could have been carried out only in the U.S.A. Each week the *Journal of the American Medical Association* publishes short obituary notices, nearly all of which record the cause of death. Selecting notices for the years 1950 and 1951 and the first two months of 1952 (and, for lung-cancer cases, 1949 also), Wynder and Cornfield sent letters containing a questionnaire to the estates of doctors listed as dying from cancer of the lung, colon, stomach, kidney, and bladder, and from leukaemia, lymphoma, and sarcoma. They finally had for analysis completed replies on 63 doctors recorded as dying from cancer of the lung, which comprised 58.9% of possible replies in that group, and completed replies on 133 doctors who died from other malignant diseases, which comprised 63.9% of possible replies in that group. The questionnaire included questions on smoking habits of the deceased doctor, on exposure to dust, fumes, and insecticides, and on the length of the responder's personal acquaintance with him.

The figures showed that in the lung-cancer group only 5.8% smoked on average less than 15 cigarettes or their equivalent a day as compared with 43.4% in the other-cancer group. As regards the heavy smokers, in the lung-cancer group 33.8% smoked 35 or more cigarettes (or their equivalent) a day, while in the other-cancer group only 12.7% did so. The period asked about in the questionnaire was the previous 20 years, and, though they do not explicitly say so, Wynder and Cornfield

assume that the average daily amounts of tobacco they record as smoked were in fact smoked over² the full 20 years. The distribution of doctors between town and country and of those specially exposed to dusts or insecticides did not vary significantly between the two groups.

The writers are aware that their method of gathering the data cannot lead to wholly reliable results. But, while the data are certainly incomplete, they are not likely to be so biased as to invalidate the conclusions. This paper adds confirmatory evidence to the previous work of Wynder himself² as well as of other investigators, including Doll and Bradford Hill in Britain.^{3,4}

EDITED BIBLIOGRAPHIES

If the pioneers have a hard time in some ways, at least they may not have to spend those long hours hunting through the literature that their successors sometimes find irksome. And so voluminous has medical literature become in the last fifty years that guides have had to be devised—for example, by Morton⁵ and Greenwood⁶—to help the inquirer find his way about it. Edited or select bibliographies of various kinds have also been published. Some cover the output of a single country, or the papers in a particular specialty, or the papers in a few selected journals.⁷ A limited bibliography of this type has recently been published to record articles and books published in France in the last few years on diseases of the cardiovascular system.⁸ The whole is in English, including a few abstracts of the more important papers, and Professor René Leriche surveys it in a preface.

On a much larger scale than these restricted lists, but avoiding the unwieldy proportions of a complete bibliography, *Abstracts of World Medicine* is published monthly by the British Medical Association. It selects from about 1,700 periodicals (or about 13,000 issues a year) those papers that seem to be of greatest interest or importance. Its subject and author indexes point to all the main papers on any medical subject soon after they are published, and also to many papers of subsidiary importance, while in the body of the journal short abstracts of them appear. As a guide to current literature, and not merely a compendium of it, the selection practised by *Abstracts* has been found by inquiry to be of special value. While the output of medical literature continues to expand each year—and it has been expanding steadily since the war—the function of an edited bibliography subserved by *Abstracts* becomes increasingly necessary if the inquiring reader is not to get lost.

The next session of the General Medical Council will open on Tuesday, May 19, at 2 p.m., when the President, Professor David Campbell, will take the chair and will deliver an address.

REFRESHER COURSE FOR GENERAL PRACTITIONERS ANTICOAGULANT THERAPY

BY

H. PAYLING WRIGHT, Ph.D., B.Sc., L.M.S.S.A.

Research Assistant, Obstetric Unit, University College Hospital Medical School

The modern treatment of all types of thrombosis is very different from that of twenty years ago. The changes are mainly dependent upon the introduction of anti-coagulant drugs, which, by preventing the initiation or propagation of thrombi, are often able to save the condition of a patient from becoming critical. Unfortunately, both heparin and dicoumarol require scrupulous control if they are to achieve successful therapeutic results without producing haemorrhage, so that their use makes admission to hospital almost essential. Nevertheless, medical practitioners will wish to have a clear understanding of the mode of action of these drugs, their method of control, and their limitations.

In the past decade it has become evident that the Morowitz theory of blood clotting (prothrombin + calcium ions + thrombokinase = thrombin; thrombin + fibrinogen = fibrin) is insufficient to account for all the successive stages in coagulation. For instance, for its conversion to thrombin, prothrombin is now known to require at least four factors, while thromboplastin (thrombokinase) is recognized as occurring in a precursor form (thromboplastinogen) which is activated by an enzyme (thromboplastinogenase) derived from tissue autolysis and platelet disruption. Besides these factors, which can be reconciled with Morowitz's ideas, there are others, inhibitory to the clotting mechanism, which cannot be accommodated by his theory. Although in this article it is impossible to set out in detail current views on the mechanism of blood coagulation, it may be assumed that in the normal person the clotting process and its antithesis, the haemorrhagic process, are so nicely balanced that neither catastrophe occurs. It is on this delicate equilibrium that the anticoagulant drugs exert their effects.

Heparin

Heparin was the first of the anticoagulants to receive wide clinical use. It is a mucopolysaccharide derived from liver, lung, and other tissues, and is believed to compose the granules of the basophil leucocytes. It acts solely on the clotting substances already present in circulating blood, and this accounts for its rapid and transitory action and its effectiveness *in vitro*. Heparin has been shown to have several actions: it prevents the combination of fibrin and thrombin; it reduces the conglutination of platelets and so inhibits the liberation of thromboplastinogenase; and, finally, it has been shown to behave as an anti-prothrombin when coupled with a plasmatic complement fraction. It is thus apparent that this anticoagulant can interfere with coagulation in at least three ways.

Control of Treatment.—Since heparin acts directly upon circulating substances, an estimate of the clotting properties of the blood must be made before each administration. For this, the determination of clotting time by the Lee-White or similar technique gives a satisfactory, though crude, guide to therapy. (The prothrombin-time estimation is not a suitable test for this purpose.) As a general rule the prolongation of clotting time to three times its normal (five to seven minutes) suffices for therapeutic purposes, and this can usually be achieved by 10,000–15,000 international units of heparin, given intravenously every four hours. Slow-acting heparin preparations for intramuscular injection have been prepared, but, owing to variable rates of absorption, their action is erratic. Moreover, they are often extremely painful.

Haemorrhage Following Overdosage.—Should haemorrhage occur during treatment a 1% solution of protamine sulphate* may be injected intravenously in doses of 5–10 ml. Protamine reacts with heparin to neutralize the latter's negative electric charge, thus destroying its anticoagulant action. Blood transfusion may also be used to control bleeding, but in haemorrhage due to heparin fresh blood must be given, since stored blood lacks the labile factor necessary for prothrombin conversion. This factor is absent from the circulation during heparin therapy and must be replaced before normal coagulation can occur.

Dicoumarol and Allied Substances

A haemorrhagic and often fatal condition of cattle, known as "spoiled sweet-clover disease," led Link and his colleagues to investigate the chemical substances found in melilot ensilage. From this they isolated a substance—dicoumarol—which they showed to be a powerful anticoagulant, but which, unlike heparin, had to be ingested and passed into the blood stream before it exerted its action. Dicoumarol is without effect upon the clotting substances already circulating in the plasma, and hence has no anticoagulant action on blood *in vitro*. Its anticoagulant action depends upon its power to modify the ability of the liver cells to utilize vitamin K in the normally continuous synthesis of prothrombin, and this alteration in prothrombin production impairs the clotting mechanism at this level. For this reason, dicoumarol acts slowly, since time is necessary for its absorption from the gut and for the prothrombin already in circulation to undergo its natural depletion.

Control of Treatment.—Treatment with dicoumarol and kindred derivatives is usually controlled by means of Quick's single-stage prothrombin-time estimation. Though this test probably measures other variable factors besides free prothrombin, it offers a safe and easy method of assessing the response of the coagulation mechanism to anticoagulants of the dicoumarol type. The whole-blood clotting-time test used in heparin control is relatively insensitive to alterations in prothrombin concentration, and is therefore unsuitable for the management of dicoumarol therapy. Nevertheless, the prothrombin-time test is not without its pitfalls, and a rigid technique must be employed. Many modifications of the method are in current use, some of which are now recognized as unreliable, and in order safely to control dicoumarol administration it is essential to use a sensitive technique and to know the extent to which results may be effected by personal and environmental variations. When these factors are satisfactorily standardized, a comparison of the patient's prothrombin time during therapy with his own premedication figure or with that of a normal subject gives a satisfactory method of assessing the response to the drug. To enable results from different laboratories to be compared they may be expressed as percentages of normal prothrombin activity. This can be done by constructing a time-concentration curve for "normal" blood with the technique employed in the particular laboratory. Such a curve is obtained by measuring the prothrombin times in serial dilutions of normal whole citrated plasma. These times are plotted against the dilution expressed as a percentage of the initial plasma. This method of recording results is now widely used.

Method of Administration.—The response to dicoumarol administration is slow, 16 to 24 hours elapsing before blood changes become apparent, while the maximal effect is seldom reached before 30 to 40 hours after ingestion. Cumulative

*1 ml. of 1% solution of protamine sulphate = 1,000 international units of heparin.

¹ *New Engl. J. Med.*, 1953, 248, 441.

² Wynder, E. L., and Graham, E. A., *J. Amer. med. Ass.*, 1950, 143, 329.

³ *British Medical Journal*, 1950, 2, 739.

⁴ *Ibid.*, 1952, 2, 1271.

effects may therefore be encountered, and for this reason prothrombin activity should be measured at the end of the first 24 hours and subsequently daily. About one in ten persons is resistant to dicoumarol and requires a greater dose or more prolonged administration to achieve the desired fall in prothrombin level; these cases need particularly careful control if haemorrhage is to be avoided. An average plan of dosage for dicoumarol is 300 to 400 mg., in divided doses, during the first 24 hours; 200 mg. during the second 24 hours; and thereafter 50 to 100 mg. daily as maintenance dose. In most patients this will reduce prothrombin activity to 25 to 35% of normal by the end of the third day. It must be emphasized, however, that derivatives such as ethyl biscoumacetate ("tromexan") and cyclocoumarol and such substances as phenylindanedione have their characteristic rates of absorption, and consequently different dosages. When the prothrombin activity has been reduced to 25 to 35% of normal for some days a dose can usually be determined which will maintain it steadily at this level. It is then safe to reduce the frequency of prothrombin-time estimations to every second day for the next week. Should no marked fluctuations occur during this time, the interval between the tests may be still further extended. However, fluctuations may occur even in a "balanced" patient, and if control tests are infrequent the risk of serious haemorrhage becomes greater.

Out-patient Treatment.—The question of out-patient treatment with the dicoumarol anticoagulants is a vexed one. In my opinion it is permissible only if the following precautions are strictly observed: (1) the patient remains in hospital until satisfactorily balanced while fully ambulatory; (2) the prothrombin activity is not depressed below 25% of normal; (3) prothrombin-time determinations are carried out at least once a week; and (4) no drugs are administered except with the knowledge of the physician in charge of anticoagulant therapy. Even under these stringent conditions, the danger of spontaneous or traumatic haemorrhage is considerable, and the practitioner should explain this risk to the patient. Haematuria is the commonest first sign of overdosage with dicoumarol and similar anticoagulants.

Haemorrhage Following Overdosage.—When overdosage with dicoumarol or kindred substances has occurred, the resulting haemorrhage can be controlled by blood transfusion. Since the prothrombin-activation factor which is absent in stored blood (Quick's "labile factor") is not the same as that which is lacking from the patient's plasma during dicoumarol therapy (Quick's "component B"), the blood of the recipient and stored blood from a donor are complementary; the patient's prothrombin-activating complex is therefore reconstituted equally as fully by the giving of stored as of fresh blood. Transfusion must be continued until the absorption of anticoagulant from the gut has come to an end and normal prothrombin constituents have been restored in the blood. The efficacy of water-soluble vitamin K, either orally or by parenteral injection, in the control of haemorrhage following dicoumarol is controversial. Recently, however, a purified form—fat-soluble vitamin K₁—has been prepared which restores the prothrombin from the haemorrhagic to the normal level within four to eight hours. The mode of action of the vitamin is obscure, but may nevertheless prove a powerful antidote in dicoumarol overdosage.

Indications for Anticoagulant Therapy

Coronary Occlusion.—The value of anticoagulants in preventing immediate propagation of coronary thrombi or the development of further episodes was investigated by the American Heart Association in 1946. The material from 16 large hospitals was reviewed by a panel of investigators who concluded that the results with this type of treatment were highly favourable. Both heparin and dicoumarol were used, often in conjunction, the heparin usually being given only until the prothrombin level of the blood was satisfactorily depressed by the dicoumarol given concurrently. When this level was reached the heparin was withdrawn and the patient maintained on dicoumarol alone. When anticoagulant

therapy was given the mortality was reduced to about two-thirds that of a control group which received conservative treatment only. This advantage was most marked during the first four weeks after the primary coronary episode. The number of thrombo-embolic complications elsewhere in the body during convalescence was also reduced to one-third that in the control group. Anticoagulant therapy must be considered as prophylactic, since it has no effect upon the progressive development of arteriosclerosis, though both heparin and, to a greater degree dicoumarol, have been stated to increase the coronary flow. Moreover, recent experimental work has shown that, in rabbits, artificially thrombosed arteries are recanalized sooner when a steady hypoprothrombinaemia is maintained.

Pulmonary Embolism.*—Intravenous heparin, followed by dicoumarol, should be given as soon as possible after embolism has occurred, so as to reduce the likelihood of further catastrophes. When propagation of the thrombus at the site of origin has been prevented the danger of detachment is much reduced.

Vascular Surgery.—When operations on large arteries are undertaken, heparin often aids in preventing thrombi forming at the site of surgical intervention.

Auricular Fibrillation.—Since mural or auricular thrombi frequently give rise to emboli when auricular fibrillation is reversed by quinidine, the risk of this complication can be much reduced by anticoagulant therapy. Prothrombin activity should be reduced to about 25% of normal, and this level should be maintained for at least five days before quinidine reversion is attempted.

Post-operative and Puerperal Venous Thromboses.—These cases respond most satisfactorily to anticoagulant therapy. Treatment is indicated when venous thrombosis has occurred in the deep veins of the leg. Prophylactic treatment may also be given to patients who have experienced previous thromboses or in whom there are predisposing factors which lead the practitioner to fear the formation of thrombi. The judicious use of anticoagulants will reduce the danger of pulmonary embolism. Venous thrombosis during pregnancy may safely be treated with dicoumarol-like substances, provided the prothrombin level is not depressed below 30% of normal. The drug should be withdrawn for at least one week before delivery is expected, both to minimize the risk of uterine haemorrhage and to ensure that the prothrombin level of the infant at birth shall not be dangerously depressed. In the puerperium, anticoagulants of the dicoumarol group can safely be administered prophylactically or when venous thrombosis has already occurred. Lochial loss is not increased if the prothrombin is maintained at the usual therapeutic levels, nor at these levels are anticoagulants secreted in the milk in sufficient quantity to affect the suckling infant.

Retinal Vein Thrombosis.—Favourable reports on the use of both heparin and dicoumarol in retinal vein thrombosis have been made, but the data available are still very meagre.

Contraindications to Anticoagulant Therapy

Immediately after Surgery.—In the treatment of surgical cases it is advisable to withhold heparin for at least 12 hours after operation. This allows time for the formation and firm attachment of thrombus plugs in the small vessels at the site of operation to take place. Dicoumarol and its derivatives can more safely be started immediately after surgery because the lag in their action allows the completion of these processes. If there is a large denuded operation site, or if ulceration or local infection is present, the risk of haemorrhage with anticoagulant therapy is much increased.

Abnormal Prothrombin Metabolism.—Exaggerated responses to anticoagulants of the dicoumarol type sometimes

*For further information on this subject see *Venous Thrombosis and Pulmonary Embolism*, by A. Neuhauf (1943: Grune and Stratton, New York), and *Thrombotic Conditions and Their Treatment with Anticoagulants*, by C. D. Marple and I. S. Wright (1950: Blackwell, Oxford).

MEDICAL EXAMINATIONS FOR NATIONAL SERVICE

The proportion of young men who are found to be unfit when called up for National Service is about 18%. These are the men who are placed in Grades III and IV by the medical boards; most are rejected for service, but some in Grade III are accepted for the lighter jobs. When these figures were announced to the subcommittee of the Select Committee on Estimates, which has been considering, from the standpoint of economy, the question of call-up, posting, and movement of National Service men, they were described as "fantastic" and "alarming"; but, of course, as a witness from the Ministry of Labour pointed out, everything depends on the standards adopted. The proportion of candidates for the Regular Army who fail on medical grounds is much greater; one witness spoke of "somewhere in the region of 40%." The Committee's report gives some interesting details about the working of the National Service medical boards, of which there are 61 in Great Britain. Each board consists of a chairman and four members, all civilian doctors, and the chairman has power to seek consultant advice where necessary. It is estimated that the examination of a recruit by each doctor in turn occupies on the average seven minutes. One point brought out in the evidence is that only three-fourths of the men are subjected to x-ray examination. This is because of shortage of apparatus and staff difficulties in the remoter parts of the country. Men who have not had an x-ray examination at their medical board are radiologically examined fairly soon after entering the Service. For economic reasons the subcommittee deplores this and recommends that Service x-ray equipment should be made available for use by the medical boards, and that urgent steps be taken to increase the number of civilian x-ray units.

When a man, having passed the medical board, joins the Service an initial military medical examination is made, normally by the unit medical officer, who has before him the form of assessment issued by the board. The number of men discharged on medical grounds during their first 14 days of service is a measure of the difference of opinion which exists between the civilian medical board and the military medical officer. This difference is very slight except in the case of psychiatric disabilities, which, of course, the board is not well placed to detect, seeing that they manifest themselves in anomalies of behaviour and not in physical signs. In 1951 the number of discharges of National Service men from the Army during their first fortnight was 7 per 1,000 of intake, and in rather more than half of these the discharge was on psychiatric grounds (meaning, as one witness stated, nearly always "mentally slow").

The report also contains an important recommendation with regard to intelligence tests. Before his medical-board examination each man undergoes an "intelligence test" supervised by Army sergeants, and the results of these tests and of any interviews which may follow them are reported to the chairman of the medical board. Stress was laid by War Office witnesses on the simplicity of these tests. No exercise of judgment or foundation of experience, apparently, is called for. But a large proportion of the gradings made by these Army testers are subsequently altered by the boards, and the subcommittee holds that there is no reason for the employment of Service men on this work at all. Any testing of this kind would be more advantageously done by specially trained civilian men or women acting under the supervision of the chairmen of the boards, and a common series of intelligence tests should be worked out by the Ministry of Labour and the Service departments in consultation.

Third Report from the Select Committee on Estimates, together with Minutes of Evidence taken before Subcommittee C and appendices. "Call-up, Posting, and Movement of National Service Men." London: H.M. Stationery Office. 4s. 6d. net.

occur. All patients with conditions in which vitamin-K absorption or production is defective, and especially those with disorders of fat digestion, are notably sensitive to oral anticoagulants. These include cases of dietary deficiency or biliary dysfunction, diarrhoea and enteritis, sprue, steatorrhoea, and resection or ulceration of the intestinal tract. Alterations of the intestinal flora brought about by drugs may also cause hypoprothrombinaemia, sometimes to a severe degree. Certain drugs, other than anticoagulants, also lower the prothrombin level of the blood, and are thus synergic in their action. The commonest are the salicylates, though caffeine, theophylline, and theobromine behave in the same way. These drugs should not be given concurrently with oral anticoagulants. Normal prothrombin production may be impaired in persons whose liver function is disturbed, so that some degree of hypoprothrombinaemia may be already present. The administration of dicoumarol to cases with Laennec's cirrhosis, infective hepatitis, carcinomatosis, or liver abscess is followed by an exaggerated response.

Renal Damage.—Impairment of renal function is a contraindication to the use of anticoagulants for two reasons. First, cumulative effects are more apt to develop, so that the danger of haemorrhage is increased. Secondly, renal vessels are particularly vulnerable, as they often prove the first site at which haemorrhage occurs in hypoprothrombinaemia. If the kidney is already injured this danger is further increased.

Next Refresher Course Article.—"Hysteria," by Dr. I. R. C. Batchelor.

IMPERIAL CANCER RESEARCH FUND

The fiftieth annual report of the Imperial Cancer Research Fund was presented at the general meeting of governors held at the Royal College of Surgeons on April 23, the chairman of the council, Professor H. R. Dean, presiding. Mr. A. Dickson Wright, honorary treasurer, said that for the first time in the history of the fund the assets totalled over £1,000,000. Excluding legacies, which amounted to £97,500, the contributions during the year 1952-3 came to close upon £25,000, an increase of £13,000 on the figure for the previous year, and the long list of subscribers illustrated the wide interest shown in cancer research. The general working expenses, however, had increased, leaving an excess of expenditure over receipts of £5,500. The large increase of expenditure was in connexion with the provision for the clinico-pathological investigations which were initiated in 1951, and had made it necessary to obtain additional laboratory space at Lincoln's Inn Fields.

Professor Dean presented the general report on the work of the fund. These new clinico-pathological investigations, which had been placed under the general supervision of Professor Geoffrey Hadfield, would increase the scope of the research work, and the institution of a second laboratory would offer excellent opportunities whereby the clinico-pathological research and the basic research into cancer might, as they should, supplement and stimulate each other. Plans had been drafted which would make it possible to establish four large research laboratories, to come into operation in July of this year, and two additional laboratories would be available in the spring of 1954. This research accommodation would provide laboratory space for at least six research workers. The special investigations which have been taken in hand relate principally to cancer of the breast and of the prostate.

The president of the fund, the Earl of Halifax, was re-elected, as was the honorary treasurer, Mr. Dickson Wright. Tributes were paid to three distinguished workers for the fund whose deaths had occurred during the past year—namely, Sir Holburt Waring, for many years treasurer, Professor W. E. Gye, the former director, and Dr. Charles Kellaway, a member of the council.

COLLEGE OF GENERAL PRACTITIONERS

In its most recent statement (*British Medical Journal*, March 28, p. 725) the College of General Practitioners announced that its peripheral activities would be organized by a number of Regional Faculties. Below are printed the names of the Faculties and the areas which it is proposed that they should serve. As in some cases county boundaries or regional hospital board areas may prove inconvenient, members or associates of the College will be free to choose to which Faculty they should belong.

Regional Faculty	Area Served
England	
London	County of London
Home Counties South	Kent, Surrey, Sussex, Hampshire and the Isle of Wight
Home Counties North	Middlesex, Essex, Hertfordshire, Bedfordshire
Oxford	Oxfordshire, Berkshire, Buckinghamshire
Cambridge	Cambridgeshire, Huntingdonshire, Norfolk, Suffolk
Bristol	Wiltshire, Gloucestershire, Somerset, Dorset
Exeter	Devon and Cornwall
Birmingham	Warwickshire, Shropshire, Herefordshire, Worcestershire, Staffordshire, Leicestershire, Rutland, Northamptonshire
Sheffield	Derbyshire, Nottinghamshire, Lincolnshire
Leeds	South Yorkshire (West and East Riding)
Manchester	North and East Lancashire (East of the London-Glasgow Road A.6), East Cheshire, Westmorland
Liverpool	South-west Lancashire, West Cheshire, North Wales and the Isle of Man
Newcastle	Durham, North Riding of Yorkshire, Northumberland, Cumberland

Map showing distribution of Foundation Membership (1,087) of the College of General Practitioners on March 31, 1953, when the College was three months old. The black dots in the small square in the right-hand corner represent membership in London in addition to those on the larger map. The Ordnance Survey Map is reproduced with the sanction of the Controller of H.M. Stationery Office (Crown copyright reserved).

Regional Faculty	Area Served
Wales	
Cardiff	South Wales, Monmouth
Scotland	
Edinburgh	South-east Scotland
Glasgow	South-west Scotland
Dundee	East Scotland
Aberdeen	North-east Scotland
Inverness	North Scotland
Northern Ireland	
Belfast	
Southern Ireland	
Dublin	
Galway	

Will members or associates who wish to make suggestions or comments upon the areas covered by these Regional Faculties please write to the secretary, the College of General Practitioners, 14, Black Friars Lane, Queen Victoria Street, London, E.C.4.

Preparations and Appliances

A FINE ADJUSTMENT INTRAVENOUS DRIP REGULATOR

Dr. H. J. V. MORTON, senior anaesthetist, Hillingdon Hospital, writes: The modern practice of giving potent short-acting drugs by the method of continuous intravenous infusion has created the need for a drip regulator capable of fine adjustment. Such an apparatus is illustrated here. It is intended for use with standard intravenous outfits, and has advantages which are self-evident. The finely threaded control knob swings sideways to allow the introduction of the rubber tube. The light alloy clamp opens to 1½ in.

(35 mm.), and grips the thinnest armboard or thickest drip stand. When used in the latter situation it should, of course, be fixed level with or lower than the infusion needle.

The drip rate can be easily altered by as little as one or two drops a minute, a degree of control valuable to the paediatrician. When used during anaesthesia, in conjunction with a rotameter or variable pendulum indicator (Morton, 1953), dosage can be adjusted quickly, precisely, and with one hand.

The instrument is strongly made, and is obtainable, with or without the clamp, from Bleas Anaesthetic Equipment, Ltd., 12, Hinde Street, London, W.1, to whom my thanks are due.

Procaine Amide

SIR,—Since our attention was drawn some time ago by Dr. G. E. H. Enderby to the use of procaine amide to augment the hypotensive action of hexamethonium, described by Dr. A. A. Mason and Dr. J. F. Pelmore (*Journal*, January 31, p. 250), we have investigated some of its pharmacological properties. The action of procaine amide has usually been discussed with respect to its direct cardiac action. But, since procaine itself is well known to be able to interfere with ganglionic transmission, a study of the effects of procaine amide on ganglia seemed necessary.

We have found in cats anaesthetized with chloralose: (1) that procaine amide in doses of 15 mg./kg. or more will cause relaxation of the nictitating membrane excited by preganglionic stimulation; (2) that in doses of 15 mg./kg. it will paralyse the slowing of the heart to vagal stimulation; (3) that in doses of 15–30 mg./kg. it does not lessen the depressor effect of acetylcholine or the pressor effect of adrenaline; (4) in doses of 15 mg./kg. or more it reduces the pressor effect of nicotine. In concentration of 20–50 µg./ml. it reduces the contraction of the guinea-pig's small intestine to nicotine without affecting its response to acetylcholine. These observations indicated that procaine amide can interfere with ganglionic function in three ganglia at least, the superior cervical ganglion and the vagal ganglia of the heart and viscera, without modifying the reactions of the effector cells. It remained to determine the mechanism of action.

Procaine amide, 10 mg., injected during perfusion of the cat's superior cervical ganglion caused complete failure of pre-transmission and abolished release of acetylcholine on preganglionic nerve stimulation. With the perfused ganglion, procaine amide antagonized the stimulant effect of acetylcholine on the ganglion. Using the electrical recording of ganglion action potentials, procaine amide was found to be able to reduce these considerably without causing any depolarization of the ganglion. These results show that procaine amide has two actions at the ganglion-inhibition of acetylcholine release, and an antagonism to the effects of acetylcholine. The second of these two actions should, of course, simply sum with that of hexamethonium, if the two drugs are given together. But the interaction of the first action, that of preventing acetylcholine release, with the action, that of preventing acetylcholine release, might acetylcholine-antagonizing power of hexamethonium, might present novel features. We find, in fact, that in the cat procaine amide and hexamethonium potentiate one another, and that the effect of a mixture is greater than that expected from simple addition of the two components.

It seems probable, therefore, that this synergism between depression of acetylcholine release and competition with acetylcholine could go some way to explain the clinical synergism observed. The question arises whether any of the hypotensive action of procaine amide can be attributed to a direct cardiac action. Our only evidence on this point suggests that, in the cat, this is not true, since the relative potency of procaine amide to hexamethonium in lowering blood pressure is actually less than its relative potency in relaxing the nictitating membrane.

Procaine amide appears to offer, therefore, a new possibility of supplementing the action of a ganglion-blocking agent with a drug active by mouth, with which it might be possible to attack ganglia at present relatively refractory to such agents.—We are, etc.,

A.C.T.H. and Tuberculous Meningitis

SIR,—The results of the treatment of acute disseminated encephalomyelitis with A.C.T.H. by Dr. H. G. Miller (*Journal*, January 24, p. 177) interested me very much, as I am working on similar lines, except that I am applying this treatment in cases of tuberculous encephalomyelitis, against the warning of this author, who supposes that therapeutic use of A.C.T.H. in tuberculous meningitis "might well be disastrous."

My experiments are limited to those cases of tuberculous meningitis in children, treated with antibiotics, which develop acute neurological symptoms in the late period of treatment (after 10 weeks). The clinical behaviour of such cases is very similar to the symptomatology of acute disseminated encephalomyelitis. Here also we observe violent attacks followed by periods of relaxation, and we too suppose that they are caused by attacks of "allergic vasculitis" on the basis of a hypersensitive reaction of altered blood vessels of the brain. Lowered chloride levels in the C.S.F. in such cases suggests that oedema of the brain may follow or accompany the changes in the blood supply. This syndrome occurs in about 50% of our cases of tuberculous meningitis treated with antibiotics. They are refractory to further application of chemotherapeutics and their mortality rate is about 70%. In despair we tried A.C.T.H. in such cases. The effects are very encouraging, especially if A.C.T.H. is applied after previous preparatory administration of intrathecal tuberculin. We give 10⁻⁷ solution purified protein derivative tuberculin intrathecally every 2–3 days, in successively increasing doses—0.2, 0.4, 0.6, 0.8, and 1 ml.—then 10⁻⁶ in the same way until a distinct inflammatory reaction in the C.S.F. is provoked as shown by a pleocytosis and increase of protein level. Then the purified protein derivative administration is stopped and A.C.T.H., 15–25 mg., is given intramuscularly four times daily. The mortality rate among children so treated fell from 68% to 33%. In cases of blockade of the circulation of the C.S.F., A.C.T.H. reduces the protein level of C.S.F. and very often re-establishes free communication.

During combined treatment with tuberculin and A.C.T.H. no chemotherapeutics are given.—I am, etc.,

B. HALIKOWSKI,
Paediatric Department
of the Tuberculosis Institute.

Warsaw.

"Butazolidin"

SIR,—In your leading article on "Benefits and Dangers of Butazolidin" (December 27, 1952, p. 1401) you commented on the toxic reactions to the drug, particularly emphasizing the risk of damage to the haemopoietic system. The following case may therefore be of interest.

A woman, aged 24 years, who had suffered from rheumatoid arthritis for many years, was given a course of butazolidin, 200 mg. twice a day, from February 9 to February 18. On February 17 she complained of a sore throat and feverishness. A provisional diagnosis of scarlet fever was made and the patient was given a course of sulphadimidine, 1 g. four-hourly, during February 19–23 without any improvement in her condition. She was therefore admitted to hospital on February 24.

On admission the patient was afebrile and was found to have slight inflammation of her fauces, associated with a generalized erythema. A throat swab was taken, but no haemolytic streptococci were isolated. A white cell count on February 25 gave 1,800 cells/c.mm., with 50% polymorphs and 50% lymphocytes. In view of the neutropenia, a further count was done on February 26, which gave Hb 9.2 g., red blood cells 4.46 million/c.mm., white blood cells 4,500/c.mm., neutrophil polymorphs 34%, eosinophil polymorphs 3%, lymphocytes 58%, monocytes 5%, platelets 340,000/c.mm. The sore throat persisted for 12 days and the rash for 15, following which there was desquamation. The patient remained afebrile during her stay in hospital. The following white cell counts were done before she was discharged on March 14: March 3, white blood cells, 5,100/c.mm., 44% polymorphs; March 6, white blood cells 4,400/c.mm., 36% poly-

morphs; March 11, white blood cells 5,700/c.mm., 62% polymorphs.

The only other drug treatment this patient had had for the rheumatoid arthritis within the previous four months, apart from the butazolidin, was aspirin.—We are, etc.,

G. E. BREEN.
R. T. D. EMOND.

Isleworth, Middlesex.

SIR,—In view of the widespread use of butazolidin for the relief of rheumatic symptoms I draw attention to another death following its administration.

A man of 59, with chronic bronchitis and rheumatoid arthritis of eight years' standing, began taking one tablet of butazolidin twice daily (400 mg. daily) on January 31. It substantially relieved his pain and enabled him to continue working. On March 13 he was "feeling fine" and was full of praise for his new tablets. His white blood count was 12,100, and showed a slight neutrophilia. His treatment was continued, but he was next seen after admission as an acute emergency on April 7. He had been ill for four days, and was then cyanosed, intensely dyspnoeic, and his circulation was failing. He had a massive consolidation of the left lower lobe, and examination of peripheral blood smears showed an absence of granular cells. He died 14 hours after admission.

It is likely that butazolidin contributed to his death, and the case emphasizes the importance of performing a white blood count immediately should a patient taking the drug develop fever or any other symptom of constitutional illness.—I am, etc.,

Sheffield.

G. R. NEWNS.

A New Diphtheria Prophylactic (N.A.F.T.)

SIR,—Since reporting the results of the experiments published in the *Journal* (February 14, p. 370) it appeared from further experiments done in guinea-pigs that different batches of the natural adjuvant varied from one another in their power of augmenting the antigenicity of purified diphtheria toxoid. It was also observed that each batch of the natural adjuvant had a definite optimum. If added to the toxoid in quantities either less or more than this optimum, the protection offered to the guinea-pigs against the challenge of the toxin by such mixtures appeared to be less than that offered by the optimum mixture. It is necessary, therefore, when testing the adjuvant power of a new batch of N.A.F. to employ several different quantities of the dried material—say 0.2 mg., 0.35 mg., 0.5 mg., and 0.65 mg. per Lf of the purified toxoid—instead of any one chosen quantity, and to compare the protection given by each of these different mixtures with that given by the toxoid alone.—I am, etc.,

Bombay, India.

D. C. LAHIRI.

Mental Hospital Service

SIR,—I hope that Dr. Otho Fitzgerald's letter (*Journal*, April 4, p. 781) will attract the attention it deserves, particularly among the junior staff in mental hospitals. There is a growing tendency to concentrate all the hospital's resources on the acute and recoverable patient and to neglect and ignore the chronics. Fortunately this attitude does not apply to all mental hospitals. Following the lead given by Dr. T. P. Rees at Warlingham Park, at least one other hospital has inaugurated a scheme for the rehabilitation of the chronic patient which has revolutionized the atmosphere in the chronic wards, stimulated the interest and imagination of the nursing staff, and literally brought back to life many patients who otherwise would have led a purely vegetative existence to the end of their days.

But all this cannot be done without the active interest and co-operation of the physician superintendent. The National Health Service has done a grave disservice to mental hospitals by encouraging superintendents to discard their administrative responsibilities and to concentrate almost exclusively on clinical psychiatry. The result of this change has been that young men entering the mental hospital service now learn nothing of the administration of the hospital and are ignorant of the facilities

available for the occupation of chronic patients in the various utility departments of the hospital. Comparatively few patients are employed on farms and gardens, yet many psychiatrists would agree that they can provide the best possible form of occupational therapy for a large number of chronic patients. Another disquieting feature is that the hospital has often ceased to be "a happy ship." Friction between lay administrators and medical staff arises, and there is a constant shifting of responsibility through all grades and divisions right back to the regional board.

I maintain that a mental hospital is so constituted that there must be one individual who is responsible to the committee for everything which happens within the hospital. He must be fully conversant both with the administrative problems and with modern psychiatric methods—a benevolent patriarch to whom all can turn for help and advice. There should be no interference with the clinical autonomy of other consultants, but at the same time the superintendent should have proved his ability as a clinical consultant himself so that his opinion would be respected and perhaps even sought when special difficulties arose. In other words, physician-superintendents should be appointed from senior consultants who have also a flair for administration and the teaching of postgraduate students. Naturally, their remuneration should be adjusted to compensate for the additional responsibilities which would attach to the job.

I shall probably be accused of advocating a reactionary measure. This would not be so if sufficient care were taken in the appointing of new superintendents only from applicants of the highest calibre, and such would, in my opinion, be attracted only if the job were up-graded in the way here suggested. A recent advertisement read: "Whole-time Consultant Psychiatrist. The appointment carries the Medical Superintendentship of — Mental Hospital." Obviously the medical superintendent is regarded as subordinate to the consultant. Unless we reverse this relationship the chronic patient is doomed.—I am, etc.,

London, W.1.

J. C. SAWLE THOMAS.

Prolapse

SIR,—I found Mr. A. J. Wrigley's refreshing account of prolapse (*Journal*, April 4, p. 778) most complete and satisfying. The only sentence that I would quarrel with is his statement that "the diagnosis of prolapse is easy." In most cases this is so, but often the painful symptoms of prolapse occur before the patient or her doctor have become aware of any uterine descent. By painful symptoms I mean that low backache and dragging in the groins which may be troublesome only at period time and is sometimes mistaken for dysmenorrhoea. These early symptoms are presumably due to stretching of the parametrial supports, and, like the pain of flat foot, is most marked when stretching is occurring, disappearing later when the prolapse is fully developed.

Diagnosis of prolapse at this early stage by the usual method of inspection during straining may be impossible if there is a good perineal support. There will then be no gaping at the introitus to reveal the descent of the cervix. Thus, if the symptoms suggest prolapse, it is advisable to retract the perineum with a Sims speculum while the patient lies in the left lateral position, and straining may then show an obvious descent of the cervix. If the uterus is retroverted this will be particularly liable to occur, and the backache of retroversion is due to this concomitant prolapse. The diagnosis in these less obvious cases may finally be made only by the empirical use of the pessary.—I am, etc.,

Birmingham.

A. L. DEACON.

Transverse Arrest of Head

SIR,—Mr. Bryan Williams is to be congratulated on his excellent account (*Journal*, April 18, p. 865) of the mechanism and treatment of transverse arrest of the head and occipito-posterior position. It is high time undergraduate teaching of the mechanisms of labour abandoned the idea that the usual engagement of the head is in an occipito-anterior or occipito-posterior position. Another concept that should be stressed more in teaching is the factor of pelvic shape rather than primary deflection of the head as a cause of posterior rotation of the occiput.

In describing the application of Kielland's forceps Mr. Bryan Williams states that only two fingers are needed to introduce the blades. In my limited experience it seems that where transverse arrest has occurred there often remains a loose rim or lip of cervix between the head and the sacral promontory, and I have always found it necessary to introduce a hand to be certain that the blades pass inside the cervix, especially as the handle must be carried far back to enable the tip of the blade to clear the promontory and slide up round the head. In De Lee's illustration of the manoeuvre¹ it is true that only two fingers are ensuring that the blade passes safely, but the whole hand is within the vagina.—I am, etc.,

Northampton.

Intercourse after Syphilis

SIR,—It is tempting to allow Dr. P. Durel's letter (*Journal*, April 11, p. 838) to stand as an answer to your expert's letters, because, after saying that he has seen no relapse later than six months after such treatment as he and colleagues now give, he hedges with quite a strenuous treatment if the spouse becomes pregnant; it reminds one of the captain of the *Pinafore*: "Well, hardly ever." Having regard to the scarcity of new syphilitic infection in, at any rate, this country, until the results are known of such operative studies of the effects of modern treatment of syphilis as are now proceeding under the auspices of the World Health Organization in this and other countries neither your expert nor any other individual syphilologist can say what is the longest period after which no relapse has occurred. And a patient in relapse is sexually as contagious after one form of treatment as after another if the relapse is within the first two years of infection.

Dr. Durel concedes in effect the point which I made—that, psychologically, syphilis can be a life sentence—yet he advocates risking it and seems to write as if we who advocate a longer period of observation wish to make this longer than that imposed after arsenical-bismuth treatment. Anyhow, I do hope that neither will so advise any man who is to marry or has married any girl in whose welfare I am interested.—I am, etc.,

London, S.W.1.

L. W. HARRISON.

Intestinal Polyposis Associated with Oral Pigmentation

SIR,—May I comment on the medical memorandum (*Journal*, March 21, p. 659) of Drs. I. Kaplan and M. Feuchtwanger on this subject? They state that this syndrome was first described by Jeghers in 1944. Fisher,¹ in his report of a case, correctly gave the credit for the original description to Peutz,² by whose name the condition is sometimes known (syndrome of Peutz).—I am, etc.,

Belfast.

R. D. G. CREERY.

Chemotherapy of Malaria and Trypanosomiasis

SIR,—In the paper on "The Chemotherapy of Malaria and Trypanosomiasis" by Dr. L. G. Goodwin (*Journal*, February 7, p. 311) no differentiation is made between the treatment of infections due to *Trypanosoma rhodesiense* and those due to *Trypanosoma gambiense*. This is a common error found in nearly all the textbooks of tropical medicine.

Early cases of *T. rhodesiense* (that is, cases diagnosed within three weeks of the onset) always do respond satisfactorily to treatment with suramin ("Bayer 205," "antrypol"). There is, in my opinion, no justification for imperilling the chances of recovery of the patient by losing valuable time in trying other drugs.

Early cases of *T. rhodesiense* do not respond satisfactorily to treatment with pentamidine. In 1940 I treated

three cases of *T. rhodesiense* at the request of Warrington Yorke with a substance which he described as "an aromatic diamidine containing no heavy metal." One of the patients was an African male in hospital awaiting operation for hernia, and was diagnosed on the first day of symptoms of sleeping sickness, with high fever, a positive blood, and only two cells per cubic millimetre in the cerebrospinal fluid. The treatment was unsuccessful in all three cases. More recent experiments in 1951 with the latest product, pentamidine, were equally disappointing.

In my opinion pentamidine has no place in the treatment or prophylaxis of trypanosomiasis due to *T. rhodesiense*.—I am, etc.,

St. John's, Antigua.

A. J. KEEVILL.

Intravenous Iron

SIR,—I was most interested in Dr. Betty D. Holt's comments (*Journal*, April 11, p. 834) on my paper on intravenous iron (*Journal*, January 3, p. 21). I would be grateful for space to reply to the points raised.

Although I have no idea how many injections are given in England per year, I have no doubt that they must amount to some thousands. Only the severest reactions are usually recorded in the medical press. With present-day preparations, therefore, intravenous iron is a safe procedure if judged on these grounds. I feel, however, that the dangers should not be minimized and that an attitude of complacency is to be deprecated. I am glad, therefore, to see that Dr. Holt is in agreement with this. I consider these reactions to be largely allergic in character. It is well known that tendency to allergy varies in different races. Perhaps racial differences would account for the absence of reaction in her cases.

Finally, in regard to dosage, my early practice was to use a commencing dose of 100 mg. and follow up on alternate days with the same dose, but, since my adverse experience, I now use 25 mg. to 50 mg. at the start. Although I see that Dr. Holt has had no troubles so far with the large doses (100 mg. to 200 mg.) used, I feel that these are too high, unless, of course, the difference in racial sensitivity is a real factor.—I am, etc.,

Romford, Essex.

I. M. LIBRACH.

Judet Acrylic Prostheses

SIR,—In recent months a number of Judet acrylic prostheses have had to be removed from patients because of mechanical failure. These failures may be due to one or more of the following factors: the unsuitability of the materials employed, design, manufacturing methods, sterilization procedures, position of insertion of the prosthesis, and fit of the acrylic head in the acetabulum. In collaboration with Dr. Zarek, of the Faculty of Engineering, King's College, University of London, experimental work is being carried out the results of which it is hoped may shed some light on the cause of these failures. The number of cases to which we have access is naturally limited. It would be of the greatest assistance if surgeons and pathologists who remove any prosthesis from a patient (which may or may not be broken), either at operation or necropsy, would be kind enough to send it to me at the Plastics Research Unit, The Institute of Orthopaedics (University of London), Royal National Orthopaedic Hospital, Stanmore, Middlesex. The following information is required: (a) a brief pre- and post-operative case history with the actual or estimated weight of the patient (personal details which might identify the patient are not required); (b) all radiographs in which the prosthesis can be seen, which will be returned; (c) details of method of sterilization and, if possible, whether the prosthesis has been sterilized on a number of occasions; (d) the prosthesis.

It is hoped that all those interested in this problem will co-operate, as an investigation of this kind can be of value only if as many as possible of the failures can be investigated.—I am, etc.,

Stanmore, Middx.

JOHN T. SCALES.

The Degradation of Flour and Bread

SIR,—In your issue of March 14 last you gave details of the composition of the new white flour as they were given by Dr. Charles Hill, M.P., in answer to a question in Parliament. The figures given are likely to make us think that all will be well with our new white flour, for they appear to show that for every nutritional constituent taken out of the present 80% flour when reduced to a 70–72% extraction one has been replaced in the new 70–72% “restored” flour, except for a slight reduction in protein.

This is far from the truth, because the figures only include three out of the ten or more vitamins of the B-complex group, and only two out of a dozen or so minerals, and do not mention the loss of the roughage (which has its own part to play in our body economy) or the loss of vitamin E. The degradation of our daily bread from about 1870 down to the present time has been a kind of rake's progress. In the space available to me it is only possible to give a very faint picture of it.

Here are a few approximate figures. The ash of whole wheat is 1.53 g. per 100 g.; in 85% extraction it is 0.75; in 80% extraction 0.59; and in a 70%, 0.41.¹ The ash contains the bulk of the minerals, and the reduction of minerals follows largely this reduction—for example, potassium is reduced from 312 to 82 mg. per 100 g. in a 70% flour, and copper from 60 to 18 mg. per 100 g. The vitamins will also show a somewhat similar pattern of degradation—for example, aneurin from 110 to 22 i.u./g., nicotinic acid from 55 to 8.4 µg./g. The three vitamins aneurin, riboflavin, and nicotinic acid are restored in the new flour to the 80% flour level only; and of two minerals, iron is restored to the 80% level of 1.65 mg. per 100 g. but not to the 3.81 mg. per 100 g. of whole meal. Calcium is dealt with differently, in a reinforced manner.

The general result of all this degradation process of whole meal to the new white “restored” flour will be an unbalanced kind of loaf reduced greatly in all its nutritive constituents—calcium, carbohydrate, and, to some extent, protein excepted. Want of balance can cause a nutritional upset as well as the nutritional deficiency diseases caused by individual shortages. It would take a considerable space to describe all these separately, but we do know that they are something that cannot be disregarded. Two will be mentioned.

In pantothenic acid deficiency there are changes in the anatomy and function of the adrenal gland, with degeneration of the cortex; oxidation of fatty acids is also impaired.² In pyridoxine deficiency the skin, haemopoietic tissue, and nervous system are adversely affected, producing cheilosis and angular stomatitis and a microcytosis accompanied by polycythaemia and fall in haemoglobin concentration.³ Generally speaking it is growing tissues that are most affected when pyridoxine is in short supply.

To conclude, I suggest that before any further steps are taken to put the new white flour on the market an inquiry should be held at once by some competent body containing members with experience in deficiency diseases—for example, members of the Medical Research Council, Nutrition Society, Ministry of Health, the B.M.A., and Society of M.O.H.s. The degradation of our daily bread has reached a stage at which there should be a call to halt.—I am, etc.,

E. H. M. MILLIGAN.

Survey of Prescribing in Scotland

SIR,—I have read with interest the article by Professor D. M. Dunlop and Drs. R. S. Inch and J. Paul (*Journal*, March 28, p. 694), but I would like to point out an inaccuracy in their figures which may account for the apparent low mean monthly script rate per 1,000 population in the Highlands and Islands.

For the County of Sutherland, the numbers of scripts given by them in Table III as issued in 1951 include only those dispensed by chemists—I have verified this—and it has apparently been overlooked that five of Sutherland's twelve doctors (not eleven as stated, although in October, 1951, one practice vacancy was in the process of being filled) have dispensing practices with a total of approximately

3,800 patients, which figure should have been deducted from the total number of registered patients. It would not be possible to correct this discrepancy by adding the number of scripts dispensed by doctors, as some are paid on a capitation basis and return no scripts except for expensive medications.

This applies to all counties in the Highlands and Islands, and the fact that Shetland has by far the lowest monthly script rate per 1,000 is doubtless accounted for by the fact that this county has proportionately the largest number of dispensing doctors.—I am, etc.,

Golspie, Sutherland.

IAN D. PENNIE.

The Foley Catheter

SIR,—Mr. G. E. Moloney in his informative contribution (*Journal*, March 28, p. 706) on pelvic evisceration and uretero-colic anastomosis reminds your readers that an anal catheter helps to keep the patient dry during post-operative recumbency.

Where hysterocystectomy with uretero-colic anastomosis has been accomplished to extinguish an anterior invasion by cervical carcinoma, my gynaecological colleague, Mr. J. A. Chalmers, and I have found a Foley's catheter the perfect conduit for draining the rectal contents during the early period of convalescence. The catheter is inserted above the ano-rectal ring and the bag is inflated, but not sufficiently to cause mucosal pressure-necrosis. A wide-bore instrument will convey away, without soiling the patient's attire, all the faeculent urine and flatus, allowing full liberty of movement, since it is “self-retaining.” It is also labour-saving, and the perineal cleanliness reassures the patient when her vitality is at its lowest ebb.

I should like to mention the use of Foley's catheter modified for another operation. When the adenomatous prostate has been removed by any method and the surgeon wishes to leave a urethral catheter in position, he fears that it may be blocked by clot or promote infection. If the bag is removed from the catheter before inserting it into the urethra, and if the eyelet occupies the vacant prostatic capsule, the bladder or the capsule may then be closed after haemostasis and the side tube of the catheter can be used for continuous irrigation. With the patient back in bed it is connected to a reservoir supplying a lotion through a drip tube. The greater tube of the catheter is connected to a receiver, another drip tube of large dimensions intervening so that inflow and outflow coincide. Thus, the two-hourly syringing, so tiresome to the nurse and her patient and often septic, is avoided.

I use initially two flasks of sodium citrate solution and follow this with 1/5,000 flavine in saline. The catheter is removed in 48 hours and the patient usually micturates spontaneously. It is lubricated with penicillin cream. This method of irrigation is to be considered as a modification only of Mr. Wilfrid Adams's “third ureter”—a ureteric catheter introduced into the bladder suprapubically after prostatic enucleation and connected to a reservoir of lotion.

If a Foley catheter could have a second side tube for irrigation, its bag intact, then the triple function could be harnessed to the patient's treatment.—I am, etc.,

Worcester.

PAUL HOUGHTON.

Treatment of Perforated Peptic Ulcer

SIR,—I have followed the correspondence on the treatment of perforated peptic ulcer with very great interest, but I am not quite sure that the routine practice of simple closure is obsolete, even though this may entail a second operation later on. I have performed personally, or through my assistants, 673 closures with only one death.

Since I standardized my treatment it has not varied. This consists, immediately the diagnosis is made, in gastric aspiration and a saline drip, and then, after the operation, further aspiration and the continuance of the intravenous saline for at least another 48 hours. I must confess that the majority of these cases were Service people, which means that there was no delay in their admission to hospital and that they were in good condition otherwise. But not a few were performed on African natives before the 1939–45 war. The

one death occurred in a young soldier who had perforated 48 hours before admission: he died a week after the operation and, regrettably, no necropsy was allowed.—I am, etc.,

Epsom, Surrey.

S. M. VASSALLO.

SIR,—Mr. Hermon Taylor (*Journal*, April 4, p. 781), in discussing the conservative treatment of perforated ulcers, says, “Clearly the method of gastric aspiration can achieve all that can be obtained by the method of surgical closure, but with the not inconsiderable advantages of avoiding an operation.” He further states that modern developments have made simple closure of perforations obsolete. To my mind, operation has several possible advantages: (1) fluid can be sucked out of the subphrenic spaces; (2) the size and situation of the ulcer can be assessed; (3) the possibility of malignant change can be largely excluded; and (4) appropriate treatment can be given if the diagnosis proves to be wrong—e.g., perforated cholecystitis, appendicitis with general peritonitis, pancreatitis, or even small-bowel obstruction.

Continuous aspiration has its disadvantages. It is usually necessary for four to five days, and entails intravenous saline with all its dangers and complications. A very high proportion of cases treated by operation only need gastric suction for about 36 hours. A rectal drip is then quite adequate to prevent dehydration.

Surely the discomforts and dangers of operation have been exaggerated during recent years. It has been my practice to combine local and light general anaesthetics, which give complete relaxation without any interference with chest or diaphragmatic movements. The patient usually wakes up almost free from pain. I have personal experience of 385 operations, and I think that a patient who cannot stand this line of treatment is most unlikely to recover from any other.—I am, etc.,

Farnham, Surrey.

STANLEY C. RAW.

Research in General Practice

SIR,—Professor Robert Platt's address (*Journal*, March 14, p. 577) was indeed stimulating, but those who try, however unpretentiously, to carry his ideas into practice do not always find that things go very smoothly. Some years ago I was taunted by a patient that British medicine lagged behind the Soviet variety inasmuch as Russian doctors were completely relieving the pangs of childbirth by injections of vitamin B. This information had been gleaned from a Soviet propaganda publication which had considered a able circulation in this country. I wrote immediately to a firm which is generous in the matter of circulars and samples, and is prominent as a manufacturer of vitamin products. I suggested that the matter might be very quickly tested by the issue to a sufficient number of general practitioners of enough vitamin B to be used in their cases, on condition that reports were sent of the results. The firm's medical adviser pooh-poohed the whole project.

On another occasion I wrote to the *Journal* on the subject of the long-term results of electric shock treatment in mental illness, because I felt that general practitioners would have more reliable views on the subject than those held by the more enthusiastic psychiatrists. If my memory serves me correctly there was no reaction, good, bad, or indifferent, from my colleagues.—I am, etc.,

Launceston.

DONALD M. O'CONNOR.

Chloroform for Bronchography in Children

SIR,—Mr. Leslie J. Temple and Dr. T. Cecil Gray, in their letter (*Journal*, April 18, p. 883) commenting on our article on bronchography in children (*Journal*, March 14, p. 601), state that it implies that the child may suffer from hypoxia during the use of our technique. This is certainly not so. We attain rapidly a short, deep anaesthesia and at all times the child is well oxygenated. We do not suggest

that chloroform should be used by the inexperienced, but we think that explosive agents are better avoided in the x-ray room.

As regards the airway, it may be difficult to prevent obstruction without it in some of those children with enlarged tonsils and adenoids. Finally, an important difference between our technique and Gray and Temple's, not mentioned in their letter, is that we do not “drown” our patients with lipiodol, as we feel that in bronchiectasis there is enough foreign material in the bronchi without adding to it more than the minimum necessary.—We are, etc.,

MARGARET I. GRIFFITHS.

T. D. CULBERT.

Manchester.

SIR,—Having used the method of anaesthesia for bronchography in children described by Mr. Leslie J. Temple and Dr. T. Cecil Gray (*Journal*, April 18, p. 883) since I was first taught it by Dr. John Halton some five years ago, I can only agree with all the authors' remarks concerning the method.

Being worried about the possibility of explosion, I too tried chloroform and other agents, but soon realized, fortunately at the cost only of minutes of acute anxiety on more than one occasion, that as deep anaesthesia is necessary it is most safely produced by ether. I feel convinced that explosions as a result of ignition of ether vapour by x-ray equipment have been much rarer than fatalities from the use of chloroform, and would join Mr. Temple and Dr. Gray in pointing out the dangers of using chloroform where some degree of hypoxia is to be expected as a result of deep anaesthesia and the introduction of oil into a diseased respiratory system.—I am, etc.,

Manchester.

TOM DINSDALE.

Antihistamines and Asthma

SIR,—Drs. A. W. Frankland and R. H. Gorrell (*Journal*, April 4, p. 761) ought to be congratulated on the skill with which they have refuted the assumption that antihistamine treatment of hay-fever causes asthma. Their further conclusion that antihistamines do not improve asthma is hardly justified by their experiments. They have given mepyramine, apparently in four separate daily doses of 100 mg., or another equivalent antihistamine, and have not seen any benefit from it. Nor have I. Antihistamines influence asthma only if a much larger dose is given than that effective in allergic rhinitis. There is ample evidence for their efficiency,^{1,2} but I have never seen a beneficial effect with less than a single dose of 300 mg. of mepyramine. An amount of 100 mg. cannot be expected to influence asthma, just as one would not expect one minim of adrenaline to influence it. It would appear essential that in therapeutic trials, controlled or uncontrolled, the doses used are not subthreshold ones, as in this case.

The difficulty with antihistamines in asthma is that the large doses required often have side-effects which make their use impracticable during the day. They are best used in single doses at bedtime, when they may secure an asthma-free night. The use of one single dose in 24 hours also avoids the development of tolerance, which easily occurs with multiple doses.—I am, etc.,

London, W.C.1.

Television and the Patient

SIR,—I should like to endorse very strongly the opinion expressed by Dr. T. Hughes (*Journal*, April 18, p. 884) in the letter under the heading “Television and the Patient.” In general, television programmes on medical subjects seem calculated to foster in the minds of ordinary people the

deplorable idea—already far too prevalent—that the attitude of the medical profession can be expressed as, "It doesn't really matter how you live: modern medical science is so wonderful that you can be made fit whatever happens—if you are properly treated." The view that it is the business of the State, through its "Health" Service, to make and keep everyone healthy is thus still further encouraged instead of the true view that it is the duty and privilege of each individual to think and live in such a way as to attain the greatest possible degree of mental and physical efficiency.

Soon after I had a television receiver installed in my home (about two years ago) I was so impressed by the possibilities of television as an educational medium that I summoned up courage to write to the B.B.C. to suggest, humbly, that it might be a very good thing if a small amount of time (perhaps 20 or 30 minutes once a month) could be devoted to a health education series in which a plainly worded and interestingly illustrated exposition of relevant biological facts could be given, coupled with hints on "keeping fit" based on these facts. After some time I received a letter in reply which said that I should be glad to know that the sort of programme I advocated was being sent out from time to time, and went on to instance the very sort of thing that Dr. Hughes has referred to. I wrote again and tried to explain as carefully as I could the difference between that kind of programme and the educational programmes that I felt could be so beneficial, but again I got a reply which seemed to indicate a complete failure to see my meaning, and I am afraid I gave up the struggle as hopeless.

Would it be possible for representations to be made to the B.B.C. on this matter?—I am, etc.,

London, N.W.3.

A. DALBY.

SIR,—As one responsible for the section on anaesthetics in the "Pain" programme referred to (*Journal*, April 18, p. 884), I think that Dr. Trevor Hughes's letter has served a useful purpose in attracting attention to the subject in the daily press. The contribution of anaesthetics to the advancement of surgery is now freely recognized in the medical profession, and the consumers—the public—are entitled to information upon it. From the comments I have heard from time to time from lay members of the public, it is clear that interest in such matters springs from healthy intelligence and but rarely from morbid curiosity.

Whatever the merits of the "rag and bottle" administration of anaesthetics may be, to many people experience of it is a distasteful memory. It is fair that the public should know that in experienced hands more pleasant methods of anaesthesia are available to all in this country—as they should be under the Health Service. Television provides a useful medium for extension of this knowledge. Can Dr. Hughes suggest a better medium, or would he prefer his patients to be kept in ignorance?—I am, etc.,

London, W.1.

I. W. MAGILL.

Polypharmacy

SIR,—Dr. A. T. Mennie (*Journal*, April 18, p. 887) overstates his case. While multiple deficiencies may be common in anaemia—though which is cause and which is effect may be hard to say—it is still a fact that the common so-called "nutritional hypochromic anaemia" can be treated adequately with iron alone. Even when combinations of therapeutic substances produce a more rapid rise in haemoglobin, speed of cure alone is seldom important.

There are those whose hypochromic anaemia responds inadequately or not at all to iron. After investigations have excluded haemorrhagic or other organic causes there may be a place for treatment with multiple agents, the nature and dosage of which should depend upon each patient's needs and not merely be determined rigidly by the contents of a capsule.—I am, etc.,

London, N.W.6.

J. I. E. HOFFMAN.

POINTS FROM LETTERS

Counting High Pulse Rates

Dr. R. J. K. BROWN (London, S.E.24) writes: Dr. E. Montuschi (*Journal*, April 4, p. 781) mentions a technique for counting high pulse rates. May I describe another which is equally applicable to both high and low pulse rates? . . . The number of beats are counted in three consecutive five-second periods: the highest and lowest figures so obtained are then multiplied by 12. For example, if these figures were 6 and 7, one could say the pulse rate was swinging between 72 and 84 (with a mean of 78). I have found this method particularly useful in paediatric practice.

Drunk in Charge

Dr. C. RUTTER (London, E.6) writes: I was interested to read Dr. A. E. M. Hartley's article (*Journal*, March 28, p. 735) on "drunk in charge." I would suggest, however, that the examination should take place immediately on arrival, before the essential questions are asked. The medical history might be long and take time to obtain in full, thus giving the person being examined time to sober up.

Research in General Practice

Mr. A. P. BERTWISTLE (Birmingham) writes: In Professor Robert Platt's admirable paper on the above (*Journal*, March 14, p. 577) he instances the experiment of cleaning the teeth on one side to find out whether the tooth-brush prevented caries. There is an important snag—the subject must sleep on his back. Most of us sleep on the left side, with the result that tartar forms more abundantly on this side, and this may have its repercussion on caries.

Comfort in Air Travel

Dr. FLORENCE ADAM THOMSON (Ipoh, Malaya) writes: I should like to refer to Part I of Sir Harold Whittingham's refresher course article on air travel (*Journal*, March 7, p. 556). I realize that considerable thought has been given to the design of aircraft seating so that passengers may have reasonable comfort in a confined space. Has it been brought to the notice of B.O.A.C. that, despite this, most passengers are quite unable to rest in comfort in the position allowed, and sleep is quite impossible except in very short snatches? I and many friends of average stature have found that after a journey there is such severe oedema of feet and legs that to walk or work in comfort is impossible for several days. Were a little extra space given on the longer runs, with tilted seating and leg rests similar to that on some American lines, passengers could rest and arrive refreshed even when no night stops are made.

Slipped Disk

Dr. HUGH GARLAND (Leeds, 1) writes: I am not quite sure when and where the term "slipped disk" was coined, but it has now passed into common usage and indeed it has become one of the stock jokes of the comedian. It is a most improper term, carrying the implication that the whole disk has slipped in some direction in relation to the vertebrae above and below, and there is a popular corollary that, having slipped out, the disk is capable of slipping back. As far as I know such a pathological state has never been seen by the human eye. I think it is our duty to discourage this terminology, and I was perturbed to see the unhappy term used in the *Journal* ("Any Questions?" March 7, p. 575). Syndromes resulting from damage to intervertebral disks have been diagnosed with increasing frequency over the past 15 years, so that to-day the disk lesion is well known to the public. The main change in the disk is one of protrusion, usually of a very localized kind, and to which the terms "herniation" or "protrusion" are very properly applied—but not "slipped."

Chlorophyll and Asparagus

Dr. JOHN DICKINSON (London, W.C.1) writes: Dr. John C. Brocklehurst (*Journal*, March 7, p. 541) has suggested that doctors should experiment on themselves with asparagus, to determine whether the smell of their urine is reduced by chlorophyll. Since supplies of this drug are expensive there is a danger that the experiment may be invalid through shortage of either doctors or asparagus, or both. Might I suggest that the Medical Research Council should send regular quantities of asparagus to two large groups of doctors? Half of these could then receive chlorophyll and half act as controls. If the experiment was conducted on a sufficiently large scale, statistically significant results could be of the greatest value to the public. Clearly, several weeks or even months of patient trial would be necessary; but nevertheless I am pleased to offer myself as a volunteer—preferably in the control group.

Obituary

H. S. PENDLEBURY, M.B., F.R.C.S.

Mr. H. S. Pendlebury, at one time a surgeon on the staff of St. George's Hospital, died on April 21 at his home at Malvern.

Herbert Stringfellow Pendlebury was the son of John Pendlebury, J.P., of Wigan, and was born there in 1870. He won a scholarship at Pembroke College, Cambridge, and took a first in both parts of the Natural Sciences Tripos. His small stature handicapped him for some games, but he played for his university at hockey. From Cambridge he entered the medical school of St. George's Hospital with a scholarship, qualified in 1896, took the F.R.C.S. in 1897, and graduated M.B., B.Ch. in 1898. In turn he served his hospital as house-surgeon, house-physician, surgical registrar, assistant surgeon, surgeon, and lecturer in surgery. He was also surgeon for many years to the Royal Waterloo Hospital, remaining on the consultant staff there until his death. When Pendlebury was training himself in surgery, Listerian principles had for some years already won their victory; but there were still a good many of the older men in the profession who thought they comprehended them, but in fact did not completely do so. It thus happened that in the 'nineties a group of eager and progressive young surgeons in London (and probably the same was done elsewhere) found themselves producing results which surpassed those obtained by some of their seniors. The expansion of abdominal surgery, set on foot very largely by Sir Frederick Treves, gave them a further opportunity; and Pendlebury was one of those who profited by all this to obtain glittering success in practice at a comparatively early age. He was a deft, rapid, and scrupulously careful operator and a very good teacher. One of his foibles was a somewhat unusual view of the meaning of punctuality, on which he was rightly very insistent: he maintained that to be punctual you must be five minutes early for your assignment, and could be almost bitter in his reproaches of any subordinate who failed to act up to this. For him an operation list commencing at 2 p.m. meant that the first patient must be in the theatre, anaesthetized, and with all the necessary ritual completed, so that the skin incision could be made as the clock struck the hour.

Pendlebury was a man of very great energy and organizing ability, which he employed in the promotion of two ventures, novel at the time, but now accepted as part of the natural order of things. The Royal Society of Medicine was one of these, founded in 1907 by the amalgamation of eighteen societies representing, for the most part, specialties in medicine and surgery. When this federation was accomplished, he was the Society's honorary secretary for some years—the most difficult ones, of course—and honorary treasurer for some years thereafter. In both capacities he served the profession extremely well. The next organization which he helped to promote was that of the Association of Surgeons of Great Britain and Ireland in 1920, in which Lord Moynehan was keenly interested. Here again his organizing ability and enthusiasm were valuable assets.

During the first world war Pendlebury served in the R.A.M.C., being attached to the 4th London General Hospital. He contributed a number of case reports to medical journals, and was the author of two chapters in Latham and English's *System of Treatment*. Besides

being a member of the Court of Examiners of the Conjoint Board, he examined in surgery for the University of Cambridge and the Society of Apothecaries.

Pendlebury married first Lilian Dorothea, daughter of the late Sir T. L. Devitt: she died in 1921, leaving as issue Mr. J. O. S. Pendlebury, who, after gaining an athletic Blue at Cambridge, was rapidly making a name for himself in archaeology, and was killed in Crete in 1941 during the German invasion of the island. He married again in 1925, his second wife being a daughter of Mr. Richard Webb. He was interested, among many other things, in education, and gave £100 to Epsom College to found a prize for Greek studies there.

ALEXANDER MITCHELL, M.B., Ch.M.

Mr. Alexander Mitchell, well known as an orthopaedic surgeon in the north-east of Scotland, died in Aberdeen on April 16, aged 72. Although he had been in indifferent health for some months, he had two days previously, with characteristic sense of duty, insisted on travelling from his home at Old Rayne to attend a hospital board meeting in Aberdeen, and it was while acting as chairman there that he was stricken with fatal illness. He faced death with the same spirit and fortitude that he displayed throughout his life, his thought being not for himself but for the trouble he might be causing others.

Alexander Mitchell was educated at Robert Gordon's College and Aberdeen University, graduating M.A. in 1901, M.B., Ch.B. in 1905, and Ch.M. in 1907. After a few years in general practice he devoted himself entirely to surgery, mainly at the Royal Aberdeen Hospital for Sick Children and Aberdeen Royal Infirmary. He served as a captain in the R.A.M.C. in the first world war, and at its conclusion became senior surgeon at the Children's Hospital, holding that position until he took charge of the orthopaedic unit at the Royal Infirmary in 1936. He organized the orthopaedic services of the north-east of Scotland and was prominent in the councils of the British Orthopaedic Associations, of which he became vice-president. He was also an external examiner in surgery to the University of Edinburgh. When he retired from active surgical practice his services were eagerly sought in hospital management and he was elected chairman of the Special Hospitals Board a year ago. Into this work he threw himself heart and soul, welcoming an opportunity for service in a field where his intimate knowledge of medical practice, both outside and inside hospital, would be of value to the community and the profession. In 1942 he was made a J.P. for the county of Aberdeen.

To every aspect of his work "Sandy" Mitchell brought a driving force and a devotion beyond praise. Chairman of the Aberdeen Division of the B.M.A. in 1929, he was elected president of the Orthopaedics and Fractures Section at the Annual Meeting in Aberdeen in 1939. He served the profession that he loved without stint and without calculation, disregarding his own lameness and labouring day and night for the sick and especially for the crippled. His main attributes were a forthright honesty that informed his every thought and action, a love of his fellow men, outstanding magnanimity, and high courage. As patients flocked to him for relief, so did his colleagues seek his advice and help. He was laid to rest at Rayne, in the land of his fathers that he knew so well and loved so much, and the whole community sorrowed at the passing of a great-hearted and beloved son.

He married in 1913 Ada, daughter of the late Dr. Greig, of Fyvie. She predeceased him, leaving two sons, one of them a major in the R.A.M.C., and a daughter. To them and to his second wife, Alice, daughter of the late Dr. David Rorie, we extend our deepest sympathy.—S. G. D.

F. W. EDRIDGE-GREEN, C.B.E., M.D., F.R.C.S.

Mr. F. W. Edridge-Green, whose work on the testing of colour vision won him international fame, died at Worthing on April 17. He was 89 years of age.

Frederick William Edridge-Green, whose family were well known in the Potteries as the makers of the famous Crown Staffordshire ware, was born in London on December 14, 1863. He received his medical education at Durham University and St. Bartholomew's Hospital, where he won a scholarship and several prizes. He graduated M.B., B.S. in 1887 and proceeded M.D. with the award of a gold medal two years later. He became F.R.C.S. in 1892. After holding the posts of resident surgical assistant at the Newcastle-upon-Tyne Infirmary and assistant medical officer at Northumberland House Asylum he became medical superintendent of Hendon Grove Asylum. At this stage of his career he had two diverse interests—the functions of the mind, especially memory (on which he published several papers), and colour vision, about which he contributed an article to this *Journal* as early as 1889. But gradually the study of the physiology of vision became his overriding enthusiasm, and he continued his researches while retaining his post at Hendon Grove Asylum. Though some of his ideas were strongly disputed by other experts, his devotion to the cause of medical research was wholly admirable.

In those days official recognition was given to the Holmgren wool test as the method of testing colour vision, and Edridge-Green was one of the first to point out the disadvantages of this method, one of his papers on the subject appearing in the *Lancet* in 1900. Although he was made a member of the International Code of Signals Committee, his views were not at first accepted, but after the publication of his treatise on *Colour Blindness and Colour Perception* in 1909 other authorities began to confirm his work, which also received the support of a committee of the British Association. Eventually, soon after the beginning of the first world war, the colour-perception lantern devised by Edridge-Green was brought into official use for colour-vision testing by the Royal Navy, the Board of Trade, the railways, and other bodies throughout the world. The bead test, used by National Service boards, was also his invention. The many honours and distinctions which later came his way testified to the importance of his work. In 1920 he was appointed C.B.E. and also made adviser to the Board of Trade, and, later, to the Ministry of Transport. At the College of Surgeons, having been prosecutor at an early stage in his career, he was Hunterian Professor in 1911 and the Arris and Gale lecturer in 1920. He was also a Beit Memorial Research Fellow and worked for a time at Cambridge. In 1930 he was president of honour at the annual meeting of the Ophthalmological Society of Paris, and six years later he was awarded the Thomas Gray Memorial Prize for his invention of the colour-perception lantern. A distinction which pleased him was the presidency of the Durham Medical Graduates Association.

Much of Edridge-Green's professional work was done as ophthalmic surgeon to the London Pensions Board, and

he was also chairman of the Ophthalmic Board of the Central London Recruiting Boards for National Service. The author of numerous papers in English and foreign scientific journals, he published a book entitled *The Physiology of Vision* in 1920 and wrote the section on colour vision and colour blindness in the *Encyclopaedia Britannica* (1922). He was an able mathematician and a skilful player of chess and bridge. Some details of his life and early struggles are contained in his book *Science and Pseudo-science*, published in 1933. His interest in the physiology of vision continued right up to his death, and only a few weeks ago he paid one of his usual visits of inspection to the factory at Hove where the colour-perception lanterns are manufactured.

In 1893 Edridge-Green married Minnie Jane, daughter of Henry Hicks, M.D., F.R.S. She died in 1901. They had two sons, one of whom died in childhood; the other, who served in the first world war, died shortly after the armistice.

JOHN GUY, M.D., F.R.C.P.Ed., F.R.F.P.S., D.P.H.

Dr. John Guy, who died at his home at Aberlady, East Lothian, on April 11 at the age of 79, was medical officer of health for Edinburgh from 1930 to 1938. He had been in the service of Edinburgh Corporation for 25 years, and was the fourth medical officer of health for the city.

John Guy was born at Saltcoats, Ayrshire, on October 4, 1873, and was educated at the University of Glasgow, where he graduated M.B., C.M. in 1894, proceeding to the M.D. six years later. He took the Cambridge D.P.H. in 1899, and he was elected F.R.F.P.S. in 1911 and F.R.C.P.Ed. in 1917. After graduation Dr. Guy held posts in Poor Law hospitals in Bradford and Leeds before becoming medical superintendent of the Bridge of Weir Sanatorium, where he stayed for seven years. Thereafter he was for a short time tuberculosis officer for Gloucestershire, the first to hold the post, before accepting a similar position at Edinburgh in 1913, an appointment made jointly by the corporation and the burgh insurance committee in accordance with the provisions relating to tuberculosis in the National Insurance Act of 1911.

When he took office as medical officer of health for Edinburgh the health services were being unified under the Local Government (Scotland) Act of 1929. At that period public health administration in the city was limited to the control of infectious diseases, environmental and veterinary services, an infectious diseases hospital, a sanatorium and farm colony, and specialist departments for tuberculosis, venereal diseases, and maternity and child welfare. Under the Act the health functions previously carried out by the parish council and the local board of control were transferred to the public health department, including the conduct of two general hospitals for the sick poor, a mental hospital with over 1,000 beds, and a newly inaugurated institution of 500 beds for mental defectives, and to these new duties was added also the task of supervising the health of 60,000 schoolchildren. The changes represented the largest single addition to the burdens of a medical officer of health, and while they called for careful assimilation they also provided an opportunity for improved co-ordination. By 1938, when he retired, Dr. Guy had succeeded in establishing a chain of three general hospitals in which the treatment of the patients was directed by the medical staff of the University of Edinburgh, whose professors were the heads of the medical, surgi-

cal, and maternity and child life units. The association of "town and gown" raised the prestige of the hospitals and earned the warm approval of the citizens. When war broke out in 1939 the three hospitals, with many more beds and new equipment, became a valuable part of the country's emergency medical service. Dr. Guy had a special regard for the school health service, and this was reflected in his introduction of more frequent medical inspections and an increased scale of specialist treatment.

Dr. Guy was a former lecturer on public health in the University of Edinburgh, on tuberculosis at the School of Medicine of the Royal Colleges, and on hygiene in the School of Social Study at Edinburgh. Together with the late Dr. G. J. I. Linklater, he was the author of a widely used textbook on *Hygiene for Nurses*. A man of deep religious principles, Dr. Guy was associated with various benevolent societies in Edinburgh. He had a keen appreciation of music, and another of his interests was farming. He leaves a widow, three sons, and a daughter.

C. J. MCSWEENEY, M.D., F.R.C.P.I., D.P.H.

We record with regret the death on April 17 of Dr. C. J. McSweeney, medical superintendent of the Cork Street Fever Hospital, Dublin.

Born at Cork in 1899, Christopher Joseph McSweeney was educated at the Christian Brothers' College and at University College, Cork, where his father, Mr. E. P. McSweeney, was a member of the staff. A brilliant student, he won a number of scholarships and prizes and graduated M.B., Ch.B., with first-class honours, in 1921. Nine years later he proceeded to the M.D. After graduation he held the appointment of extern assistant to the Rotunda Hospital, Dublin. In 1925 he took the D.P.H. and became assistant medical officer of health at Cardiff. Two years later he was promoted to be deputy to the then medical officer of health, Dr. R. M. F. Picken. Among his other duties Dr. McSweeney was in charge of the Cardiff Isolation Hospital, and he was also appointed lecturer in infectious diseases and associate examiner for the Welsh National School of Medicine.

In 1934 he returned to Ireland to become medical superintendent of the Cork Street Fever Hospital, Dublin, a post which carried with it lectureships in infectious diseases in the Dublin medical schools together with the appointment of consultant in infectious diseases for the city. In the previous year he was elected a Member of the Royal College of Physicians of Ireland, being admitted a Fellow three years later. From 1937 to 1939 he was a Censor of the College. In addition to the appointment at the Cork Street Hospital, he was deputy professor of preventive medicine at Trinity College and consulting physician in fevers to the National Children's Hospital and the Fairy Hill Open Air Hospital. He was also an examiner for nursing councils, both in Northern Ireland and in Eire, and for the D.P.H. of the Dublin medical schools.

Dr. McSweeney was the author of many important papers about infectious diseases, and his most recent book, *The Clinical Approach to Fevers*, appeared only last month. A paper which he wrote in 1941 was entitled "A Public Health Programme for Eire"; this was published in the *Irish Journal of Medical Science*. He married Miss Evelyn H. Donegan in 1923, and she survives him, together with one son.

We are indebted to Dr. R. M. F. Picken, for the following appreciation: During the first half of the present century, when infectious diseases were still prevalent and epidemics fairly frequent, and while the new personal health services were developing quickly, the most acceptable members of public health departments were those who could turn their minds to new problems or sudden emergencies and cope with them without close supervision. McSweeney was pre-eminently of this type, a type which the public health service has found it hard to retain because of the poor material prospects. When he came to the public health department of Cardiff he was still a very young practitioner. He soon showed that he had this sort of initiative as well as unusual ability and assiduity. A problem became all-absorbing to him until he had found some practical channel for its issue. Thus he undertook from the beginning the management and clinical supervision of an institution earmarked for early cardiac rheumatism in children until it was a going concern. When variola minor broke out in epidemic form in South Wales he threw himself into its diagnosis and control so vigorously that his help was sought in a neighbouring urban district, where his energy and diagnostic skill were instrumental in bringing it quickly to an end. In his latter years in Cardiff he was both deputy medical officer of health and medical superintendent of the isolation hospital and lecturer in infectious diseases in the Medical School, arduous tasks which he fulfilled with signal success.

McSweeney had a delightful temperament, warm, kindly, and friendly to all those in any station of life with whom he came in contact. He had a keen sense of humour and a ready wit. I think he was happy in South Wales and appreciated the qualities of those natives of this other island with whom he worked. We, of course, saw less of him after he became medical superintendent of Cork Street Hospital, Dublin, but we watched with interest and appreciation his development as a clinician and a teacher, and judged from his writings and from fairly frequent personal contacts that he must have had a great and beneficial influence on his younger colleagues and his students. He had just taken up residence in a new hospital which he had been planning for years and which was about to be opened. We mourn his untimely death and extend our heartfelt sympathy to his widow, who was also at one time a teacher in the Medical School in Cardiff, and to his young son.

EUGEN POLLAK, M.D.

Dr. Eugen Pollak, lecturer in neuropathology at Manchester University, died at the Manchester Royal Infirmary on April 9, aged 62. A Viennese by birth and a widower for many years, Pollak was a refugee from the Nazis, arriving in Oxford soon after the rape of Austria. In the Radcliffe Infirmary he found a temporary home in the company of del Río Hortega and Gustav Steiner, with whom he worked in the department of the ever-hospitable Hugh Cairns. Pollak never doubted the outcome of the war, but he must have thought his return to Austria unlikely. In Oxford he was cheerful, courageous, and prepared to bide his time. He longed for work, but demanded nothing; what he was given to do he did willingly, and he never complained. Del Río Hortega was already installed as Oxford's neuropathologist. He and Pollak were as different in personality as they were in training, and with the added difficulty of language there was little contact between them: the Spaniard looked with suspicion on the Austrian whose scientific upbringing made it difficult for him to recognize the concept of the mesoglia. Pollak's opportunity was to come soon. In 1939 he was invited by Sir Geoffrey Jefferson to organize a department of neuropathology in the university service of neurosurgery in Manchester. The acceptance of this offer

he never had cause to regret, and from his letters it was clear that he was happy there—as happy indeed as any Viennese could be in exile. Before he came to England the vivacious Pollak was a prolific writer and was well known for his contributions on tuberculous sclerosis, Wilson's disease, and the neuroglia. His publications, based on his work in the departments of Professors Obersteiner and Marburg, mostly appeared in the *Arbeiten aus dem Neurologischen Institut* and in the *Jahrbücher für Psychiatrie und Neurologie*. He was the author of the section on the anatomy of the spinal cord, medulla, and pons in Bumke and Foerster's *Handbuch der Neurologie*. The forced change of country, however, and the building up of a new department, and latterly the threat of ill-health, disturbed the lines of research on which he had been working, and he never really regained the threads. Dr. Pollak's only daughter lives in Vancouver.

W. H. McM. writes: We remember Eugen Pollak as a hearty man, upright in bearing, dark, clean-shaven, and with an excellent sense of humour. Always confident and at times dogmatic, he could be counted upon to enliven equally a discussion on the political future of Europe or on the functions of the neuroglia. In moments off duty we knew him as a *bon viveur*, with an extensive and practical knowledge of the chef's art, and a lover of music. In the early days over here he knew little English, but he was always resourceful. Once, with an obvious effort of will, he declined a second helping of a rich entremet, pointing to his waist-line and explaining, "For me, please, it is too 'periculous.'" Had he been a younger man Pollak might have done more original work in the kindly environment of Manchester, for he had both originality of outlook and great technical skill. As it was he built up a valuable collection of material which will serve others in good stead. Beneath a brave and cheerful façade Pollak was a lonely man who grieved over the fate of his country and also the death of his sister, another victim of racial intolerance.

We record with regret the death of Dr. ALBERT COLEMAN at his home at Croydon on April 13, the day after his 54th birthday, after a long and trying illness. Albert Coleman was born at Manchester and educated at Manchester Grammar School. In 1917 he was awarded an open classical exhibition at Wadham College, Oxford, but the war prevented him from continuing with his classical education. After active service as a combatant officer with the 2nd Battalion the Manchester Regiment, he entered Manchester University, where in 1923 he gained the prize in clinical medicine and graduated M.B., Ch.B. In 1929 he became a Member of the Royal College of Physicians of London. After graduation he held the appointments of house-physician and house-surgeon at Manchester Royal Infirmary and of resident medical officer at Ancoats General Hospital. In 1926 he was appointed a house-physician at the Brompton Hospital, where he was later resident medical officer for two years. In 1932 Dr. Coleman settled in practice at Croydon, where he rapidly developed a large practice and established a reputation for his sound clinical judgment. He was also a skilful anaesthetist, and in 1942 obtained the Diploma in Anaesthetics of the English Royal Colleges. He was appointed an anaesthetist to Croydon General Hospital in 1936 and was also on the staff of the Bethlem Royal Hospital, the Seamen's Hospital, Greenwich, and Warrington Park Hospital. In 1946-7 he was chairman of the Croydon Division of the British Medical Association, a position he held with distinction. He held definite opinions about the advent of the National Health Service and its impact on the relationship between doctor and patient, and he also had emphatic views about the committee-bound structures he felt had been erected, but he had a kindly and happy disposition and made no enemies.

His recreations were shooting and photography, in which he took great enjoyment and possessed considerable skill. Some of his colour photography won him international repute. The sincere sympathy of his colleagues, friends, and patients will be extended to his widow and two daughters.

We are indebted to Dr. P. POSFORD for the following appreciation: The death of Dr. Albert Coleman has left a sad gap in the ranks of the medical profession. He was a fine doctor, much respected for his skill and professional judgment by a wide circle of doctors in and around the Croydon area, and, while he took great pains to apply the latest advances for the cure of disease, he never forgot that the patient was a person first of all. He was the kindest of men, always gentle, and quick to help those in trouble, and he had a keen and subtle sense of humour. It was always a great pleasure to be with him. It was my privilege to attend him in his last long illness, and, while he bore physical pain with great and quiet fortitude, he derived his main strength to face up to the reality of death from his firm faith in God, which was of more value to him than the medicine of his doctors.

Medical Notes in Parliament

Health Visitors

Mr. SOMERVILLE HASTINGS asked the Minister of Health on April 20 how many health visitors per 10,000 of the population were employed in England and Wales, which were the highest and lowest ratios, and in which county or county borough these were found.

Miss PAT HORNSBY-SMITH informed him that on December 31, 1951, the number of health visitors employed by local health authorities (two part-time being taken as roughly equal to one whole-time) was 0.9 per 10,000 of the population. The highest and lowest ratios were 3.5 in the county of Radnor and 0.16 in the Soke of Peterborough.

Health Service Inquiry

Miss PAT HORNSBY-SMITH, Parliamentary Secretary to the Ministry of Health, stated on April 23, in reply to Mr. A. Blenkinsop, that the Minister hoped to be able in a few days to give further information about the composition of the committee of inquiry into the National Health Service.

Dr. BARNET STROSS asked to what extent the terms of reference of the committee included powers to consider salaries paid to medical and non-medical staff, and the economies that might be effected by employing consultants on a full-time basis only.

Miss HORNSBY-SMITH replied that the Minister would certainly not expect the committee to deal with actual rates of pay. For the rest, the Secretary of State for Scotland and the Minister of Health were anxious not to hamper the committee in their work by seeking to restrict their field of inquiry.

Poliomyelitis Research

Mr. JOHN T. HALL on April 23 asked the Minister of Health if he was aware that constant appeals were being made for funds on behalf of the National Fund for Poliomyelitis Research, what steps were being taken to combat this disease, and whether he would consider increasing Government assistance to facilitate the work of finding a cure.

Miss PAT HORNSBY-SMITH replied that the Minister was aware of these appeals, and welcomed help which the fund might be able to give to supplement research. Treatment was provided within the National Health Service mainly by the hospitals, in an increasing number of which special units were being provided. An extensive programme of research was being sponsored by the Medical Research Council, and was not restricted by lack of funds.

Tobacco and Cancer

Mr. FREDERICK WILLEY asked the Minister of Health on April 23 what further research he was undertaking consequent upon the report of his chief medical officer that suspicion continued to be thrown on tobacco, especially heavy cigarette-smoking, for the disturbing increase in male mortality from cancer.

Miss PAT HORNSBY-SMITH replied that this matter had been referred to the Standing Advisory Committee on Cancer and Radiotherapy, and the Minister was awaiting their advice. Meanwhile the existing research would be continued.

Litigation Against Doctors

Air Commodore A. V. HARVEY on April 23 asked the Minister of Health what steps he was taking to safeguard doctors from litigation resulting from their work in the Health Scheme.

Miss PAT HORNSBY-SMITH replied that officers of the department were discussing with representatives of the profession the relations, financial and other, between hospital authorities and their medical staffs when legal actions were brought against either or both.

Food Hygiene

Mr. G. H. OLIVER on April 23 asked the Minister of Health what steps were taken to ascertain whether persons employed in the preparing, cooking, and serving of food in hotels, restaurants, and road-side cafés were free from infectious diseases such as tuberculosis.

Miss PAT HORNSBY-SMITH answered that there was no general power to require the persons concerned to be medically examined for this purpose, and the Minister was advised that the present state of our knowledge did not suggest that such a power would be justifiable as a means of preventing the spread of infection.

Medico-Legal

DAMAGES AGAINST HOSPITAL

Damages of £4,000 were awarded by Mr. Justice Gerrard on April 22 to Mr. R. J. Crawford, aged 52, against Charing Cross Hospital. Mr. Crawford alleged that damage to his left arm sustained during an operation was caused by negligence. The defendants, the board of governors, denied liability. The judge ordered a stay of execution pending appeal.

In view of the concern which cases of alleged negligence have recently been causing the medical profession, it is to be hoped that it will be found possible to take the case to appeal.

The operation, which was performed at Charing Cross Hospital on July 7, 1950, was on the bladder, and the patient was placed in the Trendelenburg position, with shoulder rests. His left arm was abducted and a vein in it used for blood transfusion. After the operation the arm was found to be partially paralysed. His right arm was already paralysed from an attack of acute poliomyelitis in childhood.

In his judgment Mr. Justice Gerrard said that the operation had been completely successful and allegations of negligence against the surgeon had been rightly withdrawn. It was the anaesthetist who had administered the blood transfusion, and the judge held that he had been negligent in the circumstances of the case in not avoiding the extension of the plaintiff's arm, at any rate to the degree he permitted, for longer than necessary. He found that negligence had contributed to the very severe degree of brachial paralysis. In assessing damages at £4,000 the judge took account of the plaintiff's poor state of health.

Messrs. Hempson's, acting on behalf of the Medical Defence Union, instructed counsel to hold a watching brief on behalf of the surgeon and the anaesthetist.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending April 11 (No. 14) and corresponding week 1952.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, where returns are approximate.

† Includes primary and influenzal pneumonia.

‡ Includes puerperal pyrexia.

Vital Statistics

Smallpox in the North Country

Up to noon, April 27, there had been 26 confirmed cases of smallpox, including 6 deaths. Since last week's report there has been one new case—in Bury C.B. This patient was a woman aged 69, vaccinated in infancy.

Infectious Diseases

In England and Wales during the week ending April 11 the number of notifications of measles increased by 2,222, from 21,166 to 23,388, and whooping-cough increased by 110, from 2,508 to 2,618, while scarlet fever decreased by 137, from 1,403 to 1,266, and dysentery by 98, from 423 to 325.

With only a few exceptions a rise in the incidence of measles was reported in every county. The largest increases were Yorkshire West Riding 515, from 1,381 to 1,896; Durham 159, from 549 to 708; the combined five south-western counties 455, from 2,089 to 2,544. The only outstanding exception to the general rise was a fall of 329 in Surrey, from 1,444 to 1,115. The largest rise in the number of notifications of whooping-cough was 44 in Durham, from 88 to 132, and the largest fall was 43 in Warwickshire, from 182 to 139. A fall of 27 in London, from 96 to 69, was the largest fluctuation in the local trends of scarlet fever. 19 cases of diphtheria were notified, 8 more than in the preceding week. The chief feature of the returns of diphtheria was a rise from 0 to 4 in Cheshire.

38 cases of acute poliomyelitis were notified. These were 3 fewer for paralytic and 3 more for non-paralytic cases than in the preceding week. The largest returns were London 6, Middlesex 4, Essex 4, Warwickshire 4 (Birmingham C.B. 4), and Kent 3.

The chief centres of dysentery were Lancashire 82 (Liverpool C.B. 34, Manchester C.B. 19), London 45 (scattered through 16 boroughs), Leicestershire 41 (Leicester C.B. 41), Yorkshire West Riding 21, and Middlesex 20.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1944-52 are shown thus -----, the figures for 1953 thus ———. Except for the curves showing notifications in 1953, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

England and Wales in 1951

With welcome promptitude the Registrar-General for England and Wales has produced the medical tables of his *Statistical Review* for the year 1951 only four months after the corresponding volume for 1950. The following figures extracted from it compare death rates per million in England and Wales with those in Scotland for 1951.

Cause of Death	England and Wales	Scotland
Tuberculosis of respiratory system ..	273	379
Tuberculosis, other forms ..	41	55
Malignant neoplasms, including neoplasms of lymphatic and haematopoietic tissues ..	1,951	2,065
Diabetes mellitus ..	84	118
Vascular lesions affecting the central nervous system ..	1,549	1,940
Heart diseases ..	3,638	4,410
Hypertensive disease ..	474	314

England and Wales in First Quarter

In the first quarter this year the stillbirth rate fell to a new low level for any March quarter in England and Wales, and the infant mortality rate was the second lowest. There were 3,957 stillbirths, giving a rate of 22.5 per thousand total births, as compared with 23.3 in the corresponding quarter in 1952 and 38.3 in 1938. Deaths of children under 1 year of age numbered 5,645, or 33.8 per thousand live births. This was only slightly higher than the rate of 33.4 for 1952 March quarter. The corresponding figure for 1938 was 69.3.

Deaths numbered 171,268, giving a rate of 15.8 per thousand population, as compared with 13.4 in 1952 and 19.1 in 1951 (when there was also an influenza epidemic). Live births numbered 171,705—almost the same number as deaths—giving a rate of 15.8 per thousand population, as compared with 15.9 for 1952 and 16.3 for 1951. All figures given above relate to first quarters.—*Registrar-General's Weekly Return for England and Wales*, No. 15.

Week Ending April 18

The notifications of infectious diseases in England and Wales during the week included scarlet fever 994, whooping-cough 2,847, diphtheria 18, measles 18,861, acute poliomyelitis 34, dysentery 282, paratyphoid fever 7, and typhoid fever 2.

Medical News

Southampton Medical Society's Centenary.—The Southampton Medical Society held its centenary celebrations at the University of Southampton on Saturday, April 18. The Vice-Chancellor of the University, Mr. D. G. James, welcomed 200 members and their guests at an afternoon meeting at which Sir Russell Brain, P.R.C.P., delivered an oration on "Evolution in Medicine." The chair was taken by the president of the Society, Dr. R. S. Swindell, who was accompanied on the platform by the Mayor and Mayoress of Southampton, the Sheriff, the two Members of Parliament for Southampton, and the president of the Medical Society of London, Dr. Cuthbert Dukes. In the evening there was a dinner attended by 140 members. Amongst the guests were the Mayor, who proposed the toast of the Southampton Medical Society, the Bishop of Southampton, the Vice-Chancellor of the University, and others who had taken part in the afternoon's proceedings.

Rockefeller Foundation Grants.—In the Rockefeller Foundation's most recent quarterly report is the announcement of two substantial grants to medicine in Britain. The first is a grant of over £20,000 to the London School of Hygiene and Tropical Medicine for a three-year study in public health. This work, which is being carried out in Hertfordshire under the direction of Dr. J. H. F. Brotherhood, lecturer in public health at the school, is concerned particularly with the care of the elderly sick and the use of that families make of the Health Service. The second is a grant of £7,000 and \$5,400 to the Welsh Regional Hospital Board for the support of the Neuropsychiatric Research Centre at Whitechurch Hospital, Cardiff. Here, under the direction of Dr. Derek Richter, work is in progress on brain metabolism, the effects of anaesthetics on the brain, hallucinations, and suggestibility. Notable grants made by the Rockefeller Foundation towards medical projects outside Britain include \$500,000 for the development of the medical division of the American University of Beirut in the Lebanon, and a grant of \$121,000 to the Indian Council of Medical Research for postgraduate medical fellowships.

Cerebral Palsy Centre in Belfast.—Lady Wakehurst, wife of the Governor of Northern Ireland, recently opened Malcolm Sinclair House, the cerebral palsy treatment centre of the Northern Ireland Council for Orthopaedic Development. As a result of a survey financed by the council and carried out by the Department of Social and Preventive Medicine at Queen's University it has been estimated that there are 500 spastic children in the province. The centre is intended to provide treatment for those of them likely to be able to benefit from it. After the opening ceremony Dr. C. D. S. Agassiz, physician-superintendent, Queen Mary's Hospital for Children, Carshalton, gave an address on cerebral palsy. Among those present at the opening were the Minister of Health and Local Government and the Minister of Education.

Royal National Institute for the Blind.—The Queen has commanded that the National Institute for the Blind shall in future be known as the Royal National Institute for the Blind.

Crash Helmets for Motor-cyclists.—At long last the idea of protective headgear for motor-cyclists, so ably advocated by the late Sir Hugh Cairns, is catching on with the public. Both official sources and the trade testify to this. The British Standards Institution is now preparing a standard specification for the helmets ("protective hats" in official parlance). Helmets must be light and capable of withstanding both impact and compression tests. The outer shell must be weather-proof and without dangerous projections: peaks, if worn, should be flexible. Between the harness fixing the helmet to the head and the outer shell a space with padding is recommended.

Pharmaceutical Industry and the Metric System.—Twelve months ago the annual general meeting of the Association of the British Pharmaceutical Industry adopted a resolution that bulk supplies of solid drugs, liquid galenicals, and pharmaceutical chemicals should be sold to pharmacists by metric weight and measure instead of by Imperial measure as at present. Most of the large pharmaceutical firms have agreed to this proposal. The target date for the change is July 1, but the process of altering packs and containers is bound to take some time.

Boiler-scaling and Pneumoconiosis.—By Regulations which came into force on April 22 the Minister of National Insurance has added the occupation of boiler-scaling to those covered for pneumoconiosis under the National Insurance (Industrial Injuries) Act. This will allow boiler-scalers with pneumoconiosis to obtain benefit under the Act.

Nepal and W.H.O.—At the sixth World Health Assembly, which opens in Geneva on May 5, a request from Nepal to join W.H.O. will be considered. At present there are 79 Member States and 3 Associate Members (Morocco, Southern Rhodesia, and Tunisia).

Foreign Members of the Royal Society.—Among the four distinguished scientists elected Foreign Members of the Royal Society last month were Professor M. J. C. R. Courrier, deputy director of the Collège de France, Paris, who is noted for his work on endocrinology, and Professor H. J. Muller, of Indiana, U.S.A. Professor Muller's classical experiments on the chromosomes of the fruit fly *Drosophila* are familiar to most students of biology and medicine.

Sir Robert Robinson, F.R.S., Waynflete Professor of Chemistry at Oxford, has been awarded the Priestley Medal of the American Chemical Society. This is the society's most important annual award. In the medical field Sir Robert is particularly noted for his work in connexion with the synthesis of penicillin and, more recently, of steroid hormones.

Dr. John Gillies, reader in anaesthetics at Edinburgh, has been awarded the Henry Hill Hickman medal for outstanding work in anaesthesia. The presentation is being made in London by Dr. F. M. R. Walshe, F.R.S., on May 1 at the annual general meeting of the Section of Anaesthetics of the Royal Society of Medicine.

Dr. C. B. Allsopp, D.Sc., reader in physics at Guy's Hospital Medical School, has been appointed to the London University Chair of Physics Applied to Medicine, tenable at the medical school.

Professor R. M. Walker, professor of surgery at Bristol University, has been made an honorary Fellow of University College, London.

COMING EVENTS

Territorial Medical Officers' Dinner.—The annual dinner of the Territorial Army Medical Officers' Association will be held on May 8. Further particulars concerning the dinner can be obtained from the honorary secretary, 19, Queen Anne Street, London, W.1.

Grenfell Volunteers' Reunion.—The annual reunion of Grenfell Volunteers will take place at the Overseas League, Park Place, St. James's Street, London, S.W.1, on May 6, from 3 p.m. to 5.30 p.m. The speaker will be Dr. W. A. Paddon, who is in charge of the hospital station at North-west River, and the chair will be taken by the Reverend Henry Gordon.

Society for Endocrinology.—A symposium entitled "The Determination of Adrenal Cortical Steroids and Their Metabolites" will be held by the Society of Endocrinology at the Medical Society of London, Chandos Street, London, W.1, on May 21 at 9.30 a.m. Non-members wishing to attend are asked to communicate with Professor N. F. MacLagan, Westminster Medical School, London, S.W.1.

National Marriage Guidance Council.—The seventh annual conference of the National Marriage Guidance Council is to be held at Llandudno from May 14 to 17. The theme of the conference will be "Marital Conciliation," and those wishing to attend are asked to communicate with the office secretary, National Marriage Guidance Council, 78, Duke Street, Grosvenor Square, London, W.1, from whom further details may be obtained.

Laboratory Animals.—The Laboratory Animals Bureau has arranged a symposium on laboratory animals to be held at the Royal Society of Medicine, 1, Wimpole Street, London, W.1, on May 14 at 2.30 p.m. The chairman will be Dr. H. J. Parish, and other speakers include Mr. A. N. Worden, Mr. A. E. Mundy, Mr. J. Scarnell, and Dr. J. S. Paterson. The symposium will be followed by an open discussion.

NEW ISSUES

British Journal of Ophthalmology.—The next issue of this journal (Vol. 37, No. 5) will be available in a week's time. The contents include:

NOTES ON OPHTHALMOLOGICAL PRACTICE IN LUND. Sven Larsson.
CAUSES AND TREATMENT OF CONGENITAL ECCENTRIC NYSTAGMUS. J. Ringland and Anderson.
ARTERIOLE INVOLVEMENT IN DIABETIC RETINOPATHY. Norman Ashton.
VASCULAR CHANGES THAT OCCUR DURING THE PHASIC VARIATIONS OF TENSION IN CHRONIC GLAUCOMA. J. H. Dobree.
CORNEAL THICKNESS IN INTERSTITIAL KERATITIS. Charles Cook and Maurice Langham.
EXPERIENCES WITH THE LINDNER-GUIST OPERATION. A. Lister.
CORRESPONDENCE BETWEEN VISUAL ACUITY, REFRACTIVE ERROR, AND THE SPEED OF VISUAL PERCEPTION. T. H. Eames.
UNUSUAL APPEARANCE IN A CASE OF EALE'S DISEASE. A. G. Cross and D. P. Choyle.
INFRA-RED IMAGE CONVERTER IN ROD SCOTOMETRY. M. F. P. Marshall.

Issued monthly; annual subscription £4 4s., single copy 8s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, May 4

CAMBRIDGE UNIVERSITY.—At Department of Pathology, 4.30 p.m., Dr. P. Lépine (Institut Pasteur): Electron Microscope Studies in the Virus Field, with Special Reference to the Study of Intracellular Development of Viruses.

● POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. H. Wirtz (Basle): Osmotic Work of Mammalian Kidney.
UNIVERSITY COLLEGE.—At Physiology Theatre, 4.45 p.m., Sir Rudolph Peters, F.R.S.: Inhibitors and Intracellular Chemical Dissection.

Tuesday, May 5

CAMBRIDGE UNIVERSITY.—At Department of Pathology, 4.30 p.m., Dr. P. Lépine (Institut Pasteur): Present Position of the Poliomyelitis Problem: Research and Epidemiology.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. E. J. Moynahan: Urticaria.
ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Humphry Davy Rolleston Lecture by Professor R. A. McCance, F.R.S.: Overnutrition and Undernutrition.

ROYAL EYE HOSPITAL.—5 p.m., Mr. T. M. Tyrrell: Cataract Surgery and its Complications.

ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Dr. D. Hunter: Prevention of Occupational Disease.
WRIGHT-FLEMING INSTITUTE OF MICROBIOLOGY, St. Mary's Hospital Medical School.—5 p.m., Almoth Wright Lecture by Dr. Leonard Colebrook, F.R.S.: Almoth Wright—Pioneer in Immunology.

Wednesday, May 6

● BRITISH MEDICAL ASSOCIATION.—6.30 p.m., Sir Charles Hastings Lecture by Professor F. A. E. Crew, F.R.S.: Medicine and Social Policy.
INSTITUTE OF DENTAL SURGERY.—5 p.m., Dr. F. W. Clement (Toledo, U.S.A.): General Anaesthesia in Dental Surgery.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Histology of Normal Skin.

LONDON UNIVERSITY.—At School of Pharmacy, 5.30 p.m., Dr. W. O. Jones, F.R.S.: Formation of Alkaloids in Plants.
OXFORD UNIVERSITY.—At University Museum, 5 p.m., Litchfield Lecture by Professor W. T. Astbury, F.R.S.: Some Leading Questions in the Fine Structure of Biological Fibres.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. R. J. Ludford: Tissue Cultures—Pathological Aberrations of Cellular Structure and Functioning.

Thursday, May 7

FACULTY OF HOMOEOPATHY.—5 p.m., Dr. D. M. Gibson: Observations on Homoeopathy in Relation to Psychoneurosis.

● HAMPSTEAD GENERAL HOSPITAL.—3 p.m., Dr. D. Hector-Jones: Radiology of the Large Gut; 4.15 p.m., Mr. Harland Rees: Urinary Calculi.
LONDON UNIVERSITY.—At School of Pharmacy, 5.30 p.m., Dr. W. O. Jones, F.R.S.: Formation of Alkaloids in Plants.

● POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. H. S. Banks: Acute Meningitis.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Humphry Davy Rolleston Lecture by Professor R. A. McCance, F.R.S.: Overnutrition and Undernutrition.

ROYAL EYE HOSPITAL.—5.30 p.m., Miss M. Savory: Influence of Cortisone on Inflammatory Eye Conditions.

ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Dr. J. L. Nickerson: Current Research in Ballistocardiography.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. M. A. Partridge: postgraduate demonstration in psychiatry.

Friday, May 8

INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. F. R. Bettley: Atopy.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Mr. T. Holmes Sellers: Treatment of Pleural Infection.

● POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. Russell Fraser: Use of Radio-iodine in Thyroid Diagnosis.

ROYAL EYE HOSPITAL.—5.30 p.m., Miss J. M. Dollar: Surgery of the Orbit.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Obstetric and Gynaecological Conference. Dr. Hugh McLaren: Early Diagnosis of Carcinoma of the Cervix.

Saturday, May 9

WEST MIDLANDS PHYSICIANS ASSOCIATION.—At Gulson Hospital, Coventry, 11 a.m., general meeting

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Aitken.—On March 2, 1953, at Queen Charlotte's Hospital, London, W.1, to Jean, wife of Dr. C. A. M. Aitken, a son—Timothy John McClelland.

Bailey.—On April 7, 1953, to Jeanne, wife of David Bailey, F.R.C.S., twins—Timothy and Patricia.

Benstead.—On March 30, 1953, at the Christiana Hartley Maternity Hospital, Southport, to Mrs. Nancy and John Benstead, a son—Richard John Rand.

Cameron.—On April 3, 1953, at Maryfield Hospital, Dundee, to Frances, wife of H. MacDonald Cameron, M.B., B.Ch., D.Path., a son.

Charlton.—On April 16, 1953, to Maureen (formerly Rodgers), M.S.R., wife of John C. Charlton, M.B., B.Ch., of Lurgan, Station Road, Mickleover, Derby, a son.

Comper.—On April 18, 1953, at Farnborough Hospital, Kent, to Pamela (formerly Mayes), wife of Dr. John Comper, a son.

Drewitt.—On March 18, 1953, at Ivy Lodge, Lockwood Street, Driffeld, Yorks, to Kathleen Rose (formerly Blair), S.R.N., wife of Dr. A. H. Drewitt, a daughter—Suzanne Elizabeth Blair.

Evans.—On April 10, 1953, at the Hammersmith Hospital, London, W.1, to Marjorie, wife of Lynn A. J. Evans, F.R.C.S., a son.

Forbes.—On April 15, 1953, to Pamela, wife of John Forbes, M.D., of Pen-y-wern, near Mold, Flintshire, a son.

Foxell.—On April 13, 1953, at Suffolk House Nursing Home, Stanmore, Middlesex, to Maureen, wife of Dr. Alan Foxell, a son.

Manson.—On April 4, 1953, at Moffat Hospital, Kanye, Bechuanaland Protectorate, to Jocelyn, M.S.R., C.T., wife of John M. S. Manson, M.D., D.T.M.&H., D.Obst.R.C.O.G., a daughter.

Pickford.—On April 14, 1953, at Wisbech, Cambridgeshire, to Whinifred, wife of Dr. Steven Pickford, a son.

Powell.—On April 1, 1953, at Amman Valley Hospital, Glamorgan, Carmarthenshire, to Muriel (formerly Davies), wife of Dr. F. I. Powell, "Brynteg," Gannart, Carmarthenshire, a son—David Huw.

Pratt.—On April 12, 1953, at the Duke of York Nursing Home, Bradford, Yorks, to Dorothy (formerly Boothroyd), S.R.N., wife of Dr. Peter Pratt, a brother for Christopher.

Scriven.—On April 20, 1953, at Wrecclesham Grange Nursing Home, Farnham, Surrey, to Dr. Jeanne (formerly Edwards), wife of Dr. W. H. Scriven, M.B.E., a son.

Watkinson.—On April 5, 1953, at St. James's Hospital, Leeds, to Marie, wife of Dr. Geoffrey Watkinson, a brother for Anne.

Welch.—On April 11, 1953, at Elvet House, Dean Road, South Shields, to Dr. and Mrs. H. D. Welch, a daughter.

MARRIAGES

Newborne-Skelton.—On April 18, 1953, at St. Giles Church, Oxford, Laurence Perceval Anthony Newborne, M.D., to Mary Skelton, M.C.S.P.

Tannert-Whalley.—On April 11, 1953, in London, John Tannert to Elizabeth Whalley, M.B., B.S.

DEATHS

Corfield.—On March 20, 1953, at the Middlesex Hospital, London, W.1, Walter Francis Corfield, M.D., D.P.H., formerly of Colchester, Essex, aged 73.

Croft.—On April 21, 1953, at Lawn Bank, Tarleton, near Preston, Lancs, Lawrence Croft, M.B., B.S., aged 71.

Davies.—On March 21, 1953, at "Conquerors," Stunts Green, Hurstmonceux, Sussex, Frederick Spencer Davies, M.R.C.S., L.R.C.P., late of Buckhurst Hill and Harlow Common, Essex.

McGowan.—On March 20, 1953, at his home, 18, Clare Road, Halifax, Joseph McGowan, M.B., B.Ch.

Sutton.—On March 19, 1953, Margaret Joan Sutton, L.R.C.P.&S.Ed., L.R.F.P.S., of Poynton Park, Poynton, Cheshire, aged 28.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Prophylactic Chemotherapy of Measles

Q.—Some practitioners favour the prophylactic use of sulphonamides or penicillin in the early stages of measles. Is any evidence available to prove that such treatment cuts down the incidence of complications due to secondary bacterial invaders?

A.—The early damage to the cells of the mucous membrane in measles is virus-induced and cannot be affected by chemotherapy. The effect of this damage, however, is to produce a "soil" which facilitates bacterial infection so that the majority of the complications are bacterial in nature. There thus seems a reasonable case for prophylactic chemotherapy. But, when considering chemoprophylaxis, two different situations must be borne in mind. In the open hospital ward the child will be exposed to the bacterial flora of many unrelated persons. The danger of acquiring a secondary bacterial infection is therefore increased, and prophylactic penicillin is worth considering. When so used, the danger of inducing a chronic ward infection with a penicillin-resistant strain must be kept in mind; if complications arise unexpectedly, the organism isolated must immediately be tested for sensitivity and appropriate steps taken. In private practice the argument for prophylactic chemotherapy is less sound. Here the patient will be exposed solely to the family bacterial flora, and secondary infection will be less commonly encountered. Further, the danger period is short—three to five days—and during this time the child should be under daily clinical observation, so that it should be possible to bring any complication which does arise under immediate control. My own view is that such treatment should be considered only between the age of 6 months to 2 years, and even then only in the severe case of measles. It should never become a routine, but always be guided by clinical judgment.

Finally, one might perhaps emphasize that the complication of greatest importance is otitis media. For this reason the drumheads should be inspected daily during the early danger period so that penicillin may be started at the earliest sign of inflammation. (In the earliest days of the sulphonamides their value as prophylactics was reasonably well established, but one would now hesitate to advocate their use for this purpose in view of their toxicity and the greater efficiency of penicillin.)

Seaweed Baths

Q.—What is the therapeutic basis for the use of seaweed baths? What do they contain, in what conditions are they useful, and how are they given?

A.—The procedure of this bath is as follows: fresh seaweed is treated with boiling water until a jelly is produced; the jelly is added to a reclining-bath of warm sea-water in which the patient immerses himself. Subsequently the patient is given an ordinary sea bath, rubbed down, and packed in hot towels. These baths are available only at a few seaside resorts; no chemist's pack containing seaweed is on the market.

Seaweed thus administered can have no specific action, as none of its constituents will be absorbed through the skin. The total effect of the procedure outlined above is similar to that of an ordinary warm reclining-bath—namely, it brings about relaxation of the patient as a whole and of the muscles and joints in particular. This effect will be temporary only.

Dangers from the Use of Relaxants in E.C.T.

Q.—As a psychiatrist without any special anaesthetic training, is there any unwarrantable risk in my administering a relaxant, such as succinylcholine or gallamine triethiodide, with small doses of a barbiturate before E.C.T.? What precautions should I take apart from having facilities for controlled respiration? What are the dangers of laryngeal spasm and of cardiac arrest, particularly in senile patients?

A.—If the doses of the relaxant and of the barbiturate are correct for the particular patient, the only real risk involved is that of temporary respiratory arrest. The administrator should have sufficient experience and confidence in performing rhythmic inflation of the lungs to maintain good ventilation until spontaneous breathing returns. This will usually be within a few minutes. Very occasionally the return of spontaneous breathing may be delayed for longer. Even so, adequate and correctly performed controlled respiration will tide the patient over until the effects of the relaxant have worn off. There is little danger of spasm of the glottis with these relaxants unless for some reason mucus or stomach contents come in contact with the larynx during the recovery phase. In any case, if the barbiturate dosage is small no harm will result. Cardiac arrest during E.C.T. is no more likely to occur with a relaxant than without, so long as adequate oxygenation is maintained at all times.

Phosphorus Poisoning

Q.—It is stated that in phosphorus poisoning no oil may be given. Could you tell me the reason for this and what harm the oil might do? Also, what is the chemical reaction of potassium permanganate in such cases?

A.—Phosphorus is insoluble in water, but readily dissolves in fat. In the absence of fat it is absorbed from the alimentary tract, but the speed with which it would be absorbed would almost certainly be increased if edible oil were given. Liquid paraffin, however, has been recommended in treatment presumably because it is not absorbed and carries away the phosphorus in it.

Potassium permanganate oxidizes phosphorus to its oxides, which in turn react with water to form phosphoric acids. Both the reagent and products of the reaction will be extremely irritating to the stomach. Repeated gastric lavage is probably the most rational therapy.

Aspermia

Q.—A healthy man of 30 is sterile owing to complete aspermia. What is the aetiology, prognosis, and correct method of investigation and treatment?

A.—This is a formidable question, the full answer to which is quite outside the scope of "Any Questions?" The aetiology can be either obstructive, spermatozoa being prevented by duct blockage from reaching the urethra, or due to failure of spermatogenesis. The former most commonly follows infection of the upper genital tract (e.g., gonococcal epididymo-orchitis), but may also be the result of aplasia of the vas or congenital anomalies of the epididymis. Failure of spermatogenesis may be the result of primary or secondary hypogonadism, congenital absence of the germinal epithelium, trauma, or infection. Mumps after puberty, with bilateral orchitis, may result in testicular atrophy and aspermia (though this is not invariable). Hernia operations may be followed by testicular ischaemia and resultant failure of spermatogenesis. If the testicles are not in the scrotum at puberty, spermatogenesis is unlikely to occur and aspermia follows.

The prognosis clearly depends upon the aetiology. If the germinal epithelium is destroyed the condition is hopeless; if spermatogenesis has never started (secondary eunuchoidism) there is a hope of stimulating it by suitable treatment.^{1,2} If spermatogenesis is taking place and the duct system is blocked, surgery offers a potential solution.

Investigation involves repeated seminal analysis to establish the existence of the condition (a single aspermic ejaculate means very little). If the testicles are small, urinary follicle-stimulating hormone assay will differentiate primary hypogonadism (with a high F.S.H. titre and hopeless prognosis) from secondary failure (with a low titre). If the testicles are normal in size, testicular biopsy will reveal the existence of spermatogenesis, thus indicating an excretory block; or else damage to the germinal epithelium. However, according to Bayle,⁴ testicular biopsy causes a risk of blocking the vasa efferentia as a result of the slight haemorrhage which is inevitable; he therefore advocates open surgical exploration of the testicle with incision of the head of the epididymis. If this reveals the presence of spermatozoa, and patency of the vas deferens can be established, then vaso-epididymostomy is performed—bilaterally whenever possible. In surgically suitable cases this operation has given a 66% cure rate in Bayle's hands. Apart from surgery for obstructive aspermia, treatment appears to hold out hope only when there is secondary hypogonadism as mentioned above. Then prolonged treatment with testosterone (preferably by implantation) or with chorionic gonadotrophin seems to have led to normal fertility at least in some patients. For further information the reader may be referred to the monograph by Hotchkiss.⁵

Unnecessary Vitamin B

Q.—Is any harm likely to follow prolonged dosage with any of the B vitamins when the diet is already adequate in this respect?

A.—There is no direct evidence that the prolonged dosage of well-nourished people with any of the B vitamins is likely to be harmful. Theoretically, an excess of one might cause imbalance of the others, as has been claimed to occur in cases of subnutrition; and the manufacture of B vitamins, such as nicotinic acid, by intestinal organisms might be suppressed by the administration of large exogenous doses. It is unlikely, however, that these theoretical objections have practical validity.

Allergy to Condoms

Q.—A man who has used a well-known make of condom for years has in the last few months been troubled with itching, redness, and, on one occasion, oedema of the skin of the penis for a few days after use of the sheath. The irritation is relieved by an antihistamine cream. Is the powder on the condom likely to be the irritant? Is a change of make desirable, or do most manufacturers treat sheaths with the same powder? The man is unwilling to complicate intercourse further by using any sort of "barrier cream" unless this is really necessary.

A.—Sensitivity to rubber seems far more likely than sensitivity to the powder. This point could be settled by carrying out a patch test with rubber which has been carefully washed to remove any of the powder, and another patch test either with the powder alone or with rubber on which powder has been allowed to remain. Sensitivity to rubber is usually due to chemicals used in processing rather than to the rubber itself. For this reason sensitivity to one type or brand of rubber does not necessarily imply sensitivity to others. Manufacturers are not always very willing to reveal the exact composition of their products, and once the dermatitis has been definitely identified as due to contact sensitivity the best plan for the patient would be to try various makes in order to find one which will not bring on this trouble.

A barrier cream, in any event, is not likely to be successful, and in a case of this sort the only solution will be for the patient to avoid this particular make of rubber.

NOTES AND COMMENTS

C.S.F. Changes in Psychoses and Epilepsy.—Dr. J. H. FLEISCHACKER (Shenley) writes: My attention has been drawn to the question and answer on C.S.F. changes in psychoses and epilepsy ("Any Questions?" January 31, p. 285), where a paper of mine was mentioned. While it is true that the problem—with the techniques used in this laboratory—has been followed up systematically only by myself and co-workers,^{1,2,3,4} it may be said that an increase of globulins in the C.S.F. of schizophrenics was described first by Golant-Ratner,⁵ later by Kafka and Samson⁶ and Neal *et al.*⁷ All authors used different techniques, and came to the same conclusions. Such findings have since been confirmed among others by Schenk⁸ and von Storch *et al.*,⁹ and also by German and French workers.¹⁰ These findings, though "typical" only and "non-specific," are in my opinion of high differential-diagnostic significance, but their pathogenetic or aetiological importance is not clear.⁴ The controversy about the value of these findings is due, essentially, to the fact that there is no agreement on the "norm of C.S.F.s."¹¹ I cannot help feeling that C.S.F. from patients suffering from organic and often active diseases of the C.N.S. should not be considered as "normal."

Toxaemia in Pregnancy.—Dr. JOHN SOPHIAN (Salisbury, Southern Rhodesia) writes: In your issue of February 21 (p. 466) you furnish a reply to a correspondent inquiring under "Any Questions?" about the present view of the aetiology and pathology of toxæmia of pregnancy. In this you state that the present tendency is to regard its aetiological basis as uterine and placental ischaemia. Reynolds¹ has shown the interdependence of uterine blood flow on tension of the uterine wall in the rabbit. He has also demonstrated² the fact that the primiparous uterus develops marked heightening of tension from the 20th week onwards—a period during which toxæmia of pregnancy has its greatest incidence. Such researches indicate with certainty that the aetiological thesis must include increased tension of the uterine wall in its explanation when it is appreciated that it has been shown in rabbits by Franklin and Sophian³ that diversion of the renal blood flow from cortex to medulla is provoked by increasing the uterine tension. Especially is confirmation to be found in the renal manifestation of the toxæmic state. In the great majority of diseases of the kidney oedema and albuminuria have never been denied a renal origin. Ischaemia of the kidney has been invoked by Goldblatt⁴ and Shorr and Zweifach⁵ as responsible for the production of renal pressor substances. The triad of symptoms can have their explanation in ischaemic renal changes which the utero-renal reflex can provoke. In its turn the reflex is dependent on heightened tension of the uterine wall, which Reynolds has found to be present in the primiparous uterus in that period usually contemporaneous with toxæmic manifestations. Reduced blood flow in uterus and placenta is material in considering foetal survival alone. But the toxæmic state imperils the maternal organism as well, and your reply has failed to include its consideration.

THE PREMENSTRUAL SYNDROME

BY

RAYMOND GREENE, D.M., M.R.C.P.

Physician, Royal Northern Hospital and New End Hospital, Hampstead

AND

KATHARINA DALTON, M.R.C.S., L.R.C.P.

General Practitioner, Edmonton, London

The Literature

"Premenstrual tension," as it has hitherto been called, is the commonest of the minor endocrine disorders. The fact that a large number of women suffer from a variety of symptoms, unpleasant at their mildest and at their severest incapacitating, during the ultimate seven to ten days of the menstrual cycle is well known; but in this country very little has been done to alleviate their distress. This is partly due to the attitude of the patients. Just as, before the days of stilboestrol, women in general accepted the unpleasant symptoms of "the change of life" as a necessary part of the business of being a woman, so still they pass through one week of discomfort in every month, usually without complaining to their doctors but not necessarily without disturbing the tranquillity of their homes. The frequency of the condition is testified to by the fact that in one American factory, employing 1,500 women, 36% applied for treatment in the premenstrual phase (Bickers and Woods, 1951). Israel (1938) stated that symptoms of the kind to be described occur in 40% of otherwise healthy women. It is, we are convinced, equally common in this country, and it is therefore curious that, although many papers on the subject have been published in the U.S.A., we have been able to trace only one in a British journal (Singh *et al.*, 1947), which did not refer to British patients.

The term "premenstrual tension" is unsatisfactory, for tension is only one of the many components of the syndrome. Its use has commonly led to a failure to recognize the disorder when tension is absent or is overshadowed by a more serious complaint. We have preferred to use the term "premenstrual syndrome," but as our investigation has progressed it has become clear that this term also is unsatisfactory. Though the syndrome most commonly occurs in the premenstrual phase, similar symptoms occasionally occur at the time of ovulation, in the early part of the menstrual phase, and even, rarely, in the first day or two after the flow has ceased. The term "menstrual syndrome," though correct, for in each individual the symptoms recur at monthly intervals, may wrongly create the impression that they occur only during menstruation. We have finally decided to retain the term "premenstrual syndrome" in the full realization of its imperfection. The full elucidation of its cause may later suggest a more appropriate and more accurate nomenclature.

The first description of the syndrome is that of Frank (1931). He records a condition of indescribable tension and a desire to find relief by foolish actions difficult to restrain. There were often severe headaches and palpable oedema, especially of the face, hands, and feet, accompanied by oliguria and an increase in weight. Sometimes there were diffuse spontaneous subcutaneous haemorrhages, asthma, and, in rare instances, epileptiform seizures. All symptoms were rapidly relieved at the onset of the menstrual flow, but recurred at varying times as the end of the cycle drew near. The condition of the patients became worse if the onset of the flow was delayed. Soon other symptoms with a similar periodicity were observed, including a remarkable degree of oedema, which caused, in two cases described by Thomas (1933), a gain in weight of 12 to 14 lb. (5.4 to 6.4 kg.), relieved on the first day of menstruation by a diuresis of 4.5 litres, continued on the succeeding days.

Sweeny (1934) described tightness of the clothing and stiffness of the hands, and found that 30% of 42 healthy women gained 3 lb. (1.4 kg.) or more in the premenstrual phase. Puech (1942) laid stress on premenstrual asthmatic attacks, rhinorrhoea, fever, and lumbar pain. Israel (1938) recorded ulcerative stomatitis and transient nymphomania. Of 38 patients described by Gray (1941), 5 had nymphomania and 15 some form of "psycho-sexual disorder." Rubenstein (1942) stressed the incapacitating headache common at this time, in one patient associated with abnormal hunger; and Morton and McGavack (1946) were inclined to associate this with hypoglycaemia. Morton (1946) drew attention to the frequent association of the other symptoms with pain in the breasts.

Stieglitz and Kimble (1949) found, in a series of 67 patients, that 68% suffered from emotional instability, 65% from headache (in 12 instances amounting to typical migraine), 50% from backache, 47% from depression, 36% from aching in the thighs, and 9% from "bloating" of the abdomen. Of Morton's (1950) 29 patients, all had transient emotional instability, and the majority had pain in the breasts, increased appetite, lower abdominal pain, abdominal bloating, and gain in weight. Almost half had palpable oedema, about one-third had

menstrual irregularity, and a few had nausea and vomiting, increased sexual desire, and pruritus vulvae. One patient had headache, papilloedema, vertigo, and projectile vomiting of a degree suggesting an intracranial tumour. Cooke (1945) reported that 84% of crimes of violence by women occurred during or immediately before the menses. Morton *et al.* (1952), in a study of prison inmates, found that crimes of violence had been committed in 62% of the cases in the premenstrual week, in 19% at mid-cycle, in 17% during menstruation, and in 2% after the end of menstruation.

Analysis of 84 Cases of Premenstrual Syndrome

This series contains the histories of 84 cases of premenstrual syndrome which were treated with ethisterone and/or progesterone, and an analysis of results of treatment in 78 cases. All cases were seen between 1948 and 1952 and attended for a follow-up interview in 1952. Of the 84 patients in the series, 16 were first seen in hospital by R.G. Most of the remainder were collected by K.D. in her own practice (which has a National Health panel of 5,000), after the successful treatment of her own case, and were referred to R.G. Sixteen patients were referred to K.D. by her fellow general practitioners.

All the cases had attacks of various symptoms, which occurred during the premenstrual phase, during menstruation or ovulation, or at the time of a missed period, and all cases were symptom-free at other times. All cases included in the series had experienced attacks during each of the last three menstrual cycles; thus any chance coincidence between the attack and menstruation was eliminated. Any case in which the time relationship was not definite was temporarily excluded, the patients being treated symptomatically and asked to keep a calendar.

The "presenting" and other symptoms which occurred during attacks are shown in Table I. "Presenting symptoms" always occurred with each attack, but the other

In view of the suggestion of Salmon (1947) that the onset may be related to sexual dissatisfaction, a search was made for this and other possible psychological causes. No case of sexual maladjustment was found. The incidents (not necessarily significant) associated with the onset of symptoms in our 84 cases were as follows: puberty, 27; childbirth, 15; menopause, 14; widowed, 1; divorced, 1; mumps oophoritis, 1; thyroidectomy, 1; marriage, 3; unknown, 21.

Menstrual History

Fig. 1 shows the usual time of onset of the attack. In this series 70 patients expected attacks in the premenstrual week, 9 at the onset of menstruation, and 4 during menstruation.

FIG. 1.—Time of onset in relation to flow.

One patient had regular attacks only at ovulation, and 3 had bimensual attacks at ovulation and premenstrually. One of these had ovulatory bleeding. When, as at puberty and in the climacteric, periods are missed, the attacks nevertheless occur on the expected dates. Table V and Fig. 2 show the age at which the first menstrual loss occurred. This was normal in 72 cases, with only 2 cases (2.4%) occurring at the early age of 10 years, and only 5 cases (6%) occurring later than the normal time of onset (arbitrarily assumed to be 11 to 16 years).

Table VI shows the duration of menstrual loss. In only three cases was it abnormally short (two days), and in only one abnormally long (10 days).

FIG. 2.—Age at onset of symptoms.

TABLE V.—Age at First Menstrual Period

Years:	Normal Age Limit										Total
	10	11	12	13	14	15	16	17	18	?	
Cases	2	6	10	19	19	12	6	3	2	5	84
%	2.4	7.1	12.0	22.6	22.6	14.2	7.1	3.6	2.4	6.0	100

TABLE VI.—Average Duration of Menstrual Loss

Days:	1	2	3	4	5	6	7	8	9	10	?	Total
Cases	—	3	11	17	23	14	12	—	—	1	3	84
%	—	3.6	13.1	20.2	27.4	16.7	14.2	—	—	1.2	3.6	100

TABLE VII.—Length of Menstrual Cycle

Days:	Under 21	Normal Length			Total
		21-30	31-42	Irregular	
Cases	1	78	4	1	84
%	1.2	92.8	4.8	1.2	100

Table VII, giving the length of the usual menstrual cycles, shows that the cycle exceeded the normal 30 days in four cases only—in women aged 16, 17, 30, and 31 years. The series is conspicuous for the normality of the menstrual history. An irregular cycle had been present in one woman of 49 for twelve months, and presumably heralded the climacteric. In one woman of 27 ovulatory bleeding had occurred regularly at the 14th to 15th day of a 28-day cycle, and she also suffered from migraine at this time. In this respect our experience differs from that of Singh *et al.* (1947), who found a high incidence of abnormal menses.

Two patients had "slight" dysmenorrhoea—that is, the patient had some discomfort relieved by simple analgesics, but the pain was not sufficient to interfere with normal work or necessitate lying down. The other 82 patients had no dysmenorrhoea. One case of associated severe dysmenorrhoea has since been observed.

Effect of Pregnancy

TABLE VIII.—Parity of Series

	Our Series	Registrar-General's Figures (Ages 15-45)
Single women	13 (15.5%)	43.2%
Married, no children	13 (15.5%)	13.3%
" 1 child	25 (29.8%)	18.3%
" 2 children	11 (13.1%)	14.4%
" 3	13 (15.5%)	5.7%
" 4	5 (6.0%)	2.7%
" 5 or more children	4 (4.8%)	2.4%

Table VIII shows the parity of the series. The patients conceived easily and none had required medical advice on account of infertility. Most had their children in close succession, and all but two married women who had not had a child in the previous twelve months stated that they were practising some form of contraception. Three normal deliveries and one miscarriage at ten weeks occurred during treatment.

TABLE IX.—Health After First Trimester of Pregnancy

More energetic, symptom-free	36 (62.1%)
Symptom-free	18 (31.2%)
Symptoms (depressed 2, migraine 1, asthma 1)	4 (6.9%)
Total	58 (100)

Table IX shows the state of health of the patient after the first trimester. After the third month of pregnancy the premenstrual symptoms ceased in all but four patients, and 36 patients reported feeling more energetic than usual.

Toxaemia occurred in 11 of 58 parous women and complicated 21 of 128 pregnancies, thus accounting for the following obstetrical complications: surgical induction, 12; caesarean section, 4; forceps, 2; stillbirth, 3; sterilization, 1.

In 5 out of 11 cases the premenstrual syndrome began after the pregnancy complicated by toxemia. The possible association between the syndrome and toxemia is under further investigation.

Effect of Childbirth

In all cases in which the syndrome existed before pregnancy the attacks occurred with increased severity at the first menstruation after childbirth. Three patients with migraine had an attack during the puerperium; 15 dated the onset of regular attacks from childbirth.

In seven cases childbirth was followed by increasing weight and lethargy in addition to the premenstrual syndrome, a condition easily misdiagnosed as myxoedema, but which responded to ethisterone or progesterone therapy.

In view of the frequency of the syndrome no sound conclusions about familial incidence can be drawn from so small a series. It may, however, be worthy of note that the mothers of 29 of our patients had suffered from migraine: of these, 14 suffered from attacks which were related to menstruation and which ceased at the menopause. Seven of our patients reported similar conditions in their sisters, in five instances in relation to menstruation. One patient reported that her father suffered from migraine. Two patients who were cousins were able to trace premenstrual migraine in four generations.

Is Water Retention the Cause of the Syndrome?

That the symptoms are due to water retention is strongly suggested by the oliguria and gain in weight which announces their arrival and the diuresis and loss of weight which accompanies their relief at, or soon after, the onset of menstruation. To the observations already quoted may be added those of Thorn, Nelson, and Thorn (1938), who found a premenstrual gain in weight of more than 1 kg. in 48% of healthy women, and, be it noted, a mid-menstrual gain in 76%. They showed that at neither time was the gain attributable to increased intake of food, an important point in view of the increased appetite occasionally reported. Morton (1950) found that in his series of cases of "premenstrual tension" a higher proportion (52%) gained weight and that 45% had pitting oedema. Bickers and Woods (1951) found a good correlation between the gain in weight and the severity of the symptoms, and reproduced them by injections of "pitressin." Relief of the symptoms by various diuretic measures has been reported. Greenhill and Freed (1940) claimed success in all their patients treated with ammonium chloride and a diet low in sodium, and in a later and larger series (Greenhill and Freed, 1941) in 34 patients out of 40. Thorn and Emerson (1940) were successful with a diet low in sodium and high in potassium. Stieglitz and Kimble (1949), in order to avoid the chloride ion, preferred ammonium nitrate and obtained relief in 91% of their patients. Argonz and Abinzano (1950) treated 30 patients with large doses of vitamin A because of its reported diuretic effect, and claimed success in every case. Bickers and Woods (1951) relieved all symptoms with the new diuretic pyralamine-8-bromothephyllyne, which reduced the average gain of weight from 5.2 to 1.4 lb. (2.4 to 0.6 kg.). Their results were less good with ammonium chloride, which reduced the gain only to 4.3 lb. (2 kg.). Vainder (1951) was successful in 153 cases treated with "pyrabom" (pyralamine-8-bromothephyllyne).

Nevertheless, it is necessary to be on guard against too ready an explanation of the syndrome solely by water retention. Thorn, Nelson, and Thorn (1938), as we have seen, found that a gain in weight occurred more often at mid-cycle than in the premenstrual phase. Similar symptoms do sometimes occur at the time of ovulation, but they are far less common. Thorn and Emerson (1940) were disposed to explain this by the experimental fact that progesterone and oestradiol both have the capacity to cause water retention, and that, whereas only oestradiol is operative at mid-cycle, both are present before menstruation; but, for reasons which will later be obvious, this explanation is not

acceptable. In our series, symptoms occurred at mid-cycle in only four cases. Such women usually have two attacks, and sometimes these last long enough to merge with each other, especially when the cycle is short and the gap between menstruation and ovulation therefore also short. One unfortunate Irishwoman complained: "I only feel well when I am poorly." If we include mastalgia with the other symptoms we can assure ourselves that a factor other than water retention is involved. Greenhill and Freed (1941) noted that this symptom, alone in the syndrome, was not improved by dehydration, a fact which we have repeatedly confirmed.

Moreover, observation of a patient by one of us in 1938 (Fig. 3) suggests that a factor other than water retention

in "dog units," oestradiol 700, progesterone 400, oestrone 200-300, pregnanediol 140, testosterone 80, and testosterone propionate 25. Despite this, as we shall see, there is ample evidence of the effectiveness in treatment of progesterone, testosterone, testosterone propionate, and methyltestosterone. Still more surprising is the statement of Chiray *et al.* (1940) and Rubenstein (1942) that occasional cases respond to oestrogens, a claim we have been unable to confirm. Moreover, Singh *et al.* (1947) were able to induce attacks with oestrogens.

Though at first sight the water-retaining properties of progesterone and testosterone appear incompatible with their success in treatment, a hypothetical explanation may be suggested. The effects of progesterone on the excretion of

FIG. 3.—Occurrence of pain in relation to 11 menstrual cycles, together with weight changes during four cycles in a patient.

may sometimes be involved. She complained of attacks of migraine, occurring usually at intervals of a fortnight. She was intelligent and co-operative, and kept careful notes of her symptoms over a period of 11 cycles. During four cycles she plotted her weight day by day. These 11 cycles varied in length from 24 to 27 days. The attacks were of two kinds, occurring either during the interval or near the beginning of menstruation. The intermenstrual attacks, which all lasted for one day only, occurred nine times on the 14th or 15th days before menstruation. The two exceptions occurred on the 10th day before (when, uniquely in this study, no menstrual attack succeeded it) and on the 17th day before (when, again uniquely, it was accompanied by uterine haemorrhage and succeeded by a scanty menstrual flow). The menstrual attacks occurred in 10 cycles. They varied in length from one to three days, and their onset varied between the third day before the beginning of the flow to the second day after the beginning of the flow, in this way differing from the majority, in which all attacks were premenstrual.

It is important to observe that in the cycle in which there was an intermenstrual but no premenstrual attack, the weight dropped sharply by over 4 lb. (1.8 kg.) in the first half of the intermenstrum (the attack occurring at the nadir) and rose again by almost 4 lb. (1.8 kg.) in the second half (without any attack at the zenith). In the succeeding cycle weight changes were far less obvious and bore no relation to the attacks. Later in the series of cycles, one was observed in which the intermenstrual attack occurred before the nadir, though the premenstrual attack occurred at the zenith, and one in which an attack occurred intermenstrually before the nadir and premenstrually without a significant rise. Such observations enjoin some caution in assuming that water retention is the sole cause of intermenstrual and premenstrual or early menstrual migraine.

Another difficulty to be overcome arises from the reported effects of sterols in treatment. Oestrogens, androgens, and progestogens all have the property of causing water retention (Thorn and Engel, 1938; Kenyon *et al.*, 1940). Thorn, Nelson, and Thorn (1938) estimated that the relative potencies of the common sterols in this respect were, represented

oestradiol may more than counterbalance its weaker direct effect on water metabolism. That progesterone has this effect is shown by the observations of Smith and Smith (1931, 1938), which have been amply confirmed (Burrows, 1945).

Why Does Water Retention Occur?

The fact that two peaks of oestradiol secretion occur in each normal menstrual cycle—one at the time of ovulation and one in the premenstrual phase—suggests a hypothetical explanation of the retention of water at these times. That oestrogens are capable of causing water retention is well known, especially from the observations of Zuckerman and his colleagues (Krohn and Zuckerman, 1937; Aykroyd and Zuckerman, 1938; Zuckerman *et al.*, 1938).

Direct evidence of an excess of oestrogens at the time of the occurrence of symptoms is of doubtful validity. Frank (1931) and Frank *et al.* (1934), it is true, claimed that their patients' blood contained twice the normal amount of "ovarian hormone," and that after the relief of symptoms by x rays applied to the ovaries the ovarian hormone level became normal; but the difficulties inherent in the estimation of ovarian hormones in blood make it necessary to accept the statement with reserve. Morton found that vaginal smears were suggestive of excessive oestrogenic activity. On the other hand, Frank's suggestion of a high renal threshold for oestrogens was found by Israel (1938) in fewer than half his patients, which led him to suggest that the cause of the trouble was not so much a high level of oestradiol as a lack of antagonism by progesterone.

The concept of an abnormally high oestradiol/progesterone ratio has much in its support. Greenblatt (1940) contested the suggestion because in most of his patients he found a normal progestational pattern in their endometria and a normal excretion of pregnanediol; though he also noted a deficient excretion of oestrogens. Gray (1941) failed to find any correlation between the premenstrual syndrome and anovular cycles, and in the series reported by Bickers and Woods (1951) the basal temperature curve was invariably biphasic and the endometrial pattern progestational. Provenzano (1944) found a normal pattern in 12 out of 15 patients. It should, however, be pointed out that the hypothesis that the cause of the syndrome is an abnormally high

oestradiol/progesterone ratio does not at all depend on the demonstration of a consistently high level of the former or low level of the latter, since only the ratio between the two is on trial.

The hypothesis is supported by several observations. Morton (1946) has reviewed the evidence that painful breasts, so common a feature of the syndrome, are due to a high oestrogenic level, and he (Morton, 1950) was able to induce the syndrome artificially by the administration of large doses of oestrogens in two castrates and one post-menopausal woman, thus confirming the earlier observations of Singh *et al.* (1947). That the administration of progesterone is effective in relieving it was shown by Gray (1941), Puech (1942), and Albeaux-Fernet and Loublié (1946), and has been amply confirmed by ourselves. The hypothesis is further supported by the experimental evidence produced by Gillman (1942), who showed that progesterone administered to baboons reduces oestrogenic perineal swelling to normal in from four to seven days, an observation confirmed by Krohn (1951). Herlant (1939) had previously suggested that this effect was due to the suppression of the gonadotrophic activity of the pituitary by progesterone, but Krohn pointed out that the effects are too rapid for such an explanation and thought that a direct antagonism in this respect between oestrogens and progesterone was a more likely explanation. The pregnanediol output was subnormal in 10 of Morton's (1950) 29 patients, the endometrial pattern showed progestational deficiency in 22, and the basal temperature curve was "anovular" in 23.

Water Retention and the Oestradiol/Progesterone Ratio

If water retention due to an abnormally high oestradiol/progesterone ratio is the cause of the symptoms, how is it brought about? Several explanations have been postulated. Is there, for instance, a change in the metabolism of sodium, a sodium retention bringing about a water retention? Thorn, Nelson, and Thorn (1938) and Thorn and Emerson (1940) found that the excretion of sodium and chloride is decreased before and increased after both ovulation and menstruation. Morton (1950) found at these times a diminished excretion not only of sodium but also of potassium and chloride. Danforth *et al.* (1946) failed to find any consistent fluctuation in sodium or potassium metabolism, but confirmed the common rise in weight reported by other workers and found it to be associated with a decline in haematocrit and plasma proteins. Greisheimer *et al.* (1946) found no constant menstrual change in the blood, in pH, CO₂ content, chloride, or total base either in the premenstrual syndrome or in the controls, and concluded that the menstrual cycle is not characterized by any regular change in the acid-base equilibrium of the serum. Males showed as much fluctuation as females. The success of the treatment of the premenstrual syndrome by reduction in sodium intake has been noted above.

Many points are still obscure and several difficulties in interpretation have yet to be overcome; it does, however, appear that the best working hypothesis is that which postulates a cyclical change in sodium (and therefore in water) metabolism which occurs to a slight extent in healthy women and to an exaggerated extent in sufferers from the premenstrual syndrome. The rhythm of this change seems to be controlled by the level of oestradiol in the tissues, and this in its turn to be under the partial control of progesterone. Excessive water retention may therefore be present even with a fairly low level of oestradiol if progesterone is entirely lacking; or absent even with a very high level of oestradiol if progesterone is present in adequate amounts. It is the oestradiol/progesterone ratio which determines whether or not symptoms occur.

Symptomatology

If this hypothesis is correct a ready explanation of many of the symptoms is available.

Migraine and lesser degrees of headache may well be due to an increased hydration within the indistensible cranium.

We have seen a male patient suffering from the oliguria and water retention which so often follow epidemic encephalitis who had frequent attacks of the severest migraine which were entirely prevented by the reduction of salt and water in his diet and the administration of urea. That urea is a useful treatment in some cases of migraine was always taught by Sir Walter Langdon-Brown and has been often confirmed by many workers—for example, Brown (1943)—and on other grounds water retention has been incriminated in migraine by the work of Földes (1933) and of Goldzieher (1941). Bickers and Woods (1951) produced the symptoms of the premenstrual syndrome by the injection of "pitressin" and found a close correlation between the consequent gain in weight, the severity of the symptoms, and the subsequent diuresis. The occasional epileptiform fits may be looked upon as the natural counterpart of the pitressin-water test for epilepsy.

There is no evidence that fluid retention causes bronchospasm. Indeed, the persistence over several days of premenstrual "asthma" suggests that the bronchial obstruction may be due to a less transient cause. A more prolonged obstruction by swelling of the mucosa may be present, though we have not yet confirmed this suggestion by bronchoscopy. The relationship between hyperaemia and oedema of the upper respiratory tract and the pelvic organs has long been recognized. It has been briefly reviewed by Greene (1943). The relationship was known to Hippocrates and was brought to the attention of the moderns by Mackenzie as early as 1884. He observed that the nasal mucosa of women becomes congested before the menstrual periods and that actual bleeding may then occur ("vicarious menstruation"). Some women, as Hoesason (1938) pointed out, suffer at this time from rhinorrhoea. Mortimer *et al.* (1936, 1937, 1939) showed that in monkeys there is an increase in colour of the nasal mucosa at monthly intervals coincident with the swelling of the sexual skin. The nasal changes were, indeed, 8% more regular as a sign of ovarian activity than menstrual bleeding itself, and were most obvious in the fertile months of September and October. Immature and adult monkeys of both sexes, whether intact or castrate, react to oestrogenic treatment by reddening of the nasal mucosa, which occurs even if the nasal tissue is transplanted elsewhere (Bachman *et al.*, 1936).

The papers from the Montreal school were followed by several clinical reports of good results in the treatment of atrophic rhinitis by injections or local applications of oestrogenic substances. That these results may be accounted for by the selective concentration of oestrogens in the nose is suggested by the experiments of Fisher *et al.* (1936). The immediate effect of this concentration is local vasodilatation, as Reynolds and Foster (1940) showed. Apart from their specific action, oestrogens produce hyperaemia in many tissues (Hechter *et al.*, 1940) and it is natural that this hyperaemia should be greatest in those tissues in which a concentration of oestrogens occurs. This hyperaemia is due to the liberation of acetylcholine in these situations (Reynolds, 1939; Reynolds and Foster, 1940), and effects similar to those of oestrogens may indeed be obtained by spraying the nose with neostigmine (Bernheimer and Soskin, 1940). The rhinorrhoea of the premenstrual syndrome—and perhaps the asthma as well—is thus explicable by the excessive local activity of oestradiol which would be expected *ex hypothesi*. The oedematous nasal mucosa may lead to blocking of the exits from the nasal sinuses and consequent "vacuum headaches."

The occasional association of premenstrual mastodynia with the commoner symptoms can be plausibly explained by the relatively high oestrogenic level without involving the consequent water retention. The evidence that the "painful nodular breast" is caused by excessive oestrogenic stimulation has been reviewed by Morton (1946) and by Greene (1950).

That so-called rheumatic pains may be due to water retention is well recognized. The rather ill-defined pain and tenderness in the soft tissues of obese women (often referred

to as "fibrositis" and "panniculitis") usually responds well to a dehydrating regime. A possible explanation has been offered by Copeman (1949).

The dermatoses of the premenstrual syndrome are less readily explicable on the present hypothesis. The explanation must await further work on the relationship between steroid metabolism and the state of the human skin. That such a relationship exists is clinically obvious. The laboratory evidence has been reviewed by Burrows (1945).

Treatment of the Syndrome

It has been indicated that numerous treatments have been suggested in the past. These include the following.

Dehydration.—References to this method of treatment have been cited in the discussion on the possibility that water retention is the cause of the syndrome. There seems little doubt that in a fair proportion of cases it is effective. It was not adopted in the present series. It has been tried by one of us (R. G.) in earlier cases with occasional success. It is greatly disliked by the patients, and only those suffering from the severest symptoms can be bothered with it for more than a few months. The newer diuretics have not been tried.

Androgens.—The "literature" of the subject leaves little doubt that androgens may be useful (Greenblatt, 1940; Albeaux-Fernet and Loublié, 1946; Freed, 1945, 1946; Chiray *et al.*, 1940). Androgens, such as testosterone propionate, which must be administered by injection, are no longer worthy of serious consideration. Methyltestosterone, administered by mouth, is sometimes effective, especially in those patients in whom mastalgia is a prominent symptom. It is less generally successful than progesterone in relieving other symptoms of the syndrome. Its chief disadvantage is the danger of virilization. It occasionally happens that the dose needed to relieve symptoms is high enough to cause acne, the growth of a slight moustache, and lowering of the voice. Menstruation may be suppressed.

Vitamins.—M. S. Biskind (1943) was influenced in his views by the occurrence of glossitis in the syndrome and obtained relief by the administration of vitamin B. He quoted G. R. Biskind and Mark (1939), who had shown that in vitamin-B deficiency the liver's ability to inactivate oestrogens may be impaired. With G. R. Biskind and L. H. Biskind (1944) he published 11 cases, all relieved by this therapy. In a small series treated by one of us (R. G.) before the present one was begun no success was achieved. Bickers and Woods (1951) were also unsuccessful. The effectiveness of vitamin A has been vouched for by Argonz and Abinzano (1950). Vitamin A has not been tried by us. If, as is suggested, its efficacy depends on its diuretic properties, it can hardly be expected to compete with mersalyl, urea, or the newer diuretic drugs.

Oophorectomy and X-ray Treatment of Ovaries.—These have been used successfully by Frank (1931). They are measures obviously too drastic for the present day.

Treatment with Progestogens

Progesterone has been used successfully by Gray (1941), Puech (1942), and Albeaux-Fernet and Loublié (1946). These workers administered the hormone by intramuscular injection. No report has so far appeared of the use of ethisterone, or of progesterone other than by intramuscular injection.

All patients in this series were treated by means of progestogens. The results of the treatment of 84 patients are presented. All were treated between January, 1948, and June, 1952, some of those included in the analysis of symptoms being excluded from consideration here for lack of a sufficiently long period of observation.

Cases of mild and moderate severity were treated at first by means of ethisterone, given in oral doses of 30 to 150 mg. daily for twelve days from the fourteenth day of the cycle. If at the end of the cycle a patient remained symptom-free, she was observed at monthly intervals. If she improved without becoming symptom-free, treatment was continued

Cases 6, 18, 19, 20, 21, 30, 66, and 83 did not report back after treatment. Cases 85 and 86 not included in previous analysis owing to insufficient history.

until she became symptom-free. If no improvement occurred she was given intramuscular injections of progesterone instead, in doses at first of 10 mg. daily during the second half of the cycle. Later it was found that an injection of 25 mg. on alternate days was equally effective. Severe cases were treated by this method from the outset. Patients who responded to this treatment were kept under observation: if they were only improved, treatment was continued until they were symptom-free. Those who became symptom-free but afterwards relapsed for lack of treatment were selected for treatment by means of implantation, doses from 200 to 500 mg. being employed. In a few cases in which treatment with oral ethisterone or intramuscular progesterone was used, the symptoms instead of being completely relieved were postponed until the later days of menstruation or even until the post-menstrual phase. Such patients were subsequently treated with ethisterone or progesterone throughout the entire month, and were ultimately treated by implantation.

Tables X and XI show the results obtained. The oral administration of ethisterone gave complete relief in 22 cases (47.9%) and partial relief in a further 8 cases (17.4%).

TABLE XI.—Comparison of Results of Treatment with Ethisterone and Progesterone Injections

Result	Ethisterone		Progesterone		Total After Final Treatment	
	No.	%	No.	%	No.	%
Symptom-free	22	47.9	51	83.5	66	84.7
Improved	8	17.4	4	6.6	6	7.7
Postponed attack	1	2.1	—	—	—	—
No relief	14	30.5	4	6.6	3	3.8
Not known	1	2.1	2	3.3	3	3.8
Total	46	100	61	100	78	100

Of the 14 cases unsuccessfully treated 9 had complete relief and 1 partial relief when treated with intramuscular progesterone, 2 obtained no relief from intramuscular progesterone, and 2 patients did not report the result. The results with intramuscular progesterone in 61 cases were more satisfactory—51 (83.5%) became free from symptoms, 4 (6.6%) improved, and 4 (6.6%) obtained no relief. Of the 4 patients unsuccessfully treated with progesterone 2 were treated with methyltestosterone, 5 mg. twice daily, from which one obtained complete relief and one partial relief. One patient unsuccessfully treated failed to report the result of treatment with ethisterone. The remaining unsuccessfully treated woman, aged 45, had suffered from toxæmia in all her five pregnancies and had been sterilized in 1942. In 1949, after the unsuccessful trial of progesterone she was given an artificial menopause by means of radiotherapy. After this her migraine, which had previously been premenstrual, became weekly, and had remained so when last seen in March, 1952.

Table XII summarizes the final treatment of 78 patients: thirty are symptom-free without regular medication and 43 much improved that regular medication is unnecessary; 28 were treated with progesterone implants, and, of these, 27 had complete relief and one partial relief of symptoms.

TABLE XII.—Final Treatment in 78 Cases

Final Treatment	Total Cases	Total %	Free		Improved		No Relief
			No.	%	No.	%	
Observation	34	43.6	30	44.7	4	57.1	—
Progesterone implant	28	35.8	27	40.5	1	14.3	—
Continuing ethisterone	7	8.9	7	10.4	—	—	—
" progesterone	3	3.9	2	2.9	1	14.3	—
Testosterone	2	2.6	1	1.5	1	14.3	—
Artificial menopause	1	1.3	—	—	—	—	1*
Not completed	3	3.9	—	—	—	—	—
Total	78	100	67	100	7	100	1

In three cases "not completed," patients did not report after change of treatment.

* Migraine worse after artificial menopause.

Summary

A large proportion of women, estimated by one author as 40%, suffer a variety of distressing symptoms during the final week or so of the menstrual cycle. In occasional cases, similar symptoms may occur at monthly intervals at other points of the cycle. They are probably produced by water-retention, and the evidence at present available suggests that this in its turn is due to abnormal elevation of the oestradiol/progesterone ratio.

Various treatments aimed at either dehydration or a correction of the disturbed hormonal ratio have proved partially effective. Treatment with a progestogen is almost invariably successful. In mild cases relief is usually obtained by the oral administration of ethisterone in a dosage of 25 mg. twice daily during the second half of the menstrual cycle. A larger proportion of patients can be relieved by the intramuscular injection of progesterone, 25 mg. on alternate days during the same phase of the cycle. Such cases are more effectively treated, with less labour for the patient, by the implantation of progesterone, which remains effective for many months.

THE PREMENSTRUAL TENSION SYNDROME AND ITS TREATMENT

BY

LINFORD REES, M.D., B.Sc., M.R.C.P., D.P.M.

Regional Psychiatrist for Wales; Consultant Psychiatrist,
East Glamorgan and St. David's Hospitals

Premenstrual tension is a syndrome occurring during the second half of the menstrual cycle and consisting of a number of mental and physical symptoms. The syndrome is composed of marked general tension and irritability, together with one or more of the following symptoms: anxiety, depression, bloated abdominal feelings, swelling of subcutaneous tissues, nausea, fatigue, painful swelling of the breasts, headaches, dizziness, and palpitations. Less frequently there may be increased sex desire, excessive thirst, increased appetite, and hypersomnia. The symptoms usually start about seven to fourteen days before menstruation and pass off soon after the onset of the menses, although some patients continue to have symptoms throughout the period. The syndrome must not be confused with the premenstrual discomfort experienced by many women. The premenstrual tension syndrome may seriously interfere with work and social activities, and can be incapacitating. The condition is by no means as uncommon as suggested in some reports.

Literature

The aetiology of the condition is still obscure. Frank (1931), who introduced the term "premenstrual tension," considered it to be due to excess of circulating oestrogen. Israel (1938) believed the syndrome not to be due to excess oestrogen itself, but rather to the action of unantagonized oestrogen resulting from faulty luteinization. Gillman (1942) and Hamblen (1945), in contrast, implicate progesterone as the responsible hormone. Convincing evidence in support of the hypothesis of faulty luteinization permitting the action of unantagonized oestrogen as the primary cause of premenstrual tension is, however, given by Morton (1950).

Water retention is postulated by Greenhill and Freed (1941) as the immediate cause of premenstrual tension symptoms. Hoffman (1944) considered that an unstable nervous system was an important factor, and a number of authors have expressed the opinion that the condition seems to be more frequent in unstable women.

Rees (1953), in a psychosomatic study of 145 subjects, including normal and psychiatric patients, found that marked premenstrual tension could exist in normal women of stable personality and that many severely neurotic women were free from it. In neurotic patients with premenstrual tension

there was a positive correlation between degree of premenstrual tension and degree of personality instability and severity of neurosis. Rees, while in general supporting the theory that the condition was primarily physiogenic and due to changes resulting from defective progesterone secretion, stressed that the syndrome was of complex causation in which personality and constitutional and emotional factors operate in addition to the primary physiogenic changes.

There is now considerable evidence to suggest that the bodily changes of the premenstrual tension syndrome are primarily due to a lack of progesterone, which allows the unopposed action of oestrogens during the second half of the menstrual cycle. It is known that oestrogens cause sodium and water retention. Hydration is a common feature of the premenstrual tension state, and many patients put on from 2 to 9 lb. (0.45 to 4.1 kg.) in weight during the premenstrual phase and lose a corresponding amount with the diuresis following the onset of the menses. Oestrogens stimulate growth of the epithelia of the breast, vagina, and endometrium, and this together with hydration may account for painful swelling of the breasts. Hypoglycaemia and hyperinsulism have been noted to occur during premenstrual tension states (Billig and Spaulding, 1947; Morton, 1950) and may be the cause of increased appetite and fatigue noted in some patients. These changes in the internal environment cause a number of specific symptoms and also may result in autonomic lability, causing such symptoms as palpitations and dizziness. The patient's reaction to these changes can be influenced by such factors as personality type and stability, emotions, attitudes, and degree of autonomic instability.

The treatment of premenstrual tension can therefore be directed at different aetiological levels. (1) Psychotherapy, including explanation and re-education to improve attitudes, relieve symptoms, and minimize degree of incapacity. (2) Dehydration by means of diuretics to relieve symptoms due to hydration and possibly to facilitate elimination of the noxious agent. (3) Administration of progestogens to compensate for any lack of progesterone and to antagonize action of oestrogens. (4) Administration of androgens to antagonize action of oestrogens as suggested by Greenblatt (1940), Geist (1941), and Freed (1945).

Gonadotrophins are generally considered to be ineffective (Bowes, 1950), and as oestrogens tend to intensify symptoms (Morton, 1950) they are contraindicated.

Present Investigation

The following therapeutic methods have been studied in a group of 30 patients suffering from severe premenstrual tension: psychotherapy; dehydration therapy using ammonium chloride; administration of progestogens, including progesterone by injection and ethisterone by mouth; and administration of androgens in the form of methyltestosterone by mouth. The patients have been observed for from six months to four years, giving a total of 207 cycles.

The assessment of premenstrual tension was made from data obtained during clinical interview and from special daily records of symptoms. Detailed instructions were given to patients regarding the daily recording of symptoms, so that scoring was, so far as possible, kept standardized. The day-to-day records were kept for some months before starting treatment, and the data so provided permitted a detailed assessment of the premenstrual tension and provided a baseline for measuring the effects of treatment.

Clinical Data.—The age distribution of the group was 15-24 years, 8%; 25-34, 56%; 35-44, 36%. Most patients had developed premenstrual tension before 35 and about one-fifth before the age of 20. Two developed premenstrual tension after childbirth, and three just before the menopause. 80% of the group were married. The mean age of menarche was 14.7 years and the frequency distribution of menarchial ages was similar to that described by Ellis (1947) for normal British women. The symptoms of premenstrual

tension usually started about seven to ten days before the period and usually cleared up soon after the onset of menstrual flow, but in some patients they occasionally continued throughout the menses. The symptomatology of the group was as follows: tension, 100%; irritability, 100%; depression, 80%; emotional lability, 80%; anxiety, 73%; swelling of fingers or legs, 73%; painful swelling of breasts, 63%; fatigue, 63%; headaches, 63%; insomnia, 40%; pruritus, 40%; palpitations, 40%; nausea, 37%; marked thirst, 20%.

Results

Psychotherapy

Premenstrual tension was not found to be amenable to psychotherapy alone. Psychotherapy of a simple kind can help the patient in understanding the condition and can improve her attitude and reaction to it. The tense, anxious, striving obsessional type of woman feels greatly frustrated by the interference with physical, mental, and social well-being caused by the premenstrual tension state. She may tend to force herself to keep up the tempo of her work and life in spite of her symptoms. This tends to lead to greater frustration and increase in tension. In this type of patient an understanding of the nature of the condition and the fact that there is an underlying physiological basis for her symptoms can help, together with the advice to modify the demands she makes on herself in relation to her premenstrual symptoms. The person who, on the other hand, is hypochondriacal or very dependent may allow the premenstrual tension state to interfere unnecessarily with her work and social activities. Again explanation, and re-education with the aim of producing a more salutary attitude to her symptoms, can be helpful.

Sixteen patients of the group were attending the psychiatric clinic for treatment of neurosis in addition to premenstrual symptoms. In all these the onset of premenstrual tension antedated the onset of neurosis. Some of them recovered from their neurosis without any significant improvement in premenstrual tension symptoms; conversely, some patients showed improvement in premenstrual tension with hormonal therapy without change in the coexisting neurosis. These facts indicate that premenstrual tension cannot be regarded as being primarily a neurosis.

Suggestion is not thought to play an important part in the condition. Most of the patients develop premenstrual symptoms without realizing the relationship to the menstrual cycle. Exhibition of inert tablets given as a control to hormone therapy produced no significant improvement.

Dehydration Therapy

Dehydration treatment was applied by giving enteric-coated tablets of ammonium chloride in 7½-15-gr. (0.5-1-g.) doses three times a day for twelve days before the period, with restriction of sodium intake. This was found to be effective in preventing the development of swelling of the fingers, legs, face, and other parts of the body. It was also successful in removing these if they had already developed.

The majority of patients reported that they felt more comfortable and had relief of the following symptoms in particular: bloated feeling in abdomen, heavy feelings in head, swelling of subcutaneous tissues and tightness of skin, general pruritus, and pruritus vulvae.

Although effective in preventing excessive water retention and its attendant symptoms, the method was not always effective in relieving the nervous tension, irritability, depression, and anxiety. This suggests that hydration is not responsible for all the symptoms of the syndrome. This is borne out, too, by the fact that some women develop signs of hydration midway between the periods without signs of hydration tension that develops premenstrually, and in the emotional tension that disappears at the onset of some patients the nervous tension disappears at the onset of the menses in spite of the fact that hydration may continue for some days afterwards.

Progesterone Treatment

Progesterone was given intramuscularly on alternate days for twelve days before the period in five patients, and was found to be effective in relieving the symptoms of premenstrual tension. In view of the practical disadvantage of a treatment involving a series of injections an extensive trial was given to the orally active preparation ethisterone. This was given to all patients in the series, and observations were made on over 100 cycles.

Ethisterone was given for twelve days before the period, starting with 5 mg. twice daily, increasing to 10 mg. twice daily if necessary. Most patients responded to a dosage of 5-10 mg. daily. In about 85% of the trials ethisterone was found to produce significant relief of premenstrual symptoms. The signs and symptoms of hydration were prevented and there was usually relief of tension, anxiety, depression, fatigue, headaches, bloated feelings, and pruritus. The pain of dysmenorrhoea was not relieved, and often the patient reported increased pain indicative of more powerful uterine contractions. Occasionally delay of a few days in the onset of the menses was noted when the patient was on ethisterone.

Androgen Treatment

Treatment with methyltestosterone has been tried in 10 patients and observations were made on 40 cycles. It was given in doses of 10 mg. daily for twelve days before the period. Marked relief of premenstrual tension symptoms was obtained, including tension, irritability, anxiety, and depression; also signs and symptoms relating to hydration were prevented. As with ethisterone, the period may be delayed and uterine contractions more painful.

The relief of symptoms of premenstrual tension with methyltestosterone seems to be as effective as that given by ethisterone.

Discussion

The complex symptomatology comprising the premenstrual tension syndrome is of multiple causation. Some of the symptoms and signs are attributable to the effects of hydration, others are due to proliferative changes in the breasts and uterus. Some are possibly due to changes in blood sugar, whereas others are manifestations of autonomic imbalance. Subjective factors, such as the patient's emotional stability, personality, and her attitudes, will also influence the intensity of the degree of incapacity resulting from various symptoms.

Our observations and therapeutic results appear to lend support to the theory that the primary cause is lack of progesterone secretion, permitting the unantagonized action of oestrogens.

Oestrogens are known to cause sodium ion and water retention and proliferative changes in the breast and endometrium, and also to cause various chemical changes in the blood, including hypoglycaemia and increased carbohydrate tolerance (Billig and Spaulding, 1947; Morton, 1950). These effects would appear to explain many of the symptoms and changes associated with the premenstrual tension state.

Treatment with ammonium chloride causes diuresis and removes or prevents excessive hydration, and may also serve to aid the excretion of oestrogens or other agents that may be pathogenetic in premenstrual tension. Our evidence suggests, however, that hydration does not account for the whole of the syndrome.

Progesterone and ethisterone treatment was found to be effective in alleviating not only hydration and its symptoms but also nervous tension, irritability, depression, anxiety, etc. Progesterone promotes diuresis (Selye, 1950), and our observations with ethisterone suggest a similar effect, in contrast to the water-retaining effects of oestrogens. Testosterone also promotes diuresis (Selye, 1950) and is similar in chemical constitution to ethisterone.

Ethisterone and testosterone are both diuretic and antagonistic to oestrogen, and this would appear to be the rationale for their beneficial therapeutic effects on premenstrual tension.

The conclusion is that the simplest method of treating premenstrual tension is by means of diuretics such as ammonium chloride, and, if this is not effective, ethisterone or methyltestosterone should be tried.

Summary

The clinical features of premenstrual tension are described and the possible mode of origin of the various symptoms is discussed. Hydration, blood chemistry changes, autonomic nervous system responses, as well as psychogenic and personality factors are believed to play a part in the syndrome. A working hypothesis on which treatment was based is postulated.

Treatment was applied at various aetiological levels, including psychotherapy, dehydration therapy, and administration of progestogens and androgens.

Psychotherapy has an important but limited role. Dehydration therapy was found to alleviate some of the symptoms only. The most effective methods of treatment were administration of a progestogen such as ethisterone or an androgen such as methyltestosterone during the second half of the menstrual cycle.

BRIGHT'S DISEASE

AN ATTEMPT AT A STATISTICAL ASSESSMENT OF THE CLASSIFICATION PROPOSED BY ELLIS

BY

J. B. ENTICKNAP, M.D., D.C.P.

AND

C. L. JOINER, M.D., M.R.C.P.

(From the Departments of Pathology and Medicine,
Guy's Hospital, London)

[WITH SPECIAL PLATE]

In 1827 Richard Bright described the disease of the kidney to which his name is still attached. His cases included all forms of renal disease unassociated with obvious changes in the lower urinary tract, and so were composed mainly of the three main groups of chronic pyelonephritis, hypertensive nephrosclerosis, and true nephritis. The second of these was clearly separated by Allbutt (1895-6), and the last has been defined by Osler (quoted by Osman, 1939) as "bilateral, non-suppurative inflammatory disease of the kidneys." The importance and frequency of the first group as a cause of Bright's disease has only recently been recognized.

Numerous attempts have been made to subdivide these cases, but none has received general acceptance. Ellis (1942), as a result of a combined clinical and pathological investigation of "about 600" cases, "about 200" of

which were fatal, suggested that nephritis could well be separated into only two groups, which he called types I and II.

Type I nephritis is characterized by an abrupt onset with haematuria, and is often preceded by an acute infection such as a sore throat. In most adequately treated cases recovery is complete. Death may occur in the acute stage, and some cases follow a progressive course ending in death in a few months. Other cases appear to recover completely, yet after many years develop renal failure and hypertension.

Type II nephritis, on the other hand, is of insidious onset and usually presents as oedema with albuminuria. There is no history of preceding infection, and haematuria is uncommon. The course of the disease is steadily downhill, and if renal failure and hypertension supervene the oedema tends to abate. Many of these patients die from secondary infection and the remainder from hypertension or uraemia.

Ellis further suggested that the two types were not only clinically distinct but were associated with specific renal histological changes and were unrelated aetiologically. Davson and Platt (1949) supported his conclusions with the exception of the last, upon which they reserved judgment.

The present communication describes a similar investigation of a comparable group of cases, with the difference that, where possible, clinical and pathological diagnoses were made quite independently. There were two main objects. The first was to examine the lesions found in fatal Bright's disease, and the second was to see what support analysis of a further group of cases lent to Ellis's views.

Material and Method

In all, 154 cases were examined. They were those that had been indexed as Bright's disease in the necropsy records of this hospital during 1931-51. No non-fatal cases were investigated, so no comprehensive survey of the natural history of these diseases can be offered.

Twenty-seven of these cases have not been included in the analyses: 8 of them because there was a history of toxæmia of pregnancy, 2 because of industrial exposure to heavy metals; 1 was a typical case of polyarteritis nodosa, and 1 was associated with scleroderma; in the remaining 15 cases the clinical or pathological material was incomplete.

The clinical diagnoses were made on the ward records, which were examined by C.L.J., only very few of the patients being seen by either of us during life. The original necropsy reports were consulted, where necessary, only for the macroscopic observations, the histological data presented being derived from an examination of preserved material by J. B. E. At first these investigations were entirely independent, and extreme care has been exercised to avoid either diagnosis being influenced by evidence proper to the other. In all cases in which clinical and pathological diagnoses differed a re-examination was made, the only additional information at each observer's disposal then being the fact that a discrepancy had been encountered. It was rarely found possible to alter a diagnosis at this stage, and if agreement was not reached the available information was discussed and a definite decision on grouping was made. In only 9 cases (7.1%) was agreement then reached, leaving 19 cases of disagreement. All analyses, except where otherwise stated, have been based on the assumption that, wherever pathological and clinical conclusions conflicted, those drawn from the latter material were the correct ones.

Nomenclature

The classification proposed by Ellis has been used throughout, and his criteria for the diagnosis of nephritis of

types I and II have been strictly adhered to. He does not include chronic interstitial nephritis in his table, but follows the recent trend of referring to these cases as chronic pyelonephritis (Ellis and Evans, 1933; Longcope and Winkler, 1933; Weiss and Parker, 1939; Platt and Davson, 1950), of which condition they are thought to represent a healing or healed stage. In our diagnoses we have depended largely on the descriptions quoted, and since the lesions closely resemble those of the healing stage of "ascending" renal infection we shall, for convenience, call them "chronic pyelonephritis."

The term "nephrosis" is restricted to a predominantly tubular condition in which there is no evidence whatever of inflammatory disease and of which we have encountered only one case.

In the diagnosis of nephrosclerosis the descriptions of Allbutt (1895-6), Ellis (1938), and Platt (1948) have been followed.

The other conditions in Ellis's table have been seen in numbers too small to merit further discussion (e.g., amyloidosis), or not at all (e.g., focal nephritis), or have been excluded (e.g., toxæmia of pregnancy).

Results

Of the 154 cases examined 15 had been admitted in terminal uraemia, and, although clear histological pictures were seen in 13 of them, no further clinical diagnosis could be made. In the remaining two of these and in seven other cases in which the diagnosis could be established clinically, no more precise conclusion than "contracted kidney" (see below) could be reached from the pathological material. To 16 cases renal lesions were unexpected necropsy findings to which there were no relevant clinical notes. In the remaining 116 cases clinical and pathological diagnoses could be made.

TABLE I.—Distribution of the Cases by Their Clinical Diagnoses

	This Series	Platt and Davson (1950)*
Acute type I nephritis	9	23
Chronic type I nephritis	21	25
Type II nephritis	24	26
Pyelonephritis	12	16
Benign nephrosclerosis	14	24
Malignant hypertension (primary)	13	3
Amyloid disease	2	
Lipoid nephrosis	1	
Clinical uraemia (Table IIIA)	15	
Incidental necropsy findings of Bright's disease (Table IIIB)	16	
	127	
Toxæmia of pregnancy	8	2
Exposure to heavy metals	2	
Scleroderma	1	1
Polyarteritis nodosa	1	15
No diagnosis	15	
	154	

* These authors made their diagnoses on all available clinical and pathological information; in our series this procedure would have doubled the number of cases of pyelonephritis.

TABLE II.—Cases Which Were Both Clinically and Pathologically Diagnosed as Specific Conditions

	Acute Type I Nephritis	Chronic Type I Nephritis	Type II Nephritis	Chronic Pyelonephritis	Acute Microscopical Form of Periarteritis Nodosa	Total No. of Cases of Inflammatory Disease	Benign Nephrosclerosis	Primary Malignant Hypertension	Amyloid Disease	Lipoid Nephrosis	Total No. of Cases of Degenerative Disease	Combined Totals

% (1/4)	78	47	57	55	0	70	80	92	100	100	93	81

General Discussion

Highly significant agreements have been found between clinical and pathological diagnoses made on Ellis's criteria after great care had been exercised to avoid collusion. We must conclude, therefore, as did Davson and Platt (1949), that his classification does fit the observed facts. This does not, however, necessarily imply that the features of types I and II require acceptance in every particular. Indeed, it may mean no more than that the less dramatic clinical stories are associated with the less remarkable pathological pictures. Thus while the percentages for the chronic inflammatory diseases shown in Table II (4) represent significantly more agreements than would be obtained by chance, they clearly do not in our hands imply a very high degree of diagnostic accuracy. The independent operation of personal factors may be very important here and cannot be allowed for other than by examining an adequate series with sufficient care. It is of course common experience that any case of more than ordinary complexity may, in the hands of different clinicians and different pathologists, give rise to widely differing opinions as well as to discrepancy between the *ante mortem* and *post mortem* diagnoses; but we believe that the nature of these 154 cases and the materials on which our diagnoses have been based are such that our conclusions are unlikely to be very different from those of other observers making use of the same criteria. If this is so the figures quoted strongly suggest that these criteria may not have been exclusive enough.

It seems to us, therefore, that Ellis's types I and II of nephritis are not mutually exclusive entities, but in his Croonian Lectures little attention was paid to this possibility. The more guarded conclusions of Davson and Platt (1949), the fact that in their investigation clinician and pathologist found it necessary to confer before agreement was reached, and their statement that pathological diagnosis was often made by deciding which was the predominating lesion make it clear that in their series there was some evidence in its favour. In particular, their Case 11, in which the changes of malignant hypertension were found in a type II kidney, may be noted—a combination that we also saw in one case.

We think it more probable, therefore, that the different appearances of type I and type II nephritis represent variations in the response of the renal parenchyma to a single disease rather than to entirely different processes. If this be so, and in view of the difficulties experienced in diagnosis, it seems to us that this classification has little to recommend it from a descriptive point of view. We present no new aetiological evidence, but others have already suggested (Davson and Platt, 1949) that some criticisms may be levelled on these grounds. The pathogenesis has not been elucidated, and it is not necessary to specify the pathological lesion present before giving a prognosis to a patient diagnosed clinically. It may be considered preferable, then, to await some aetiological indications, since these are the only basis for a lasting classification, before accepting a new terminology for nephritis.

Conclusions

In our series of 154 fatal cases of Bright's disease we found chronic pyelonephritis to be about as common as all other forms of inflammatory disease. Acute glomerulonephritis occurred fairly often, but we have no data from which to calculate a fatality rate for this condition. We regard it as an entity separate from and probably commoner than the acute microscopical form of polyarteritis nodosa.

We have obtained significant agreements between independent clinical and pathological diagnoses in all the major groups in the classification suggested by Ellis. Those for degenerative disease and for acute type I nephritis were much better than those for chronic inflammatory conditions. Considerable overlapping was discovered between types I and II of nephritis, and only 63% of them were accurately diagnosed.

From these figures we conclude that the Ellis classification does fit this series of cases, but in its most important aspect, the separation of types I and II of nephritis, it so lacks precision that its adoption hardly seems justified.

We found type II nephritis to be renal failure of insidious onset which may be associated with a variety of pathological conditions. These included acute nephritis, pyelonephritis, and hypertensive and polyarteritic renal lesions. Kidneys showing more than one histological feature said to be individually characteristic were common.

For the present, therefore, it seems that there is little reason for departing from the time-honoured procedure of classifying nephritis into acute, subacute, and chronic forms on clinical grounds. Recognition of nephritis—the acute form of which can usually be distinguished—chronic pyelonephritis, and vascular lesions is probably all that can be accomplished on morphological grounds alone.

Summary

A series of 154 fatal cases of Bright's disease occurring in Guy's Hospital between 1931 and 1951 have been examined independently by us, one making a clinical and the other a pathological diagnosis. The diagnoses were compared and an attempt was made to analyse the results statistically.

Of the lesions responsible for fatal Bright's disease, chronic pyelonephritis accounts for a large proportion, and acute nephritis is not uncommon.

Significant agreement between clinical and histological diagnoses was discovered in all groups when the Ellis classification was applied to these cases. Those for chronic inflammatory conditions were, however, less close than for any of the other major forms of renal disease. Considerable overlapping was encountered and diagnosis was often difficult.

Type II nephritis as diagnosed clinically may be due to several different pathological lesions.

For the present it is suggested that the classification of clinical nephritis into acute, subacute, and chronic forms be continued, and that pathological subdivision be restricted.

We wish to thank Dr. W. J. Martin, of the Department of Statistics, London School of Hygiene and Tropical Medicine, for advice and help with the presentation of the data.

During the twelve months to November 30, 1952, 4,858 children came into the care of the L.C.C., while 4,169 were discharged. On that date there were altogether 8,027 children in care. This represents an increase of about 700 over the previous year, and of 2,300 compared with three years ago. The numbers in the various age-groups were as follows: Under 2 years, 681 children; 2 to 5 years, 1,411; 5 to 15 years, 4,964; and over 15 years, 971. Of the children taken into care during this period, 45 had no parents, 269 were abandoned, 2,637 were taken into care owing to the illness or infirmity of their parents or guardians, and 631 came as a result of "fit person" orders. These figures were given at a meeting of the Children's Committee of the L.C.C. on April 27.

[WITH SPECIAL PLATE]

Arterial occlusion, due entirely or partially to thrombosis, is a result of various pathological processes. In every case, however, it is a serious development which endangers the vitality of the organ or extremity concerned. It is evident that details of treatment must be defined according to the primary disease and the artery affected. Apart from promoting the collateral circulation and other measures designed to balance the disproportion between blood supply and local oxygen requirements, it is the dissolution or recanalization of the obstructing clot which should be the ultimate aim of treatment.

We have already presented evidence that the rate of recanalization of venous channels which had been thrombosed experimentally was greatly accelerated when the prothrombin activity was adequately lowered by the administration of suitable doses of a dicoumarol anti-coagulant (ethyl biscoumacetate, "tromexan") (Wright, Kubik, and Hayden, 1952). Encouraged by the findings of a preliminary investigation upon recanalization of arteries (Kubik and Wright, 1950), a more complete experimental study has been undertaken to assess the value of dicoumarol treatment in thrombosis in these vessels.

Methods

Since it was found that blood prothrombin levels fluctuated considerably during anticoagulant treatment and that doe rabbits often died from uterine haemorrhage, full-grown young bucks were used throughout the following experiments.

Under pentobarbitone sodium anaesthesia the femoral artery was exposed for a length of 2 cm. on one or both sides through a longitudinal incision on the median aspect of the thigh. The stripped length of vessel was lifted on fine ligatures spaced about 1 cm. apart, so that its lumen was able to be compressed in three sections. Just enough pressure was applied to the ligatures to prevent the blood flowing in the artery while 0.02 ml. of thrombin solution (1,000 units per ml.) was injected through a fine intradermal hypodermic needle into the middle section and 0.02 ml. of 10% sodium morrhuate into the proximal and distal ones. In those animals in which mechanical interference to the vessel caused arterial constriction, a solution of papaverine hydrochloride (1.25%) was applied to overcome the spasm (Morrison, 1952). The injected substances were maintained in the occluded sections for ten minutes, after which time the pressure on the ligatures was gradually released.

A small flow of blood was occasionally apparent immediately after the release of the pressure, but when fresh blood came in contact with the sclerosed areas and with a local thrombin coagulum, thrombosis occurred within

a few moments and could be recognized from the outside of the vessel as a fusiform dark-red section, incompressible when gently pinched.

In our preliminary report (Kubik and Wright, 1950) peripheral gangrene was often found in the foot after thrombosis of the femoral artery. This was possibly due either to injury of the femoral nerve or to thrombosis of the arteries of the foot produced by morrhuate carried peripherally by the blood stream. This complication did not occur with the improved technique described here.

After arterial occlusion the animals were divided into two groups: (A) those which received ethyl biscoumacetate daily by mouth, starting 24 hours after the thrombus had been formed; and (B) those which, as controls, received no treatment. The ethyl biscoumacetate, as a suspension in methylcellulose ("cellofas") (Wright, Kubik, and Hayden, 1952), was given through a short rubber tube, which was passed to the back of the pharynx so that regurgitation could not occur. The dosage was controlled by prothrombin estimations carried out three times a week, using the Quick single-stage technique on blood drawn by ear-vein puncture. The prothrombin time aimed at for every animal was 30 seconds (rabbit normal, 9 seconds), and, to achieve this, doses of 100–300 mg. per kg. body weight were required daily. Prothrombin-level fluctuations in rabbits are, however, both rapid and profound, and in the course of the experiments several animals were lost through concealed haemorrhage into the caecum. Nevertheless, the prothrombin times in the majority were maintained between 25 and 35 seconds throughout the experimental period, and only these animals are included in this report.

An arteriographic technique was used to follow any changes which might occur in the occluded vessel, the first x-ray film being taken 24 hours after thrombosing to show the extent of the obstruction. Under pentobarbitone sodium anaesthesia, a 3-cm. midline abdominal incision was made, the gut was held aside within the body cavity, and the aorta was exposed for a length of about 1 cm. A fine hypodermic needle (No. 16), inserted into a polythene tube about 20 cm. long and with a syringe attachment at the distal end, was introduced into the exposed aorta. Through this, 2 ml. of thorotrast, as contrast medium, was injected during a period of 4 seconds and the x-ray film was taken while it was still flowing in. Double-wrapped 10 by 12 in. (25 by 30 cm.) "improved fast Ilfex film" with exposure factors of 53 kV, 50 mA, and 0.5 second was used throughout.

Further x-ray films were made with the same technique at two-weekly intervals for Group A and at four-weekly intervals for Group B.

Results

It was early apparent that a considerable difference in the time required for the recanalization of the femoral arteries occurred between those animals which received adequate anticoagulant treatment and the untreated controls. In the eight animals in Group A, the average time taken for one or both vessels to become patent was only 3.25 weeks, while in Group B none of the six controls were patent by 8 weeks, and further x-ray films taken at various later dates showed no evidence of recanalization at any time. The details of both groups are set out in the Table. Typical arteriograms of animals (Nos. 6 and 10) from each group are shown in the Plate, Figs. 1 and 2.

The criterion of "occluded" or "patent" is, moreover, a stringent one. In Group A, when one artery has become patent, the thrombus in the remaining occluded vessel generally shows a considerable reduction in its length, even though complete patency has not been established. A longer period of treatment would presumably further reduce the size of the occluding mass, if not allow of its entire removal. In the control group, on the other hand, no such changes were evident, the size of the occlusion showing no material diminution; indeed, in one animal (No. 12) which was

specially kept, the artery was still fully occluded after eleven months. Other animals of this group were destroyed at varying intervals.

Histological sections of arteries from animals of both groups were examined at the end of the experimental period. In the treated group the animal was sacrificed after the patency of the femoral artery had been established by arteriogram. Fig. 3 shows a photomicrograph of the artery from rabbit No. 6, which was open after three weeks of anticoagulant treatment. The intima appears normal except at one point where there is a small residual mural thrombus. The lumen is otherwise free from obstruction.

In the control group histological sections were taken through the vessel at the level of the obstruction. Fig. 4 shows a typical organizing thrombus with fibroblasts and haemosiderin granules in the granulation tissue matrix three months after arterial obstruction had been produced (rabbit No. 10).

Discussion

In comparison with the interest shown in the influence of anticoagulants on experimental venous thrombosis, little attention, so far as we know, has been paid to corresponding changes in arteries. Experimental work on coronary occlusion has been undertaken, but even here the arterial block was produced by ligation of a branch of the coronary vessel. The result of subsequent anticoagulant therapy on the myocardial infarction so produced was described by Beattie and his colleagues (1948). Le Roy and Nalefski (1948) investigated the possible ill effects of dicoumarol on the myocardium, but it is obvious that neither of these groups of workers were interested in the effects of their therapy on the primary occlusion, or the technique of ligation would not have been used.

It is remarkable that, though a considerable number of experiments have established the fact that the administration of dicoumarol or its derivatives reduces the formation of intravascular coagulation (Marple and Wright, 1950), the experimental investigation of the influence of these drugs on preformed thrombi *in situ* has been omitted. Loewe (1947) and Loewe and Hirsch (1947) suggested that the administration of heparin facilitated the reopening of veins recently occluded by fresh unorganized thrombus, but a study of thrombosed arteries has been largely neglected, though it obviously has a wide clinical application.

Experimentally it is difficult to produce conditions similar to those occurring in the majority of occlusive arterial diseases. First, in the naturally occurring process the endothelium undergoes changes which cannot be reproduced in the experimental animal; the actual thrombosis occurs in a vessel previously diseased. Secondly, in clinical practice, except in cases of embolism, the obstruction develops gradually and there is, as yet, no experimental method for producing such a progressive occlusion. In the third place, the inflammatory character of certain of the arterial diseases cannot be fully imitated, though recently Rabinovitch and Pines (1949) have claimed satisfactory results in reproducing this change in veins by injecting staphylococci into the wall

of the blood vessel. In our method, using both thrombin, which produces a red coagulum, and morrhuate, which damages the endothelium, we believe that many of the features of normally occurring arterial occlusion are paralleled.

In assessing the results presented here it must be borne in mind that rabbits are relatively resistant to the coumarin group of anticoagulants. Their plasma possesses a considerably greater prothrombin activity than that of human blood (Quick, 1936). Larger doses and more prolonged treatment are consequently needed to influence their prothrombin levels to correspond with the human equivalent. In these animals, moreover, wide fluctuations of prothrombin activity while receiving coumarin treatment make it difficult to maintain them at an adequate level without the risk of haemorrhage. The results which we have obtained, however, make it clear that the administration of the anticoagulant has, under the conditions of our experiments, the effect of promoting the recanalization of the thrombosed lengths of the arteries.

How this effect is brought about is still uncertain, but in a previous paper (Wright, Kubik, and Hayden, 1952) we described our findings and suggested a possible mode of action of ethyl biscoumacetate on venous thrombi. The increased rate of recanalization observed is possibly due to the normally continuous action of fibrinolysin, which is usually masked by the continual deposition of small quantities of fresh fibrin on the thrombus surface, and which is disclosed in the presence of anticoagulant when fibrin deposition is prevented. The action of the anticoagulant would therefore appear to be an indirect one.

From preliminary experiments it was found more difficult to thrombose an artery than a vein, but once occluded it remained so. We did not observe any spontaneous recanalization in our control group even after many weeks. In the light of this it is difficult to explain the disappearance of the arterial thrombus with ethyl biscoumacetate treatment wholly by its indirect action. Schmid and Stockinger (1951) observed that dicoumarol, and still more ethyl biscoumacetate, significantly depressed the growth and dividing power of fibroblasts in tissue culture. This effect was present even in the low concentrations found in the blood during anticoagulant therapy. It is therefore possible that the organization of the thrombus is modified by these drugs, and this plays a leading part in promoting the recanalization of the intra-arterial thrombus.

Application of experimental data to human pathology is always somewhat hazardous. The conclusion seems justified, however, that adequate prolonged treatment with dicoumarol in general and with ethyl biscoumacetate in particular has a favourable influence on the reabsorption of arterial thrombi, provided therapy is started soon after occlusion has occurred. Such treatment may result in reopening of the occluded vessel when the obstruction is due to thrombotic and not to arteriosclerotic changes.

Summary

A method for producing thrombi in rabbits' femoral arteries is described.

The time taken for recanalization to take place in control and anticoagulant-treated animals was recorded by arteriography.

The treated group showed an average recanalization period of 3½ weeks, while the controls were still occluded after several months.

The influence of anticoagulant treatment is dependent upon the maintenance of a low prothrombin level.

A discussion of the possible mode of action is offered.

We wish to express our thanks to Dr. C. J. Hodson and to members of the x-ray diagnostic department for their help with this work.

METABOLIC CHANGES ASSOCIATED
WITH OPERATION*

BY

IAN W. MACPHEE, M.D., F.R.C.S., F.R.C.S.Ed.
 Research Assistant in Surgery, University of Liverpool

That the recovery from injury follows a recognized pattern has been known from very early times. This was clearly appreciated by John Hunter (1794). In 1872 Bauer observed that an increased elimination of nitrogen followed upon haemorrhage, and Hawk and Gies (1904) showed that the actual operation of venesection without withdrawal of blood was enough to cause increased urinary output of nitrogen and sulphur. This increased nitrogen loss was also noticed by Benedict (1915) during prolonged starvation. Since that time many observers have noted this increased nitrogen catabolism as a result of injury, associated with increased phosphorus, sulphur, and potassium loss (Cuthbertson *et al.*, 1939; Cuthbertson, 1942; Wilkinson *et al.*, 1949). The varying nature of the injuries causing this has tended to emphasize that something inherent in the trauma, or some underlying response, might be common to many and various injuries done to the body, and deprivations to which it might be exposed.

Wilson and Stewart (1939) noted that, in burns, sodium was lost from the extracellular fluids into the cells of the damaged tissues, and also into the erythrocytes of the general circulation. The observations of Cuthbertson *et al.* (1939) on the urinary excretion of potassium and nitrogen led them to believe that the increased excretion of these substances was due to muscle catabolism following operative injury, but they noted that potassium was lost in greater proportion than nitrogen when compared with their relative concentrations in muscle protoplasm. Howard *et al.* (1946) have also shown that the nitrogen, potassium, sulphur, and phosphorus loss is not proportional to their content in muscle, and that the greatest potassium loss occurs in the first 24 hours. Blixenkrone-Møller (1949) demonstrated that the maximal potassium loss after operation precedes the maximal nitrogen excretion.

Wilkinson *et al.* (1950) demonstrated that after surgical operation potassium is lost in the urine in high concentration when the potassium intake is low, that the loss is greatest in the first three days after operation, and that it precedes in time the nitrogen loss, which persists throughout the first post-operative week. In a previous paper Wilkinson *et al.* (1949) had drawn attention to the marked retention of sodium and chloride in the early

post-operative period, occurring at the same time as the phase of increased potassium loss. Annersten and Norinder (1946) had previously observed a slight reduction in serum sodium and chloride after operation. They did not believe that these changes were significant. Similarly Wilkinson *et al.* (1951) noted such slight changes, but again did not believe them to be an explanation of the retention of sodium and chloride after operation.

I first became interested in this problem in 1948, when I observed the retention of chloride and of sodium after operation. The effect was thought to be very similar to the results of the administration of 11-deoxycorticosterone acetate (D.C.A.). In view of the observations of Hans Selye, it was believed that these electrolyte changes might well be due to increased adrenocortical function following the stimulus of operation. It was decided to observe these changes again and, at the same time, to measure adrenocortical function.

Results

Electrolyte Changes

Fig. 1 shows the typical features of the electrolyte changes in the plasma and urine before and after operation. In all cases a great reduction in the excretion of sodium and of chloride in the urine was observed immediately following operation; this persisted for about seven days. After this, the sodium and chloride excretion in the urine tended to rise above the pre-operative level. Associated with these changes, a constant but much diminished fall in serum sodium and plasma chloride was detected during the same period. A return to the pre-operative level occurred about the end of the first week.

During the same period the serum potassium concentration appeared to be variable and showed no pronounced change. In general, the concentration of potassium in the

Fig. 1.—Typical examples of electrolyte changes in blood and urine.

*Part of a thesis submitted for the degree of M.D. of the University of Glasgow.

serum was slightly elevated during some part of the post-operative period. Fig. 2, a composite diagram of the potassium excretion of another series of eight cases under the same conditions, demonstrates the continued loss after operation of potassium in the urine during the period of negligible potassium intake. The increased excretion of potassium appears to decline after the third post-operative day.

From the previous work discussed above, and as a result of observations made in the present study, it seems that after operation a reduced excretion of sodium and chloride is to be expected, associated with an increased excretion of potassium. The changes in the blood, however, are not so well established. As has been stated, the decrease in plasma chloride and serum sodium immediately after operation observed by Annersten and Norinder (1946) and by Wilkinson *et al.* (1951) was not considered by them to be significant. The changes in serum sodium of the nine cases of the present series are typically represented by those shown in Fig. 1. The majority are greater than the experimental error of the method used, and, though small, seem to be none the less real. This applies also to the plasma chloride changes detected in ten patients. Since the potassium lost must, in the end, result, be derived from cell potassium, it was thought that the small apparent loss of sodium and chloride in the body fluid after operation, at a time when the body is retaining sodium and chloride, might be due to a replacement of cell potassium by sodium and to an increase in cell chloride. Fig. 3 shows the results of the study of erythrocyte sodium and plasma sodium in another series of six patients. In four of the cases the estimations were made on the day before and after operation. The results show that the decrease in plasma sodium after operation equalled almost exactly the increase in cell sodium (Fig. 3, A and B). In two of the cases the estimations were performed on the day of operation, and on the fourth post-operative day (Fig. 3, C and D). By this time the changes had been reversed; the cell sodium content was now below the pre-operative level and the plasma sodium was above the pre-operative level.

Similar estimations of cellular and plasma potassium were undertaken on these patients, but no constant and appreciable changes were detected. Though no conclusion can be deduced from this small experiment, it does suggest that the slight decrease in serum or plasma sodium after operation is due to that amount of sodium entering the tissue cells.

Body Water Changes

Blood Volume.—(a) *Haemoglobin and haematocrit estimations:*—At the same time as the observations were made on electrolyte changes, some estimations of any

changes to be detected in the body water were also made. Fig. 4 shows the pre- and post-operative haemoglobin and haematocrit levels in the original nine patients of the series. There seem to be two distinct reactions in this series. As would be expected following any haemorrhage, five patients show evidence of haemodilution. The second group of four patients, under the same circumstances, show evidence of haemoconcentration.

(b) *Plasma volume:* In only two patients of this series was the plasma volume determined by the dye method. No significant reduction in plasma volume was detected. (c) *Plasma proteins:* Estimations were undertaken in five patients before and after operation. In four the total plasma protein content was reduced, and in one the increase was not significant. As will be seen from the Table, there was a general reduction in both the albumin and the globulin fraction after operation. (d) *Blood pressure:* These recordings were made in five patients in whom any degree of post-operative shock could be definitely excluded. No significant alteration in blood pressure, except on the day of operation, was noted in any case.

Plasma Protein Content Before and After Operation

Day:	-2	-1	0	+1	+2	+3

Extracellular Fluid-space Volume.—This was estimated in only two patients, using sodium thiocyanate. As only relative changes were to be considered, the inaccuracy of the "thiocyanate space" as a measure of the extracellular fluid space was not important. No significant change was observed after operation.

Total Body Water.—Because more elaborate methods, such as the use of deuterium oxide, were not available, changes in total body water were estimated by means of changes in body weight. Fig. 5 shows a typical example of the changes in body weight, measured in pounds, following operation in patients weighed at the same time each day, in the same clothing, on the same machine, and after a 12-hours fast. A weight loss is noted in three of the cases, a gain in three, and no change in one case. The daily weight loss for the average

Similar estimations of cellular and plasma

male during starvation and without water depletion has been estimated as about 260 g., or 9 oz. (Wright, 1940). If after operation the nitrogen loss is even greater than in starvation alone, a still greater weight loss might be expected. Any weight gain or maintenance of previous weight must therefore be a measure of water retention within the body. Four of the seven cases appear, therefore, to show a water retention after operation.

Urine Volume.—In this paragraph only urinary volume studies are under review. Fig. 6 is a composite diagram of

Fig. 6.—Composite diagram of the average fluid intake and urine output of the nine cases.

the average daily fluid intake and urine output of the nine patients. Except for the day of operation, the urine output in the first six days after operation appeared to remain remarkably constant in these adequately hydrated patients. During the next four days the urine output increased, and approximated to the fluid intake.

Evidence of Increased "Glucocorticoid" Activity

The tests used here to measure increased secretion of corticoids are not necessarily the best for the purpose, but simply those most suitable for performing as routine estimations in a teaching hospital.

Fig. 7.—Composite diagram of circulatory eosinophil counts in six of the nine cases.

Fig. 8.—Composite diagram of blood-sugar changes in four of the seven cases in which sugar determinations were made.

Fig. 9.—Composite diagram of urinary 17-ketosteroid excretion a day in seven of the nine cases.

were made in seven of the nine patients. Fig. 8 shows the blood-sugar levels in four of the seven patients. These four patients showed a considerable rise in blood sugar in the immediate post-operative phase. The remaining three patients had no change in the blood-sugar levels after operation.

It is interesting to observe that, of the three patients in whom there was no evidence of decreased eosinophil counts after operation, one showed increased blood-sugar concentration after operation. Further, of the three patients who showed no evidence of an increase in blood sugar after operation, all showed a considerable fall in eosinophil counts. Thus, applying both tests, only two patients did not give any evidence of increased "glucocorticoid" activity after operation.

Evidence of Increased Androgen Formation

17-Ketosteroid Excretion.—Fig. 9 is a composite diagram of the excretion of 17-ketosteroids a day in the urine following operation. Seven of the nine cases showed evidence of increased 17-ketosteroid excretion on the first or second day. The increased ketosteroid excretion in these cases tended to fall below the pre-operative level by about the sixth day. Of the two cases which did not show an increase in ketosteroid excretion after operation, one was excreting 17-ketosteroids at the upper limit of normal in the pre-operative phase. This was followed in the early post-operative period by a marked fall, followed by a sharp rise again on the fourth day.

Discussion

The Electrolyte Changes

The reduction in the excretion of sodium and chloride in the first week after operation, and the increased excretion of potassium previously noted by Blixenkrone-Møller (1949) and by Wilkinson *et al.* (1949, 1950, 1951), are confirmed in the present series. This study also indicates that these features are common to relatively minor surgical procedures, where no intravenous electrolyte or blood replacement therapy has been undertaken either at the time of operation or thereafter. Gamble (1942) has shown that the intravenous infusion of saline is sufficient, by itself, to cause an increased excretion of potassium in the urine. This factor can be excluded in the present series.

It would seem that the increased excretion of potassium after such operations is a phenomenon similar to the increased potassium excretion following operative fracture of the long bones, as demonstrated by Cuthbertson *et al.* (1939). Cuthbertson (1942) considered this to be part of an intimate response of the organism to trauma. His findings, and those of Wilkinson *et al.* (1950), indicate that the potassium loss after operation occurs to a degree greater in proportion than the nitrogen loss, that it precedes the nitrogen loss, and that it terminates before the phase of negative nitrogen metabolism has ceased. Blixenkrone-Møller has detected an increased potassium excretion within six hours of operation. Benedict (1915) and Howard *et al.* (1946) have shown that the potassium loss during starvation and in progressively diminishing diets is directly proportional to the nitrogen loss when compared with the concentration of both substances in muscle.

It would appear, therefore, that factors over and above rest in bed and starvation are effective in causing the sodium and chloride retention and increased potassium excretion associated with operation. Selye (1950) believes that these electrolyte changes are a part of the "stress" response, and partly due to an adrenocortical response to injury. Similar retention of water and salt with increased excretion of potassium is observed after the injection of 11-deoxycorticosterone acetate (D.C.A.) in animals (Ferrebee *et al.*, 1941), and in man (Ingle and Thorn, 1941), and also after the administration of A.C.T.H. (Forsham *et al.*, 1948; Mason *et al.*, 1948; Elkinton *et al.*, 1949).

The Cellular Electrolyte Changes

The older concepts that the cell membrane offered an impermeable barrier to the passage of sodium and potassium is now known to be incorrect. Maizels (1949) has shown that in blood stored at 37° C. an active expulsion of sodium from the cell takes place, accompanied by an uptake of potassium. Mullins *et al.* (1941) have shown the rapid penetration of the erythrocyte by radioactive potassium, and to a less extent by sodium, in three hours. During anaerobic metabolism, in the absence of glucose, the potassium concentration of the serum (Danowski, 1941), or the brain-tissue fluid (Dixon, 1949), has been shown to rise, owing to a loss of potassium from the cells of the respective tissue. Ferrebee *et al.* (1941) have shown clearly that, in dogs, symptoms of cellular depletion of potassium may arise after the administration of D.C.A. It has also been shown that in animals fed on a low-potassium and high-sodium diet partial replacement of deficient cellular potassium can be induced by increase in cell sodium (Heppel, 1939; Miller and Darrow, 1940). Fenn and Cobb (1936) found that after prolonged indirect stimulation of muscles in anaesthetized rats, potassium was lost from the muscle cells and replaced by sodium. After two hours' rest these changes were reversed, indicating that no permanent damage had been done to the muscle.

From all these observations there is strong experimental and clinical evidence to show that potassium and sodium, under certain circumstances, may be interchangeable across the cell membranes. Such an interchange would account for the increased potassium excretion following operation. It would also account for the relatively slight fall in the serum sodium and chloride observed here, and considered not significant by Annersten and Norinder (1946) and by Wilkinson *et al.* (1951). The short study of intracellular electrolyte in the present series confirms this conclusion—an increased erythrocyte sodium content being observed in the immediate post-operative period, and the plasma sodium being reduced by the corresponding amount. No change was noted in the erythrocyte potassium content. This does not invalidate the assumption that the potassium has been derived from tissue cells, as demonstrated by the workers already cited.

The question why potassium should leave the cell under a variety of circumstances seems to be open to two interpretations. Gamble (1942) believes that, in conditions of clinical dehydration, water and potassium pass out from the cell, depending upon the changes in extracellular fluid and electrolyte. In the present series of cases no question of extracellular dehydration arises. Indeed, it has been shown that water and electrolyte, probably in equal relative proportion, are retained within the body.

Another concept, which seems to fit the facts in a more extensive range of conditions leading to the same end-result, has been suggested by Maizels (1949). It is indeed curious that the normal cell-to-tissue cation equilibrium should remain established at any time. As Maizels has indicated, this accumulation of potassium in the cell against the concentration gradient has long been a cause for speculation. Maizels, from his own observations, does not believe that an active excretion of sodium from the cell requires an active absorption of potassium. He believes that potassium passes into the cell passively, and secondarily to the active expulsion of sodium.

It would therefore seem that, following operation or trauma, the relative permeability of the cell-membrane is altered, potassium is liberated, and any tendency to a marked rise in extracellular potassium is prevented by the rapid excretion of that ion in the urine. Either, to replace this cell base, sodium appears to enter the cell from the surrounding extracellular fluid, or else, if Maizels's view is accepted, the "pumping" mechanism breaks down, sodium is not sufficiently expelled from the cell, and perhaps, to maintain the correct osmotic tension, potassium leaks out into the tissue fluids.

Alterations in Body Water

Plasma Volume.—Wilkinson *et al.* (1951), in a series of 10 cases, demonstrated a decrease in plasma volume immediately after operation—directly by the dye method (T 1824) and indirectly by changes in haemoglobin and haematocrit readings. Studies of plasma-protein fractions indicated that this was due to a reduction in plasma albumin and an increase in plasma globulin. These results, in association with some of the electrolyte changes considered above, led them to suggest a transudation of water, albumin, sodium, and chloride into the tissues at the site of injury. Their cases all received blood transfusion at the time of operation, and were undergoing major surgery. In the present investigation the direct plasma-volume studies were not extended sufficiently to be of any value. So far as indirect mensuration may be of value, five of the patients showed evidence of haemodilution in the immediate post-operative phase and four showed evidence of haemoconcentration. No confirmation of a relative reduction in plasma albumin with an increase in globulin was obtained.

Extracellular Space Volume.—Wilkinson and his associates, in their study of the total extracellular space volume in the same cases, did not observe any regular change in the post-operative period. The studies in the present paper are too few to be of value, but they do tend to confirm this finding.

Total Body Water.—As has been shown in the present series, evidence has been obtained of an increase in total body water in some of the cases. Whether this is due to an increase in the extracellular extravascular space as determined directly by Wilkinson and his associates, or whether it is due to an increase in cellular water, has not been determined here. As Darrow has shown (Gamble, 1942), the excretion of potassium in infantile diarrhoea is associated with cellular dehydration. On the other hand Fenn and Cobb (1936), in their experiments on continued muscle stimulation, showed that the passage of sodium and chloride into the cells was associated with an increase in the intracellular water space.

Urine Volume.—The gradual approximation of the urine excretion to the fluid intake late in the post-operative period would tend to suggest that a water retention had occurred at an earlier stage. The relative diuresis for each patient seems to occur on a different day after the first post-operative week. For this reason the combined chart masks this relative diuretic effect.

Evidence of 11-Oxysteroid Activity

Eosinophil Counts.—Forsham *et al.* (1948) and Carlisle (1950) have indicated that both A.C.T.H. and cortisone depress the circulating eosinophil count. Cope *et al.* (1951) point out that it is specifically cortisone and 17-hydroxycorticosterone which exert this influence in the adrenalectomized animal. The depression of the eosinophil count, provided the reduction is at least by 50%, has often been used in clinical medicine as a measure of adrenocortical activity (Roche *et al.*, 1950). Unfortunately, accurate eosinophil counting is difficult, and Godlowski (1951) has demonstrated that heparin in large doses may produce an eosinophilia in spite of injected cortisone or A.C.T.H.

In the present series six of the nine patients who showed the electrolyte and water disturbances described above also showed a reduction of the eosinophil count by 50% in the immediate post-operative period.

Annersten (1949), in measuring the post-operative rise in blood-adrenaline concentration, has observed an immediate post-operative rise in blood sugar. In an earlier paper (Annersten and Norinder, 1946), a raised blood sugar was also observed on the first and second days after operation. In view of the observations of Annersten (1949) and the work of Cannon (1929), this early hyperglycaemia is undoubtedly due to the liberation of excess adrenaline. Although not commented upon, the results of Annersten

(1949) show that the blood adrenaline is falling by the second post-operative day, whereas the high blood-sugar level is maintained. In the present series a considerable rise in blood sugar occurred in four of the seven patients studied, little or no change being observed in the three others.

Urinary 17-Ketosteroid Excretion

The whole 17-ketosteroid excretion in women, and a part of it in men, is derived from cortical androgens (Forbes *et al.*, 1947). The remainder in men, about 4–6 mg. a day, is derived from testicular tissue.

It was early noticed (Fraser *et al.*, 1941) that there was a diminished excretion of 17-ketosteroids in the urine following trauma and surgical operations. However, the same workers (Forbes *et al.*, 1947) demonstrated later that they had missed an early rise in 17-ketosteroid excretion in the first 24 hours after operation. After this, ketosteroid excretion fell to its lowest point about the fourth or fifth day, and by the tenth day regained normal levels. Control patients showed that starvation alone did not cause this rise, and then fall, in excretion. Landau *et al.* (1948) also showed that starvation by itself decreases the total 17-ketosteroid excretion. A sharp rise in the excretion of 17-ketosteroids followed by a fall to below normal levels in 30 patients suffering from haemorrhage, fractures, burns, infection, and operation was shown by Stevenson *et al.* (1944). A similarly elevated 17-ketosteroid excretion was noted by Freeman *et al.* (1944) after severe muscular fatigue. Talbot *et al.* (1945) found evidence of increased urinary excretion of 11-oxysteroid-like substances in active Cushing's syndrome, in adrenal cortical virilism, after burns, and in post-operative patients. Cope *et al.* (1951) observed increased excretion of 11-oxysteroids in acute medical conditions such as diabetic ketosis, congestive cardiac failure, bronchopneumonia, coronary infarction, and status asthmaticus. Forsham *et al.* (1948) demonstrated an increase of both 17-ketosteroids and 11-oxysteroids in the urine after A.C.T.H. therapy. This finding has been confirmed by Sprague *et al.* (1950) in a large series of cases.

In the present series seven of the nine patients showed a large increase in ketosteroid excretion in the first two days after operation, followed by a fall reaching a minimum at the sixth post-operative day. Of the two patients who did not show increased ketosteroid excretion, one showed a slight fall. The other case, excreting 17-ketosteroids before operation at the upper limit of normal, had at that time a very low eosinophil count. After operation 17-ketosteroid excretion fell dramatically, associated with a marked rise in the eosinophil count.

Conclusions

Some evidence has been produced of increased 11-oxysteroid secretion and 17-ketosteroid excretion as a measure of increased adrenocortical activity after operation. This has often been shown in recent years in association with trauma, burns, acute medical conditions, and operation itself. The present study has shown that these changes are also associated with alterations in electrolyte and water balance. Changes of sodium, chloride, and water retention, associated with increased potassium excretion and with exchanges of sodium for potassium within the cells, are very similar to the effects of 11-deoxycorticosterone. Though they may be accounted for by other means, such as local accumulation of fluid and electrolyte in damaged tissues, the fact that they are associated with other evidence of adrenocortical activity suggests that they are themselves linked with such activity. Prunty (1949) has recognized a similar phase of decreased plasma sodium and chloride in acute porphyria. The study of eosinophil counts, uric acid excretion, and neutral reducing steroid excretion indicated an increased adrenal activity during the acute phase of the disease. As Selye has suggested, such a response may occur in a variety of conditions, all in themselves a reflection of injury to the organism.

The retention of sodium chloride and water in the body after operation, in amounts greater than apparent needs, has now become recognized. The diminished urinary excretion of chloride in the first weeks after operation vitiates the urinary chloride estimation as a measure of body chloride requirements. This has been accepted by Marriott (1951). Attempts to replace the apparent chloride deficiency will only lead to water and salt overload. I believe that plasma chloride estimations in the post-operative period are of greater value in estimating body chloride deficiency. Even these determinations, as has been demonstrated in this paper, will give a false low reading.

The importance of potassium in the serum and extracellular fluids has been well recognized ever since the work of Ringer (1883). In recent years great interest has been focused on the loss of potassium in various acute medical and surgical conditions. Brown *et al.* (1944) described low levels of serum potassium in chronic nephritis, associated with muscular weakness and paralysis. Holler (1946) drew attention to a similar low potassium level during the treatment of diabetic coma. It is, however, largely due to the work of Darrow and his associates that clinical potassium deficiency has become widely recognized (Govan and Darrow, 1946; Darrow, 1948; Darrow and Pratt, 1950). As shown by these and other workers, potassium can be lost to the body in gastro-intestinal disorders such as diarrhoea (in children), sprue, intestinal fistulae, prolonged vomiting, and in certain types of diet, such as the Borst diet (Kolff, 1950).

Tarail and Elkinton (1949) have demonstrated that in both normal and potassium-depleted patients the kidney has a limited minimal excretion of potassium, below which minimal level the excretion does not appear to fall. This continued potassium loss, even in the presence of cellular potassium deficiency, they believe to be an important factor in producing further depletion. If, in addition to these other sources of potassium deficiency, the incident of a surgical operation increases the urinary potassium loss, cellular potassium depletion is further increased, and the production of a state of clinical potassium deficiency is hastened. The fact that the rapid mobilization of cellular potassium after an operation is often associated with a rise in serum potassium concentration makes the recognition of cellular depletion all the more difficult. I have seen several patients with a cellular potassium deficiency in which the serum potassium, though falling from a concentration greater than normal, was still within the normal range when electrocardiographic evidence of cellular potassium deficiency was detectable.

ANNULAR PANCREAS

BY

B. F. SWYNNERTON, D.M., M.R.C.P.

Weir Research Assistant, Wandsworth Hospital Group

AND

NORMAN C. TANNER, F.R.C.S.

Senior Surgeon, St. James' Hospital, London

The commonest developmental abnormalities of the pancreas concern the ductal systems. Accessory pancreatic tissue—isolated masses separate from the main gland—occurs not infrequently in the stomach or duodenum, but may be found in most of the abdominal viscera. Other anomalies are pancreas divisum (Hyrtl) consisting of two separately functioning glands; bifid tail of the pancreas; and annular pancreas in which a band of pancreatic tissue encircles the duodenum, usually in its second part. Cysts and fibrocystic disease may occur.

In 1933 McNaught was able to find descriptions of only 40 cases of annular pancreas in the literature, the first three referring to the condition in birds, in which it is apparently a normal finding (Ravitch and Woods, 1950). In June, 1952, the total number of cases recorded was at least 75, and it is significant to note that 20 of these have been recorded since the end of 1949, indicating a higher actual incidence than the statistics show. In the absence of obstruction, cases may easily be overlooked either at operation or at necropsy.

A further case has recently been brought to light during an operation for chronic duodenal ulcer by one of us (N. C. T.).

Case Report

A male clerk aged 30 was admitted on October 13, 1951, with a history of two and a half years' epigastric pain two hours after meals, relieved by food, rest, and alkalis. There had been periods of freedom of up to nine months. He had no vomiting, but had lost 28 lb. (12.7 kg.) in weight since the onset. After investigation elsewhere he was told that a duodenal ulcer was present. The only abnormality

detected was a gastric succussion splash. A gruel fractional test meal showed a high acid curve rising to 65 ml. N/10 free HCl at one hour.

A barium-meal examination disclosed a spastic deformed duodenal cap with folds radiating from an ulcer scar. There was no gross obstructive lesion of the second part of the duodenum. In view of his relapse despite more than one good course of medical treatment, he was operated upon on October 16. The presence of an anterior chronic duodenal ulcer was confirmed. The rest of the viscera appeared normal, except that, about 2–3 cm. below the junction of the first and second parts of the duodenum, the organ was encircled by pancreatic tissue of healthy appearance and texture, the abnormal part being a band about 1–2 cm. in diameter (see illustration). A subhiatal vagotomy and Heineke–Mikulicz pyloroplasty was then carried out. During the pyloroplasty opportunity was taken to feel the duodenum from within its lumen, and there appeared to be no appreciable constriction. The patient made an uncomplicated recovery from this operation, and an insulin test meal 17 days later showed a much lower acidity and no secretory response to the insulin.

Nine months after operation the patient was symptom-free, and a further barium-meal examination showed no delay in emptying of the stomach and no evidence of constriction of the duodenum.

Discussion

Aetiology.—The condition affected males in 50 out of the 64 cases in which the sex was recorded. Various theories have been advanced concerning the embryological origin of the ring—for example, persistence of the left half of the ventral anlage of the pancreas which ordinarily atrophies, fixation of the ventral bud of the pancreas to the duodenum before rotation of the gut, or a smooth spread round the duodenum as is said to occur in birds. Other congenital abnormalities have been found associated with the annular pancreas in some 20 cases, the most frequent being malrotation of the abdominal viscera.

Symptomatology.—Patients with annular pancreas may present at any age with symptoms due to the condition, or the condition may be symptomless. The youngest recorded case was in a 16-mm. embryo (Weissberg, 1935), while two cases were operated upon at the age of 74 (Smetana, 1928; Custer and Waugh, 1944). Thirty-seven cases had symptoms due to the annulus. Most of the nine presenting in the first decade appeared shortly after birth, with symptoms of high intestinal obstruction or with jaundice probably due to compression of the common bile duct. If symptoms have not developed by this time it would seem reasonable to suppose that the patient has a good chance of remaining symptom-free throughout life. A study of the literature suggests that this is not the case. Adults usually present with high intestinal obstruction, with symptoms suggesting peptic ulceration, or, less commonly, with acute haemorrhagic pancreatitis. In the first there may be rapidly progressive or recurring episodes of obstruction. This sometimes results from pancreatitis of the annulus, but this is not a constant finding in those specimens which have been sectioned. Those patients with a history suggesting peptic

Diagram showing band of pancreatic tissue encircling the duodenum.

ulceration may indeed have peptic ulcers as in the present case. Eight additional cases associated with peptic ulcers have been recorded (gastric 3, duodenal 5). Four further patients had a history of haematemesis or melaena. Acute haemorrhagic pancreatitis is a rare presentation, but has been recorded.

Differential Diagnosis.—The diagnosis has been suggested pre-operatively in eight cases. It will be considered only when there is a sufficient degree of deformity or obstruction to be shown by a barium-meal examination. Other possibilities to consider include congenital bands associated with malrotation, tumours of the pancreas or sphincter of Oddi, ulcer and rarely primary or secondary cancer of the second part of the duodenum, and pressure by enlarged glands from without.

Treatment.—If surgical treatment is indicated the choice of procedure lies between section of the ring and some form of by-pass operation. The former carries some risk of fistula formation, and so the site of division should be protected by a drain to the exterior. This may be combined with longitudinal division and transverse suturing of the duodenum, the suturing being made in such a way as to drain the cut ends of the pancreatic annulus into the lumen. This duodenoplasty overcomes any intrinsic duodenal narrowing and the possibility of recurrent obstruction. Partial gastrectomy is a somewhat severe method of dealing with an annular pancreas unassociated with other gastroduodenal disease. Gastro-jejunostomy introduces an undoubted risk of stomal ulceration, and, if feasible, duodeno-jejunostomy would be preferable.

Summary

A case of annular pancreas is reported. The finding was an incidental one at operation for chronic duodenal ulcer. No obstruction of the duodenum was produced, and the presence of the condition did not affect the operative treatment of the ulcer.

We are indebted to Drs. R. Quilliam and A. Jenkins for the radiological reports and to Mrs. Mace for the picture.

SLIDING HERNIAS THROUGH THE OESOPHAGEAL HIATUS

BY

G. RIOS-SOLANS, M.D.*

(From the Gardiner Institute of Medicine, University of Glasgow)

[WITH SPECIAL PLATE]

The anatomical abnormality of hernia through the diaphragm was first referred to in 1570 by Ambroise Paré, who noticed the condition at a post-mortem examination and attributed it to trauma. Fothergill (1746) described a congenital variety. The first diagnosis during life was made by Newman (1888), who also performed the first operation for its cure. Akerlund (1933) made a careful study of all types of diaphragmatic hernia, and his classification has formed the basis for much subsequent work. In recent years the frequency of diaphragmatic or hiatus hernia has been fully recognized, and there are many publications available on the subject.

*Working as a scholar from Spain under the British Council.

The present paper deals with only one variety of hiatus hernia, the so-called "sliding hernia," which is the commonest of all, and which has been excellently described by Allison (1951). A sliding hiatal hernia is chiefly encountered in adults who are past middle age, and must therefore be regarded as quite distinct from a congenital defect. In considering its aetiology, two matters appear to be of prime importance: (1) the exact anatomical status of the so-called "cardia," or junction between oesophagus and stomach; and (2) the part played, structural and physiological, by the terminal part of the oesophagus as it passes through the diaphragm.

The So-called "Cardia"

In a study of the cardia, clarity in certain anatomical points is essential: (a) the nature of the boundary between the oesophageal and gastric mucous membranes; (b) the normal relationship of the boundary of the two mucous membranes to the exit through the diaphragm; (c) the question of a real anatomical sphincter at or close to the boundary; and (d) the site of the change in shape from tubular (oesophagus) to saccular form (stomach). These points can be made out only by careful microscopic examination of the whole zone in specimens removed in the post-mortem room and fixed by most careful technique to preserve and identify exact relationships. Macroscopic methods such as changes in colour, difference of shape, and even x-ray films taken during life are not exact enough, and may indeed be very misleading. Oesophageal structure is clearly identified microscopically by its stratified squamous epithelium, and stomach structure by its characteristic mucous membrane. Microscopical investigation clearly shows that the junction of the two mucous membranes is not a ring, but follows an irregular curve. Moreover, although the junction of the two mucous membranes is clean-cut, it is not unusual to find areas of gastric mucosal glands lying below the stratified oesophageal lining membrane. The opposite, however, does not occur.

In the photomicrograph (see Plate) this transition is clearly seen, and the two muscular layers are also well demonstrated. The point should also be noted, as has been found microscopically, that the diaphragmatic muscle does not clasp the oesophagus at a fixed level or point—there is an agglomeration of muscle fibres and loose fibrous tissue which allows the oesophagus to slide up and down for a short distance, this being essential for the normal respiratory movement of the diaphragm. In what may here be termed normal cases, accurate marking showed that the level of the diaphragmatic insertion and the junction of the two mucosae never coincided. Oesophageal stratified epithelium was always found at this level, indicating that the normal junction is below the diaphragm and just above the point where the saccular expansion of the stomach begins. This explains the curious observation that carcinoma of the fornix of the stomach extends to the cardia. That is to say, it invades the lowest tubular portion, with resultant incompetence or stenosis. No observation has been made of a carcinoma of the oesophagus (properly called) subsequently invading the fornix. It would seem, therefore, that a tumour always infiltrates the same structure and the change of lining membrane constitutes a barrier. A gastric carcinoma which invades the lowest tubular part invades its own structure, not the oesophagus.

Terminal Part of the Oesophagus

No evidence was found microscopically of any true muscular sphincter at the lower end of the oesophagus. As has been stated, the joining line between the two mucosae is an irregular curve and never a ring, and a ring form would almost be required for a true muscular sphincter. Thus, as Barrett (1952) has pointed out, the cardia and sphincter mechanism are not synonymous.

Lendrum (1937), in a careful anatomical study of the cardia in 150 cases, also concluded that no ring-shaped muscular reinforcement was present. No muscular thickening was found in the present investigation. Although there is thus no obvious and clearly defined muscular sphincter, this does not exclude some potential sphincter mechanism of a kind less positive than, for instance, the pylorus of the stomach. I believe that a segment of the oesophagus, extending for about 1 in. (2.5 cm.) above the stomach, may act as a sphincter. This view is supported by our knowledge of cardiospasm (first described by Purton in 1821), in which there is no ring of closure but a narrowing over about 1 in. (2.5 cm.) of the tube. This, indeed, is the basis of Heller's operation, with an incision in the oesophagus about 1 in. (2.5 cm.) in length.

There are many other views concerning a potential sphincter mechanism between oesophagus and stomach, and the action is often nowadays referred to as resembling a "pinch-cock"—generally adequate, but easily overcome to permit regurgitation. Lendrum (1937) has even suggested that muscular fasciculae in the stomach wall may on contraction contribute to a sphincter action, but this view has not received support. As Alvarez (1939) points out, the diaphragm will act as a sphincter when the intra-abdominal pressure is very high. Its action cannot be important, however, since patients with patency of the hiatus or hiatus hernia do not have continuous regurgitation.

The sphincter action, such as it is, is clearly under nervous control by Auerbach's plexus and by the sympathetic and parasympathetic systems.

Patency of the Oesophageal Hiatus

The question of patency of the hiatus was investigated in the post-mortem room of the Western Infirmary in 50 consecutive necropsies, in adults between the ages of 31 and 78 years. A finger—sometimes two fingers—was inserted into the hiatal region from the abdomen, and cases in which one or two fingers could be inserted for a distance of 2-3 cm. are described as *positive*, and the others as *negative* (see Table). Cases in which an operation had been performed in

the area of the stomach or adjacent parts were excluded. The Table shows that in 13 of the 50 cases examined (26%) the hiatus was to some extent open so that herniation above the diaphragm would easily be possible. It is not thought that the laxity of tissues in the cadaver would account for this, in view of the numerous negative results. It must be remembered that three important structures pass through the diaphragm close to one another—the aorta, the inferior vena cava, and the oesophagus. The first two openings are always firmly closed, so that herniation is virtually impossible; it is only the oesophageal opening which is not.

The oesophageal passage is elliptical in shape, to allow for considerable distension of the oesophageal tube as food passes through it, and the extra space is filled up by loose fibrous tissues. Here is obviously a weak spot in the separation of the abdominal and thoracic cavities.

In the series of cases referred to, patency was found only in the anterior and left lateral part of the hiatus, and never in the posterior and right lateral part, although loose fibrous tissue surrounds the oesophagus on every side. The reason is clearly because (Gray, 1926) only the anterior and left side is covered by peritoneum on the abdominal side, and it is only in such a place that a sliding herniation can arise.

X-ray Findings Compared with Post-mortem Findings

Johnstone (1952) and Pickard (1952) have both reported a surprising number of hiatus hernias during routine x-ray examination of the gastro-intestinal tract, but only when the patient is placed in the "head-down and feet-up position," as first recommended by Soresi in 1919. Pickard's percentage in such x-ray examinations was 11%, in contrast with 26% in my series of post-mortem observations. There must be some reason for this discrepancy, and it is suggested that it is only when patency is well marked that the hernia appears during x-ray examination.

Summary

An investigation has been made of various points concerning the aetiology of the "sliding" type of hiatus hernia.

It was evident that before reaching any conclusion a careful study of the so-called "cardia" was essential—that is to say, of the junction between oesophagus and stomach and of the passage of the oesophagus through the diaphragm.

The results of macroscopic and microscopical examinations of this area are given in detail.

There is no clearly defined anatomical sphincter at the lower end of the oesophagus, and the squamous lining ends in an irregular curve and not in a ring. This, however, does not exclude a broad but weak contractile mechanism in the lower part of the oesophagus.

In an unselected series of adults carefully examined in the post-mortem room, patency of the hiatus was detected in 26%. This finding has been interpreted as evidence of potential hiatus hernia. The patency was always found at the anterior and left lateral part of the passage of the oesophagus through the diaphragm.

This investigation was carried out during the tenure of a British Council Scholarship. I am indebted to Professor Sir John McNee for help and guidance, and also to Professor D. F. Cappell and his staff for many facilities in the department of pathology at the Western Infirmary, Glasgow.

A recent survey by the National Agricultural Advisory Service has shown that washed eggs are specially likely to go bad after storage. This is an important factor, since the survey also revealed that an average of one egg in three is soiled in the nest. Research into this problem is being carried out by the Food Investigation Organization.

OSTEOID OSTEOMA

BY

E. H. STRACH, M.Ch.Orth., F.R.C.S.

Senior Orthopaedic Registrar, Alder Hey Children's Hospital, Liverpool

[WITH SPECIAL PLATE]

Osteoid osteoma is a benign tumour of bone. Since its first description (Jaffe, 1935) many cases have been reported in the American literature, but there are singularly few publications on this subject in the British literature, and only one case report (Vaughan-Jackson, 1950). This would suggest that osteoid osteoma is a rarity in the British Isles, whereas it is more likely that the condition often passes unrecognized. This would seem to be of no great consequence, because the lesion is benign and if untreated probably heals spontaneously after many years (Sherman, 1947b; Moberg, 1951). On the other hand, amongst the abundant case reports from the United States and Canada are some of patients who underwent unnecessarily radical treatment such as amputation and resection because of a mistaken diagnosis of malignancy or tuberculosis. The recognition of osteoid osteoma is therefore of importance. The following case is reported as a typical example of the condition.

Case Report

A girl aged 12 was referred to the orthopaedic department of Alder Hey Children's Hospital in September, 1950, suffering from pain in the tip of her right second toe of two years' standing. She did not recall having injured the toe. The pain was slight and intermittent at first, but during the past few months it had been more severe, especially at night.

On examination there was a bulbous, tender soft-tissue swelling of the terminal phalanx. The toe-nail was slightly deformed. A radiograph showed a small, rounded, well-defined, translucent area in the tip of the terminal phalanx containing what appeared to be a minute sequestrum. An inflammatory lesion was suspected, and amputation of the terminal phalanx was carried out in November, 1950. The wound healed by first intention and all symptoms subsided. When the patient was seen in March, 1952, the stump was found to be satisfactory and there were no complaints.

Pathological Report.—Gross Appearance: The terminal phalanx of a toe disarticulated at the joint. On longitudinal section, at the tip of the phalanx, there is a well-circumscribed yellowish-grey finely trabeculated lesion 3 mm. in diameter. At the distal end the normal cortex cannot be distinguished from the lesion. It is moderately firm in consistency and does not exude pus on compression (see illustration, Special Plate). **Microscopical Examination:** "The proximal portion of the phalanx shows a perfectly normal picture. As one progresses distally, the cortex beneath the nail shows well-marked narrowing and osteoclastic absorption. In some small areas it has been destroyed and replaced by the expanding central lesion. The distal end and a little of the undersurface of the phalanx show a similar picture. The lesion itself consists of irregularly arranged trabeculae of osteoid in which there is early calcification. The intervening spaces are filled with a vascular matrix, consisting of large numbers of cells with fibrillary processes, which at the edges of the spaces are arranged as rows of active osteoblasts. In some areas previously formed and calcified trabeculae are being destroyed by osteoclasts. Occasionally there lies between the lesion and the surrounding bone a fairly narrow zone of the vascular matrix mentioned above, devoid of

trabeculae of osteoid or bone. The lesion is a typical osteoid osteoma. There is no histological evidence of infection, and cultures from the lesion were sterile."

Discussion

In retrospect the case appears to be typical of the condition, and the diagnosis should have been suspected on clinical and radiological grounds. An almost identical case has been reported (Pritchard and McKay, 1948) as occurring in the terminal phalanx of the second toe of a boy of 13 in whom the diagnosis of tuberculosis was made and the phalanx was amputated.

Osteoid osteoma occurs in adolescents and young adults and is rare after the age of 30. It is twice as common in males as in females. It is a single lesion, more common in the bones of the lower limbs than elsewhere.

Characteristic clinical features are the well-localized and persistent pain, often worse at night, and the local tenderness. Swelling is a less constant sign, and is confined to the soft tissues if the lesion is in the spongiosa of a small bone. Should the tumour be situated in or near the cortex of a long bone a bony thickening due to reactive periosteal new-bone formation may be present. Other signs of inflammation, local or general, are consistently absent. If the lesion is situated in the vicinity of a joint it may cause a non-specific synovitis (Sherman, 1947a).

Radiologically, there is a well-defined rounded translucent area, seldom larger than 2 cm. in diameter. In the early stages the contained tumour nodule is radio-translucent, but later the osteoid material becomes calcified and looks like a sequestrum in the x-ray film. Often there is a narrow ring of increased density surrounding the lesion.

The tumour may be situated either within the cancellous bone or in the cortex of a long bone (subperiosteal or subcortical). In the latter situation it gives rise to a marked periosteal reaction, and dense subperiosteal bone is deposited which may obscure the translucent lesion. In this particular situation it is difficult to differentiate it from a chronic infective lesion—the chronic subperiosteal abscess (Brailsford, 1942). Only histological and bacteriological examination will decide whether it is an osteoid osteoma or an inflammatory process.

Treatment by local excision or curettage has been found satisfactory by all authors and no recurrence has been reported.

Summary

A case of osteoid osteoma is reported. The clinical, radiological, and pathological features are described.

I wish to thank Mr. F. C. Dwyer for permitting me to publish this case, and am indebted to Dr. E. G. Hall for his detailed pathological report.

The London County Council has a scheme whereby medical officers employed by the council at maternity and child welfare centres are exchanged with paediatric registrars at the following hospitals: St. George's Hospital, the Hospital for Sick Children, Westminster Children's Hospital, King's College Hospital, Guy's Hospital, Paddington Green Children's Hospital, and the Queen Elizabeth Hospital for Children. In addition there is an exchange system with St. James's Hospital, Balham, and a paediatrician from St. Thomas's Hospital goes to North Lambeth Babies' Care Welfare Centre to take weekly child welfare sessions.

Medical Memoranda

Haemolytic Disease in a First-born Infant

Haemolytic disease is rare in first-born infants; the stimulus of a second rhesus-positive foetus is apparently nearly always required before the maternal antibody is produced in sufficient potency to affect the infant. When haemolytic disease has been observed in a first-born it has usually been explained by previous sensitization to the Rh antigen by a transfusion or injection of Rh-positive blood or a pregnancy which ended in an early abortion. The following case is of interest because it seems likely that there was no sensitization before the onset of the first pregnancy, which ended with the birth of an infant suffering from haemolytic disease.

CASE REPORT

A woman aged 27, who had been married for three years, was delivered of an apparently normal female infant weighing 7 lb. (3.2 kg.). A few hours after birth slight jaundice was noticed, and the next day the skin was a deep golden yellow.

On admission to hospital some 36 hours after birth, the infant was still deeply jaundiced, with slight enlargement of the spleen; otherwise it appeared perfectly normal. The laboratory findings were typical of haemolytic disease. The mother was Group A rhesus-negative and her serum contained strong saline and albumin rhesus antibodies. The infant was Group O rhesus-positive. The direct Coombs test was strongly positive. The serum bilirubin was 20 mg. per 100 ml.

The infant's haemoglobin fell steadily from 80% (11.8 g.) on admission to 58% (8.6 g.) on the ninth day, when, after a transfusion of 180 ml. of blood, it rose to 102%. There was a further slow fall in haemoglobin, but no further transfusion was needed.

The mother was an intelligent woman, a laboratory worker, who understood the significance of her evidence. She had previously been a blood donor, but neither she nor her parents could recall any occasion when she had been injected with blood or serum; she had, in fact, always been in good health. Furthermore, she had never had any abortions; whilst her menstrual cycle had always been irregular (4-7/24-35), the longest period of amenorrhoea prior to becoming pregnant was 39 days, ending with a menstrual loss no heavier than usual.

COMMENT

Mollison (1948) states that antibody formation may begin as early as the twelfth week of pregnancy, but it is not usually until the second or later pregnancy that haemolytic disease appears.

It is well established that the injection of rhesus-positive blood into a rhesus-negative subject acts as a most powerful stimulus to the production of antibodies, so that a woman's first-born child may suffer from haemolytic disease.

It is, however, not so well proved that, in the absence of previous sensitization, the first-born may be affected: when Levine and Waller (1946) reported 28 cases of haemolytic disease affecting the first-born, they found that 19 of the mothers gave histories of a previous transfusion or injection of blood; of the other nine cases the authors concluded that the possibility of previous sensitization could not be excluded, as it used to be a widespread practice—that is, in the U.S.A.—to inject a few millilitres of blood at birth to prevent haemolytic disease. Cappell (1946) mentioned four families in which the first-born were affected; and Spalding (1947) recorded a first pregnancy resulting in a hydrops foetalis: the mother had rhesus antibodies and there was no history of previous sensitization.

Few other cases have been published, although the incidence may well be greater than this fact suggests.

My thanks are due to Dr. J. J. Tillie for permission to publish this case and for advice, and to Dr. P. N. Coleman for laboratory reports.

Subcostal Pain Following Controlled Respiration

An unsolicited complaint of subcostal aching during the first post-operative day after controlled respiration, especially with succinylcholine relaxation, seems to be a common complication.

The cases seen so far have been confined to females aged 20 to 65 years, both athletic and sedentary. Thus in a series of 40 consecutive dental operations (12 males, 28 females) there was no complaint from the male group, but subcostal pain was noted in six (21.4%) of the females (see Table).

Agent	Male		Female	
	No. of Cases	Subcostal Pain	No. of Cases	Subcostal Pain
Succinylcholine ..	7	0	12	4
Gallamine triethiodide ..	1	0	4	1
No relaxant (thiopentone, pethidine) ..	4	0	12	1
Total cases (40) ..	12	0	28	6

The site of operation in these cases—for example, dental procedures, excision of glands of the neck, etc.—is remote from the abdomen: the pain following operative trauma in the latter presumably overshadows, or is associated with, post-operative subcostal ache. Most of the patients have required passive inflation for short periods only (5 to 10 minutes) after intubation.

This subcostal pain first appears soon after consciousness is regained, and persists for 24 to 48 hours. It varies in severity and distribution from that of a minor anterior subcostal discomfort to a severe ache encircling the costal margin and extending to the back. Forced respiration and movements involving the abdominal musculature, such as sitting up or turning, cause acute discomfort. The disturbing feature is that the patient, at the time, usually complains more of the discomfort subcostally than of the pain at the site of operation. (A young lady who awakens expecting an aching jaw, only to find something worse at her midriff, rightly asks for an explanation.)

This complication has only occasionally been seen when relaxation has been produced with other agents, and seems to be more commonly associated with the greater degree of relaxation obtained by succinylcholine. Thus, with this agent, passive inflation can presumably cause a greater degree of stretch of the respiratory musculature with minimal resistance. I do not think that the transient excitation preceding paralysis with succinylcholine is concerned in the mechanism.

That the complaint has been confined to females is probably accounted for by their inherent thoracic type of respiration, passive inflation with full relaxation causing an unaccustomed stretching of the muscle fibres of the diaphragm. As one intelligent patient put it, "My diaphragm feels as though it has just played its first game of squash for the season."

An awareness of this complication might indicate the need for less vigorous inflation during the period of complete relaxation, which should result in a decrease in the incidence of post-operative subcostal pain.

Acknowledgments are due to my colleagues at the Westminster Hospital for allowing access to their records and to Dr. G. Organe and Dr. C. F. Scurr for their helpful criticism.

TREVOR T. CURRIE, M.B., B.S.,
Anaesthetic Registrar, Westminster Hospital.

Reviews

ATLAS OF INFECTIOUS DISEASES

World Atlas of Epidemic Diseases. Part I. Edited by Professor Ernst Rodenwaldt. (Pp. 126; 52 maps. No price given.) Sponsored by the Bureau of Medicine and Surgery, Navy Department, Washington, 25, D.C. Hamburg: Falk-Verlag. 1952.

Epidemiologists are continually faced with the problem how to present data about incidence of infective diseases geographically whilst at the same time taking account of the degree of completeness of records, seasonal variation, and year-to-year variation or long-term trend. When reporting on events in a single country in a single year the problem is comparatively simple, but to present in a nutshell a world-wide picture of endemicity in relation to climate, geography, migration of population, and advance of civilizing influences, of the spread of epidemics in space and of seasonal swing in relation to latitude, is far from simple. No more ambitious attempt to accomplish this has been made than in the publication of the *World Atlas of Epidemic Diseases*.

The atlas, designed to appear in two parts, is edited by Dr. Ernst Rodenwaldt with numerous collaborators in Germany, under the sponsorship of the Bureau of Medicine and Surgery of the U.S. Navy Department. Part I, now available, consists of 40 large folding maps dealing with 17 infectious diseases and the distribution of rainfall, temperature, and population in Europe, a series of 12 basic maps of different regions of the world, and 118 pages of textual comment in German and English. The whole is bound together in a massive cover permitting removal of the maps.

The maps are beautifully reproduced and coloured according to altitude, the epidemiological data being superimposed on them by various diagrammatic devices. Seasonal swing, for example, is depicted by a circle containing a red sector which indicates by its position the month when incidence is greatest and by the length of its radius the relative frequency during that month compared with the average frequency during that month. Comparative incidence in a specified period of years is depicted by cross-hatching. Most of the maps in this part are limited to Europe and the Near East, but world maps are included for typhoid, paratyphoid, cholera in 1863-8, and leptospirosis. The climatological maps of Europe and the Near East are a most useful feature, including as they do average rainfall, January temperature, July temperature, annual temperature, and range.

It is not possible in a short review to comment on the textual matter. The defects of the basic data available from many of the countries are well known to epidemiologists and are admitted by the editors. The cost of production must have been very considerable, and it is to be hoped that the atlas, which measures 19 by 15 in. and weighs over 12 lb., will not spend its life on library shelves, for its usefulness in teaching is enhanced by the facility with which individual maps can be taken out for demonstration purposes.

PERCY STOCKS.

RADIOGRAPHY OF SKULL AND BRAIN

The Skull and Brain Roentgenologically Considered. By C. Wadsworth Schwartz, Ph.B., M.D., F.A.C.R., and Lois Cowan Collins, B.S., M.D. (Pp. 386; 335 figures. £3 17s. 6d.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1952.

That plain radiographs are essential in the diagnosis of tumours and many other lesions of the skull and brain has been recognized for nearly half a century now. What seems to be much less obvious is that plain radiographs are usually only the first step in the radiological investigation. More than one textbook on the radiology of the head has been

published in recent years in the English language confining its attention almost entirely to plain radiographs. The present work is no exception. The title would appear to imply that the reader will find the answers to the diagnosis both of skull and brain tumours and of tumour-like masses. In this he will be disappointed, particularly so far as the brain is concerned.

Although a magnificent museum collection of lesions demonstrable by plain radiography is displayed in over three hundred radiographs, the point is not made clear that in only a small minority of cases can x rays, without the aid of contrast substances, reveal the site and pathology of an intracranial mass sufficiently accurately for a surgeon to approach the lesion with confidence.

The authors first describe the normal appearances and variants seen in the skull. Chapters on congenital anomalies and fractures follow. The remaining two-thirds of the book is given to neoplasms and miscellaneous diseases. The student or uncritical reader will derive a quite false impression of the relative commonness of lesions seen in neuro-radiology. For example, nearly twice as much space is given to tumours of the skull itself, relatively rare lesions, as to gliomas—quite the commonest brain tumours. Air studies and angiography would appear to play a small part in the diagnosis of the latter, in spite of the well-known fact (mentioned by the authors) that only about 13% of gliomas calcify. The chapter on acoustic tumours is very poor. The diagnostic value of plain radiographs in cases of acoustic tumour is not made clear, but reference to Chart II, some ninety pages earlier in the book, gives 15% as the figure for widening of the internal auditory meatus visible on plain radiographs. Over 70% is the usually accepted figure.

Clinicians and morbid anatomists will also have faults to find. For example, on page 204 the authors state: "Tumours of the acoustic nerve, as a rule, develop in patients during their third decade. . . ." Of colloid cysts they say: "It is extremely rare for one of these cysts to contain sufficient calcium to be seen in the roentgenogram"; then again, "The larger cysts may block the aqueduct or posterior part of the third ventricle." The reviewer is unaware of any calcified colloid cysts in the literature. Moreover, it is generally accepted that these cysts are derived from the para-physis, a structure which lies some 4 cm. away from the aqueduct.

The many radiographic reproductions are of excellent quality. However, if a second printing is made it is hoped that Fig. 194, which reproduces the optic foramina upside down, will be correctly orientated. The interpretation of radiographs of the optic foramina is not always easy even when viewed the right way up.

J. W. D. BULL.

CAUSALITY IN THE MIND

Reason and Unreason in Psychological Medicine. By E. B. Strauss, M.A., D.M., F.R.C.P. Foreword by Sir Russell Brain, P.R.C.P. (Pp. 55. 8s. 6d.) London: H. K. Lewis. 1953.

The principle of causality—that is, the operation or relation of cause and effect—is often assumed to be valid when in fact it lacks adequate philosophic support. Psychological medicine, following in the wake of general medicine, has fallen into unreason, according to Strauss, because of its whole-hearted acceptance of causality. This has led to a pseudo-scientific attitude of mind towards aetiology and treatment. "Diseases" are regarded as entities with causes which, if known, can be removed by treatment. The urge to find a simple efficient cause of disorders, to the exclusion of other relevant agents, has produced ineffective forms of treatment.

The title of this book is that selected by Dr. Strauss for the Croonian Lectures for 1952. These and a third lecture, "Quo Vadimus?" form the book. The theme is a scrutiny of the principle of causality as it bears on the theory and practice of medicine, and in particular psychological medicine. The main force of the argument, or rather indictment,

falls on psycho-analysis. Psycho-analysis as a body of knowledge and as a therapeutic system rests on the assumption that there is an efficient cause for all neuroses and faulty adaptations to life—namely, failure to solve the Oedipus complex. The conclusions of psycho-analysis are grouped round this complex, the most significant finding of Freud and his disciples. Causality, Strauss contends, is not so plain as this. Aetiology is multiple, a network rather than a simple cause-effect relationship. His thesis, supported by cogent reasoning, is an important contribution and should be of special interest to psycho-analysts, who “inhabit a little world of their own that is apt to be quite out of touch with systems of thought which are foreign to them.”

The principle of multiple aetiology, so strongly advocated, has much to commend it. But it is not the final answer. Strauss makes no reference to the principle of synchronicity which has figured in recent work in analytical psychology. This omission might well be remedied should an enlarged version of this volume be called for.

E. A. BENNET.

STERILITY

Sterility: Its Cause and Its Treatment. Part I: The Infertile Female. Part II: The Infertile Male. By J. Jay Rommer, A.B., Ph.G., M.D., A.I.C.S. (Pp. 424; 152 figures. £4 10s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1952.

The author claims that this book crystallizes all existing thinking and knowledge on the cause and treatment of sterility, and it certainly covers a wide field. But the claims cannot be upheld, for the bibliography is far from up to date, and, perhaps more important still, many old and now outmoded ideas are put forward quite uncritically. There are also some muddled and even erroneous descriptions, such as those of the gonadotrophins and the alleged inflow of seminal fluid through the cervical canal.

Long lists of causes of sterility “culled from the literature, both American and foreign,” even with percentage incidences (of uncertain derivation) have a strictly limited value. The chapter on anatomy and embryology scarcely warrants a place and is most oddly sandwiched between “Physiology of Coitus” and “Psychic Trauma and Fertility.” It is not clear why two photomicrographs of testis showing normal spermatogenesis should be included, and still less why crystals of testosterone should deserve an illustration occupying two-thirds of a page. The aspiration of the epididymis and testis is advocated as a method of examining for spermatozoa. It is admitted that this may be quite fallacious, and may cause severe pain, so why not condemn it outright? Instead two large illustrations of the technique are shown. The most impressive aspect of the book is its general format, the standard of which is very high; but so is the price at 90s.

G. I. M. SWYER.

HAMEY THE YOUNGER

The Stranger's Son. By John J. Keevil. (Pp. 230. £1 1s.) London: Geoffrey Bles. 1953.

“Let us now praise famous men . . . but some there are that have no memorial.” Baldwin Hamley the younger (1600–76) does not belong to either class. He is not famous save among those few interested in the history of the Royal College of Physicians of London, where alone he has some small memorial. But the telling of even the meanest life—and Hamley's was very far from mean—if rightly told, may be an entrancing human document. For such telling Dr. Keevil has all the essentials. He is an industrious historian, well trained though self-trained; he chooses subjects for whom he has special understanding; and he has that narrative skill that conceals the teller in the tale. Some literary Mephisto has beguiled him into putting some of his best points into notes, but, when free of his demon, Dr. Keevil is a writer of high distinction.

The book is a sequel to Dr. Keevil's *Hamley the Stranger* which we reviewed in the *Journal* of April 11 (p. 821). The younger Hamley was most happily born and taught, for his armour was his honest thought and simple truth his utmost skill. He inherited a sound but highly conservative medical tradition and practice in London, where he was born. He drew on the advantages of education at Leyden and Oxford and the moral support of the Royal College of Physicians, to which he was devoted and of which he was a great benefactor. He was happily married to a charming and able woman. His professional integrity was spotless, and by his practice he amassed a fortune, which he disposed of most generously during his lifetime. He was ever a patron of poor scholars, and he died respected and loved. His life course crosses that of many great men of the time, including Harvey. He was to the end a cultivator, along the most rigid lines, of the classical languages, just when the Royal Society had decided to abandon them for scientific and medical discourse. Although he was a capable, industrious, and well-trained anatomist, his conservatism caused him to miss entirely the whole movement—then called “the new philosophy” but which we call “science”—active at his very doors. None of these things suggest a very eventful life, but the events of life are within and not without.

With his sympathy, his power of insight, and his skilful use of background, Dr. Keevil has produced a most readable volume which pictures practice in London 300 years ago with a vividness to which there are very few parallels.

CHARLES SINGER.

CASCADE STOMACH

L'Estomac en Cascade. By Dr. Jean Roussel. (Pp. 132; 60 figures. No price.) Paris: Masson et Cie. 1952.

This monograph is based on the clinical and radiological study of eight examples of cascade stomach in men. Each example is illustrated by retouched radiographs accompanied by explanatory diagrams. The author considers the possible cause of the condition in great detail and is satisfied that contraction of the various gastro-epiploic folds due to “perigastritis” is the essential lesion. This contraction, he believes, may result from organization in folds initially shortened by spasm due to splanchnic irritation. In one case he attributes the cascade appearance to reflex irritation from a mildly inflamed appendix. Yet as common causes of perigastritis he lists alcoholism, arteriosclerosis, chronic peritonitis, and syphilitic and tuberculous peritonitis, in none of which does spasm, such as he envisages, appear likely to occur. He rejects the opinion that gaseous distension of the colon is in any way connected with it.

Roussel associates with the radiological appearances two major clinical symptoms—epigastric fullness and loss of weight. He finds that the fullness is often accompanied by eructations, palpitation, regurgitation, and even vomiting. The loss of weight, which may be rapid and considerable, he attributes to protective anorexia, the patient refusing to eat because he feels more comfortable with an empty stomach.

The treatment advocated ranges from medical restrictions of diet through splanchnic blocks, operative adhesion section to gastro-gastrostomy with anastomosis between the upper and lower pouches of the cascade stomach. A section is also devoted to rather abstract consideration of the mechanism of production of the radiological appearances in terms of forces and tone.

The author's conclusions are too often based on abstract theories and on inductive reasoning to deserve the consideration that might otherwise have been their due. Cascade stomach may at times be accompanied by symptoms, and this deserves recognition and further study. The best service the author has done is to stimulate interest in the condition.

PREMENSTRUAL TENSION

Women are slow to complain about what they regard as woman's lot. The cramps of dysmenorrhoea, the sorrows of dyspareunia, the pangs of childbirth, and the discomforts of the climacteric may all be suffered, if not in silence, at least without complaint to the doctor. To these more notable disabilities must be added the premenstrual tension state, a syndrome thus named by Frank in 1931¹ of physical and mental symptoms occurring in the ten days or so immediately before the menstrual period and usually abating dramatically with the onset of the flow. This syndrome was the subject of an annotation in these columns two years ago,² but has otherwise received little attention in Britain. The two papers in this issue of the *Journal* describing this common condition and its treatment are therefore to be welcomed. Dr. Raymond Greene and Dr. Katharina Dalton offer the viewpoints of physician and general practitioner, while Dr. Linford Rees writes as a clinical psychiatrist, but there is close accord between their respective ideas on aetiology, symptomatology, and treatment.

In the premenstrual tension state there may be a preponderance of psychic symptoms such as mental tension, irritability, depression, insomnia, and emotional outbursts, but somatic symptoms, including headache, dizziness, nausea, lower abdominal fullness, oedema, mastalgia, thirst, and easy fatigue, are nearly always present. The time of onset of these symptoms is usually but not always immediately premenstrual, but their recurrence is characteristically cyclical. Menstruation itself is nearly always normal in frequency and duration. The degree of disability varies from patient to patient, but it has been estimated that the symptoms occur in some degree in at least one-third of otherwise healthy women.

The aetiology of the syndrome is still not completely understood, but several contributory factors are apparent. That water retention is an important feature is indicated by the frequency with which gain in weight, oedema, and oliguria mark the onset, and

diuresis and loss in weight accompany the decline of each attack. But water retention is not the sole factor or the basic fault, for measures taken to discourage or counter it while relieving the physical rarely affect the mental symptoms. Further, the water retention is associated with changes in sodium metabolism and is accompanied by manifestations of autonomic imbalance, and all of these are influenced by hormonal factors. It is natural therefore to look for some endocrine upset to account for the development of this syndrome and for some method of remedying the hormonal imbalance to relieve it. Drs. Greene and Dalton and Dr. Rees suggest as pathogenetic an abnormally high oestrogen-progesterone ratio, a hypothesis that differs little from Frank's attribution of the symptoms to hyper-oestrinism in 1931. That there is an undue preponderance of oestrogen in this condition is supported not only by laboratory data but also by clinical evidence presented in these two papers. For example, primary spasmodic dysmenorrhoea occurs only in ovular cycles in which the oestrogen-progesterone ratio is likely to be normal. Greene and Dalton found dysmenorrhoea in only 2 of their 84 patients and then only in slight degree; and they, as well as Rees, noted that treatment with progesterone, although relieving the presenting symptoms, occasionally brought on dysmenorrhoea.

If these hypotheses are valid, the rational treatment is to restore the oestrogen-progesterone balance. This can be done by supplementing the supply of the latter artificially, and indeed there have been several previous reports of the efficacy of progesterone therapy. Greene and Dalton cured nearly half of their cases and obtained improvement in another one-sixth by giving a daily dose of 50 mg. of ethisterone orally for 12 days beginning on the fourteenth day of the cycle. In severe or resistant cases progesterone had to be injected or, more conveniently, implanted, but altogether in only 3 of their 78 cases followed up were progesterone and ethisterone completely ineffective. Dr. Rees also obtained good results, and with the smaller daily dosage of 5–20 mg. of ethisterone 85% of his cases obtained significant relief. An alternative method of restoring the oestrogen-progesterone ratio to normal is to counter the relatively high level of the former by giving androgens, and Dr. Rees confirmed that methyl testosterone is at least as effective as progesterone. Methyl androstenediol might be preferable to testosterone for this as for other gynaecological disorders, because it is less likely to produce masculinization or to increase libido³—the latter a point of importance, for increased sex desire is not uncommon in the premenstrual tension syndrome.

¹ *Arch. Neurol. Psychiat.*, 1931, **28**, 1053.

² *British Medical Journal*, 1951, **1**, 1068.

³ Kupperman, H. S., and Goodman, S. J., *Amer. J. Obstet. Gynec.*, 1953, **65**, 141.

It has been claimed that the emotionally unstable are particularly liable to develop the premenstrual tension state; that sexual maladjustment, marital disharmony, or continued frustrations are responsible for its onset; and that psychotherapy must therefore be the first line of treatment. Dr. Rees discounts these claims. He believes that, while psychogenic and personality factors play a part in the syndrome, premenstrual tension is not primarily a neurosis, and that psychotherapy has but a limited, though important, role in its treatment.

The premenstrual tension syndrome therefore is a common condition, although complained of infrequently. And when some of the symptoms are described by the sufferer it is understandable by their nature that they may be discounted by the practitioner as unlikely to have a physical basis. But awareness by both patient and doctor that this is a condition which occurs frequently, which deserves diligent inquiry, which causes much misery, and which responds well to a simple form of treatment could do much to alleviate the suffering not only of the victim herself but also of her household.

EXTRAORDINARY GENERAL MEETING

On Tuesday of this week there was a Special Meeting of the Conference of Representatives of Local Medical Committees in the morning and an Extraordinary General Meeting of the Association in the afternoon to consider the implications of the following resolution put forward by the requisitionists of the latter meeting:

"That the Association, being concerned by the modification of the present method of remuneration by capitation fees agreed in the Working Party's report, requires the Council forthwith to approach the Minister of Health with proposals for the better protection (financial and otherwise) of the small-list doctor and of the doctor newly seeking entry into practice, and requests the Minister of Health not to implement the Working Party's report until the scheme for distribution of remuneration has been considered in the light of such proposals, and meanwhile to continue the present method of payment."

At the Conference (see this week's *Supplement*, page 206) Dr. Talbot Rogers, chairman of the G.M.S. Committee, gave a calm and reasoned statement of the various negotiations in connexion with the Danckwerts award and its distribution. He pointed out that the implementation of the award depended on a scheme of distribution which would be acceptable to the medical profession, the Minister of Health, and Parliament. It was obvious that any solution could

not be expected to satisfy everyone. Fears were expressed that doctors with small lists, or at least some of them, might suffer hardship; hence the rider of the G.M.S. Committee in relation to this group. The G.M.S. Committee had set up a small subcommittee composed of the medical members of the Working Party and representatives from the Medical Practitioners Union, the Assistants and Young Practitioners Subcommittee, and the Amending Acts Committee to look into the problems affecting the small-list doctor. The subcommittee found the situation much more complicated than it had thought it would be. The small-list doctors did not fall into any one category. The number of those who might suffer could not be exactly ascertained. The amount of money that might be available to those suffering hardship could not be precisely assessed. Dr. Rogers gave some of these and other facts to the Extraordinary General Meeting on Tuesday afternoon (see this week's *Supplement*, page 205). He reminded his audience that in 1951 Mr. Hilary Marquand agreed there was a case for increasing the remuneration of general practitioners, agreed to arbitration, and said that any award would not be paid out unless there was agreement on its distribution by a working party composed of representatives of the profession and of the Ministry of Health. The Working Party was to devise a scheme of distribution which would ease the entry of new doctors into the Service, would discourage the building of large lists, and would encourage group practice and help those least favourably placed. Dr. Rogers told the meeting that he himself had insisted that if the Working Party could not reach agreement on a scheme of distribution the scheme itself should also go to arbitration. He admitted there might have been some hurry in getting the scheme agreed to, but this was necessary in view of the approaching summer recess of Parliament last year and of the urgent desire of the profession for concrete results. Dr. Rogers reiterated what he stated in the morning—namely, that it had been impossible to find a solution of the small-list problem before April 1, 1953, when the new distribution scheme came into operation. Until that date they could not have obtained the necessary information; for example, it was known only this week that there were a number of new principals in the Service, and this alone would determine the final settlement for the coming year—a fact which would have a bearing on the money that will be available to do justice to those small-list practitioners at present suffering hardship. They had, he continued, recently asked the Ministry of Health to call together the Working Party once more, and this body was already in the process of getting exact

information on which to base action. Any financial readjustments that would be made when the inquiry was completed would be retrospective to April 1 of this year. He saw no difficulty in securing sufficient money to remedy any existing injustices out of the sum set aside for the purpose and also out of the increased money for final settlement.

Under the chairmanship of Dr. E. A. Gregg, the Extraordinary General Meeting was conducted in a calm and orderly fashion, and the pros and cons of the resolution before the meeting were discussed in a spirit free from bitterness. This was due in no small part to the admirable way in which Dr. W. J. Grant, of Shrewsbury, proposed the requisitionists' resolution. He claimed that the method of distribution penalized those with a list of 1,500 or under, and said he was satisfied that some doctors were now underpaid as the result of the Working Party's scheme. He insisted that there should be equal pay for equal work, and that the Government should provide extra inducements to attract doctors into difficult areas. It was wrong, in his view, to try to effect redistribution by economic pressure. He criticized the proposals in the rider of the G.M.S. Committee as a form of charity, and in particular challenged what in effect was a means test to which the small-list doctor should be subjected before financial readjustment could be made. He pointed out that the Danckwerts award had been based on an assessment of general practitioners' remuneration from all sources. Dr. Schiff, who seconded the resolution before the meeting, referred to the agreement in 1949 that in any increased remuneration the loading should be on the first thousand. Dr. Talbot Rogers pointed out that their approach to the distribution scheme had to be based on the terms of reference of the Working Party, and in 1951 both the Conference and the Representative Body gave the medical members of the Working Party full power to use their own discretion in devising the method of distribution.

Lord Horder's amendment, to which reference was made in last week's *Journal*, was accepted by the meeting, as was a similar amendment in reference to the machinery of approach to the Ministry of Health. But by the time the amended resolution was put to the vote it was clear that the great majority of those present were satisfied that the G.M.S. Committee and the Working Party were setting about their task on the right lines to remove any existing injustices. In fact, when Dr. Grant replied towards the end of the meeting he said that he personally did not mind whether or not the meeting passed the resolution, because he and his fellow requisitionists had secured

what they wanted—namely, that this problem should be fully debated, and that something should be done about it. The Extraordinary General Meeting did at least succeed in doing one thing, and that was to bring into the open the fact that the Association was as much concerned about the position of minority groups in the profession as it was about the majority. It is to be hoped that before long those adjustments will be made which will put at rest the minds of those, however few of them, who are now suffering financial hardship because of a scheme of distribution that is acceptable to the majority of general practitioners in this country.

POLYMYXIN

The first antibiotic ever shown to exert a systemic antibacterial action—gramicidin—was derived from a *Bacillus*. While combing the microbic world for further antibiotics—a search which began when the powers of penicillin were recognized—this genus was not neglected, and many species or strains have been found to yield substances with a powerful action on various other bacteria, including in some instances tubercle bacilli. That none of these has come into such general use as the better-known antibiotics is due largely to misgivings about their toxicity: all are polypeptides, and the organ which they are generally apt to damage is the kidney. The most promising among them, and now regarded by some workers as having an assured place in therapeutics, are bacitracin and the polymyxins. It is interesting that these two very similar substances, derived from closely related organisms, should have totally different ranges of activity: the organisms most sensitive to bacitracin are Gram-positive cocci, and to the polymyxins Gram-negative bacilli.

The history of the polymyxins is highly confusing, chiefly because there are five of them differing in amino-acid content and in biological effects, both antibacterial and toxic. Earlier studies were made with what is now known as polymyxin A, originally called in Britain aerosporin, and the observed toxic effects of this substance discouraged further progress and delayed the acquisition of our present knowledge. An account of these developments and of the properties of the five polymyxins now recognized has been given by Brownlee and others.¹ Those most suitable for clinical use are B and E, and there is now some clinical evidence of their utility and of their safety under certain conditions of dosage. The specific infection where they are most clearly indicated is that due to *Ps. pyocyanea*, since this organism is highly sensitive to polymyxin and often resistant to all other forms of chemotherapy. Its three main spheres of activity all happen to be amen-

⁹ Gowans, J. L., et al., *ibid.*, 1952, 7, 438.

able to treatment other than by the administration of full doses parenterally. These are, first, superficial infections which can be treated by local application. The value of this procedure in burns has been demonstrated at the Birmingham Accident Hospital by Jackson and his colleagues.² Secondly, meningitis can be treated by intrathecal injection. And, thirdly, there are the urinary infections, which call for comparatively small doses intramuscularly. It is hence not surprising that clinical reports such as those of Kagen and others³ and of Jawetz⁴ are chiefly on these forms of treatment, the parenteral dosage (if any) being only moderate and the absence of renal toxicity perhaps no guarantee that larger doses would prove equally safe.

It is therefore of some importance that Swift and Bushby⁵ are able to report having treated 53 patients with polymyxin E and 32 with polymyxin B without causing apparent renal damage in any of them. They were mainly children, who were given up to 12,500 units per kg. body weight four-hourly for five days or longer. In one case protein, casts, and red cells appeared in the urine but were apparently attributable to another cause. Other toxic reactions, chiefly pain and induration at the site of injection and fever, were much less often caused by polymyxin E than by B. Nervous effects, such as flushing, itching, and paraesthesiae, were judged to be produced in an equal degree by both, so far as could be ascertained among patients of whom many were too young to describe their sensations.

If these findings are held to prove that polymyxins B and E are not toxic to the kidneys, the conclusion is both important and somewhat unexpected. Hitherto all the polypeptide antibiotics have seemed to suffer from this disadvantage, and fractionation of them has failed to yield a component which retains antibacterial activity and lacks toxicity. Thus, according to Callow and Work,⁶ of three licheniformins, A is the least toxic but nevertheless causes renal damage. Marston and Florey⁷ report very similar findings with proactinomycin, and Newton and others⁸ with bacitracin. Nisin, although it has not been fractionated, is another polypeptide with renal effects which debar its systemic use.⁹ If polymyxins B and E are an exception to this rule, they certainly deserve a place in therapeutics, and it is to be hoped that supplies of one of them—preferably, according to these findings, E—may be made available for further study and for general use in those difficult and sometimes desperate cases where no other antibiotic will serve.

TENDON TRANSPLANTATION IN POLIOMYELITIS

Since the original work of Nicoladoni in 1880, opinion on tendon transplantation has passed through the three phases that usually follow the introduction of any new surgical procedure—enthusiastic optimism, disillusion, and now cold revaluation. To study the effects of tendon transplantation in cases of poliomyelitis is particularly difficult, for seldom is it a question of finding

a substitute for a single paralysed muscle or group of muscles, but rather of readjusting the balance of an incompletely paralysed limb. The procedure is therefore often accompanied by stabilizing operations on one or more joints. While the fixation of a joint results in an economy of muscular effort, and so may free muscle for transference, it makes true assessment of the result more complicated. Because surgery is often carried out in childhood and adolescence, the follow up is long and also made difficult by the migration of patients. The observations of the Poliomyelitis After-Care Programme in Vermont¹ (established by Lovett, co author with Robert Jones of *Orthopaedic Surgery*, after an epidemic in 1914 and continued by Ober), and those of the Poliomyelitis Clinic in Boston,^{2,3} cover not only an unusual length of time but an unusual number of cases which have been systematically treated and observed.

Because the variety of procedures used in treating the upper limb is greater than in the lower, the results of treating the lower limb can be followed up and compared more satisfactorily. Paralysis of the hip and calf inevitably affect the stability of the knee and must be corrected before a transplant round the knee-joint can be undertaken and its results judged. (It might be mentioned that the size of the quadriceps has perhaps led some workers to overrate its importance in the act of walking.) The most commonly used muscles are the tensor fasciae latae and sartorius; the biceps femoris, although an antagonist, is better. It is disappointing to note that even the ability to extend the knee against gravity does not necessarily enable the patient to discard his irons. Objectively the results are disappointing, only 30% of patients regaining active extension, but subjectively the results are good because of the increased feeling of stability at the knee.

The operations performed round the ankle may be grouped together, being designed to restore dorsiflexion, to restore plantar-flexion, or to stabilize the forefoot. The restoration of strong plantar-flexion, the most difficult result to achieve, is desirable, but it is not necessary for a good gait; transplantation of both tibialis posterior and peroneus longus is necessary for success, and in only one case did this enable the patient to balance actively on tip-toe. More helpful to the development of a good gait is the return of dorsiflexion, and it is more easily accomplished by transplantation of the peroneus longus. This, combined with a stabilizing procedure, gave a good result in almost two-thirds of the cases. Tendon transplantations round the forefoot are often combined with a variety of stabilizing procedures and are difficult to analyse. The muscle most commonly transplanted is the tibialis anterior to prevent inversion of the foot.

Surgical technique for transplantation has become standardized. Synergistic muscles are used rather than antagonists, and all transplanted tendons should be anchored to bone. Before the age of 11 the balance of muscle power and bone deformity cannot be accurately

¹ Kuhlmann, R. F., and Bell, J. F., *J. Bone Jt Surg.*, 1952, 34, 915.

³ *ibid.*, 1952, 34, 900.

estimated, and operative treatment before this will necessarily be uncertain, some 80% of patients requiring further surgery. Stabilization alone will give a good functional result in many cases. Nevertheless, the combination of the two procedures, though suitable only for cases with muscle imbalance, has a valuable place in poliomyelitis aftercare.

TEN YEARS OF "NUFFIELD"

It was in 1943, in the middle of the war, that the Nuffield Foundation was established by Lord Nuffield, and it is now nearing the completion of its second five-year programme. The two programmes have not been greatly different. In the first the emphasis was on normal health, especially child health and industrial health, but also on one specific disease—namely, rheumatism, the work on which was facilitated by a benefaction of £450,000 by Captain Oliver Bird, M.C. Up to the present nearly a quarter of a million pounds have been spent by the Foundation on research into rheumatism, including the financing of a pioneer centre at Manchester and the initiation of a scheme of fellowships. A beginning had been made in fundamental research into causes and in scientifically controlled trials of existing forms of therapy when the work on cortisone and A.C.T.H. was announced from America. Elaborate trials have been made with these hormones, which are described in the recently published review¹ as "certainly not a cure but perhaps a tool." Rational treatment based on a knowledge of causation is not yet possible in rheumatism, and the claims for the many methods of therapy in clinical use are still difficult to assess. Studies are continuing in the hope of throwing light upon the structure of tissues and the processes of rheumatic diseases which involve and damage them.

In its second five-year programme the Foundation has shifted its emphasis to biological and sociological studies. Grants have been made for investigations into cellular biology, microbiology, comparative endocrinology, immunology, and neurophysiology. In these fields, again, the research is recent and the results not yet ready for reporting. Investigations into sociological, economic, and population problems have also been generously assisted. An important object enjoined upon the Foundation by its trust deed concerns the care and comfort of the aged. This review points out, what is often overlooked by those who express alarm at an ageing population, that it is not merely life which is being prolonged but working capacity. Continued and normal activity by the elderly is an important contribution both to their own morale and to the economic well-being of the community. It is from this point of view that the Foundation is proceeding. It is financing research by psychologists at Cambridge into the manner and the rate in which skill declines with age, and into the methods by which the elderly can be helped to continue in work or to change to tasks better designed to take account of any falling off in skill.

Finally, the Foundation has made a major part of its activities the award of fellowships and scholarships both

for residents in the United Kingdom and in other parts of the Commonwealth. Over £600,000 has been set aside for these awards from the income of the Foundation during the past ten years, but the aim has been the creation of carefully selected and often short-term and experimental schemes rather than an omnibus endowment. These ten years have been a preparatory period. Readers of the report may wonder what vast achievements for human welfare will be recorded in a review of the Nuffield Foundation to be published at the end of this century.

THE MIDDLE-AGED MAN

The inevitable changes attending the contraction of life in its second half come gradually and without fuss in well-adjusted people. But the outlook is very different for the maladjusted, who interpret the normal changes as symptoms of disease. Their lives are darkened by hypochondriacal disturbances and depressing reflections. Illness to many people implies an external agent. The unhappy middle-aged woman blames "the change of life," and is thereby blamelessly exonerated from responsibility. The notion of a male climacteric is in a like category. In the literature (and in advertising circulars) the term male climacteric is becoming familiar. Is there any such condition even remotely similar to the female climacteric?

Claims have been made,^{1,2} and denied,^{3,4} that there is a rare syndrome properly described as the male climacteric. The symptoms of the presumed syndrome, briefly, are depression, irritability, lack of concentration, palpitation, weakness, and sexual impotence. All of these are present in the neuroses and in involutional depressive states, hence an objective test is recommended—namely, testicular biopsy and the results of testosterone propionate therapy. These, and chiefly the latter, are thought to provide conclusive evidence. These claims, however, have been refuted by other workers unable to corroborate them. The so-called syndrome, they assert, is a psychiatric illness. One advocate for the syndrome asserts that involutional melancholia has "a definite endocrine origin" and advises injections of testosterone propionate.⁵ Yet doctors who have to treat involutional melancholia in either sex prefer E.C.T., which gives its best results in this condition. Ageing is a complex but normal process, and it might be assumed that all glands of internal secretion take part in it. The menopause is not a disease entity despite its occasional association with nervous and other complaints. No one has described a condition in men with disturbance of hormone secretion as the only symptom of the so-called male climacteric. Landau⁶ and others who regret the use of this inexact terminology believe that the beneficial effects which sometimes accompany injections of testosterone propionate are due to the influence of suggestion on emotionally unstable persons, and that the term should be abandoned.

Evidence has been obtained⁶ that sexual energy falls steadily from the teens to the seventies. The study of spermatozoa counts and excretion of androgenic and gonadotrophic material in urine supports this observation. From this it might be inferred that the changes, which some workers assume to be pathological are part of the normal ageing process in which all functions of the mind and body share. Until an occult deficiency of testicular androgen—provided this can be estimated—is shown to bear a direct causal relation to the multiplicity of symptoms embraced by the term male climacteric, we have no ground for accepting the concept.

TEACHING PUBLIC HEALTH

The report on the work of the London School of Hygiene and Tropical Medicine for the year 1951–2 describes once again the activities of this enterprising institution, with its thirteen separate departments and its farm field station near St. Albans. In their introductory remarks Sir Archibald Gray, the chairman of the board of management, and Dr. Andrew Topping, the dean, refer to the effect of increasing costs on the finances of the school, whose credit balance was unfortunately converted into a deficit during the year. Efforts are being made to reduce expenses, but the tutorial fees, which have not been changed since 1930, will have to be increased for some of the courses beginning next October.

The report of the work of the department of public health is of special interest this year, for Professor J. M. Mackintosh has taken the opportunity to review developments during the past twenty-five years. Before the first D.P.H. course was held an informal committee of Professors Greenwood, Topley, Jameson, and Delafield was appointed to consider the future curriculum, and it was in 1931 that the decision was reached that a course of university standard could not be conducted on anything but a whole-time basis. It was about the same time that the General Medical Council published new rules allowing whole-time students to complete the course in nine months instead of one year. As the years went by the tendency was always to reduce the number of formal lectures and to make the course more tutorial in character. At the present time the greater part of the teaching is based on the study group system, which allows students to choose the subjects to which they would like to give particular attention. At the end of the 1939–45 war the whole curriculum was revised. Demonstrations of bacteriological techniques and of the chemical analysis of water and milk have taken the place of the intensive exercises in practical work which were such a time-consuming part of the diploma courses before the war, and the first term is now occupied with "a general introduction to the scope and character of the public health and social services." During the other two terms the student is brought closely into touch with the practical problems of public health administration by working under the supervision of medical officers of health. In addition, study groups are formed and the students themselves plan and execute investigations into some

problem allied to public health. An "overwhelming" majority of students found that learning through study groups was more interesting than traditional classroom work and 55% thought it to be more effective. The range of studies is gradually being extended, and in the current course the medical aspects of airport control and a discussion of general practice were introduced for the first time. "These various additions to the programme," the report states, "would overburden the course if rigidly enforced on all the students, but they are presented in the spirit of elective studies and are accepted as such by the students whose maturity and experience enables them to be selective in their interests."

These new methods of teaching public health and the swing of emphasis from some subjects to others reflect the present changing views about social and preventive medicine. The London School of Hygiene and Tropical Medicine has always been ready to move with and even ahead of the times. The present report shows that this policy has been fruitful and will continue.

COST OF PRESCRIBING

In the first full year of the Health Service general practitioners' prescriptions cost £35m. It is estimated that in the current year the cost will be about £52m. When the sum of £6.7m. (estimated) is taken off for patients' payments, the net cost to the taxpayer is still £10m. more than in 1949–50. Analysis shows that three-fifths of this total is accounted for by the cost of ingredients and not by chemists' fees.

In the summarized accounts¹ of the National Health Service for 1951–2 the Comptroller and Auditor-General states that in the thirteen months up to December 31, 1952, 282 general practitioners were reported for apparent excessive prescribing. All but eleven of these reduced their prescribing costs after warning from the Ministry and—to quote the Comptroller and Auditor-General—"without detriment to the treatment of the patients." That only a minute proportion of general practitioners were thought to be prescribing excessively gives the lie to any accusations that the size of the nation's drug bill is caused by general extravagance among doctors. Note must be taken, too, of the statement that the reduction in the prescription costs after warning of certain doctors was achieved without detriment to their standards of treatment. This may be true, but we must never depart from the recognition of the right of the doctor to be the sole arbiter of what is best for his patient. To surrender this fundamental principle would cost far more than the few thousands saved on cheaper prescriptions. Yet responsibility for one-eighth of the expenditure on the Health Service is in the hands of general practitioners, though there are reasons for this high cost which do not reflect on the prescriber, and there is no single way to economy, but most general practitioners know that there are many small ways and means of saving. Those who do not know should make it their business to find out. "Many a mickle makes a muckle."

REFRESHER COURSE FOR GENERAL PRACTITIONERS HYSTERIA

BY

I. R. C. BATCHELOR, M.B., M.R.C.P.Ed., D.P.M.

Deputy Physician-Superintendent, Royal Edinburgh Hospital for Mental and Nervous Disorders;
Lecturer in Psychiatry, University of Edinburgh

Hysteria has been known since antiquity. Its symptoms, often dramatic and apropos to the times, have compelled attention and wonder. It has had many explanations. For our present views we owe a debt to both neurologists and psychiatrists, amongst whom in the past hundred years the contributions of Charcot, Janet, and Freud have been outstanding. Treatments, lay and medical, have been as various as the theories about its aetiology. Physicians and ministers of the traditional religions have relieved many sufferers from hysteria, as also have less orthodox faiths and modes of healing. That many of these treatments have not proceeded along rational lines and have produced symptomatic improvement without insight does not by any means wholly detract from their practical usefulness.

Hysteria may appear in the form of physical or psychological disorder. The patient's emotional disturbance, which is fundamental to the illness, may be more or less completely converted into physical signs or symptoms (conversion hysteria) or it may find more direct expression in episodic mental states of a characteristic type. Overt anxiety or even panic may accompany hysterical symptoms.

The Hysterical Personality

Frequently, though by no means invariably, those who develop hysteria have shown before the onset of the illness an aggregation of traits which has been called the "hysterical or histrionic personality." It is often evident that these people, usually women, though adult in age, are to a great extent dependent still on one or other parent. Their temperaments are quicksilver, over-sensitive, over-responsive. They often fall into passionate attachments, as intense as they are transient; they make excessive demands on others, and, disappointed in their unrealistic expectations, react impulsively in spite and pique; and they attempt continually to dominate others by their whims and moods. Abnormally self-centred and vain, they seem to feel an almost constant compulsion to bolster up their egos by holding the stage and playing out dramatic roles evolved by their too vivid hopes and imaginations. Their capricious and frequent lying has often the fantastic and innocent quality of the child's. Sexually they are superficially excitable but fundamentally inhibited. Behind all this, hidden from the patient's unassisted insight, there seems to be an intense longing and need for attention and love—a need infantile in its exclusiveness and which is as great as their ability to feel deeply towards others is small. It is not surprising, then, that the environment they inhabit is more often than not emotionally on the boil. These people easily provoke antagonisms, are very difficult to live with, and difficult to be patient towards in treatment. It is salutary, therefore, always to consider such a previous personality as an essential part of the illness.

The particular symptom developed depends on one or more of several factors: it has often clearly a symbolic meaning (for example, hysterical blindness may symbolize an inability to contemplate some unpleasant reality); it may be an exaggeration of some physiological reflex (for example, hysterical vomiting) or may utilize some locus of earlier disease or injury; or it may be the outcome of

suggestions derived from the illness of a near relative or friend, or from previous medical examinations. It is advisable always to ask the patient what he thinks is wrong, and to find out if anyone in the patient's environment has suffered from anything similar. All neurotically ill people are suggestible, and, identifying themselves emotionally with others, may imitate their disabilities. The greater the individual's knowledge of special kinds of disease, the nearer his symptoms will mimic those diseases. Gross hysterical symptoms seem now to be less common than formerly, when they were often produced by unskilled and over-enthusiastic examination.

Physical Symptoms

Physical symptoms are usually in the nature of some incapacity, partial or complete, involving the sense organs or voluntary musculature—aphonia, mutism, deafness, blindness, paresis, or anaesthesia. The disability is often of sudden onset, its degree and extent tend to be variable, and its details do not coincide with the signs of neurological disease. For example, the hysterically mute individual can cough normally and may be persuaded to write his replies to questions; the sufferer from hysterical blindness may avoid obstacles in his way; the muscles of a hysterically disabled limb may be used in some movements and not in others; the anaesthesia corresponds in its distribution and in the types of sensation involved to no recognized variety of organic sensory loss.

In other cases movements may, instead of being diminished, be increased in the form of tremors. Hysterical disturbances of gait may be bizarre; other abnormalities of movement or posture—for example, tics and dystonias—may also be hysterical but are more often symptoms of organic involvement of the nervous system. Sensation also may be heightened or perverted, localized areas of hyperaesthesia may be described, and head pains or abdominal sensations complained of. In these cases the paraesthesiae are frequently reported by the patient in hyperbole: they are constant, may even be claimed to be present during sleep, and are intolerable; analgesics have little or no effect on them. All these symptoms become aggravated under observation and fixed by too often repeated examination.

The visceral symptoms of hysteria most often encountered are persistent vomiting and anorexia. Hysterical vomiting, often unaccompanied by nausea, occurs after meals and is effortless. Anorexia nervosa commonly manifests itself in a striking combination of emaciation and continued, even apparently tireless, activity. Found typically in girls and young unmarried women, this condition is not so difficult to distinguish from Simmonds's disease as is often supposed.

Mental Symptoms

The commonest mental symptoms are amnesias, fits, and disturbances of consciousness—fugues, stupors, and so-called twilight states.

Hysterical amnesias may be localized, covering some particular event, or (rarely) very extensive, involving even the whole of the patient's past life and so resulting in loss of identity. A localized amnesia may cover an incident involving guilt, and sometimes a criminal act—for example, amnesia may be claimed for the circumstances of a culpable accident, the patient saying that he suffered a "black-out." The assessment of such a black-out will centre on the

investigation of the possibility of concussion and on the history of previous similar attacks. An amnesia involving the whole of the past life of a young person is invariably hysterical.

Hysterical fits are diurnal. There is usually no typical clonic-tonic succession as in the epileptic fit, and self-injury is unusual. Tongue-biting, incontinence, and transient reflex changes do not occur. The seizures are seldom followed by complaints of headache and confusion. There is always an audience, and if attempts are made to restrain the patient he responds with wild struggling. Atypical faints and vaguely described collapses also occur commonly.

Hysterical disturbances of consciousness of longer duration may be associated with immobility, with dramatic posturings and verbal outpourings, or with wandering (a fugue). These always require expert assessment.

There is in all hysterical reactions a great tendency towards exaggeration, and the patient in his bids for attention may go so far as self-injury. Cases of dermatitis artefacta and other types of minor wounding are allied to the hysterical reactions. Suicidal gestures or attempts may also be made by individuals of hysterical personality when some thwarting produces great excitement. These attempts are usually impulsive: though they may not always be very serious, they are danger signals and urgent calls for help, and should not be dismissed as innocuous.

In sufferers from hysteria the typical mental attitude, *la belle indifférence*, is not always found. In the early stages there is often a good deal of anxiety. It is only when the establishment of symptoms has provided the terms of a truce for the conflicting emotions that a surface calm is achieved and the patient presents an attitude of bland acceptance of his disabilities. The lack of insight is then typical. The hysteric describes at length a number of painful or discommoding symptoms and goes on to state that he is not worried by them: he does not consider his symptoms nervous, declares in a sweeping way that he has had no recent anxieties, and seeks purely physical explanations for his sickness.

Diagnosis

Hysterical symptoms, which are commoner in women than in men, are developed most often around puberty and adolescence and in early adult life. They are uncommon after middle age. When occurring for the first time after the age of 45 they should be regarded as organically determined, unless the opposite has been clearly proved.

A careful physical examination is essential in every case. Hysteria is often mistaken for physical disease, and physical disease is often called hysteria. It would be profitless to attempt a list of the syndromes which may cause confusion. In perhaps the most difficult cases the question of organic neurological disease is at issue: disseminated sclerosis, brain tumour, encephalitis, myelitis, cerebral vascular disease, myasthenia gravis, and many other physical processes may be misdiagnosed. The situation is also complicated by the fact that organic brain disease may itself cause or release hysterical symptoms, and hysterical symptoms may be grafted on to the physical effects of an injury. It is helpful to remember that in a young person organic neurological disease does not usually develop so rapidly as hysteria; that there are no significant reflex changes in hysteria; and that the physically ill individual usually shows some general evidence of physical illness. It is surprising how often the eliciting of a story of some recent emotionally disturbing event leads to the forgetting of the platitude that a physical illness has also to begin some time.

Hysteria must be distinguished from other kinds of nervous and mental illness, but too precise a pigeon-holing of neurotic reactions is impossible, since many of them show an admixture of anxiety, hysterical, and obsessional symptoms. It should, however, be determined whether or not the hysterical symptoms are primary and predominant:

appropriate treatment depends on this. Hysteria mimicking severe mental illness is much less common than is widely believed. Fugues should not be lightly discounted as hysterical: many have a depressive basis and are suicidal equivalents.

The differential diagnosis between hysteria and epilepsy is often difficult. Some of the distinguishing features have been described already. An electro-encephalogram may be helpful, and an accurate description of the attacks by a witness always is.

Close attention to the patient's symptoms and appreciation of the setting of his illness are both equally important. Knowledge of the patient's previous personality and a history of neurotic illness help always in assessing present symptoms. But the diagnosis can never be considered to be on a firm basis until the precise emotionally charged situation or dilemma which has precipitated the patient's symptoms has been identified and his symptoms are seen to be understandably linked to it.

Treatment

The general practitioner, acquainted with the details of the family background and the home circumstances, is strategically in the best position to treat hysterical reactions. Unfortunately, inadequate undergraduate instruction in psychological medicine has caused many doctors to feel that they lack the necessary knowledge. Much depends too on the personality of the practitioner, his insight, the direction of his interests and his sympathies, and the pressure of his work. It is better to refer these patients for specialist opinion too soon than too late; hysterical symptoms, if disabling, should not be allowed to persist. It is pathetic to see women referred for psychiatric treatment after twenty years' history of vague abdominal pains and after "everything's been taken away" by well-intentioned but ill-judged surgery.

The doctor's attitude to this group of people, with their many complaints and clamant demands on his attention, is particularly important. He should be neither censorious nor too kind: if he is the former he will scare people away who genuinely need his help, and if he is the latter he will foster an undue emotional dependence and attachment which may become intolerable to himself. He must be a good listener.

When a current cause of the patient's anxiety can be found his problems must be clearly identified for him, and he should be helped and encouraged to tackle these in a constructive way. This sort of practical guidance, which may have to be repeated often, and the emotional maturation which time may help to bring about lead in a fair number of cases to a satisfactory result. A deeper exploration of the personality and earlier conflicts and traumata, by means of psycho-analysis, may, however, be necessary in some cases. To benefit from psycho-analysis the patient must be young, of at least average intelligence, and willing to co-operate in a long and intensive course of treatment. These requirements limit psycho-analysis to a minority of hysterical patients.

It may be sufficient for cure (particularly in the case of children) to alter the aspect of the environment which has caused the stress: a change of school, removal from danger, more suitable occupation, or the acquisition of a house of one's own may abolish the conflict which was causing symptoms. It is also quite essential for the doctor to promote an understanding attitude in the relatives, and to gain their confidence and co-operation. There is a great tendency for hysterics to adopt in a striking form the social role of the sick person. They are often adept in mobilizing sympathy and notice. They reiterate their desire to get well and back to duty, and are very apt to shift subtly the blame for their lack of progress to aspects of the environment, including the doctor and his treatment. Relatives are thus drawn into the orbit of the illness, come to see the situation entirely through the eyes of the patient, and swaddle him in too much solicitude.

Compensation cases have usually to be referred for a consultant's opinion. Too much hope is often placed in the settlement of a claim; it is in probably the minority of cases that settlement leads to rapid cure.

A thorough physical examination followed by a pronouncement that recovery is imminent may occasionally lead to the prompt disappearance of hysterical symptoms in subjects of low intelligence. But in most neurotic illnesses what is usually called "reassurance" is not enough. The jovial encouragement that there is nothing wrong and nothing to worry about merely convinces the patient that what is wrong has been missed.

Treatment may have quick and even spectacular results, but it may also have to be prolonged, and too great an insistence should not be laid on cures. In most cases, if symptoms are relieved and the patient is helped to function again reasonably happily and efficiently, that should be considered satisfactory. Sedation has a useful part to play in supportive treatment, particularly where there is much anxiety. A mixture containing potassium bromide, 10 gr. (0.65 g.), and chloral hydrate, 5 gr. (0.32 g.), or amylobarbitone sodium, 1 gr. (65 mg.), given three times a day is often sufficient for substantial relief of tension, while in the management of reactions of acute excitement and panic a large dose of a quickly acting barbiturate—for example, pentobarbitone sodium, 3 gr. (0.2 g.), will provide sleep.

It is a mistake to pay too much attention to specific symptoms. Treatment on a purely symptomatic level leads usually merely to the banishment of one presenting symptom and its replacement by another. The disabling nature of a symptom—for example, mutism, deafness—may, however, necessitate a frontal attack on it. In such a case the attempt should be made to eliminate that symptom at a single session. Up to two hours should be set aside, and the doctor's confidence in his success is more important than the method he employs. Firm persuasion and suggestion are usually enough. They may be facilitated by the intravenous injection of a barbiturate (amylobarbitone sodium or thio-pentone). It is doubtful if hypnosis is ever essential; it is never the treatment of choice. A localized amnesia may be resolved under barbiturate narcosis, but probably only if the patient is willing that it should be. Losses of identity clear up spontaneously. In some cases the dramatic intervention of the narcosis is a face-saving situation enabling the patient to relinquish a symptom which is no longer useful to him, and it is not necessarily undesirable to allow him this relief.

If further breakdowns are to be guarded against it is important that the patient should gain insight. But many hysterics reject attempts to give them insight, and recoveries occur without it. Insight should therefore be fostered but not too doggedly insisted upon.

Admission to a mental hospital is never advisable, and admission to a neurosis clinic should be arranged only in certain situations and with definite ends in view. It is often necessary where there is loss of identity, a fugue, gross paralysis, or blindness, and always in cases of anorexia nervosa. Admission may also be necessary when the home environment militates against recovery, but it is essential here to estimate whether after the period in hospital this environment is going to be improved or the patient's resources for dealing with it increased. If these precautions are not taken, when the time comes for the patient's discharge he is apt to jib and to become worse, suicidal threats may be made, recriminations are frequent, and the patient finally returns home disappointed, bitterly critical, and more difficult to handle. Admission to hospital is especially profitable where symptoms have developed on a basis of physical debility and fatigue.

Electric convulsion therapy or other "shock" treatment is not helpful.

The doctor may be asked to advise on marriage and child-bearing. Marriage as a medical prescription might

well be placed on the D.D.A.: it should not always be discouraged, but it is rarely wise to recommend it. Child-bearing should always await the attainment of emotional stability, which it does nothing to promote.

Prognosis

Prognosis depends not on the particular symptoms but on the stuff the patient is made of and the kind of difficulties he has to surmount. If the environmental difficulties are transient or modifiable the symptoms may be expected to clear up. If the trouble lies not so much in the toughness of the demands of the environment as in the inadequacy of the patient's response the outlook is less favourable. With much patience some of these handicapped people may be guided to be more healthy minded and sensible in their dealings with life's problems. Many have numerous relapses and need much propping. The longer hysterical symptoms have lasted the worse is the outlook: there is a great tendency to chronic invalidism, and the mental reaction may become as malignant as a widely disseminated bodily cancer.

Next Refresher Course Article.—"Carcinoma of the Breast," by Mr. H. J. B. Atkins.

EMPIRE RHEUMATISM COUNCIL

LORD HORDER RETIRES

The annual meeting of the Empire Rheumatism Council was held on April 29 in London. At the meeting Lord Horder, who has been chairman of the council since its inception in 1936, announced his resignation. A message from the Duke of Gloucester, the President, expressed his appreciation of the great leadership and wise guidance which Lord Horder had given over many years. Lord Webb-Johnson said that Lord Horder's decision was a matter of regret to them all, but apparently it was irrevocable. To succeed him he proposed Dr. W. S. C. Copeman, who had been for eighteen years honorary medical secretary of the council and had made valuable contributions to rheumatology. Professor R. E. Tunbridge seconded the proposal, which was carried unanimously. Dr. Copeman, in accepting the office, asked for an assurance—which was given—that the council could continue to look to Lord Horder for assistance and counsel.

On the proposition of Sir Henry Cohen, Lord Webb-Johnson was re-elected vice-chairman, and Dr. Oswald Savage and Dr. R. M. Mason were elected honorary medical secretary and deputy respectively. Sir Adolphe Abrahams moved a resolution placing on record the council's great appreciation of Lord Horder's long and distinguished services. He described him as the "W. G. Grace of Medicine"—one who would never be surpassed. Sir George Elliston also spoke to the resolution.

In presenting the financial statement of the council, Mr. W. R. C. Halpin said that there had been an increase during the year of nearly £4,000 received in donations. Donations must form the backbone of their revenue. He was ambitious for an income of £50,000 a year, short of which the council could not open its wings to the full extent. Income last year had amounted to nearly £17,000.

The annual report, which was adopted by the meeting, referred to a generous offer by Merck (North America) Inc. to supply free of charge a quantity of "cortone acetate" tablets sufficient to undertake trials which would keep 50 patients on continuous oral therapy for a year, and after that time to continue to treat *in perpetuo* those of the 50 who still remained on the therapy. Trials were being undertaken to discover the clinical and functional difference between a cortisone-treated group and an aspirin-treated group of patients, and the scheme was coming into operation in nine centres in England and Scotland.

DR. F. PARKES WEBER, 90

On May 8 Dr. Frederick Parkes Weber celebrated his ninetieth birthday. It is just upon 60 years since he became physician to the German Hospital in London. By the later 'nineties he was an ardent participant in the discussions in half a dozen or more medical societies. What has distinguished him during all these years has been his zeal for clinical studies, his search for the more enigmatical signs and symptoms of disease, and the clarity with which he has expounded what he has discovered.

Ten years ago, on his eightieth birthday, his friends at the German Hospital presented him with a volume of his *Collected Writings*—it could be the titles only, for the separate writings ran to nearly a thousand, beginning in

1890 with a contribution to *St. Bartholomew's Hospital Reports* (he was then house-surgeon at St. Bartholomew's) on abnormal foramina in the heart and its valves, and ending in 1943 with a short paper in the *British Medical Journal* on congenital jaundice in a man aged 77. Since then, of course, there have been many further contributions in this and other journals, for Dr. Parkes Weber, who, when he was only 40 or so, wrote for Albutt and Rolleston's *System of Medicine* all there was to say about the physiology and pathology of old age, has always been at heart a youth, and we can confidently hope that the weight of years will not stay his mental activity. Until a year or two ago he was present at almost every meeting of the Section of Dermatology of the Royal Society of Medicine, and it was always refreshing, and in sharp contrast to the mumbling undertone in which the discussions are often conducted, to hear his resonant speech, with no possibility of mistaking a word, as he compared the unusual case then being demonstrated with one which he had seen anything up to 60 years before. Increasing physical disability has in no way impaired his intellectual energy, the vigour and precision of his language, and his enthusiastic interest, especially in the rarer signs of disease. He is an example of the old-time scholar-physician, pedantic perhaps in the use of words—but then, words to him are real things. A rose by

any other name may smell as sweet, but a disease wrongly named may mean a distorted clinical picture. Standing on his feet (later, alas, leaning on a crutch), he would sometimes seem to be coining words and phrases to differentiate and clarify the diagnosis. His paper on naevi, published in the *British Medical Journal* 18 months ago, showed that he was still giving the same careful thought as ever to the classification of pathological conditions.

Dr. Parkes Weber—elected a Fellow of the Royal College of Physicians in 1890—belongs to a generation of medicine which has largely passed away, but the younger generations who have profited from his writings and from the unselfish help he has always given to colleagues and students will acclaim him as a great doctor, a wise philosopher, and a most courteous gentleman. He comes of a long-lived family—his father, Sir Hermann Weber, lived to 95—and his friends will hope that more and happy years remain to him. As he himself put it when he was 80, in speaking of his life as a strenuous holiday like an Alpine walking-tour, "This holiday is not yet over."

HEALTH CONGRESS AT HASTINGS

NEW APPROACHES TO PREVENTIVE MEDICINE

The annual Health Congress of the Royal Sanitary Institute, which was held at Hastings from April 28 to May 1, covered as usual a wide field of preventive medicine and public health services, personal and communal. The subjects discussed in eight sections and four special conferences ranged from building by-laws and modern plumbing to the place of the health visitor in the welfare State, from the control of tuberculosis in Tanganyika to the Middlesex development plan, from a scheme for the part-time employment of ageing persons in Finsbury to the ultra-violet deodorization of the air.

A Disease-proof Nation

The president of the Congress, Lord EUSTACE PERCY, in his inaugural address, posed the question whether the modern human being, artificially immunized against virus diseases, but at the same time carefully protected in childhood against any natural immunization, would prove to be an entirely satisfactory citizen in the future City of Health. The victorious army against the bacillus and the parasite seemed to be exposed to serious flank attacks by other enemies of the constitution whose strength had not been measured—by crippling infiltrations like arthritis, and deadly shock troops like cancer and disorders of the circulatory system. A great Englishman of the last generation had once said to him that he "had never been well enough to be really ill." Was it possible that we were preparing a race of citizens who would never be ill enough to be really well?

"For a disease-proof nation may be a hectic nation, working shorter hours at a more intense and continuous expenditure of energy, mental as well as physical; with a longer expectation of life, but possibly an actually shorter expectation of fitness for work at the new level of intensity; with larger but less reposeful leisure; protected against specific occupational hazards, but more and more exposed to the general hazard of working strain; prone to thrombosis and to nervous or mental breakdown, and making increasing demands on our newly christened science of geriatrics. Such a result, to put it mildly, would not be an 'elegant' solution of our national health problem."

A General Practice Teaching Unit

In the Section of Preventive Medicine, presided over by Mr. FRED MESSER, M.P., chairman of the Central Health Services Council, Dr. RICHARD SCOTT described the work of the Edinburgh University general practice teaching unit. By taking a few selected students into association with family doctor practice it had again been demonstrated that medicine was indivisible. "To the doctor examining the patient in the consulting-room or in his house, curative medicine, preventive medicine, and social medicine are academic concepts. What he practises is medicine."

The Hospital Paediatrician

A more cheerful picture of infant welfare clinics was given by Dr. MAURICE R. WOODS, who found that mothers of all social spheres attended them. Dr. DOROTHY EGAN, principal medical officer for maternity and child welfare, L.C.C., objected to the proposed taking over of child welfare work by the paediatric staffs of hospitals. Experience had shown that even in the atmosphere of a child welfare centre the hospital paediatrician did not find it easy to adapt himself to a purely educational and advisory role, and the change of emphasis to preventive from curative work would be even harder to bring about within the hospital itself. The general practitioner, she said, should ideally combine curative and preventive work, but if he was to do this health centres must be established and group practice become a reality, and he must be prepared to consult and work with the medical officer of health as a specialist in social medicine and epidemiology. Dr. MARY HELLIER, a general practitioner, said that for some time now a group of medical women like herself had been feeling that there was an urgent need for someone like a social worker to be available to the general practitioner.

From the chair of the section Dr. BERNARD SCHLESINGER referred to "quite unjust recent attacks in the medical press" on infant welfare clinics. At the same time he urged close liaison between the medical officer of the clinics and of the hospitals of the district, and the family doctor should not be left out of the picture. If only the family doctor had the time and also the special knowledge and interest, it would be an admirable thing if he would take weekly sessions at such clinics.

In some further discussion on health visiting Dr. JOHN BOWLBY, of the Tavistock Clinic, urged that health visitors should give more attention to mental health, cultivating especially an understanding of the unconscious processes which affected maternal attitudes. The future role of the health visitor in the welfare State was also discussed. One speaker declared the most serious problem affecting the health and welfare service to be not physical but psycho-social breakdowns. The training of the health visitor in the future should be along lines similar to those of the almoner rather than those of the nurse.

The Medical Officer of Health

From the chair of the Conference of Medical Officers of Health Dr. ANDREW TOPPING, as usual, expressed himself vigorously. The contention that the days of public health were over, he said, was completely untenable. He gave an impressive list of community health problems still to be tackled:

- (1) Development programmes for the care and control of mental ill-health.
- (2) Environmental conditions at work and in the home.
- (3) Epidemiology of non-infectious diseases.
- (4) Atmospheric, river, and sea-coast pollution.
- (5) Continuous and increasing health education.
- (6) Co-education and streamlining of the many diverse health agencies.
- (7) The ever growing need for geriatric services.
- (8) The correlation and proper recording of the medical findings of infant welfare clinics, the school medical service, the industrial medical service, and the National Health Service, and the linking up of the work of executive councils, hospitals, and local health authorities.

Dr. Topping had also a word to say about the family doctor:

"We all unite in saying publicly that the family doctor is the keystone of the medical arch, and that he is in the forefront of the battle, and nullify our statements by encouraging the public to bow down and worship the Golden Calf of Harley Street. If a man has the urge and the desire to become, say, an anaesthetist, good luck to him! . . . Why, however, should he be looked upon as a being of superior clay to the family doctor, who, we so consistently agree, is the man of greatest importance in the health service, and who must, if he is the right type, combine good medical knowledge with superhuman industry and know-

The original general practice unit at Edinburgh consisted of a practice comprising some 2,000 patients and staffed by two doctors, a public health nurse, a medico-social worker (almoner), and a secretary, all of whom were university employees. In addition, the services of a dentist, pharmacist, and chiropodist were available. The team afforded instruction to a limited number of voluntary students. As this instruction was to become a required part of university teaching, and in order that more students might be accepted, a second team, with identical staff and facilities, had recently been added, thanks largely to financial support from the Rockefeller Foundation. Some 15 students were accepted by this unit each academic term. They attended a weekly seminar as a group, and each student was also allotted one session a week, when he was the only other person present while the doctor saw patients who attended without appointment. The method of teaching was to manoeuvre the student into a position of clinical responsibility for an individual or a family, and the approach was that of the apprenticeship technique.

In the same section Dr. J. F. WARIN, M.O.H., Oxford, discussing the future of public health services, described himself as "one of the lucky ones," in that while many medical officers of health had lost touch with fever hospitals during the last five years he had been allowed to accept the post of part-time consultant to the United Oxford Hospitals, with clinical responsibility for 36 infectious diseases beds. He was sure that it was just as important as ever for the potential recruit to the public health service to have a good grounding in infectious diseases. A critical review of infectious diseases routine which he had carried out during the last six years in one large and one medium-sized county borough had revealed some "very dusty corners," and he had been amazed at some "prehistoric practices" still in existence. He gave examples of routine procedures of long standing which had served their purpose and might well be discontinued with benefit for all concerned—for example, prophylactic eyedrops for all newborn babies, fumigation of library books, and the like.

Maternity and Child Welfare Services

The integrated service of domiciliary midwifery which was started in Oxford last June, when the health department and the general practitioner went into full partnership, was also described by Dr. Warin. Under this scheme every new patient attending a local authority antenatal clinic is immediately referred to her own doctor for booking in the maternity medical service. She continues to attend the municipal clinic for antenatal care, and then is again referred to her doctor with a detailed report at the 36th week. Most cases are delivered by the midwife, but if necessary the doctor with whom the patient is booked is called in. Post-natal examination is the responsibility of the general practitioner, but the municipal service and health visitors play an important part in encouraging the patient to attend. The scheme was working, said Dr. Warin, to everybody's satisfaction.

In opening a discussion on the future of the maternity and child welfare services, Dr. F. J. W. MILLER, of Durham University, repudiated the idea put forward by some recent speakers and writers that the day of the child welfare service is over, but he felt that a time had come for a frank examination of its problems. He pointed to disappointing figures at child welfare centres in Newcastle; only 30% of the infants were taken to the centre 10 or more times in the year. In health visiting, again, the other pillar of the child welfare service, he found room for improvement; in particular the health visitor should be taken into the confidence of the medical officer of health. Regular visiting in all areas should be replaced by selective visiting, with concentration on the people who did not attend clinics, and in each district, without formal plans being made, the health visitor should be encouraged to get in touch with the family doctors.

ledge of applied psychology? The statement 'He's only a G.P.' is heard far too often, and unless something is done to get things into their proper perspective, the general standard of medical care will be seriously prejudiced."

Expertise in one facet of an almost limitless subject should not connote superiority. But Dr. Topping went on to ask why either the consultant or the family doctor should be considered superior to the doctor who elected to specialize in community health—a field almost as wide as that of general practice. The reason was not far to seek—there was nothing spectacular in removing the conditions which predisposed to tuberculosis, but a successful thoracoplasty or an avoidable tuberculous meningitis cured by streptomycin may qualify for a banner headline.

Occupational Health and Housing

Questions of occupational health took a larger place than usual in the Congress. Dr. ANDREW MEIKLEJOHN, president of the section, suggested that too much emphasis was placed on the contribution of medical service to industrial production. Such a contribution would, of course, come about as a result of efficient medical service, but it was not the primary purpose. He also said that the occurrence of accident or disease in industry was too apt to be ascribed to the human element, often meaning by that term a factor beyond control. In fact, not infrequently the cause was just carelessness, indifference to the welfare of others, or plain laziness. In other instances, important to the industrial medical officer, it arose from physical, mental, and social strains, not necessarily a part of the job, but influencing its working efficiency. Dr. Meiklejohn was a little disturbed by the tenor of some of the advocacy for a comprehensive occupational health service not restricted to factories, but embracing all workers, wherever and however employed. The attainment of an occupational health service need not involve emotion or over-statement. It would come about from the workers themselves, who, enjoying the benefits of proper homes which they alone could provide by more urgent effort, would not tolerate inferior or noxious conditions at work.

Several papers dealt with housing, one of them by the Chief Medical Officer of the Netherlands, Dr. C. BANNING, who said that statistics in Holland had failed to reveal a correlation between tuberculosis and bad housing. On the other hand, it had been shown that the children who came to child guidance clinics were in the main children from overcrowded and shared houses. Bad housing conditions played an important part in the field of mental health, and 30% of Dutch families shared their homes with others. A similar theme was developed by Dr. J. V. WALKER, M.O.H., Darlington, who, discussing housing priorities, said that less damage was done (and less housing priority therefore required) in homes with a distressing case of illness, provided there was family affection, than in the household where everybody was at odds, although superficially all appeared to be in reasonable organic health. Psychological strain, he considered, might be a reason for housing priority.

The Ageing Population

A session was devoted to the problem of the ageing. Dr. BLYTHE BROOKE, M.O.H., Finsbury, reminded the Congress that the number of persons over 65 has increased sixfold during the last hundred years; they now account for 11% of the population, and by 1977 may be expected to account for 16%. The proportion is now higher in Great Britain than in any other country except Belgium, though Switzerland comes close. He also pointed out that what these people stand in need of is more than occupation, it is a share in the life of the community.

Medical officers and executives of industrial organizations described various schemes for employing elderly workers.

The final meeting of the Congress was concerned with tropical hygiene, when Dr. JOHN LOGAN, of the Division of Medicine and Public Health of the Rockefeller Foundation, discussed environmental control in the Tropics, its

problems and opportunities, and Dr. L. D. KHATRI, deputy inspector-general of the Medical and Health Services of the Hyderabad Government, gave a remarkable account of anti-plague measures in Hyderabad State. D.D.T. was introduced as an anti-plague measure towards the end of 1949, first in Hyderabad city, and then in the endemic zone in the State. In that year the number of plague cases had been 6,858, and the number of deaths 2,069. In 1951 the numbers were respectively 464 and 104, and in 1952 they were 17 and 2. It should be stated, however, that 1949 was a year of political disturbance, and the existing anti-plague organization broke down. The figures for some of the previous years were rather lower, but since 1944 the number of cases had always run into four figures, and only in one year was the number of deaths below 1,000. From September to November, 1952, with timely and intensive treatment with D.D.T., not a single case of human plague was reported.

Reports of Societies

ANNUAL CONGRESS OF THE OPHTHALMOLOGICAL SOCIETY

The Annual Congress of the Ophthalmological Society of the United Kingdom was held from April 23 to 25 at the Royal Society of Medicine. On the first day Dr. A. MACRAE delivered his presidential address on "Prognosis in Malignant Melanoma of the Choroid and Ciliary Body." There then followed a number of short papers. After tea Professor Sir Geoffrey Jefferson delivered the Bowman Lecture on "The Syndromes of the Cavernous Sinus." The annual dinner was held at the Trocadero Restaurant in the evening.

Antibiotics in Ophthalmology

The remaining days were devoted to further short papers, some films and demonstrations, and a discussion on "The Scope of Antibiotics and Chemotherapeutic Agents in Ophthalmology."

Professor ROBERT CRUICKSHANK, who opened the discussion, declared that the variations in the sensitivity of bacteria, and the possibility of otherwise sensitive organisms developing resistant variants, made it essential that antibiotics should be used only for the treatment of specific infections and not for the treatment of clinical syndromes. If this was to be done there must be close collaboration between clinician and bacteriologist. Possible toxic manifestations of antibiotics and chemotherapeutic agents must always be remembered: allergic reactions, blood dyscrasias, and secondary effects resulting from elimination of normal flora were among the most important. Local irritation or necrosis was especially important in ophthalmology and might be assessed by the effect of antibiotics on tissue cultures. Drug resistance could sometimes be overcome or prevented by combining two chemotherapeutic agents. Synergetic effect might be obtained by using two bactericidal substances; there was a possibility, however, of antagonistic action when a bactericidal drug was used in combination with a bacteriostatic substance.

Professor ARNOLD SORSBY pointed out that the eye was pharmacologically a double organ. Diseases of the external eye responded to antibiotics in the same way as diseases of other tissues of the body. However, drugs given systemically were prevented by the blood-aqueous barrier from entering the intraocular fluids and cornea freely. Consequently the treatment of infections of the interior of the globe and cornea presented special problems. Small concentrations of antibiotics could be found in the aqueous after enormous systemic doses, but only penicillin was sufficiently non-toxic to allow such dosage. Subconjunctival injection was required if high intraocular concentration was to be obtained. Antibiotics suitable for this method of administration were penicillin and streptomycin in solution and chloramphenicol in micronized suspension. Of the

relatively non-toxic members of the sulphonamides, sulphamerazine was the most likely to be effective in intraocular infection, as it penetrated the blood-aqueous barrier the most readily.

Mr. DEREK AINSLIE then described a hitherto little-used antibiotic, polymyxin, the particular property of which was its powerful bactericidal effect against the Gram-negative bacillary organisms. He had found it suitable for subconjunctival injection, and when given in this way it was effective against both experimental and clinical infections of the cornea due to the destructive *Ps. pyocyanea*.

In the discussion which followed, Dr. G. SAUBERMANN (Switzerland) said that intraocular infections could be treated with aureomycin given intravenously. Dr. H. MILLER (France) had found that the application of antibiotics to a scarified area of the sclera induced intraocular penetration.

Nova et Vetera

PELICANS AND PINCERS

Old Instruments Used for Extracting Teeth. By Sir Frank Colyer, K.B.E., LL.D., F.R.C.S. (Pp. 245; 283 figures. 42s.) London and New York: Staples Press. 1952.

In Britain a separate dental qualification has existed for less than a century; before that teeth were extracted by surgeons, apothecaries, barbers, and quacks, and perhaps even by some physicians. The evolution of the instruments used for the extraction of teeth should therefore interest not only the dental but all branches of the medical profession, and their curiosity will be amply satisfied by the perusal of Sir Frank Colyer's book. The name of the author is sufficient guarantee of the accuracy and thoroughness of the historical research. The book is based on the Wallis memorial lecture delivered in 1938, and the unavoidable delay in publication has enabled much new matter to be added, so that, as now issued, it must be the most complete available account of all the instruments used for dental extraction from the dawn of history until modern times.

We are told there is no evidence that there were any special dental instruments known to the Egyptians, and that extraction of teeth, though practised by the Greeks, was by them confined chiefly to loose teeth, so that one of their writers commented: "As to the pincers for pulling out teeth, anyone can handle them." Yet we have no reliable illustration of dental instruments until the eleventh century in the work of Albucasis. A gap of three centuries then ensued, when Arcoli, in a commentary on a book by Rhazes, also described and illustrated such instruments. From the sixteenth century onwards we meet with many books describing a varied assortment of instruments which can be classed as pelicans, keys, elevators, and forceps, and it is under these headings that Sir Frank has described the multitude of weird and wonderful devices used by ingenious and sometimes misguided inventors. To the uninitiated it would appear that some of the instruments were too cumbersome and complicated, and we felt sympathetic with the remarks of Serre, who wrote of one curious instrument: "Such an invention could only originate from an author to whom the art was not perfectly known. . . . I know of only one dentist who has this instrument and I believe he has it only for exhibition to the ignorant." Let the reader study attentively the numerous well-produced illustrations and judge for himself if he could have told what was the purpose of the instruments pictured in Figs. 258 and 273. Probably everyone will agree with the last paragraph in the book, which reads: "This survey of the instruments used in olden days for the extraction of teeth must leave us with the grateful feeling that the use of anaesthetics and more scientifically constructed appliances has rendered the operation a less terrifying procedure."

The reader will note that many of the illustrations are from instruments in the Odontological Section of the

Museum of the Royal College of Surgeons, a unique collection which should be better known than it is. Let no one be deterred by the fact that the Colyer Museum is housed in a rather remote underground part of the College. It should be visited by every dentist and everyone interested in the history of this branch of surgery.

The most interesting fact in the book occurs on p. 57, where we learn that the oldest dental instrument in this country is housed, of all places, in the Royal College of Physicians. Is this a relic of a surgical past?

V. ZACHARY COPE.

Preparations and Appliances

THE LONG T-TUBE

Mr. RODNEY MAINGOT, surgeon, Royal Free Hospital, writes: The long T-tube, as illustrated, is a modification of the Kehr and the Cattell tubes which are now so often used in the surgery of the bile ducts. The tube is made of pure latex rubber, has a diameter of 10 English gauge (18 French gauge), is strong and durable, and is moulded into a single unit in order to avoid any weakness or defect at the point of union of the two limbs. The cross-limb measures 12 in. (30 cm.), whilst the other limb (which is led to the surface of the abdomen for drainage purposes at the end of the operation) is 13 in. (32.5 cm.) in length.

This T-tube may be employed with gratifying results after exploration of the bile ducts for choledocholithiasis; reconstructive operations upon the biliary passages for simple or malignant strictures; transduodenal choledochostomy for impacted stone in the ampulla, papillitis, fibrosis of the sphincter of Oddi, or excision of a small neoplasm of the papilla of Vater; and graduated dilatation of the lower reaches of the duct in cases of relapsing or recurrent pancreatitis. It has also proved most helpful in some difficult and hazardous gastro-duodenal resections for large, oedematous, and deeply penetrating posterior-wall duodenal ulcers.

For the common case of choledochostomy for stone in the bile ducts, after the ducts have been cleared of calculi and debris and after the ampullary region has been adequately dilated with flexible Bakes dilators, it is customary to trim the short arm of the T-tube to the requisite size so that one portion lies in the common hepatic duct whilst the other portion lies in the common bile duct. After the opening in the choledochus has been closed in a watertight fashion the long arm of the T-tube is led to the exterior.

For most of the other lesions which have been mentioned, it is advisable to pass one portion of the short arm of the T-tube downward, through the choledochostomy opening, into the duodenum, whilst the other portion above the "join" is pruned down so that it can be readily placed in the common hepatic duct.

So far as can be ascertained, there is little, if any, reflux of duodenal contents into the biliary tree, whilst the advantages of employing this indwelling tube, for the types of cases I have described, are considerable.

After many trials and adaptations this T-tube, as now made by John Bell & Croyden, Wigmore Street, London, W.1, has proved of inestimable value in the surgery of the bile ducts, and also in the occasional case of partial gastrectomy for the large callous penetrating ulcer of the duodenum.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Apnoea in Anaesthesia

SIR,—In your leading article (*Journal*, April 18, p. 875) on apnoea in anaesthesia the sting lies in the tail. The final sentence reads: "Further, the differential pressure changes occurring in the lungs and respiratory tract should not be such as to cause disturbance to the cardiovascular system." I believe that many physiologists will be surprised to learn that positive pressure ventilations can be carried out at all without causing some disturbance in the cardiovascular system. The disturbance is small, no doubt, usually well tolerated, and more than compensated by the other advantages of quiet, full ventilation which perhaps can in the particular circumstances be secured only by positive pressure inflation.

Nevertheless there are still anaesthetists so old-fashioned as to believe that in certain cases the unavoidable slight disturbance of cardiovascular function consequent upon positive pressure inflation may become of critical importance. I believe that there are critically ill patients who do better if they are allowed to breathe for themselves, and it seems to me that it is the anaesthetist's business to balance the risks and pick these cases out. One often has to do a little harm in order to achieve more good, but it seems wrong to lose sight of the fact that the "little harm" is a real thing.—I am, etc.,

Newcastle-upon-Tyne.

E. A. PASK.

Modern Anaesthesia in Prostatic Surgery

SIR,—I was most interested in the letter by Dr. H. W. Loftus Dale and his colleagues on the use of spinal plus regional analgesia for prostatectomy (March 28, p. 727). I have been using this method for several years and my experience covers over 200 cases, including many elderly and poor-risk cases.

The technique I use is briefly as follows. Premedication, morphine $\frac{1}{4}$ gr. (8–11 mg.), atropine 1/100 gr. (0.65 mg.), given one hour before operation. Frequently quinalbarbitone sodium $\frac{1}{4}$ gr. (0.1 g.) is given before commencing the anaesthetic. Ephedrine-procaine 1 ml. solution is injected intraspinally; then, after administering a low spinal anaesthetic using heavy cinchocaine, a field block of the lower abdomen is performed. The anaesthetic solution consists of 200 ml. of 1 in 2,000 amethocaine hydrochloride solution to which 0.5 ml. 1 in 1,000 adrenaline and one ampoule of hyaluronidase are added. The ilio-inguinal and ilio-hypogastric nerves are blocked on each side medial to the anterior superior iliac spine, and a bilateral lower rectus sheath block is carried out. Anaesthetic solution is then infiltrated along the midline from umbilicus to pubis. Finally, a few millilitres of solution are infiltrated into the neck of the scrotum on each side of the division of the vasa. The procedure is a little more difficult in obese patients, but the use of a longer needle with, perhaps, a little more anaesthetic solution will usually provide a satisfactory result.

This form of anaesthesia produces an excellent operating field for the surgeon. There is minimal respiratory muscle paralysis, so that the patient tolerates the Trendelenburg position very well. The fall in blood pressure is rarely very great and is usually adequately controlled by one or two small intramuscular injections of a vasopressor. In our experience reactionary haemorrhage and clot retention are uncommon. I would like to endorse Dr. Loftus Dale's opinion of the value of this method of anaesthesia for prostatectomy.—I am, etc.,

Salford.

MARK SWERDLOW.

Cerebrospinal Fluid Pressure

SIR,—I was interested in Dr. David Bowsher's article (*Journal*, April 18, p. 863) on the C.S.F. pressure, in which there are many important points which must be challenged.

Dr. Bowsher says, "Fluids are virtually incompressible, and so do not obey Boyle's law." For "fluid" surely is here meant "liquid"; according to the *Shorter Oxford English Dictionary*, fluid is "a general term including both gaseous and liquid substances consisting of particles that move freely among themselves so as to give way before the slightest pressure," whereas a liquid is "a material substance in that condition in which its particles move freely over each other (so that its masses have no determinate shape) but do not tend to separate as do those of a gas. Fluids are divided into liquids, which are incompletely elastic, and gases, which are completely so." The use of the words fluid and liquid as synonymous is a common mistake, but should not occur in a scientific statement. It follows from this that Boyle's law has no relevance to the argument, the law being that the volume of a gas varies inversely as the pressure. Although for practical purposes liquids may be considered incompressible, nevertheless under great pressure there is a slight diminution of volume, and up to pressures of 65 atmospheres the compression is proportional to the pressure. It follows that a closed rigid container may be filled to capacity under atmospheric pressure (that is, zero pressure if we choose to call it so for simplicity's sake), or it may be filled under any pressure chosen. In the example given (Fig. 1) extra liquid introduced into the cylinder will rise in the U-tube, by displacement, and will indicate by the height of its new level the pressure within the cylinder. A motor-car could not be raised by a hydraulic jack if pressure were not imparted to the liquid contents.

In Fig. 3 we are not informed of the units of the axes of the graph, but it is clear from visual measurements that there is a considerable alteration of pressure between A and B, whatever units of pressure may be employed. Surely the pressure within the elastic tube necessary to change its cross-section from ellipse to circle will depend also on forces acting outside the tube; if we are dealing with a vein in the subarachnoid space, it will depend on the C.S.F. pressure around the vein, tending to collapse it, as well as on its elasticity (or rigidity) and the intravenous pressure. Applying his argument, Dr. Bowsher states that a volume increase in the tube bringing it from an elliptical to a circular cross-section will cause no increase of pressure—although his graph shows there is an increase of pressure which he contends is small—but will displace liquid into the U-tube, which elevates the height, H, by the additional h_1 . This h_1 is clearly the manometric increase of pressure; his manometer is not only measuring volume, it measures pressure, which he seems to ignore.

"The dura is inelastic." This statement is incorrect, as anyone who has watched a craniotomy in a case of high intracranial pressure can observe for himself. When the bone flap is raised, the dura mater will immediately stretch slightly but unequivocally. And if before the dura mater is opened the bone flap is replaced it will be found to be "riding" in its defect and will need force to be rendered flush with the surrounding cranium, in its former position.

"Partially collapsed veins can be changed from elliptical to circular cross-section without increase in pressure." This misleading statement has been dealt with above, and is disproved by the published graph Fig 3. And if an increase in intravenous pressure does not change them, what does?

Dr. Bowsher later states that "it has hitherto been held" that the rise in the pressure of the C.S.F. (presumably in the lumbar theca) on abdominal compression is due to failure of C.S.F. to be absorbed while its secretion continues. I do not know who has held this view, but it is certainly neither held nor taught in knowledgeable neurological or neurosurgical circles. It has been taught for many years that such a rise is due to the increase of pressure in abdominal veins being communicated to the vertebral plexus of veins and thereby the lumbar C.S.F. In Queckenstedt's test, the compression of the jugular veins leads to distension of the intracranial veins, as Dr. Bowsher correctly states, and they distend (or become circular) because the pressure within them rises inevitably; and there is some displacement of C.S.F. into the spinal theca. The pressure within the cranium rises, and can be measured by a manometer attached to a needle in the ventricle, and the pressure rise can also be measured by lumbar manometry. Dr. Bowsher here puts the word pressure in inverted commas; does he not believe he is measuring pressure with his manometer? Of course, the quantity of liquid filling his manometer vitates to some extent the actual figure of the

pressure; his reading will be slightly less than the actual pressure present before he connected up his manometer. And to render this error as small as possible all spinal manometers should be constructed with tubing of as fine a calibre as is practicable.

"The dura must therefore be looked upon as adhering to the cranium and vertebral canal." Yes, the dura (except for its great partitions) is adherent to the inner surface of the skull; that is an anatomical fact, and for that reason only the dura covering the brain in the intact skull can be considered inelastic. But the dura is not adherent to the spinal canal; that also is an anatomical fact and cannot "be looked upon" as anything else. Weed and others, to whom Dr. Bowsher refers, realized this, and on the presence of this extradural spinal space containing veins and fatty areolar tissue rests their explanation for their various "tilting" experiments to which Dr. Bowsher refers. Indeed, in certain positions this spinal extradural space is under negative, that is, less than atmospheric, pressure. Were the dura not loose in the spinal canal displacement of C.S.F. from the cranium could only occur at the expense of spinal venous blood.

Dr. Bowsher makes other comments concerning the maintenance of the normal C.S.F. pressure, a subject much too large to be dealt with by correspondence, and I have already trespassed excessively on your valuable space. May I suggest that he refers to a summary of this subject in the section on the nervous system in *Recent Advances in Surgery* (Churchill, 1948), where the more important references may be found. Finally, in his summary Dr. Bowsher states that "there has been a fundamental misconception with regard to spinal manometry": I suggest that the misconception lies with Dr. Bowsher.—I am, etc.,

London, E.1.

D. W. C. NORTHFIELD.

SIR,—How comes Dr. David Bowsher to ignore in his article, "The Cerebrospinal Fluid Pressure" (*Journal*, April 18, p. 863), the work of the late Sir Leonard Hill on this subject,¹ the correctness of which, as I have stressed,² is verified clinically by observation of the retinal venous pressure response at the disk?—I am, etc.,

Nottingham.

THOMSON HENDERSON.

The Training of Physiotherapists

SIR,—A certain prominence has been given lately in medical journals to the training of physiotherapists, and we feel that certain points ought to be clarified for the medical public. Physiotherapists in this country belong to three groups: (1) the Physiotherapists Association, (2) the Faculty of Physiotherapists, and (3) the Chartered Society of Physiotherapy. The Cope Report, drawn up by a committee of nine members, six of whom were in active association with the Chartered Society, whereas the other two bodies were not represented, recommended to hospital authorities to employ exclusively members of the Chartered Society; and the first circulars of the Ministry of Health were drawn in this spirit. The injustice of this Report, however, has been rapidly realized, and the Minister of Health stated in Parliament on March 19 that the Cope Report would not be implemented, and that he would further withdraw the temporary instructions in the Ministry circular referring to the employment of chartered physiotherapists, and make new regulations fair to all associations concerned.

We are at a loss to understand this tendency of the Chartered Society to monopolize physical treatment in this country. Apart from the fact that it goes against the liberal principles that dominate medical work, nothing has demonstrated the superiority of the members of the Chartered Society over those of the other associations of physical treatment practitioners. We must emphasize that hospitals employing members of the Physiotherapists Association and the Faculty of Physiotherapists are perfectly satisfied that the training of members of the Association and the Faculty is not inferior to that of the Chartered Society.

We are astonished at the boosting of the Chartered Society training in the letter by the president and vice-

chairman of the council of that society (*Journal*, March 14, p. 615). The "schools" to which he refers are neither owned nor controlled by the Chartered Society, but are part of State hospitals. Thus the Chartered Society is using publicly owned and publicly maintained hospital facilities to bolster its monopolies. This, by the way, is an anomaly which undoubtedly will be corrected by Parliament. The education plan formulated by the Physiotherapists Association, and supported by education authorities, experienced teachers, and the medical profession, provides for the co-operation of the technical colleges and teaching hospitals. Physiotherapy training schools should be a part of a university and the physiotherapy qualification should be a recognized university diploma. The present standard of the Chartered Society, on whatever level it is assessed, is parochial compared to the real aim of producing a physiotherapist who can take his place as an accepted member of a medical team, receiving alike the support of the medical profession and the confidence of the public.—We are, etc.,

A. P. CAWADIAS,
President.

The Physiotherapists Association,
London, W.1.

S. S. KNIGHT,
General Secretary.

The Metric System

SIR,—I think Dr. J. W. Shackle (*Journal*, April 18, p. 887) has confused the origins of the ml. and c.cm. The litre, as now defined, has no relationship to the metre and is not based on any linear measurement at all. Hence the thousandth part of a litre is not a cubic centimetre. The fact that the new litre has a volume of 1,000.027 c.cm. is a tribute to the skill of our forebears, and means that for practical purposes the thousandth part of the old litre (c.cm.) and new litre (ml.) can be regarded as identical. There is one volume used in medicine, however—namely, that of the haemocytometer chamber—which is still based strictly on a linear measurement. Haematologists are correct in using the term cubic millimetre, and would be wrong to speak of a "millimil."

I think Dr. Shackle may be unaware of the historical basis of all this, and would respectfully refer him to an excellent article on it by Dr. J. M. Hamill.¹

Dr. Shackle rightly mentions the danger of the misplaced dot. May I remind your readers that a misplaced "squiggle" on the drachm sign is also dangerous? There are many published examples of overdosage from this.—I am, etc.,

Enfield.

C. ALLAN BIRCH.

SIR,—So far, no serious arguments have been made against the introduction of the metric system into medicine. The latest one, advocated by Dr. R. A. C. Herron (*Journal*, April 25, p. 938), seems utterly frivolous. If I understand him correctly, the metric system should not be used because "for some reason of habitual usage" no one in Zurich would understand what is meant by 0.5 mg. or half a milligram. Apparently it is necessary to say or write 0.0005 g. If milligrammes were regularly used for small doses, fractions of any sort would only occasionally be used, for, as near as makes no difference, 1 mg. = 1/60 gr., 0.5 mg. = 1/120 gr., and doses smaller than 1/120 gr. are seldom used. If very small doses are employed then micrograms (μ g.) are very convenient—e.g., 50 μ g. of vitamin B₁₂ (= 0.05 mg., or gr. 1/1200).

Dr. John Primrose (*Journal*, April 4, p. 782) says he uses the metric system for his scientific work but prefers to "prescribe opiates in vulgar fractions of a grain." Why is morphine gr. $\frac{1}{4}$ more convenient than 15 mg. of morphine? No one would dream of prescribing pethidine in the old system. It is purely a matter of what one is used to, and there is a lot to be said for getting rid of these fractions of a grain, which sometimes are absurdly small, as the dose of digitaline, which is gr. 1/600 in the old system.

A great deal has been written about the allegedly cumbersome numbers used in the metric system. For instance, Dr. C. Langton Hewer (*Journal*, February 21, p. 450) quotes the pre-anaesthetic dose of paraldehyde as 3.55 ml. per 6.35 kg., but the approximate metric equivalent is 0.5 ml. per kilogram, which has already been pointed out by Professor W. C. W. Nixon and Mr. T. D. Whittet (*Journal*, March 14, p. 619). It cannot be too strongly emphasized that exact equivalents are not required. Doses in the old system are *adjusted* to the convenience of the system, and in general "round numbers" and "simple fractions" are employed—for example, 5 gr., 30 gr., $\frac{1}{4}$ gr., $\frac{1}{100}$ gr., etc. If doses now ordinarily expressed in the metric system are accurately changed into the old system, equally cumbersome figures are obtained—for example, 1 g.=15 $\frac{2}{5}$ gr. and 1 ml.=16 $\frac{9}{10}$ minims. No one has used this argument against using the old system, but it equally applies.

There is no doubt that the metric system is simpler and far less cumbersome than the old system. All medical students would welcome it, and its introduction into medicine would bring our subject into line with all the other sciences all over the world. I have vivid memories of my dismay in having to learn and understand the apothecaries' system after having used and easily understood the metric system for years while doing science at school and at the university. British and American textbooks and journals are extensively read in other countries, and the old system of dosage often employed must be incomprehensible to many readers, even when they have a perfect knowledge of English.—I am, etc.,

Thornton Heath.

G. P. BAKER.

Iron Therapy

SIR,—I have followed the correspondence on iron therapy with interest and await the results of the investigations of Professor P. Larizza and Dr. S. Ventura (*Journal*, April 18, p. 885).

As a general practitioner, my chief worry has always been the tolerability of iron compounds. I decided to carry out a clinical test of ferrous gluconate, the results of which were published in February this year.¹ I found that a ferrous gluconate preparation gave most satisfactory results. Not only is it an adequate substitute for ferrous sulphate, but causes no digestive disturbances whatsoever. I would draw this new preparation to the attention of all general practitioners who have been bothered, as I have been bothered, by the inability of a large proportion of secondary anaemias to tolerate ferrous sulphate and other compounds.

To quote your Italian correspondents, it may be incautious to infer that ferrous gluconate used by itself is a more efficient haematinic than ferrous sulphate, but I am prepared to assert from the results I have obtained that it is every bit as good, and its easy tolerance and absence of side-effects make it by far the most useful preparation that we have available to-day.—I am, etc.,

Cardiff.

Blood Grouping and Cancer of Stomach

SIR,—Professor Ian Aird and his colleagues (*Journal*, April 11, p. 799) appear to have shown that persons of blood group A have a greater susceptibility to cancer of the stomach than have those of blood group O. Such studies of varying susceptibility to disease should be vigorously pursued because information of immediate practical value may be obtained. For instance, Chevallier and Desoille¹ showed that workers who handle benzene and are of blood group O are much more susceptible to ill-effects than are those of blood group A, while those of blood groups B and AB have a susceptibility intermediate between these two groups. Indeed, these authors go so far as to suggest that the possession of blood group A should be essential for all workers in benzene. Unfortunately, this work has not, so far as I can discover, been pursued either in France or elsewhere. Of less immediate practical importance is the apparent fact that more leukaemics are of blood

group A than of blood group O, while haemorrhagic diseases seem to be most common among people of group O.

Unfortunately the published work has dealt with relatively small series of cases, but if the workers and funds were available it should not be difficult to collect a large series of observations from the records of the hospitals of this country.—I am, etc.,

London, W.1.

A. PINEY.

Respiratory Function

SIR,—Dr. K. W. Donald, in Part I of his article on the assessment of respiratory function (*Journal*, February 21, p. 415), remarks that it is still not known why a person should be uncomfortable when exercise causes him to ventilate about half the air that he can shift at rest without distress, by voluntary hyperventilation.

Could the answer be that during exercise the cardiac output is greatly increased from both sides of the heart and the pulmonary vascular bed becomes dilated and even new channels opened up, with a great increase in the quantity of blood in the lungs? This will prevent full alveolar expansion and ventilation, a condition somewhat analogous to the pulmonary congestion of mitral stenosis. Has the blood volume of the lungs during exercise been compared with that during voluntary hyperventilation?

Secondly, during exercise an oxygen debt is built up and there is a temporary anoxaemia not present during voluntary hyperventilation. This will have an additional effect of increasing the dyspnoea.—We are, etc.,

Champion Reefs, S. India.

GEOFFREY FFRENCH.

B. N. KRISHNAMURTHY.

Erythrocyte Sedimentation Rate Irregularities

SIR,—The recent papers on erythrocyte sedimentation rate irregularities by Gilmour and Sykes¹; Goldberg, Glynn, and Bywaters²; Goldberg and Conway³; and Alexander⁴ prompt me to report the findings of my own investigations, which were begun in 1949.

One of the disadvantages of the Westergren method is the difficulty of obtaining at the bedside the exact degree of dilution of blood with sodium citrate solution. It was thought that such dilution errors could be overcome by the use of heparin (solid) as an anticoagulant. Very irregular E.S.R.s were observed by this method—one patient with an E.S.R. of 60 mm. appeared to have an E.S.R. of 5 mm. a week later. It seemed that the change of anticoagulant might be the cause of these anomalous readings, and so the matter was investigated. It was found that irregular (low) one-hour readings were associated with the use of solid anticoagulants such as heparin and the oxalate mixture of Heller and Paul.⁵ These irregularities were found to be caused by an excessive prolongation of the aggregation phase of sedimentation (Cutler⁶) due to an inhibition of rouleaux formation. This inhibition occurred more frequently in deoxygenated blood, and it was found that, if blood known to have a high E.S.R. was equilibrated with carbon dioxide, rouleaux formation was so inhibited that the one-hour E.S.R. reading was reduced to normal limits. This inhibition appears to be a metastable state, for after an interval of 30–50 minutes the *whole column* of blood suddenly becomes coarsely granular (intense rouleaux formation) and very rapid sedimentation then occurs. If this inhibition lasts over 45 minutes and the E.S.R. is read at one hour a falsely low reading will result. This metastable state might be considered to be a hysteresis phenomenon. Such prolonged inhibition of rouleaux formation could not be obtained with blood using a liquid anticoagulant (3.8% sodium citrate solution). E.S.R. irregularities with blood using a solid anticoagulant were eliminated by diluting this blood with 3.8% sodium citrate solution.

This phenomenon appears to be the same as that originally observed by Lundgren⁷ in hirudinized blood. The effect of CO₂ and O₂ on the E.S.R. has in the past been considered

to be unimportant, for, though CO₂ was found to decrease and O₂ to increase the E.S.R., the changes were found to be small (Leendertz⁸ and Ito⁹). These findings were based on experiments using liquid anticoagulant—3.8% sodium citrate solution as originally used by Fåhræus.¹⁰ When the solid oxalate mixture of Heller and Paul began to be employed for the determination of the E.S.R. by the Wintrobe method, it appears that previous work was not repeated to ascertain whether findings related to liquid anticoagulants also applied to solid anticoagulants.

Full details of this work have been submitted for publication.—I am, etc.,

Subserous Duodenal Haematoma

SIR,—In his medical memorandum (*Journal*, March 28, p. 712) Mr. D. I. Stirk records a case of subserous duodenal haematoma resulting from a "non-penetrating and apparently trivial injury." I should like to record a similar case in which the injury was sustained in an identical manner.

A child aged 6 years was admitted to hospital four days after a blow in the left hypochondrium from the handlebars of his bicycle. After the injury he continued his journey home, but subsequently complained of recurrent bouts of upper abdominal pain, followed in 24 hours by anorexia and vomiting of bile-stained fluid. An enema had been given on the second day with a good result. On admission to hospital the child was found to be slightly pyrexial, had a dry tongue, and abdominal examination revealed rigidity of the left side, maximum in the left hypochondrium. Rupture of the spleen was diagnosed and laparotomy advised. This showed absence of any free fluid in the peritoneal cavity, but revealed a large tense black sausage-shaped swelling about 6 in. (15 cm.) in length in the region of the upper jejunum. This was thought to be gangrenous bowel, but immediately this was touched the tense lesion burst and extruded a quantity of black blood clots. The lesion was then discovered to have been a subserous haematoma. The first 15 cm. of the jejunum and its mesentery appeared to be grossly disorganized and was resected. An end-to-end anastomosis at the duodeno-jejunal flexure was done. The child made an uneventful recovery. Examination of the specimen showed disorganization of most of the tissues by blood clot, but the actual bowel mucosa appeared to be healthy.

It is of interest to note that this injury occurred in the same fashion as the case reported by Mr. Stirk—that is, by a child riding a bicycle. There were no external signs of bruising and the injury at first seemed trivial, its effects being seen only after some hours. This lesion is quite distinct from a traumatic rupture of the mesentery with free intraperitoneal haemorrhage, and its signs are delayed in onset. This is a point well to be borne in mind when one remembers that these types of accidents commonly find their way to casualty departments and are often first seen by a junior member of the hospital staff.—I am, etc.,

Ipewich.

A Paper Not Read

SIR,—Several most serious issues for the medical profession as a whole are involved in the case of *Crawford v. Charing Cross Hospital*. Having attended the whole proceedings and heard the judgment, the features which cause the greatest concern are the following:

Nothing was done or left undone which in any way departed from widely accepted practice at that time, practice which had indeed never produced a palsy throughout the long professional career of the anaesthetist.

The angle of abduction was within the right angle—to quote the judgment: "an angle of 80 degrees or thereabouts."

Mr. Justice Gerrard expressed the view that he did not think the problem of negligence or no negligence turned upon current practice. He admitted the advantages of abduction of the arm for good blood flow and general observation.

Mr. Ewing¹ had warned against the dangers of abduction. The anaesthetist, never having met a brachial palsy and therefore considering his precautions adequate, did not read the article in spite of being aware of its existence. To quote the judgment: "Nice questions might arise as to how far a medical man could excuse his ignorance of a technical development that he had not met in his reading of his professional journals." It was the anaesthetist's "duty to follow up the writings on a subject which concerned him closely." "I think it was regrettable slackness that left Dr. X in ignorance of the opinions of distinguished men on an important subject so closely affecting his own work at the time he came to administer the drip to the plaintiff."

Does written advice transcend in importance long practice and experience in guiding our actions?

We practise our profession at first largely as we have learnt it from our teachers, and improve as the years go by from our own experience combined with discussion and selective reading from the vast modern output of literature. Current practice is always lagging—and often how rightly so—well behind the pioneers of new methods. This dangerous precedent that such practice can become negligent within a few months of a new paper is one which must be fought in the Court of Appeal and even, if need be, in the House of Lords.—I am, etc.,

London, W.1.

Dosage of Stilboestrol

SIR,—With reference to recent correspondence regarding the dose of stilboestrol the following observations may be pertinent so far as prostatic cancer is concerned.

In treating this condition the optimum dosage is basically determined by the amount of oestrogen required to control or retard the progress of the growth, qualified by there being no unreasonable risk that this quantity will evoke dangerous side-effects or complications. With regard to the former, objective evidence of tumour control can only be directly adduced from serial histological examination in cases where repeated biopsy is practicable during treatment. At the same time, owing to known variations in the natural course of the untreated disease, indirect information afforded by a study of the survival periods of patients receiving oestrogens will only establish the efficacy of a particular dosage if a large series of cases is reviewed.

Both these aspects have received attention in a recent survey of a personal series of 150 consecutive cases of histologically proved prostatic cancer treated with oestrogens. These cases, extending over the period 1942–52, have been divided into three groups receiving respectively a sustained dosage of 1–5 mg., 15–30 mg. and (more recently) 100 mg. stilboestrol daily. Repeated histological examination of the growth on two or more occasions during treatment was possible in 33 patients,¹ and evidence was obtained to show that, after an initial favourable response to small and large doses alike, many tumours ultimately became oestrogen-resistant. In some instances, however, a tumour which had apparently become resistant showed further evidence of response to oestrogens when the dose of stilboestrol was increased, and a distinction was thus apparent between growths showing a relative and an absolute loss of sensitivity. Although in no case was complete regression of a tumour achieved, it seemed likely that a failure to obtain prolonged retardation of growth in some represented the effect of inadequate dosage rather than a spontaneous increase of biological activity. This view is supported by a study of the survival periods of the entire series of cases, in that the average duration (making appropriate allowance for the comparatively recent introduction of the highest dosage) seems to be significantly increased in those receiving larger amounts of stilboestrol.

It would appear, therefore, from the direct and indirect evidence afforded by these methods of investigation, that,

so far as tumour activity is concerned, sustained treatment with at least 100 mg. daily is advisable. It is frequently alleged that prolonged dosage of this magnitude is more liable to evoke troublesome nausea and vomiting than when smaller quantities are prescribed. In my experience, however, this has not proved to be the case, the few examples encountered having been treated satisfactorily either by subcutaneous oestrogen implants of comparable strength or by supplementary castration. More recently, in instances where the primary growth has responded well to oestrogens but in which metastatic activity has subsequently increased despite sustained therapy, a few advanced cases have been treated by bilateral adrenalectomy and cortisone substitution with gratifying immediate results.—I am, etc.,

Radioactive Phosphorus in Treatment of Menorrhagia

SIR,—We do not share Mr. D. K. Sambrook's cheerful opinion (*Journal*, April 18, p. 883) of x rays as a method of controlling simple uterine bleeding. In fact, our deep dissatisfaction with irradiation of the ovaries is based on studies of over 200 women who suffered from the side-effects of castration. For instance, the incidence of serious and persistent menopausal flushing and sweating is 50%, three times the normal, while the sudden onset of sexual anaesthesia or, at a later date, of senile vaginal changes must surely be considered as the cost of irradiation.¹ No doubt Mr. Sambrook, like ourselves, has to treat the side-effects of irradiation with oestrogens, but I am sure he will admit that it is a great nuisance to his patients and to himself, especially if his treatment creates a new and worrying symptom, post-menopausal bleeding. Our experiments with P³² were carried out in the hope that bleeding might be controlled without the effects of ovarian irradiation. We do not yet know if certain patients might resume normal menstruation after P³², nor do we know how many patients might reach the normal menopause.

We freely admit Mr. Sambrook's point that P³² cauterization of the endometrium does not attack the cause of the bleeding. In fact, in the vast majority of patients we do not know the cause, although we have discovered the wisdom of avoiding vague phrases such as "unbalanced production of oestrin" and "hyperoestrinism." The Birmingham students have a habit of asking us what we mean by such phrases. Both Mr. Sambrook and ourselves are recommending damage or destruction as therapy; we apply a β -ray "cautery" to the endometrium, he recommends x rays to the ovaries. We disagree with Mr. Sambrook in that we believe the ovaries are of importance at the menopause. It remains to be seen if there are ill-effects and dangers associated with irradiation of the uterus with P³². Lastly, we wish to state that our report was a preliminary one. We do not know if endometrial "cautery" by β -rays will prove itself as an effective therapeutic agent in menorrhagia.—We are, etc.,

Nikethamide by Mouth

SIR,—Unfortunately, it is letters like the one written by Dr. J. V. Cope (*Journal*, April 18, p. 885) that tend to make us "qualified quacks" in the eyes of specialists, hospital staff, and newly qualified doctors. It makes it difficult for G.P.s to obtain clinical assistantships, and will further remove us from scientific and accurate work demanded in hospital. The letter is entirely uncritical in description and coloured by erroneous subjective observations. We teach our patients

(wrongly) words like "cardiac debility" and in time become so enchanted by this meaningless word that we now try to teach it to each other instead.

Let us forget "subclinical cardiac debility" (which is so easily cured by nikethamide) along with "symptomless avitaminosis," "anaemia" when the haemoglobin is 98%, and "rheumatism of the knees" when the correct diagnosis is probably climacteric arthritis.

It is not the N.H.S. that has lowered our status as G.P.s but merely the fact that we now allow a much larger proportion of our patients to seek hospital advice and thus expose—I tried to avoid the phrase—the skeletons in our cupboards.—I am, etc.,

Luton.

H. JARVIS.

SIR,—May I endorse Dr. J. V. Cope's remarks on nikethamide by mouth and his appeal for further observations (*Journal*, April 18, p. 885), my own being frustrated by a shortage of cases of chronic bronchitis?

I was recently driven to prescribe nikethamide, 15 min. (0.9 ml.) orally in water, for severe paroxysmal dyspnoea in two advanced bronchitics with no clinical signs of heart failure. Both had already been treated with ephedrine, isoprenaline sulphate ("neo-epinine"), watery and oily adrenaline by injection, and "rybarvin" type inhalation. Both claim really dramatic relief and have been using it regularly for three months. This militates against the effect being purely psychological, together with the fact that I only imagined it to be a placebo myself and did not extol its virtue.

It is difficult to see why Dr. J. G. Macarthur (*Journal*, March 7, p. 547) did not start with usual dosages, though easy to appreciate that a patient in the throes of nausea and vomiting might report unfavourably or not very objectively on the agent which had caused it. Before estimating blood nikethamide levels and then consigning a possibly valuable paper and useful therapeutic agent to the dustbin, could he not also ask them how they react after a normal dose given orally—with appropriate controls, of course? This point has received somewhat cursory attention in the present paper, and, from what one can gather, will receive none at all in its sequel.

Whether this drug helps the patient is of rather more interest than its physiology.—I am, etc.,

Staines, Middlesex.

J. A. SINDELL.

Treatment of Ringworm of the Scalp

SIR,—Dr. S. Cochrane Shanks (*Journal*, April 4, p. 780) has written a similar letter on a former occasion.¹ No one doubts that, under the ideal conditions to which he refers, the chances of permanent alopecia following x-ray epilation are virtually nil. It may be that the continued embarrassment of prescribing wigs for the victims of earlier decades results in the over-emphasis of this therapeutic tragedy.

Some doubt exists, however, regarding the choice between an anaesthetic and the restraining couch, and not all radiotherapists, it seems, are in agreement with Dr. Shanks. Beare and Cheeseman,² reporting on 1,004 cases of scalp ringworm, advocate the use of anaesthesia for children between 1 and 3 years, mental defectives, and obstreperous subjects. Even if one encounters a case of *M. canis* infection that is "sufficiently persistent to warrant epilation"—and I have yet to do so—it should not influence one against the simpler and normally successful treatment. Nor would I expect the radiotherapist to abandon his x-ray epilation because of his occasional failure. During the Newcastle epidemic there were 13 "failed x-ray cases" in 1949.³

Without quoting a single reference, Dr. W. A. Dewar (*Journal*, April 14, p. 780) claims that the majority of authorities are in favour of x-ray epilation for *M. canis* ringworm. In fact, the reverse is true, and it would be unfortunate if such an ill-founded assertion were to gain credence. The mycologists, Lewis and Hopper,⁴ state:

"In several publications we have called attention to the tendency to spontaneous cure and to the success of local measures alone when tinea capitis is caused by *M. lanosum*." Muende⁵ writes: "The fact that animal microsporum infections usually respond to such simple treatment should encourage one to conduct careful cultural examinations of infected hairs before resorting to the commoner techniques of x-ray and thallium epilation." I would also refer him to Duncan,⁶ and Schwartz *et al.*⁷

Dr. Dewar considered that, to ensure against missed cases, routine Wood's lamp investigation should have been carried out at the schools involved in the investigation. The frequency of erythema reactions and also of coincident glabrous skin involvement as a means of diagnosing *M. canis* scalp infections renders this unnecessary.

Surely the experiment of waiving the school exclusion rule should be judged by the subsequent incidence of ringworm in the area concerned. Following on the cases reported up to March, 1952, three more cases occurred in March and two in May. All five came from different schools, at which they were of course allowed to continue attendance. From May, 1952, to April, 1953, not one case of *M. canis* ringworm has been reported in the County Borough of Newport.—I am, etc.,

BERNARD A. THOMAS.

Leprosy at Large

SIR,—The photographs I enclose were taken on March 23, 1953, two days after I found this case of leprosy in a rigor, hiding in a farm-labourer's cottage. The patient came to England a known and declared leper in 1947, and was for six months in a hospital for tropical diseases. She was discharged into our population to roam from home to home, hiding, as is the way of lepers, aided by her devoted husband. The condition of the husband, son, and home in the case that I now report was only what you would expect where the mother has no hands and virtually no feet. About a year ago another woman in this district with an unaccountable leonine frontal development was found by her

[A. T. Schofield, A.R.P.S.]

[A. T. Schofield, A.R.P.S.]

G.P. to have unsuspected leprosy. This letter is not intended to report the case clinically at this stage: it is intended to be a reminder of the existence in England of a disease one of the most striking social attributes of which is concealment. Its infectivity is low.

To admit lepers to England and not to follow them up may be followed by concealment, unnecessary suffering, crippling deformity, and thus a small additional burden to the community. This matter has already been vigorously represented by the district medical officer of health to the Ministry of Health and to his Member of Parliament without any alteration to the existing legislation concerning the notification and control of this disease.—I am etc.,

Steeple Ashton, Wilts.

FITZ HAYTHORNTHWAITE.

** The Public Health (Leprosy) Regulations, which provide for the notification of cases of leprosy direct to the Chief Medical Officer of the Ministry of Health, came into operation on June 22, 1951, several years after the discharge from hospital of the patient described by our correspondent.—ED., B.M.J.

West Memorial Lecture

SIR,—The students of the Welsh National School of Medicine have decided to establish a suitable memorial to the late Professor Cecil McLaren West, Professor of Anatomy in the school from 1927 until his untimely death in 1951. It is agreed that the memorial should take the form of a biennial lecture to be delivered in the medical school and designated the West Memorial Lecture.

To endow such a project it is desired to raise not less than £600, the interest on which can be used for the expenses of the lectureship. An appeal for contributions is addressed to all those who came into contact with Professor West. Members of the Medical School staff and past and present students have been approached, but this letter is addressed to all those members of the profession who would like to contribute towards the Memorial Fund. The closing date of the appeal is June 30, 1953. Any further particulars may be obtained from the chairman of the Memorial Committee at the undermentioned address, but all contributions should be sent to the Bursar, University College, Cathays Park, Cardiff. Cheques should be made payable to "The West Memorial Lecture Fund."

It is confidently hoped that the many friends of the late Professor West will help in establishing a worthy memorial to one whose life and work meant so much to so many.—We are, etc.,

JOHN H. HUGHES,
Chairman.

H. HUGHES.
JOHN PRYDE.

Cardiff.

Obituary

Sir DAVID ROCYN JONES, C.B.E., M.B., D.P.H.

We record with regret the death on April 30 of Sir David Rocyn Jones at the age of 80. He was county medical officer of Monmouthshire for nearly forty years, and during the course of time he became one of the best-known and most popular men in the public life of South Wales and Monmouthshire.

David Thomas Rocyn Jones was born at Rhymney on November 16, 1872. His grandfather was famous in his day as a bone-setter in Cardiganshire. His father became a great friend of Hugh Owen Thomas, the pioneer of orthopaedic surgery in Liverpool, and David Rocyn Jones at one time thought of becoming an orthopaedic surgeon, as, in fact, his brother did. From Lewis's School, Pengam, he went on to the University College of South Wales at Cardiff, and later to University College, London. He continued the study of medicine at Edinburgh, where he graduated M.B., C.M. in 1897. Shortly after graduating he set up in general practice in Abertillery, having secured the appointment of surgeon

[Barratts Photo Press, Ltd., London]

to Powell's Tillery Collieries. Being also part-time medical officer of health of the town, he developed an interest in public health and took the D.P.H. of Oxford in 1904. Four years later—one of 97 applicants for the post—he became the first whole-time medical officer of health for Monmouthshire, the county of his birth. In 1908 preventive medicine was in its infancy, and Rocyn Jones built up a service which under his guidance went from strength to strength. Sufferers from tuberculosis had particular reason to be grateful to him, for in 1911 he was one of the founders of the Welsh National Memorial Association for the Prevention and Treatment of Tuberculosis.

David Rocyn Jones was a man of great geniality and wide interests, and he did not confine his activities to public health work. Very few medical officers of health can have played such an active part in public life as he did. Passionately fond of Rugby football, he was president of the Welsh Rugby Football Union at the time of his death, having been first elected to the Union in 1908. He saw the advance of Rugby football in Wales through many years of success, and at the time of his death he was regarded as "the grand old man" of Welsh Rugby. A leading figure in the affairs of the British Medical Association, he was chairman of the Monmouthshire Division in 1923 and president of the South Wales and Monmouthshire Branch in 1930-1. He was appointed a member of the consultative council of the Ministry of Health for Wales in 1919, and in later years he became a member of the Welsh Regional Hospital Board and chairman of the North Monmouthshire Hospital Management Committee. Controller of V.A.D.s for Monmouthshire and a member of the council of the Terri-

torial Army Association, he was appointed surgeon-in-chief of the St. John Ambulance Brigade in Wales in 1936. He was also prominent in the Priory for Wales of the Order of St. John, and was a Knight of Grace of the Order. For many years he was a county magistrate, being formerly chairman of the Bedwellty division of magistrates. He was a staunch Congregationalist, being a member of the Monmouthshire Congregational Union. With all this public work to his credit, it was not surprising that Rocyn Jones received many honours. He was appointed C.B.E. in 1920 and Deputy-Lieutenant of Monmouthshire in 1947. A year later he was knighted.

Always interested in education, Rocyn Jones was determined to strengthen the bonds between Monmouthshire and South Wales. He was a member of the court of governors of the University of Wales and represented the university on the council of the Welsh National School of Medicine. He was also vice-president of the court of governors of the University College of South Wales and Monmouthshire.

He married in 1901 Alla, daughter of Alderman S. N. Jones, of Abertillery. She died in 1950. There were four sons of the marriage, one of whom was killed in Italy during the last war. His son, Gwyn, succeeded him as county medical officer of health of Monmouthshire in 1946, and his eldest son, Nathan, is an orthopaedic surgeon in Cardiff.

We are indebted to Dr. R. M. F. PICKEN, Provost of the Welsh National School of Medicine, for the following appreciation: The death of Sir David Rocyn Jones at the age of 80 was not unexpected, but it leaves a gap in the professional, administrative, and sporting life of South Wales and Monmouthshire which will not be filled. He was a man of very striking personality, strong views, and great courage. Those of us who were concerned both with the organized medical services and with university education saw a great deal of him throughout the past thirty years, especially in the councils of the Welsh National Memorial Association for the Prevention and Treatment of Tuberculosis, of the Cardiff Royal Infirmary, of the University College of South Wales and Monmouthshire, and of the Welsh National School of Medicine. He took a very prominent part in the discussions and negotiations leading up to the establishment of the Welsh National School of Medicine as an independent chartered institution in 1931. Although he was strongly opposed to the separation of the school from the university college—of which he was latterly senior vice-president—he supported its work loyally and vigorously after the severance took place. I look back with great pleasure and gratitude to the friendship and kindness which he always showed to myself, in spite of the fact that I might be regarded as one interested in the school's independence. His knowledge and experience of administrative procedure was invaluable to younger men, and he was sure to pounce on any breach of order or departure from orthodoxy. As president of the Welsh Rugby Union he did much to prevent any departure from clean amateurism and the best sporting spirit in football circles.

He was a strong supporter of everything which is fine in the Welsh way of life, but there was nothing narrow or parochial in this support. Indeed he always looked back with joy and appreciation to his young days as a student in Edinburgh, and for many years was the moving spirit in an association of old students in South Wales of that university. We of the profession in this area have watched the careers of his sons in medicine with great satisfaction, and extend to them our deepest sympathy in their bereavement.

W. P. writes: Sir David Rocyn Jones was a man with a unique collection of characteristics blended together, the sum total of which resulted in what is popularly called a "character." I knew and worked under him for twenty years—not that one ever worked under him; one worked with him. He was never "the boss" in the accepted sense

of the term, but was always referred to affectionately as "the Old Man." The welfare of his medical, nursing, and administrative staffs was always his primary concern, and anyone who attempted to interfere with this welfare did so at their peril. One never hesitated to consult Sir David about professional problems or private difficulties. During his period of office in Monmouthshire he built up a health and school medical service which earned a high reputation; in fact much of his pioneer work helped in the organization of the public health services generally. He was in all senses of the term progressive, and in some ways could be regarded as a visionary. His passing is mourned by countless friends both inside and outside the medical profession.

JAMES THOMSON, C.B., C.M.G., M.B., C.M.

Major-General James Thomson, who served with distinction in the Army Medical Services in the war of 1914-18, died at Aberdeen on April 17 at the age of 90.

James Thomson was born on July 15, 1862, and was educated at the University of Aberdeen, where he graduated M.B., C.M. in 1886. Immediately after graduation he entered the service of the Army Medical Department, becoming captain in 1887. He took part in the Nile Expedition of 1898, being awarded the British medal and the Khedive's medal, with clasp, and in the following year he was promoted major. By the time war broke out in 1914 he had attained the rank of lieutenant-colonel in the R.A.M.C., and thereafter he shouldered many heavy responsibilities. He was appointed C.B. in 1917 and C.M.G. in 1919, in which year he attained the rank of major-general. In 1918, after having been D.D.M.S. of 8th Corps, he was selected to succeed the late Major-General Sir William G. Macpherson as Deputy Director-General of Medical Services of the British Armies in France. After the war he became D.D.M.S. to General Sir Ivor Maxse, who was at that time commander-in-chief of Northern Command. Major-General Thomson, who was a Knight of Grace of the Venerable Order of St. John of Jerusalem, retired from the A.M.S. in 1920. He married Miss Mary E. Marr, daughter of Surgeon-Major G. Marr, I.M.S., in 1897.

We record with regret the death on March 21 from cerebral arteriosclerosis and thrombosis of Dr. W. F. CORFIELD. He was 73 years of age. Walter Francis Corfield was the younger son of the late Dr. W. H. Corfield, professor of hygiene, University College, London. From Westminster School he went on to study medicine at University College Hospital, where he qualified in 1904. After holding appointments as house-physician and assistant in the bacteriological laboratory at U.C.H. he graduated M.B., B.S. in 1907, and took the D.P.H. in the following year. He then travelled with a patient for about a year, and later became medical officer of health and school medical officer at Colchester, a post for which he was well suited and which he occupied with distinction. During the first world war he served in the R.A.M.C., attaining the rank of major. From 1924 to 1930 he served as secretary of the Essex Branch of the B.M.A., and he represented his Division at the annual meeting in Manchester in 1929. When he retired from his post in Colchester he became medical adviser to the Kuwait Oil Company: his capacity for organization and his training as an M.O.H. were most valuable in this work, which he liked and was interested in. During the course of his career Corfield wrote numerous articles for the medical journals covering a wide range of public health subjects. For about 20 years he spent his annual holiday at Lenzerheide, a Swiss ski-ing resort. He excelled at the old-fashioned telemark turn, and his knowledge and experience of the country and of snow conditions was exceptional. An active member of the Ski Club of Great Britain, he was at one time a judge for the second-class test. Corfield

took his ski-ing and everything he did seriously, and was always on the lookout for an opportunity to improve his technique in other sports and games. He was a delightful companion, cheerful, calm, never angry, with a lively sense of humour, and he will be missed by a large number of friends. He leaves a widow.

Dr. ALBERT RILEY died suddenly at his home at Audley, Staffordshire, on December 27, 1952, at the age of 58. Albert Riley was born on October 24, 1894, the elder son of the late Mr. D. W. Riley, and was educated at the Newcastle Middle School, where he was head prefect and sports champion. After leaving school he took a post with the National Provincial Bank at Wakefield, Yorkshire, before joining the Forces and serving overseas with the King's Royal Rifles in the war of 1914-18. He was subsequently commissioned in the Cheshire Regiment and later transferred to the Royal Flying Corps. After demobilization he returned to his pre-war work for a time, and then decided to study medicine at the University of Manchester, where he graduated M.B., Ch.B. in 1924. After working as a ship surgeon for a time he settled in practice at Audley with the late Dr. William Megaw, eventually taking complete charge of the practice. Always a great lover of sport, his chief interest lay in cricket, and after he himself had ceased to play he became president of the Audley Cricket Club. He had all the attributes of the ideal family doctor, and will be remembered for many years in Audley. At the funeral on December 30 the parish church was filled with mourners who wished to pay their last respects to a greatly beloved physician. He is survived by his widow and one son.—J. L. B.

Dr. FREDERICK GILBERT LAUGHTON-SCOTT died at Tunbridge Wells on April 1, aged 66. His devotion to healing was of major importance in his life. From King's College, Canterbury, he went to Merton College, Oxford, with a classical scholarship, and his love of the classics and English literature remained with him throughout his life and gave him a humanity and breadth of vision which endeared him to both patients and friends. He studied medicine at Guy's Hospital, where he won an open scholarship in 1911, qualifying in 1914. During the 1914-18 war he served as a temporary surgeon in the Royal Navy, and on his return to England he did a considerable amount of work for the Ministry of Pensions on the treatment of shell-shock and allied conditions. He had an inquiring and critical mind and early in 1930 became interested in the rheumatic diseases. He cared intensely that his work should bring to medicine something in the nature of a genuine and recognized advance in therapeutics, and to this end he bent all his energies and lived to see his work on fibrositis accepted favourably. But his most outstanding characteristic that will be remembered for the longest time was his loyalty—a loyalty to the ethics of the profession, to his work, his patients, and to his many friends. This loyalty remained with him to the end of his last illness, borne with great courage and thought for others.—C. B. H.

The death occurred at Harrogate on April 5 of Dr. HUGH ROBERTSON at the age of 81, a few weeks after he had completed sixty years in medical practice. Hugh Robertson was born on August 7, 1871, and was educated at the University of Glasgow, where he graduated M.B., C.M. in 1893, proceeding to the M.D. in 1907. He was elected F.R.C.S.Ed. in 1899. After graduation Dr. Robertson was in practice at various places in Scotland, including Airdrie, Rutherglen, and Patna, in Ayrshire, where he was medical officer to the parish of Waterside. He moved to Harrogate in 1914, and for 26 years he was medical officer of Ashville and New College there. He also took an interest in local affairs and was a member of the town council from 1928 to 1935. A founder member and twice president of the Harrogate St. Andrew's Society, he was a great authority on Robert Burns and his work, and he was also an enthusiastic angler. Dr. Robertson, who was twice married, leaves a widow, and a daughter by his first marriage.—G. N. B.

Medical Notes in Parliament

PAY-BED REGULATIONS CRITICIZED

The new regulations relating to pay-bed accommodation in hospitals (S.I. 1953, No. 420) were discussed in the House of Commons on April 29, when Mr. A. BLENKINSOP, for the Opposition, moved a prayer for their annulment.

He said the broad effect of the regulations was to confirm recent increases in charges for amenity beds; to reduce pay-bed charges by sums which would vary even from hospital to hospital, according to very complex calculations that had to be made, but in general amounting to a reduction between 5 and 10%; and to provide for an increase in the maximum fees which could be charged by specialists giving treatment in pay-beds to their private patients.

He argued that pay-beds, although necessary initially to ensure that specialists should be broadly spread throughout N.H.S. hospitals, had always been an anomaly in the Health Service. These regulations, designed to ensure an increased use of pay-beds, would mean an increase in the sense of injustice among those who found themselves pushed further back in the queue for free treatment. They undoubtedly added to the specially favoured position of the part-time specialist in hospitals, as against the full-time specialist, ensuring that he should have more beds at his disposal as well as providing for additional maximum fees. Yet it was the part-time specialist whose service needed to be examined with some care in the Health Service. If there was room for cutting down expenditure it might well be there. It was the full-time specialist who on the whole gave the most economical service in the Health Service.

The pay-beds were not being fully used, and no doubt it would be said that they were too costly and these regulations were intended to ensure that they were more fully used and that the hospitals got more money. But large numbers of the beds were being sterilized for the use of specialists. In Stoke 55% of the pay-beds of the management committee were unoccupied, and the figures from Tyneside suggested a comparable proportion. The Minister, by these regulations, was encouraging the extension of a two-level service, one quality for those who could afford to pay, and a lower quality for others.

Mr. SOMERVILLE HASTINGS said that the Minister wanted these pay-beds used for ordinary patients when they were not occupied by paying patients, but the doctors thought otherwise—and they were on the spot. The doctors knew that only when they could get a patient into hospital at once, instead of having to wait three or four months, could they maintain and increase their private practices.

Mr. ANEURIN BEVAN said that in his initial discussions with the representatives of the Royal Colleges he was told that if he wished to keep the specialists at the hospital he must allow them to have their private patients there; otherwise there would be a direct encouragement to go to nursing-homes. He was extremely reluctant to agree, because he saw in it a grave breach of the general scheme. The medical profession was not entirely exempt from commercialism. Once the specialist was given the opportunity of having private patients in hospital he had a vested interest in increasing the number of private patients, which was exactly what happened. There was no justification, under proper administration, for a waiting-list at a hospital and empty beds in that hospital. The empty beds were kept there so that specialists could offer their patients who could afford to pay a bed at once. It could become a very evil racket.

Government Reply

Mr. IAIN MACLEOD, Minister of Health, replying to the discussion, pointed out that the schedule attached to the regulations remained broadly the same as that to the 1948 regulations, with the addition of certain new operations and procedures—for example, the development of fitting contact lenses. He had recently sent out, in conjunction with the regulations, guidance to hospitals. If the primary desire

*Supplement, March 28, p. 94.

of a patient was for privacy, and it was a non-serious case, he should have his attention drawn to amenity beds if such existed in the hospital. Secondly, if his need for admission was urgent on medical grounds he had a right to be admitted, and there was again no need for the whole charges to be paid. Thirdly, if he desired a Section 5 bed it must be made absolutely clear to him—and there must be undertakings given in writing—that he understood in full the implications of what he was doing.

The object of these regulations was not to reduce the charge to private patients; it might have that result, but the object was to carry out fairly the 1946 Act. The 1948 regulations laid down that a standard daily charge, plus an average daily cost per in-patient representing medical care, plus various percentages, was to be the amount charged. It had been found that the regulations were treble unfair. The percentages were now to be added to a sum which excluded the cost of paying medical staff. Secondly, they had been shown to be unfair because they included certain services which had little or no reference to the private block. Thirdly, they were unfair because the percentages had been found to be too high.

On the question of the new fees, he said that the fees had been unaltered since 1948, and in 1949 Mr. Bevan had agreed that they should be examined. That examination had taken place, and after consultations with the various consultant officers and the professions the new figures represented fairly general agreement. Hospital charges reflected actual costs, whereas medical fees had been subject to rigid ceilings since 1948, in spite of the fact that there had been enormous developments in medical technique since then.

The number of Section 5 beds at the latest count in February this year was 6,113, or 1.2% of all staffed beds. The number of Section 4 beds (part-payment) was 1.3%. So 97.5% of all beds in the Service were absolutely free. Compared with the end of 1950 those figures showed that there had been a decrease of 4.5% in Section 5 beds and an increase of 13% in Section 4 beds, while the free beds had increased by no fewer than 18,156, or 4.1%. In view of those figures no one could say that the present Government had taken advantage of Section 5 to multiply the number of pay-beds beyond what was conceived in the Act, or would do so.

No Word of Approval

It had been said that this was a new policy, and in some respects one in favour of the specialists. The best witnesses to call on that were the specialists. In the *British Medical Journal* of March 28* their joint committee commented on these regulations and his attitude towards them. He regretted to say that there was no word of approval for him throughout their comments. The specialists had wanted to abandon the detailed schedule. He had said, "No." They had wanted not a detailed price ceiling, but a few general ceilings within which they would adjust their amounts to the paying capacity of their patients. He had said, "Whatever might happen in the future, the time is not ripe for that." They had wanted a reduction straight away in the case of pay-beds. He had said, "That cannot be done without legislation, and I see no prospect of that." Those were the only three points on which he had interfered in these regulations, which had been prepared by the consultant officers of the Ministry.

Mr. BLENKINSOP asked what proposals the Minister had in mind to ensure that the empty beds were used for ordinary patients. Mr. MACLEOD said that he had called for a special report on the occupancy of these beds. The details were almost complete, and as soon as he had them he would be happy to discuss the matter.

The motion to annul the regulations was rejected by 261 votes to 233.

BETTER MATERNITY BENEFITS

The National Insurance Bill, for which the Minister claimed that it made the most generous provision for motherhood yet provided, was given a second reading in the House

of Commons on April 29. It was stated during the debate that at the time the National Insurance Act, 1946—which it amends—came into operation there were 18,786 maternity beds in N.H.S. hospitals, and the most recent return was 19,369.

The point which attracted most attention was the introduction of the home confinement grant of £3, making for the first time a differentiation between the allowances to women who went to hospital and those who had their confinement at home. Fears were expressed that this might be an inducement to women who ought to go to hospital to remain at home for the sake of the extra money. Against that was quoted the report of the National Insurance Advisory Committee that representations had been made that the financial advantage under the present scheme of having the confinement in hospital was causing an excessive demand on maternity beds which ought primarily to be used for cases likely to need hospital attention.

Pharmaceutical Goods Prices

Mr. A. BLENKINSOP on April 30 asked the Minister of Health whether he was in a position to make a statement arising out of his discussions with manufacturers of pharmaceutical goods about the prices of proprietary brands. Mr. IAIN MACLEOD said that he could not at present, but added that this was a matter which was under very serious consideration by the Government.

Supplies to China

Mr. JOHN TILNEY on April 30 asked the President of the Board of Trade if he would make a statement in connexion with the supply of certain pharmaceuticals to China.

Mr. PETER THORNEycroft replied that pharmaceuticals were not subject to the embargo which the United Kingdom had maintained on certain exports to China ever since it was imposed by the previous Government after the United Nations resolution of May 18, 1951. Since August, 1951, however, exports to China of certain pharmaceuticals which would be of value to the maintenance of large military forces had been limited to normal civilian requirements. A number of Western European governments had hitherto permitted exports of these pharmaceuticals without restriction and this had tended to frustrate the controls which we have maintained. These governments had, however, now agreed to impose similar restrictions to ours.

Universities and Colleges

ROYAL COLLEGE OF PHYSICIANS OF LONDON

At a quarterly comitia of the College held on April 30, with the President, Sir Russell Brain, in the chair, the following were elected Fellows of the College: F. B. Byrom, M.D. (Australia); R. Jeremy, M.B. (Australia); A. T. Jones, M.D. (Cardiff); M. McC. Baird, B.M. (Canada); E. B. Brooke, M.B. (Carmarthen); B. B. Bhatia, M.D. (India); T. F. McN. Scott, M.D. (United States); J. S. Harris, M.D. (Woodford Green); J. N. Cumings, M.D. (London); O. F. Thomas, M.R.C.P. (Liverpool); R. Knox, M.D. (London); J. MacD. Holmes, M.D. (Stafford); Mary J. Wilmers, M.D. (London); H. E. Holling, M.B. (London); Beryl D. Corner, M.D. (Bristol); G. Davison, M.D. (Cramlington); J. R. Forbes, M.D. (Flintshire); R. M. Kark, M.R.C.P. (United States); F. H. Kemp, M.B. (Oxford); S. Lazarus, M.D. (Glasgow); J. Smart, M.D. (London); J. F. Bromley, M.B. (Birmingham); Muriel J. L. Frazer, M.D. (Belfast); Sir William P. Mallinson, B.M. (London); H. G. Miller, M.D. (Newcastle-upon-Tyne); A. W. Woodruff, M.D. (London); W. W. Gooddy, M.D. (London); A. G. W. Whitfield, M.D. (Sutton Coldfield); D. I. Williams, M.B. (London); R. A. Henson, M.D. (London); Sir Frank Macfarlane Burnet, M.D., F.R.S. (Australia); J. F. Fulton, M.D. (United States); G. L. Keynes, M.D., F.R.C.S., F.R.C.O.G. (London); and C. Laubry, M.D. (France).

Lord Horder was appointed delegate of the College to the annual cremation conference to be held at Llandudno from June 29 to July 1.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending April 18 (No. 15) and corresponding week 1952.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenzal pneumonia.

§ Includes puerperal pyrexia.

Vital Statistics

Cancer and Tuberculosis Deaths

In England and Wales the provisional 1952 death rates for all forms of cancer were 2,149 and 1,850 per million population for men and women respectively. The 1951 figures were 2,120 and 1,822. The rise in the rate for men includes an increase from 530 to 567 per million population for deaths assigned to cancer of the lung and bronchus, making a total increase since 1947 of 47%.

The provisional death rate for respiratory tuberculosis in 1952 was 212 per million persons. This is a decrease of 23% from the previous year, and is less than half the figure for 1947. The rate for other forms of tuberculosis was 28 per million persons, compared with 41 for 1951.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1944-52 are shown thus ----, the figures for 1953 thus ———. Except for the curves showing notifications in 1953, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The largest fluctuations in the trends of infectious diseases in England and Wales during the week ending April 18 were falls of 4,527 in the number of notifications of measles from 23,388 to 18,861, and 272 for scarlet fever, from 1,266 to 994, and a rise of 229 for whooping-cough, from 2,618 to 2,847.

The largest decreases in the local trends of measles were 490 in Yorkshire West Riding, from 1,896 to 1,406; 347 in Warwickshire, from 980 to 635; 245 in Essex, from 948 to 703; and 239 in Hertfordshire, from 627 to 388. The largest fall in the notifications of scarlet fever was 42 in Kent, from 70 to 28. The largest rises in whooping-cough were 93 in Lancashire, from 463 to 556, and 57 in Essex from 136 to 193. 18 cases of diphtheria were notified, less than in the preceding week.

34 cases of acute poliomyelitis were notified during the week. These cases were 2 fewer for both paralytic and non paralytic cases than in the preceding week. The largest returns were Surrey 5 (Wimbledon M.B. 2) and Sussex 1 (Brighton C.B. 2).

282 cases of dysentery were notified, 43 fewer than in the preceding week. The largest returns were Lancashire 8 (Liverpool C.B. 36, Manchester C.B. 21, Preston R.D. 14) London 33, Leicestershire 28 (Leicester C.B. 28), and Middlesex 17 (Edmonton M.B. 12).

Week Ending April 25

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,047 whooping-cough 3,206, diphtheria 25, measles 13,731, acute poliomyelitis 41, dysentery 419, paratyphoid fever 8, and typhoid fever 2.

Infant Mortality Record

The infant mortality rate for England and Wales in 1952 fell to 27.6 per 1,000 related live births, the lowest ever recorded in this country. It was 2.0 below the rate for 1950 the previous lowest. Comparative rates in other countries were: In 1952, Sweden 20, Netherlands 23, U.S.A. 29; in 1951, New Zealand 23, Australia 25, Canada 38, France 51 Belgium 66, Italy 67.

On the basis of 1951 death rates, the estimated expectation of life of a male child at birth would be 65.8 years and that of a female child 70.9. These figures compare with 48.5 and 52.4 respectively in 1901.

The birth rate last year was the lowest recorded since 1941. There were 673,559 live births, representing a rate of 15.3 per thousand population. This was 0.2 below the rate for 1951. Of every thousand live births, 46 were illegitimate—5 per thousand fewer than the average for the preceding five years. The births registered in 1952 exceeded the deaths by 176,269; the corresponding excess for 1951 was 130,309 and the average excess for 1946-50 was 281,195.

Deaths during 1952 numbered 497,290, giving a rate of 11.3 per thousand population, compared with 12.5 in 1951 and 11.6 in 1950. This is the second lowest rate recorded in spite of a rate in the last quarter (12.4) which has been exceeded only twice since 1925.—*Quarterly Return for England and Wales*, fourth quarter of 1952.

The provisional maternal mortality rate (excluding abortion) per 1,000 live and stillbirths in England and Wales in 1952 was 0.59, a new low record. The previous lowest rate was 0.66 in 1951.

The provisional neonatal death rate (babies under 4 weeks of age) for last year was 18.9 per 1,000 related live births. In the previous year the rate was 18.8, and in 1939 it was 28.3.

Smallpox in the North Country

Up to noon, May 5, 27 confirmed cases of smallpox had been reported, including 7 deaths. There was 1 new suspected case in a soldier recently returned from Egypt. The new case reported since last week was a man aged 43, vaccinated in infancy.

Medical News

Royal College of Surgeons.—On May 5 the Queen laid a memorial stone to commemorate the first phase of the building operations at the Royal College of Surgeons. The ceremony took place in what will eventually be the Great Hall of the College. Enclosed in the stone is a casket containing copies of the College Calendar and other documents placed there by two postgraduate students from the residential college, Dr. H. Chesterfield Evans, of Brisbane, and Dr. C. B. Walker, of Ipswich. In his speech of welcome to the Queen the President of the College, Sir Cecil Wakeley, said that work was proceeding on the three new floors of museums, a gift from the Wellcome trustees, on the laboratories, and on the library. Work on the College of Surgical Science, presented by Lord Nuffield, was due to begin within a few months. The Bishop of London (Dr. Wand) dedicated the memorial stone and prayed for blessing on the new project. The President then presented the architect and representatives of the contractors to the Queen, who accepted from the architect a gold and tortoiseshell trinket-box belonging originally to George IV. After expressing the thanks of the College to her Majesty for laying the stone, Sir Cecil gave her a copy of Sir John Bland-Sutton's book, *The Story of a Surgeon*.

Minister's Committee on Health Service Costs.—Last week in the House of Commons the Minister of Health, Mr. Iain Macleod, announced the composition of the small independent committee of inquiry which he is asking to look into the costs of the Health Service. The chairman, as already noted (April 11, p. 840), is the Cambridge economist Mr. C. W. Guillebaud. The members are Professor J. W. Cook, F.R.S., regius professor of chemistry at Glasgow; Sir Geoffrey Vickers, V.C., a member of the National Coal Board and previously its legal adviser; Sir John Maude, formerly Permanent Secretary to the Ministry of Health;

and Miss B. A. Godwin, a member of the General Council of the Trades Union Congress. The secretary is Mr. E. Halliday, of the Ministry of Health. The committee's terms of reference are: "To review the present and prospective cost of the National Health Service; to suggest means, whether by modifications in organization or otherwise, of ensuring the most effective control and efficient use of such Exchequer funds as may be made available; to advise how, in view of the burdens on the Exchequer, a rising charge upon it can be avoided while providing for the maintenance of an adequate Service; and to make recommendations."

British Occupational Hygiene Society.—A new society for the promotion of the science of occupational hygiene, the British Occupational Hygiene Society, was inaugurated last month at the London School of Hygiene and Tropical Medicine. The society's first president is Dr. T. Bedford, D.Sc., director of the Medical Research Council's Environmental Hygiene Research Unit, and the founder members include engineers, chemists, and physicists, as well as medical men, concerned with the maintenance of healthful conditions of work. The society will provide a forum where medical and non-medical workers in this field can share their experience. The honorary secretary is Mr. P. C. G. Isaac, lecturer in public health engineering, King's College, Newcastle-upon-Tyne.

Doctors and Sickness Insurance Schemes.—The International Social Security Association is preparing for discussions with the World Medical Association on the question of co-operation between the medical profession and sickness insurance institutions. According to the International Social Security Association, which represents institutions concerned with social security matters in 39 countries, this co-operation is not always as close as might be hoped. The problem is being discussed this week at a meeting in Düsseldorf.

The Radcliffe Infirmary.—Oxford University has reached agreement in principle with the board of governors of the United Oxford Hospitals for a new building plan on the Radcliffe Infirmary site which will strengthen the clinical school in two ways. First, the Nuffield professor of clinical medicine will have all his beds concentrated at the Radcliffe Infirmary instead of half at the Churchill Hospital. Secondly, the board of the faculty of medicine has recently recommended that the next Nuffield professor of surgery, to be appointed in succession to the late Sir Hugh Cairns, should for preference be a general surgeon. This is to be made possible by the provision of a new department, also in the Radcliffe Infirmary, with about 50 beds, operating-theatre, and laboratories. Temporary arrangements for increasing the number of beds at the Radcliffe Infirmary until the new building is complete are now being made by the board of governors.

Refresher Course for General Practitioners.—Some copies of the book, *Refresher Course for General Practitioners*, are still available. It comprises the first 55 articles printed in this popular *Journal* series. Each deals with a common problem of medical practice, and has been written (and fully revised) by an acknowledged authority. The price of the book is 25s. (post free). Orders should be sent to the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Training of the Hospital Matron.—The King Edward's Hospital Fund for London is to run a 10-month residential course for prospective matrons and assistant matrons from the four Metropolitan Regions. The first course will start in September and be limited to 12 candidates. The sisters will live at 22, Holland Park, London, W.11. The course is a preparatory one, being designed primarily for the sister who shows promise of administrative ability, and the emphasis will be on the human aspects of management. The King's Fund already runs courses for ward sisters and for hospital administrators.

College of General Practitioners.—On April 30 the number of Foundation Members of the College was 1,911.

Nuffield Provincial Hospitals Trust.—The Investigation into the Functions and Design of Hospitals has moved from 33, Doughty Street, London, W.C.1, to the Trust's headquarters at Nuffield Lodge, Regent's Park, London, N.W.1 (telephone: Primrose 8871).

Professor W. T. J. Morgan, F.R.S., has been appointed deputy director of the Lister Institute of Preventive Medicine. Professor Morgan, who has been on the staff of the Lister Institute since 1928, is noted for his work on the chemistry of immunology.

Professor Joseph Gillman, head of the department of physiology at Witwatersrand University, has been awarded the South Africa Medal by the South African Association for the Advancement of Science. The South Africa Medal fund was instituted by members of the British Association in commemoration of their visit to South Africa in 1905.

Dr. F. I. Ashton has received the Queen's Commendation for Brave Conduct for his part in rescuing people trapped by the floods at Sutton-on-Sea, Lincolnshire.

COMING EVENTS

Symposium on Virology.—The Institut d'Hygiène et de Bactériologie at Lausanne has arranged a symposium on "Some Present Problems of Virology" to be held at Lausanne on May 22 and 23. Each paper will be followed by a discussion, and the papers will be read in either English or French. The fee for the symposium is 15 Swiss francs. Further information may be obtained from Professor Hauduroy, 19, rue César Roux, Lausanne.

Liverpool Medical Exhibition.—The 1953 Liverpool Medical Exhibition is to be held at St. George's Hall, Liverpool, from May 18 to 22. The exhibition, which will be open from 11 a.m. to 6.30 p.m. daily, will be opened by Dr. E. Noble Chamberlain.

British Empire Leprosy Relief Association.—The annual general meeting of the British Empire Leprosy Relief Association will be held in the Conference Room, Church House, Great Smith Street, London, S.W.1, on May 21 at 3 p.m. The chair will be taken by the Rt. Hon. Oliver Lyttelton, who will deliver the main lecture. Dr. Robert Cochrane will speak on the treatment of leprosy.

Ross Institute of Tropical Hygiene.—The Ross Institute Industrial Advisory Committee will hold an open meeting in the council chamber of the Rubber Growers' Association, 19, Fenchurch Street, E.C.3, on May 21 at 2.15 p.m. The subjects for discussion will include "Tropical Health Problems and Their Connexion with Industrial Relations," "International Health Work," and "Malaria in Malaya."

Cancer and the Viruses.—Dr. Pierre Lépine, Director of the Virus Research Department of the Institut Pasteur, Paris, will speak at the Institut Français, 15, Queensberry Place, London, S.W.7, on May 12 at 6 p.m. The subject of his address, which will be given in French, will be "Le problème du cancer dans ses relations avec les virus."

Bart's Exhibition.—St. Bartholomew's Hospital, E.C.1, is holding an exhibition of its historical documents and other treasures from May 14 to 16. The exhibition will be open to the public each day from 10.30 a.m. to 6.30 p.m., and visitors should enter through the main gate in West Smithfield.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Application should be made first to the institution concerned.

Monday, May 11

INSTITUTE OF PSYCHIATRY.—5.30 p.m., lecture-demonstration by Dr. E. Stengel.

MEDICAL SOCIETY OF LONDON.—8.45 p.m., Annual Oration by Sir Russell Brain, P.R.C.P.: Need for a Philosophy of Medicine.

● POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. H. S. Banks: Coliform Infection in Gastro-enteritis.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor H. R. Dew: Post-operative Intravascular Thrombosis.

ROYAL EYE HOSPITAL.—5 p.m., Professor Arnold Sorsby: Diseases of Metabolism and their Ocular Signs.

ST. ANDREWS UNIVERSITY.—At Surgery Lecture Theatre, Dundee, 5 p.m., Sir W. Heneage Ogilvie: Problems of the Gastro-oesophageal Junction.

UNIVERSITY COLLEGE.—At Physiology Theatre, 4.45 p.m., Sir Rudolph Peters, F.R.S.: Inhibitors and Intracellular Chemical Dissection.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—At Royal Society of Medicine, 8.30 p.m., Cavendish Lecture by Viscount Simon: The Doctor in the Witness Box.

Tuesday, May 12

CHELSEA CLINICAL SOCIETY.—At South Kensington Hotel, 7 for 7.30 p.m., annual dinner.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. A. Dudgeon: Virus Diseases.

● INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Hammersmith Hospital, 3 p.m., Professor J. Chassar Moir: Use of Radiology in Labour.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Moynihan Lecture by Dr. R. B. Cattell (Boston): Extra Hepatic Obstruction of the Bile Ducts.

ROYAL EYE HOSPITAL.—5 p.m., Mr. T. M. Tyrrell: Surgery of Glaucoma and its Complications.

ST. ANDREWS UNIVERSITY.—At Surgery Lecture Theatre, Dundee, 5 p.m., Sir W. Heneage Ogilvie: Pitfalls in Surgical Diagnosis.

WRIGHT-FLEMING INSTITUTE OF MICROBIOLOGY, St. Mary's Hospital Medical School.—5 p.m., Almroth Wright Lecture by Dr. J. G. Davis, D.Sc.: Some Public Health Aspects of Milk.

Some Public Health Aspects of Milk.

Wednesday, May 13

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. A. Dudgeon: Virus Diseases.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.—At Royal Free Hospital School of Medicine, 8.30 p.m., Miss Sybil Campbell (Metropolitan Magistrate): A Day in the Life of a Metropolitan Magistrate—With Particular Reference to Problems of Punishment.

● POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Professor A. Frazer: Disordered Function of the Small Intestine.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. R. J. Ludford: Tissue Cultures—Malignant Growth.

ROYAL EYE HOSPITAL.—5.30 p.m., Mr. L. H. Savin: Ophthalmic Neurology.

Thursday, May 14

ALFRED ADLER MEDICAL SOCIETY.—At 11, Chandos Street, W., 8 p.m., Dr. D. S. MacPhail: Psychotherapy for Criminals.

BRITISH INSTITUTE OF RADIOLOGY.—8 p.m., annual general meeting: 8.30 p.m., 32nd Silvanus Thompson Memorial Lecture by Dr. L. H. Gray, Ph.D.: Initiation and Development of Cellular Damage by Ionizing Radiation.

CAMBRIDGE UNIVERSITY.—At Senate House, 5 p.m., Rede Lecture by Professor A. D. Gardner: The Proper Study of Mankind.

● HAMPESTEAD GENERAL HOSPITAL.—3 p.m., Mr. G. Qvist: Vascular Disease of Limbs: 4.15 p.m., Dr. M. Kremer: Epilepsy.

HONYMAN GILLESPIE LECTURE.—At University New Buildings, Edinburgh, 5 p.m., Dr. C. F. Rolland: Diabetes in Pregnancy.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Mycology—Structure of Pathogenic Fungi and their Identification.

● INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Chelsea Hospital for Women, 4.30 p.m., Mr. A. W. Bourne: Hypertension in Pregnancy and its Prognosis.

LONDON UNIVERSITY.—At Guy's Hospital Medical School, 5 p.m., Dr. N. G. Emmelin (Lund): Secretion of Saliva.

NUFFIELD ORTHOPAEDIC CENTRE, Wingfield-Morris Orthopaedic Hospital.—8.30 p.m., Mr. P. Wiles: Posture.

● POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. G. E. Burch (Louisiana): Vectorcardiography.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Surgeon Commander F. Ellis, O.B.E., R.N.: Desirable and Tolerable Levels of Warmth in Warm Climates (with special reference to the requirements of men in the Royal Navy).

ROYAL EYE HOSPITAL.—5.15 p.m., Dr. T. H. Whittington: Non-Paralytic Strabismus: Care and Treatment of the Squinting Child.

ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Professor G. Gustafson (Sweden): Modern Methods in Dental Histology.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. A. S. Paterson: postgraduate demonstration in neurology.

postgraduate demonstration in neurology.

Friday, May 15

BRITISH INSTITUTE OF RADIOLOGY.—5 p.m., meeting of medical members.

FACULTY OF RADIOLOGISTS.—At Royal College of Surgeons of England, 2.15 p.m., Diagnosis Section Meeting. Dr. R. Astley: Triacuspid Atresia; Dr. D. E. Truscott: Radiological Control of Kidney Injuries; Dr. P. G. Keates: Some Physiological Observations Made During Excretion Urography; Dr. W. Horner Smith: Reliability of Excretion Urography in the Diagnosis of Bladder Tumours.

● GUY'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Fison Memorial Lecture by Sir Lawrence Bragg, F.R.S.: X-ray Analysis of Protein Molecules.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. R. T. Brain: Common Skin Diseases in Children.

OSLER CLUB OF LONDON.—At 11, Chandos Street, W., 7.45 p.m., Dr. J. N. Morris: History of Social Medicine.

OXFORD UNIVERSITY.—At Radcliffe Infirmary, 5 p.m., Litchfield Lecture by Dr. R. B. Cattell (Boston): Advances in Pancreatic Surgery.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Mr. John Bruce: Hazards of Major Surgery.

● POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Professor A. Frazer: Disordered Functions of the Small Intestine.

● ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS.—5 p.m., William Blair-Bell Memorial Lecture by Dr. Henry Roberts: Observations on Micturition in the Female.

ST. ANDREWS UNIVERSITY.—At Surgery Lecture Theatre, Dundee, 5 p.m., Sir W. Heneage Ogilvie: Independence and Authority in Medical Practice.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Obstetric and Gynaecological Conference. Mr. H. C. Hanley: Urological Problems During Pregnancy.

Pregnancy.

Saturday, May 16

BIOCHEMICAL SOCIETY.—At Department of Physiology, Medical School, Hospitals Centre, Birmingham, 1.45 p.m., scientific papers.

● INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Queen Charlotte's Hospital, 11 a.m., Professor W. C. W. Nixon: Disordered Uterine Action.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

A Heavily Furred Tongue

Q.—How should a man of 40 with a persistently and heavily furred tongue be investigated and treated? The condition started 6 months before an operation for appendix abscess 14 years ago, and has only remitted once since—during the month immediately after operation. The patient also suffers from buccal ulcers and flatulence and distension after meals occasionally. There is no evidence of local sepsis. All the teeth have been removed in an effort to cure the condition.

A.—It is not always easy to account for a furred tongue. It only occasionally produces symptoms, and these then seem to be made worse by worrying. It is important to see that the patient is taking a normal diet, not slops, and that he is not smoking or drinking to excess. Nasal obstruction should be excluded, and likewise constipation or the excessive use of aperients. The coexistence of a furred tongue, flatulence, and distension suggests the syndrome of reverse peristalsis. This is usually due to an irritable focus in the alimentary tract or a reflex disturbance from elsewhere. It would be well to begin investigation by an x-ray examination of the gall-bladder, as this may have been infected at the same time as the appendix. If this is normal the patient should have a barium meal and follow-through, with particular reference to the possibility of a lesion in the lower ileum. A test meal may be done to exclude achlorhydria. Finally, a gastroscopy may be performed to look for gastritis, though it will prove difficult to treat it if it is found.

Repeated Failure of Lactation

Q.—A healthy woman of 27, now in her third pregnancy, has with her previous two children had considerable difficulty with breast-feeding. Despite all the usual measures taken after delivery, the supply of milk has been inadequate on both occasions and has had to be supplemented very extensively within the first few weeks. There seems to be no psychological difficulty and she is anxious to feed the new baby. She is now 25 weeks advanced in pregnancy, and, although the breasts are enlarged, no secretion can be expressed from the nipples. Are there any measures which can be taken during the pregnancy to increase the supply after delivery?

A.—There are some women who, despite all treatment, fail to lactate in successive pregnancies, and in these it is assumed that there is a failure of development of gland tissue or some inherent fault which prevents the breast responding to the various factors which determine lactation after childbirth. For this minority little can be done. The majority of women, however, can breast-feed satisfactorily given the determination to do so, proper management, and a lusty child with a good sucking reflex.

In the case described the only treatment necessary at present is to ensure that the woman has a good diet, protein being especially important. As pregnancy progresses attention should be paid to the nipples to see that they project well. Thereafter it would probably be best to follow the scheme advocated by H. K. Waller. This includes daily massage of the breasts with deliberate expression of colostrum during the last six weeks of pregnancy. After labour, engorgement of the breasts should be treated with small doses of stilboestrol for 24 to 48 hours. As lactation becomes established the breasts should be "stripped" after

each feed—that is, they should be completely emptied by manual expression.

Drug treatment to increase the supply of milk is generally unsatisfactory. There would be no harm, however, in giving for five to seven days either thyroid 6 to 10 gr. (0.4 to 0.65 g.) daily, or Lugol's iodine 6 minims (0.35 ml.) twice daily, starting on the fifth day of the puerperium.

Combined Diphtheria-Pertussis Inoculation

Q.—At what age do the experts advise that a combined diphtheria-pertussis inoculation should be given?

A.—It is assumed in this question that a combined diphtheria-pertussis prophylactic is already accepted as safe and effective as well as being administratively convenient. In regard to safety, there is some evidence that the slight risk of post-inoculation poliomyelitis, which may accompany injections in areas where poliomyelitis is prevalent, is particularly associated with an alum-containing diphtheria-pertussis mixture. This risk may be lessened by using a mixture of diphtheria toxoid and pertussis vaccine without alum, although there are as yet no published data on this point. As regards effectiveness, experimental and field studies indicate that the antigenic potency of diphtheria toxoid is not adversely affected, and may be enhanced, by mixture with pertussis vaccine. Whether this mixture affects the antigenic value of the pertussis vaccine is less certain.

If and when the combined prophylactic is shown to be both safe and effective there will be arguments for and against inoculating children either in the first six months or in the second six months of life. In favour of early inoculation, say from three months onwards, is the fact that 5-10% of children develop whooping-cough in the first year of life, and about two-thirds of the deaths from whooping-cough occur in this age group. On the other hand, it is not known if children are as well protected by pertussis immunization in the early months of life as they are when they receive the vaccine rather later. There is the further risk in diphtheria immunization that children of 3 to 6 months of age may still have some diphtheria antitoxin passively transferred from the mother, and this antibody may interfere with the child's response to the diphtheria prophylactic. In view of these considerations it might be advisable to begin immunization with a combined prophylactic around 6 months of age, and give a reinforcing dose 2-3 years later. Until the combined prophylactic has been proved to be safe and effective, pertussis immunization (three monthly doses) could be begun at 3 to 4 months and diphtheria immunization at 6 to 8 months of age. Obviously, no advice can be given about the best combined prophylactic at this stage.

Prognosis in Pneumoconiosis

Q.—What is the prognosis in pneumoconiosis and the likelihood of tuberculosis supervening?

A.—The word "pneumoconiosis" covers such a multitude of differing pathological and clinical conditions that it is impossible to answer the simple question that is asked. In cases of acute silicosis arising in the abrasive soap industry, death has occurred within three years of first exposure,¹ and patients with beryllium and aluminium pneumoconiosis have died 3 years and 18 months respectively from first exposure.^{2,3} At the other extreme, aged miners may be found to have advanced pneumoconiosis which must have originated during their work anything up to 60 years previously, and the milder forms of any pneumoconiosis may be compatible with a normal span of life. Life tables for a miscellaneous group of cases of simple pneumoconiosis and silico-tuberculosis are given by Turner and Martin⁴ and for certified coal-miners by Stewart.⁵ The prognosis of coal-miners with pneumoconiosis is also discussed by Berard, Martin, Ode, and Roche⁶ and that of a miscellaneous group of silicotics by Baldi.⁷ From these papers it emerges that cases of these kinds of simple pneumoconiosis have a prognosis not very greatly different from that of the ordinary

population so long as their pneumoconiosis does not become complicated by tuberculosis, when the prognosis is much worse. The more rapid the onset of pneumoconiosis, and usually, therefore, the younger the man, the greater the liability of conversion at some time to silico-tuberculosis and the worse the prognosis. Cases with "massive fibrosis" have a worse prognosis, and cases with open tuberculosis seldom live more than two years. The liability to develop open tuberculosis appears to be much greater in cases of pure silicosis than in the various forms of mixed dust pneumoconiosis such as those of coal-workers and foundry workers. This is shown by the much higher tuberculosis death rates that have prevailed in the pure silica risk industries than in coal-mining and foundries. Other forms of pneumoconiosis than silicosis—for example, asbestosis, aluminosis, berylliosis—do not appear to predispose to tuberculosis.

The frequency with which tuberculosis is found to complicate pneumoconiosis depends upon the diagnostic criteria and upon the material used for the study. For instance, in post-mortem examinations of coal-miners Rogers¹ found tuberculosis in 75.8% of cases with massive fibrosis, Gooding² found it in 26% of all cases. Theodos and Gordon³ found a positive sputum in 13% of coal-miners admitted to hospital, whereas in a community survey in a coal-mining district Cochrane (unpublished) found that only 1% of all cases of massive fibrosis had a positive sputum. The diagnosis of tuberculosis on the grounds of a positive sputum is the only way of making the diagnosis certain. When clinical and radiological criteria are also admitted, the proportion of cases of pneumoconiosis with tuberculosis will be found to range from about 5% to 75%, depending upon the selection of cases and the diagnostic whim of the observer.

Shortening the List of Notifiable Diseases

Q.—Can a local authority shorten the list of diseases notifiable in its area as well as lengthen it?

A.—"Notifiable disease" is defined by section 343 of the Public Health Act, 1936, as any one of nine named diseases, plus any infectious disease which the local authority (with the approval of the Minister) may declare to be a notifiable disease within its area.

A local authority has no power to shorten the list of named diseases, but only those which became notifiable by a resolution of its own council. To remove such a disease from its list a further resolution of the council is required and also the approval of the Minister.

In addition, the Minister has power to make regulations under section 143 of the Public Health Act, 1936, for the treatment of persons affected with any epidemic, endemic, or infectious diseases, and for preventing the spread of such diseases. These regulations include provisions requiring notification of the diseases to which they apply, and may extend to the whole of England and Wales or any part thereof. Regulations made by the Minister may of course be amended or revoked by him.

Eosinophils in C.S.F.

Q.—What are the causes of eosinophilia in the C.S.F.?

A.—Very little is known about the incidence of eosinophils in the cerebrospinal fluid, and less still about their significance. Only rarely are these cells seen, and then mainly in cerebral syphilis and in some cases of acute meningitis, always provided there has been no blood admixture. Eosinophils might also be found in the C.S.F. in allergic conditions.

NOTES AND COMMENTS

Implantation of Hormone Pellets.—Dr. R. P. EDKINS, Ph.D. (Pharmaceutical Research Department, Organon Laboratories, Motherwell, Lanarks), writes: With regard to the previous notes on this matter (February 28, p. 519, and March 14, p. 632) it must, as Mr. A. R. G. Chamings states, be regarded as dangerous to boil these pellets, as most of the hormone substances used soften or actually melt under this treatment, and at the best the pellets will become deformed. A simple and invariably successful method by which either fused or compressed pellets which have been accidentally contaminated may be re-sterilized without fear of melting or distortion consists in keeping the pellets in a solution of phenol (0.5%) or phenylmercuric nitrate (0.002%) or other substance having similar bactericidal activity, at a temperature not below 37° C. or above 80° C. for 24 hours; the addition of a small percentage of a surface active agent such as cetrimide (0.025%) to the phenol solution (or other bactericide, provided there is no reaction between them) is an added advantage, as it promotes efficient wetting of the surface of the pellet. After this treatment, the pellet may then be implanted directly, after preliminary drying, if desired, on a sterile towel. It must be realized that this treatment will sterilize only the external surface of the pellet; but, since it is internally sterile by the process of manufacture, it is only the outer surface which will require re-sterilization if the pellet is accidentally contaminated. It is emphasized that it is undesirable to apply this process to pellets which have already been implanted and which have either been removed intentionally or extruded.

Poisonous Snakes.—Sir HAROLD SCOTT (Braintree) writes: Your expert in his reply on the treatment of bites by poisonous snakes ("Any Questions?" April 4, p. 793) rightly stresses the specificity of antivenins. As the use of such is generally urgent and they may not be immediately obtainable, a first-aid treatment which will delay the action of the poison deserves to be more widely known. Almost 30 years ago (in 1924) the fact was observed that soaps could detoxify snake venoms, and in 1945 Ahuja and Brooks in India showed that local injections, at four or five points surrounding the site of the bite, each of 0.5-1 ml. of 5% emulsion of "lifebuoy" carbolic soap (say to a total of 5 ml.) might delay the action of the poison for some hours, at least two and often more. Carbolic soap is to be found in many houses, and it might be kept made up in a 5% strength at local dispensaries in countries where snake-bites are likely to occur. Bleeding should be encouraged by crucial incisions.

OUR EXPERT writes: I agree that local injection of soap emulsion in the region of the bite might be worth trying in an emergency, but it should be stressed that it is only a first-aid treatment, and should never be regarded as a substitute for antivenin. The idea of using soap suspension in this way arose from some work on the effect of surface-tension suppressants on tissue poisons, including bacterial toxins and certain snake venoms. It has since been shown that soaps, particularly those of the unsaturated fatty acids, have some retarding effect on the venoms of rattlesnake, asp, cobra, krait, and ringhals. This effect has been shown both *in vitro* and *in vivo* in laboratory animals, including pigeons. I believe that the injection of carbolic soap emulsion has recently been used by Ahuja and Brooks as first-aid treatment of snake-bite in man. I am grateful to Sir Harold Scott for raising this point, which perhaps should have been included in my reply to the original question.

Corrections.—The figure for Foundation Membership of the College of General Practitioners given in the legend to the map in the *Journal* of May 2 (p. 990) should have read 1,807.

In the article entitled "Controlled Hypotension in Neurosurgery with Hexamethonium and Procaine Amide" (May 2, p. 961) by Dr. David Aserman, acknowledgment was inadvertently omitted to the fact that the procaine amide used in the investigation was generously supplied by Messrs. E. R. Squibb and Sons.

MEDICINE AND SOCIAL POLICY*

BY

F. A. E. CREW, M.D., F.R.C.P.Ed., F.R.S.

Professor of Public Health and Social Medicine, University of Edinburgh

The name of Sir Charles Hastings is imperishably inscribed in the records that tell of the development of the medical profession and of the ascending social status of the doctor. To him the members of the British Medical Association are deeply indebted. It is but fitting, therefore, that from time to time they should remember him and praise him. To be permitted to act as the channel along which their gratitude may flow is indeed a high honour, and of this I am duly sensible. For this undertaking I possess one qualification that is somewhat rarer than it used to be. It so happens that Sir Charles Hastings was an Englishman who took his medical degree at Edinburgh; so am and so did I, although ninety-four years after the man whose mantle I am momentarily privileged to wear.

Sir Charles Hastings is best remembered for the outcome of his interests in matters political. He was successfully active in the establishment of an improved relationship within the medical profession and between the profession and the society which this served. It is perhaps not inappropriate, therefore, that in this memorial lecture I should attempt to focus your thoughts upon the interconnexion between medicine and politics—two fields of human interest and activity that, in a country such as this, have come to share a common purpose: the achievement of human and social betterment.

This being so, my delight in having in the Rt. Hon. Walter Elliot a chairman with so exceptional a record of high achievement, both in medical science and in statecraft, can readily be appreciated. His presence, for which I am indeed grateful, helps me greatly to make this occasion one when, in the words of Sir John Simon, "statecraft and medical knowledge should sincerely take counsel together for the health of the people."

In the narrow limits of this lecture I propose to speak of medicine as a social science and to restrict myself to a consideration of its uses as an instrument of social policy in this country. That which I have to say, therefore, refers only to the last hundred years or so of this country's history. Medicine could not begin its development as a social science and could not be used by society for the attainment of certain social objectives until many things had come to pass. The population of this country had to grow large and come to live in great aggregates in cities and towns; the dark satanic mills of industry had to be stoked with the health and vigour of the people, to their great detriment; diseases which flourish when great aggregations of people must lead unhealthy lives in most

insanitary conditions and against which no defence is available had to threaten all, so that exposure to a common danger would evoke a demand for common action; a great discontent with things as they were had to develop and the demand that they should be changed had to become clamant; there had to evolve a widespread acceptance of the view that much of the prevalent disease was the product of the conditions which great masses of the people endured, that it was preventable and should be prevented, that it was a barrier standing athwart the road of social progress that must be flung down. Moreover, and especially, there had to come into being an acceptance of the view that to prevent disease and to promote health were sound business propositions.

The role of government had to change from what it was when the policy of *laissez faire* prevailed. It had to intervene actively and creatively in the affairs of the community in response to the pressure of public opinion, and one of its major preoccupations had to become the care of the people's health. A machinery that would enable Parliament to safeguard the public health had to be designed and elaborated.

The interests of medicine had to become greatly enlarged; it had to add to its great store of clinical knowledge new knowledge that could be applied to the preservation of the health of the people as a whole. The concepts and methodology of a new disease-preventive, health-promotive medicine had to be elaborated.

Inquiry into Preventable Illness

My story therefore begins with the appointment by Parliament of a Commission of inquiry into the working of the Poor Laws following the passing of the Reform Bill in 1832. This Commission, in its search for evidence from which firm conclusions might be drawn, engaged the services in 1834 of three medical men to inquire into the prevalence and causation of preventable sickness in the cities and towns of Great Britain. This event is surely to be regarded as being of quite extraordinary significance, for it created a completely new situation. It initiated a system in which recommendations rooted in medical knowledge began to shape social policy and to guide legislative action. The information thus gleaned formed the basis of the Commission's *Report on the Sanitary Condition of the Labouring Population of Great Britain* which was issued in 1842. Recommendations contained within this report determined the direction which developments relating to the use by society of medicine as an instrument of social policy were to take during the next half-century. They made it

*Sir Charles Hastings Lecture given at B.M.A. House, London, on May 6.

perfectly clear that so far as the application of medical knowledge to the affairs of the community as a whole was concerned, whilst diagnosis and prognosis largely remained the responsibilities of medicine, there were many diseases of great social importance of which the therapy, to a very large extent, was to become the accepted responsibility of central and local authority, taking the form of adequate social and political action. The pharmacy of this new disease-preventive, health-promotive medicine was to be the council chamber of local authority and the House of Commons, and its major therapeutic instrument the sanitary engineer.

To these recommendations, quite inevitably, political implications were attached, for they involved very heavy expenditure and even necessitated the institution of a new department of government. In 1843 a Royal Commission was appointed to consider these implications, and, in response to the recommendations contained in its report, a Government Bill for the improvement of the public health was introduced in the House of Commons in 1845, and 1848 saw the passage of the Public Health Act, which provided for a central General Board of Health with local boards to abate nuisances and to deal locally with matters relating to the people's health. Here again an event of great significance occurred. To this Board, after considerable opposition had been overcome, a medical member was appointed, thus ensuring that at the highest level medical advice should be available for the shaping of policy.

In 1854 this Board was reconstituted, and to it an advisory council, which included a number of medical men, was attached. In 1858 this General Board of Health came to its end, but its salaried medical officer and its medical duties were transferred to the Privy Council. Then in 1871 the medical interests of the Privy Council were transferred to a new central board, the Local Government Board, which had a complete medical department. Finally, in 1919, there came into being the Ministry of Health, essentially as we now know it.

Influence of Medicine upon Legislation

This procession from the General Board of Health to the Ministry of Health depicts the very great and steadily progressive expansion of the attention given by Government to problems relating to the preservation and augmentation of the people's health, and it also reveals the steady growth of the influence of enlarging medicine upon legislation.

The extent of this increasing care of the people's health by Government and the consequent expansion of legislation based upon recommendations rooted in medical knowledge can perhaps best be appreciated by reference to the list of Acts of Parliament that relate directly to measures designed to protect the population against the hazards of disease. In 1837, when Queen Victoria ascended the throne, the Statute Book contained but one—the well-intentioned but futile Act for providing quarantine. But between 1848 and 1948 some fifty Acts of major importance, of ever-widening scope, and relating directly to matters affecting the public health, were added. Of these the most recent, the most impressive, and those which most clearly illustrate the growing recognition of the interdependency of health and welfare and the expanding collaboration of politics and medicine in the general field of human ecology, are the National Health Service Act of 1946, the Children's Act of 1946, and the National Assistance Act of 1948.

These Acts indicate overtly that the Government accepts full responsibility for the provision of a wide variety of means whereby the people's health can be safeguarded and augmented. The Minister must now equip himself with the means of knowing what the public needs in political

terms and with the means of satisfying these needs in administrative ways. No longer does governmental action wait on agitation.

During the last half of the nineteenth century medical knowledge and skill were harnessed to the task of sweeping the physical environment clean of the various living and non-living agencies which were shown to be causally related to disease. The expanding medical services of central and local authority dealt not directly with the human population itself but with the conditions and circumstances of the external physical environment in which the community lived. These medical services did for the individual and for the small community those things which they themselves could not do, protecting the individual and the community against dangers that with the passing of the great epidemics came no longer to be generally recognized.

Health-promotive Services

Then, in the first half of the present century, as concepts of disease causation widened, there evolved a completely new kind of medical activity based upon the recognition that the population was divisible into categories, biological and social, and that each of these presented different medical problems which demanded different methods of disease prevention and health promotion. To serve their various needs there came into being special medical services designed to care for such categories as the mother and child, the school-child, the industrial worker, the pensionable, and the variously handicapped; and new branches of medicine—for example, paediatrics and industrial medicine—made their appearance and developed. The importance of this development lies in the fact that the concepts underlying it and the methodology that was elaborated in connexion with it pertained to what was tantamount to an entirely new kind of medicine, group medicine as contrasted with the medicine of the individual, disease-preventive and health-promotive medicine, and applied to the affairs not of individuals but of communities and the categories within them.

Possibly the greatest value of this later development was to be found in the education of the people in the ways of healthy living, in the changing group patterns of behaviour, in securing the co-operation of great numbers of citizens in endeavours directed toward health promotion, and in bringing to their awareness the existence and scope of the medical services of central and local authority and the philosophy of health-promotive medicine.

The education of the general public concerning the nature and causes of health, and concerning also its personal and social value, is undoubtedly a prerequisite to all successful endeavour by governmental agencies and by the medical profession towards the augmentation of the public health. Only when people ardently desire health can the benefits that medicine has to offer be enjoyed to the best advantage; only then can Government translate this desire into project and scheme. During the nineteenth century on the continent of Europe it was made abundantly clear that a Government, no matter how benevolent in intent, could not impose a regimen of health upon a disinterested people. Thus it was that this development of what may be called the category health services and their indirect education of the general public made the further development of the health-promotive services generally both necessary and inevitable as the appetite of the people for health continued to grow.

Changing Pattern of Morbidity and Mortality

The effects of this employment of medicine as an instrument of social policy are best revealed in movements of such rates as the crude death rate, the infant mortality rate, the survival rate, and in the shift in the life expectancy. They are revealed also in the changing pattern of morbidity and mortality and the changing age structure of the population. It is not suggested that the intervention of medicine in social affairs alone was responsible for these changes; for other and very powerful agencies were at work. There had been occurring during the course of the century under

review a gradual but definite uprising of the general standard of living, in the level of education, of nutrition, of housing, of the conditions of work, and of social security. It is difficult, if not impossible, to disentangle the separate effects of any one of these factors. Nevertheless, it is essentially reasonable to postulate that in the production of the changes that occurred medical intervention played a by no means unimportant part. In saying this I am but repeating what Sir Charles Newman in this Sir Charles Hastings Lecture of the year 1928 stated so much more elegantly: "Health," he said, "is Everyman's duty. It must be every man's Quest ere it can become a national Conquest. . . . The vastly improved health of the people in our generation has no doubt been partly due to the fuller application of medicine and sanitation, but still more to the forces of education, sociology, and biology."

In 1948 the crude death rate was but half of what it had been a hundred years before and the infant mortality rate only a quarter. To the life expectancy of the individual, which in 1848 was about 40 years, 25 and more years had been added. Of the total mortality at all ages at the beginning of the century almost half was recorded as being due to the infectious diseases; at the end of the century these diseases were responsible for only about one-sixth of all deaths. In 1948, of the diseases formerly exceedingly prevalent, some, such as cholera and typhus, were no longer to be found in the list of the causal agencies of death in this country. Typhoid and smallpox had become rarities and diphtheria had lost its importance. Scarlet fever and rheumatic fever were no longer to be feared and the venereal diseases were rapidly passing under control. The pneumonias, though still common, had become far less lethal than formerly, for the case fatality rate had fallen almost to nothingness even amongst the old. The mortality among children under 10 years of age had so greatly diminished that it was only one-sixth of what it had been in 1900. These are indeed triumphs in the achievement of which medicine can rightly claim to have played no little part.

In this successful rebellion against untimely death the weapons that medicine used were of two kinds—those that belong to the armamentarium of the new preventive or health-promotive medicine and those that are the instruments of the older and far more evolved clinical or curative medicine. The former kind took the form of measures for the control of the causal agency of the disease and for the increase of the resistance of the individual to the attack of the disease-evoking agent—for example, sanitation, the encouragement of hygienic personal and public habits in the community, vaccination, and immunization. The weapons of curative medicine consisted for the most part of specific measures taken to modify the action of the causal agency or to mitigate its effects—for example, the introduction of the serum treatment for pneumonia in the 1920s was directly responsible for a steep fall in the death rate from this disease. A similarly dramatic fall later followed the introduction of the sulphonamide drugs, and yet another was directly due to the introduction of penicillin. The introduction of insulin brought continued life to thousands of diabetics. Improvements in surgical, anaesthetic, blood transfusion, and radiotherapy techniques all made their contributions.

Principal Causes of Mortality

But as great as the powers of preventive and curative medicine had become, disease had not been conquered. Great victories had been won, but the war was by no means ended. Diseases that formerly claimed but a lowly place in the list of the causes of disability and death came to occupy a position of dreadful prominence. First among the great killers to-day stand diseases of the cardiovascular system, responsible for rather more than one-third of the total deaths at all ages. Close on their heels come cancer, violence, and tuberculosis. High among the causes of morbidity are peptic ulcer and nervous disorders and, among the elderly, diabetes.

There are relatively far more old people in the population now than there were a century ago. The diseases of the cardiovascular system and malignancy occur far more commonly in the old than in the young; it is to be expected, therefore, that as the age-structure of a population changes as ours has changed their incidence will rise. But this does not explain the sharply rising incidence of cancer of certain sites, of the lungs for example. The great increase in the habit of cigarette-smoking and the increasing vitiation of the atmosphere are under suspicion as contributory factors, but as yet the evidence is not completely firm. An increase in the number of deaths from violence was to be expected as the population grew older and became increasingly urbanized, as mechanization became introduced to augment the power of labour, and as the speed of multiplying transport continually mounted. To-day, in the 5-14 age group, violence, taking the form of an accident, is the major cause of death in the male.

Tuberculosis continues to hold its high place among the enemies of achievement because its causation is multifactorial. Though there is a micro-organism which is the prime causal agent, genetic and socio-economic factors are also involved. The therapy that is demanded, therefore, must consist in a combination of medical and social intervention, and as things are at the moment the power of medical therapy, though great, is to a considerable extent made impotent because of the inability on the part of society immediately to provide those environmental conditions which would segregate the infective sufferer and protect the rest of the community from the hazards of infection.

Into the causation of gastric ulcer possibly genetic and certainly social factors enter. The mental strains of modern life, the widespread unhappiness among such as are not sustained by simple and firmly held religious faiths or their equivalent, the complexity of human interrelationships and the uncongenial and even unhealthy nature of many occupations, the carelessness of many concerning personal habits, have all been blamed for the rising prevalence of this complaint.

Mental illness has a higher incidence in the older age groups than in the younger. Thus its incidence in the over-70 age group is more than twice that in the population as a whole. The figures showing the number of admissions into mental hospitals can be misleading, since not uncommonly they include readmissions. Moreover, it is probable that a far higher proportion of the mentally ill in the population are admitted to hospital than formerly. Not so long ago lunatics were segregated in asylums; now the mentally ill are cared for in mental hospitals. Nowadays psychiatry offers several kinds of therapy, and in many forms of mental illness there is a hope of cure. It is not possible to make an accurate comparison between the incidence of mental illness now and a hundred years ago, but it is by no means unlikely that an actual increase has occurred. Be this as it may, the load constituted by the chronically and hopelessly mentally ill is exceedingly heavy and is an impediment to social advancement.

In very general terms it can therefore be concluded that the conquest of infectious diseases, of the diseases that formerly decimated the young, and of the diseases of privation is fairly complete, and that, as a consequence of this, certain diseases formerly relatively infrequent in their incidence have come to assume a considerable prominence. The diseases of plenty have come to be more common and the chronic diseases of the mature and senescent—genetic, metabolic, degenerative, and malignant—have now become so prevalent as to command the attention not only of the medical profession but of society as a whole. Furthermore, and again in very general terms, it can be concluded that the diseases which have passed or are passing rapidly under control are those in which the causal agencies have their existence in the external physical world of the community, whilst the diseases that have now come to figure so prominently among the causes of chronic disability and death are those in the causation of which a variety of factors operate—a few

genetic and some which relate to personal habits, but in the main those which exist in the external *social* world of the community.

Social Adjustment

The diseases that have passed under control are, for the most part, the diseases of biological man. Man shares his external physical world with a multitude of other living things with which, if he is to flourish, he must establish an equilibrium. In this physical environment there are the micro-organisms that cause disease; these must either be eliminated or, alternatively, between them and the human subject there must become established by natural or artificial means a harmonious relationship. As a consequence of advancing knowledge in such fields as sanitary science, parasitology, and entomology, and especially bacteriology, such elimination has become possible and harmony between biological man and many of the pathogenic micro-organisms in his external physical world can be established.

Man elaborated that aggregate form of living which we know as a human society in order, presumably, to facilitate his dominion over a hostile environment and to make easier the satisfaction of certain fundamental human needs. He is a gregarious animal, and it may be assumed that he found by experience that living in aggregates made the production of food and shelter more certain, gave greater protection, satisfied his yearnings for companionship, and secured the continuance of his kind. The early forms of human society certainly seem to have conferred much advantage upon their individual members. Their kinship relationships and their rituals did much to shift the load of emotional difficulty from the individual on to the broader back of the group as a whole. It would seem that man's elaboration of this social organization from the primitive to the modern has produced an external social world that at many points is violently in disharmony with human needs, and also that the speed of this societal evolution has exceeded man's ability to adjust.

To great numbers of purposeless, bewildered, and perplexed individuals in our society who feel that they have a right to be healthy, since adjustment is beyond their unaided ability, the conditions that exist are intolerable, and in their attempts to escape from the uncongenial there would seem for them to be an easy and respectable route, that of vague, ill-defined, and symbolic illness. Such illness, in no sense a display of malingering, is a common excuse for masochistic sloth, for those who delight in mortification for its own sake, and for the inefficient. Much sickness of this kind is to be regarded as dramatized discontent born of disharmony, as a malaise of maladjustment, and the profession of medicine, therefore, being forced by circumstances to restrict its activities to dealing with the symptoms rather than with the cause, is largely employed in perpetuating the conditions that are primarily responsible for such sickness. Indeed, with the world as it now is nothing could be more calamitous than to rob the people of this kind of sickness, for as things are there appears to be no escape from perplexity and uncongeniality for thousands amongst us other than through the narrow neck of the bottle of medicine. To a large extent one of the major social functions of medicine has thus unfortunately become the provision of comfort for the inefficient and of support for those who, because of their own inadequacies, cannot cope with circumstance.

The nature and causes of health are as yet but imperfectly comprehended. Certainly health is more than biological efficiency, much more than the smooth working of a multitude of interdependent component parts of a machine: it is partly a thing of the spirit of man, a by-product of the exercise of human aspiration and of the satisfaction of attempting or of achieving the worth-while in life. It is a state of harmony, within oneself and between oneself and the external world.

Attitude towards Health

The different income groups within the population and

by significant differences in respect of the incidence of a variety of illnesses. Many of these are undoubtedly true reflections of differences in the conditions and circumstances of their environments and occupations. Though the benefits of medical care have latterly been made available to all, not all of those to whom they are available are in a position to profit therefrom. The different social categories are not so much to be distinguished nowadays by differences of income as they were in former times, as by differences in their modes of spending the money that is earned. It can be spent in ways that are conducive to the maintenance and augmentation of health or otherwise, and much depends upon the attitude towards health and to the desirability of securing it that prevails in the different groups. And even though the desire for healthiness were equal throughout society the chances of securing it are by no means equally distributed. Thousands of the population are still imprisoned in the hideous squalor of the legacy that was left to us by the nineteenth century. Others are bound by the shackles of tradition, ignorance, and superstition. Such imprisonment, such bondage, are not compatible with the maintenance of health, and under such circumstances there is very little that purely medical therapy can do.

Society for its continuance requires that a vast variety of tasks shall be undertaken. Some kinds take the form of strenuous physical labour, others are sedentary; some are in the open air, others in the vitiated atmosphere of office and factory; some are creative and emotionally and intellectually satisfying, others are dull routine drudgery. Very many of these occupational categories have their own peculiar health hazards, some being positively dangerous. In general terms the amount of minor illness occurring among those undertaking a particular kind of work is an index not only of the danger to health but also of the uncongeniality of the work that is demanded. It is small among those who are doing work that is satisfying to them and which is regarded as important by others; it is considerable among those who are called upon to perform work from which they derive no contentment. Here again purely medical therapy is largely impotent and only social therapy can hope to eradicate the causes of such sickness.

The great disparity between the numbers now marrying each year and the number of houses that are available to them is undoubtedly an indirect cause of much discomfort and distress that often leads to actual illness, both mental and physical. In the establishment of that micro-environment which is the home, if this is to be health-promoting in respect of its general conditions and atmosphere, the family grouping can claim an exceptional importance. Evidence that has been accumulated shows beyond all doubt that the interrelationships between the individuals constituting the family play a most important part in determining the state of the mental health of the component individuals. Yet the kind of society that we have developed so far has imperilled the very continued existence of the family group and has made the achievement of a harmonious interrelationship among its members difficult of achievement.

An Urgent Need

Though these developments undoubtedly have their repercussions in the medical field, medicine itself has no therapy which can be applied to the resolution of the problems they create. It would seem, indeed, that the great and urgent need of the day is that the encouragement thus far given by society to the medical scientist shall be given with the same readiness and in the same magnitude to other social scientists also from whose studies it can be expected that there may emerge knowledge that could be transformed into the power to repair the present disease-evoking qualities of society and its institutions.

This is of importance also because of the complexity and social importance of the problem of the progressive increase of the proportion of the aged within the population that has resulted very largely indeed from the success

evoking agencies resident in the external physical world. The proportion of the aged has risen because the birth rate has fallen and because the survival rate, especially amongst the younger age groups, has risen. Though the net reproduction rate of the population has fallen, of those that are born fewer now die in infancy, childhood, and early maturity, and so live on to die in late maturity and old age. Since the reproduction rate has fallen to half of what it was a century ago and since the survival rate has risen so dramatically, it follows that there are now relatively far fewer young in the population than there used to be and relatively more old, and so the mean age of the population has steadily risen, and indeed is still rising. At present the life expectancy among those aged 65 and over is not substantially greater than it was a hundred years ago. But should the ardent quest for the power to control the cardiovascular and malignant diseases be successful, then the life expectancy of the individual would at once leap to become far greater than it now is.

Since in great numbers of instances death at present amongst the old is not the gentle end of a long and progressive waning but is a last phase in the progress of some particular disease, it follows that in increasing measure the patients of the physician will be those in the older age groups of the population and that the commonest of the most serious diseases with which he must attempt to deal will be the malignant and the cardiovascular diseases, chronic in their course and disabling in their effects.

That branch of medicine which is now becoming known as geriatrics will assume an importance both in medical education and in practice equal to that of paediatrics in the early decades of the present century. But sickness in old age differs from sickness in youth or maturity in that, since in a large number of instances the old either live alone or inconveniently with relatives or others, the attention, domestic and nursing, that the patient requires is not readily available. The social aspects of such disease are no less important than are the purely medical, and therefore social as well as medical therapy is demanded.

A Growing Economic Burden

As things are in our society the economic burden constituted by those of pensionable age and over within the population is already heavy and must grow heavier still if the present trends continue. It is society's will, in accordance with the prevailing social ethic, that life shall be preserved and prolonged; the ethic of medicine binds the physician to the same obligation. In the medical sciences the quest for the knowledge that will give power to control the degenerative and malignant diseases eagerly proceeds; yet in the social structure as we know it there is no place for the old, and much illness among them would seem to derive from a sense of sudden extrusion from the community. Disease of this kind is the reaction of the total personality to the uncongenial circumstances to which the individual is suddenly exposed. Feeling unwanted, many amongst the old do not exercise their skills and to their own hurt futilely rebel against the conditions that imprison them.

Since it is not improbable that the life expectancy of the individual will become further, and perhaps greatly, extended, it behoves society to ensure that the problems thus created do not lead to crisis and catastrophe. The life span being thus extended and healthiness being assured to the senescent, the relation between the chronological and the physiological age of the individual will need to be reviewed. Manifestly the school-leaving age and the age on retirement in a population in which the life expectancy is 75 years might well be much higher than in one with a life expectancy of 45 years. But there will be much need for knowledge on which the education of the middle-aged in the art of growing old can be based, for guidance clinics for the senescent, for the development of a system whereby the process of withdrawal from society and from work as the power of adjustment and

into society by the infant. Medicine as a social science must be heavily involved in these matters, but its role must remain a subordinate one to that of the statesman, whose policies are shaped by advancing knowledge in all those scientific disciplines which deal, directly or indirectly, with those features of a human society which affect the public health.

Problems of Colonization

Medical intervention of the same kind has created even more acute and serious problems in other and relatively undeveloped countries. During the course of the period of the phase of colonization in which we as a people indulged, we introduced into many parts of the world the medicine that is part of our own culture, proclaimedly using it with benevolent intent to improve the lot of the indigenous peoples whose cultures differed greatly from our own. We inserted nineteenth- and twentieth-century Western European scientific medicine into the cultures of peoples who, according to our own standards, were still living in the equivalent of our own Middle Ages. By doing so we have largely helped to destroy those cultures and have created problems of far greater complexity than those which we attempted to solve.

In India, for example, the population has been increasing at the rate of four and a half millions every year, and that this is largely the result of the introduction during the period of British rule of our standards of sanitation and medical care is beyond doubt. India is at present quite incapable of feeding from her own resources her immense and rapidly growing population, and so, quite inevitably, much poverty and even more misery are the lot of millions. The major task facing the Indian statesman is that of finding solutions to the social and economic problems thus largely created by medical intervention.

In Africa the introduction of modern European medicine for the benevolent purposes of saving life and of eradicating disease from the indigenous populations has been largely and directly responsible for the magnification of a cluster of problems that relate to the interrelationship of the different ethnic groups. In South Africa the policy which the medical services have there pursued seemingly has been in discord with the policies of the presently predominant political party.

In many parts of the Empire it has been shown that the effects of medical intervention far outpace those of the other services which are directed towards social amelioration, and that in so doing create problems that threaten to bring all such betterment to an end. The eradication of many and prevalent diseases responsible for much death, disability, and inefficiency—malaria, venereal diseases, yellow fever, and the like—has become a relatively simple matter, but their elimination can result in a complete disruption of the prevailing economic system so that famine can threaten to become the regulator of population growth unless wise statecraft intervenes.

Perhaps the lesson that is to be learnt is that medicine is but one of many activities that are directed to human and social amelioration; that medicine can bring under control the environmental factors causing the major diseases of a native people far more speedily than the other services can create the conditions that are necessary if those thus saved and made healthy are to flourish, and that possibly in all projects for social amelioration of this kind what is needed is a time-table of intervention so that the medical services are timeously introduced as part of a complete and comprehensive project which does not neglect the educational, economic, and other aspects of the problem.

Repercussions

Thus, both in this country and overseas, medical action has given rise to repercussions that take the form of grave and serious social problems, problems unlike those which medicine has so far solved in that it

the supporting and the supported categories within a population, and with the increasing disparity between the number of mouths to be fed and the available food resources of the world, the problem that the *bouche inutile* creates gains in importance. In this country within the National Health Service it is already being found that the existing facilities cannot cope with newly discovered and enlarging needs. The authorities concerned are being forced to give serious consideration to the construction of a calculus of priorities. Great, therefore, becomes the need for the provision of the means whereby greater and more detailed knowledge concerning the variety and the needs of the public for those services can be secured. The changing age-structure and the changing pattern of morbidity are prominent among the factors that are creating the demand for the expansion of medical and hospital services at a time when the financial resources of the nation are strained.

It is to be remembered that in their beginning the medical services were encouraged because it was thought that such medical intervention would prove itself to be a sound business proposition. It would certainly seem that the reasons for the encouragement of medical research and of the practice of preventive and of curative medicine have changed, though not completely, since then. It would be difficult to maintain that the medical care of the old, permanently disabled by chronic illness, or of the idiot and imbecile beyond all human aid is economically desirable. Such matters are not to be considered in economic terms, for moral principles are involved. They do not create difficulties within the medical profession, for this is governed by an explicitly stated code; but they do constitute problems of profound difficulty and complexity for society as a whole. There is to be discerned a growing interest in such matters as the sterilization of the unfit and euthanasia, which can be regarded as an indication that the gravity of the problem is becoming recognized and that the search for a possible solution has begun. I refer to this matter only to attract your attention to the possibility that in the future the social ethic may come to be in conflict with the ethic that at the moment prevails within the profession of medicine.

Changing Needs

The medical ethic in its origin and development was associated with the development of the profession of medicine as a body concerned with the diseases of individuals. It regulates the relationship of physician and patient, often as intimate a relationship as that of the confessional. Like the Church, the medical profession would seem to claim that it is concerned with matters outside the province of the State, that its obligations are to the individuals that seek its aid, and that it is not in any way concerned with the social consequences of its benevolence. Concerning many matters of interest and importance to society—contraception, sterilization, euthanasia, divorce, for example—there are medical aspects. But concerning them there would seem to be no purely medical opinion, but merely the conflicting views of medical men and women whose attitude towards such matters as these is moulded by their sincerely held religious faiths, so that the opinions expressed derive their strength therefrom.

Yet it is with such matters as these that those medical men and women who serve in the field of population medicine, of medicine as applied to the affairs of the population as a whole, are becoming increasingly involved. They are required to present to the departments of government or to committees of local authority a purely medical opinion concerning them and to relate this to the action that is being considered. Such expert opinion commands the serious attention of those whose responsibility it is to consider and weigh all relevant knowledge and opinion and translate this into scheme and project.

It is not improbable that public opinion in this country concerning the value of the individual life, beginning at the moment of conception, will change. Indeed, there is plentiful evidence that both among the general public and within

the medical profession it is already changing fast. The social ethic, like the law that sustains it, is mutable. It may come to be regarded as ethical by the great majority of the general public to terminate the life that from birth is imprisoned in a body without a brain or to bring to a peaceful ending a life that flickers fitfully in a body that is tortured by agony beyond endurance. Should this happen, will the ethic of medicine remain inviolate or will it become modified as the social ethic changes?

If not, then it is not improbable that in the future the ethic of the medicine of the individual and that of the medicine that is applied to the affairs of society as a whole may come to differ, to make even greater the divergence in respect of their philosophies that even now distinguishes them. The ethic of the former belongs to an age that is swiftly passing and is becoming inappropriate to the circumstances of a world in which the major quest is for social amelioration rather than for personal continuance.

The major obligation of medicine in increasing measure will be towards society, and medicine will continue to be one of the most potent instruments that society will use for the achievement of its aims. It will be for medicine, along with the other social sciences, continually to examine and to define the changing and enlarging needs of socialized man, in respect of health conservation and augmentation, and for politics to design and to provide the means whereby society can be so shaped that these needs are satisfied.

But all such endeavour must remain barren unless the citizen, knowing its value, desires health and, seeking it, eagerly and intelligently makes use, in the conduct of his private and public life, of the knowledge and of the facilities thus made available.

TREATMENT OF POLYCYTHAEMIA RUBRA VERA*

BY

RONALD BODLEY SCOTT, D.M., F.R.C.P.

Physician to H.M. the Queen; Assistant Physician,
St. Bartholomew's Hospital; Physician to Woolwich
Memorial and Surbiton General Hospitals

The cause of polycythaemia rubra vera remains unknown; indeed, the very nature of the disease is still debatable, although perhaps a majority would favour its inclusion with leukaemia in the group of unexplained, and apparently purposeless, mesenchymal proliferations. Our ignorance limits treatment to the empirical and the symptomatic. In general the therapeutic aim has been to maintain a normal blood count. It is therefore pertinent to inquire whether its achievement relieves the patient's symptoms or prolongs his survival, and in what manner the disease terminates.

Associated Diseases in Polycythaemia Vera

There are symptoms, such as a sense of fullness in the head, vertigo, flushing, dizziness, and pruritus, which can be attributed without question to the changes in the blood and which disappear when the erythrocyte count falls to normal. They need to be separated from those of vascular degeneration, arterial hypertension, gout, peptic ulcer, renal calculus, and other common companions of polycythaemia vera. Videbaek (1950) has shown that the disease, as treated in the past, shortens the expectation of life; in his patients the mean survival from the time of diagnosis was six years for men and nine for women (Fig. 1). Whether maintenance of a normal erythrocyte count prolongs

*A paper read to the Section of Medicine at the Joint Annual Meeting of the British Medical Association and the Irish Medical Association, Dublin, 1952.

FIG. 1.—Percentage of patients with polycythaemia vera surviving at the end of each year compared with the survival for the general population of the same age (Videbaek, 1950).

survival is unknown, because no series of untreated cases is available and because satisfactory control has been exceptional. Videbaek's figures will provide a useful yardstick for measuring the efficacy of newer methods of treatment, but they show that a long period of observation is required before any conclusions are justifiable.

The causes of death in polycythaemic patients are relevant to this question of survival. It is a disease of middle and later life, and it is not surprising to find it accompanied by the degenerative states common in these epochs. Table I

TABLE I.—Associated Conditions in 36 Patients with Polycythaemia Vera

Arterial thrombosis:		
Cerebral	..	4
Mesenteric	..	3

Pyelonephritis	..	1
Diabetes mellitus	..	3
Gout	..	1
Various	..	3

shows the frequency of complicating disease in the present series of 36 patients, and is representative of the larger experience of other authors. Vascular disease occupies the first position; but peptic ulceration, renal calculus, and gout are all more common than in patients of like age without polycythaemia.

The causes of death reveal the importance of these associations (Table II). It is rare for death to be immediately attributable to the progress of the polycythaemic process; perhaps the examples of leukaemia and the even less

TABLE II.—Causes of Death in Polycythaemia Vera (from Lawrence, 1949; Videbaek, 1950; Stroebel, Hall, and Pease, 1951)

	Not Treated with P ₃₂		Treated with P ₃₂		S.E. of Difference

Leukaemia ..	6	5.6	10	23.3	6.8
Other causes ..	46	42.4	16	37.2	—
	108		43		

common instances of secondary myelosclerosis fall into this category. More than half the deaths are due to vascular accidents, most frequently thrombotic; calculous pyelonephritis accounts for as many as 18% in one series (Videbaek, 1950), and leukaemia for 6%, while causes apparently unrelated to polycythaemia are responsible for the remainder.

Aims of Treatment

There is no evidence that vascular degeneration is more common in the polycythaemic patient than in others; it is logical, therefore, to attribute the frequency of thrombosis to the increased viscosity of the blood, and reasonable to hope that maintenance of a normal count will diminish, or at any rate defer, the incidence of such catastrophes. Renal calculus depends on the increased excretion of urates, a product of the bone marrow's overactivity, rather than on the elevated erythrocyte count; its control by measures which discourage this activity might be anticipated.

Restraint of the hyperplastic bone marrow seems, therefore, to be a rational treatment. It would control the erythrocyte count and relieve the "true" polycythaemic symptoms. The restoration of normal levels, both for erythrocytes and for platelets, might be expected to diminish the risk of thrombosis. Uric acid excretion, the increase in which is probably a function of bone-marrow hyperplasia, should fall to normal, lessening the danger of stone and renal infection. It must be stressed, however, that, although these effects can logically be anticipated, there is as yet no incontrovertible proof that, excepting the relief of true polycythaemic symptoms, they do in fact occur.

Methods of Treatment

From what has been said it will be clear that treatment of patients with this disease is often a matter of complexity: arterial or venous thrombosis, dyspepsia, gout, or renal calculus may dominate the picture, and the management of these disorders against a background of polycythaemia may call for many difficult decisions. This communication, however, concerns itself only with methods of controlling the polycythaemic process and not with these problems of general management.

Until recent years the two therapeutic measures in common use were venesection and the haemolytic agent phenylhydrazine, either alone or in combination. By these means many patients have been kept free from symptoms for long periods, but both methods have practical and theoretical disadvantages. Repeated bleedings and the haemolysis occasioned by phenylhydrazine are bone-marrow stimulants, and, although the erythrocyte count may be kept within bounds, there is no like effect on the leucocytes or the platelets. The dosage of phenylhydrazine is difficult to control and its action is sometimes unexpectedly abrupt. More important is the iron deficiency which results from continued venesection; in many patients treated in this way chlorotic polycythaemia (Rosenthal and Bassen, 1938) appears, the haemoglobin reading falling below normal although the erythrocyte count remains high. An impasse is reached in which the increased viscosity of the blood and its attendant perils demand further bleeding, which will inevitably reduce the haemoglobin level enough to cause anaemic symptoms.

During the past decade, chemical and radiotherapeutic methods of treatment have been devised which meet our theoretical requirements better than the two already discussed, in that they aim to abolish the bone-marrow hyperplasia. Nitrogen mustard is representative of the first group and will certainly procure remission in many patients. Its action is short-lived, and relapse usually occurs within six months (Spurr, Smith, Block, and Jacobson, 1950); moreover, its side-effects are often unwelcome. The folic acid antagonists have been used, but results are indifferent (Bell and Davis, 1950). Radiotherapy is undoubtedly more satisfactory. It is best applied by total body irradiation (Richardson and Robbins, 1948), and the results are excellent. Only three patients of the present series were treated

FIG. 2.—Polycythaemia vera in a woman aged 50. Satisfactory control with venesection and radioactive phosphorus.

in this manner, and good remission was obtained in all; one of them remains well after more than three years. The method is, however, cumbersome, and treatment may take several weeks.

Radioactive Phosphorus

A more convenient means is by the administration of the radioactive isotope of phosphorus, P^{32} . This was first employed in 1940 by Lawrence, and the results in several large series have been published in the United States (Erf, 1946; Reinhard, Moore, Bierbaum, and Moore, 1946; Lawrence, 1949; Stroebel, Hall, and Pease, 1951; Wiseman, Rohn, Bouroncle, and Myers, 1951). The following remarks are based largely on these reports.

P^{32} is prepared from red phosphorus by one of several methods; it decays at a constant rate, emitting only beta rays, and has a half-life of 14.3 days. Its radioactivity is measured in millicuries, one millicurie being that amount of radioactivity produced by the disintegration of 37,000,000 atoms per second. When administered, P^{32} is incorporated in the nucleoproteins, particularly of rapidly dividing cells, and finds its way mainly to the bone marrow, liver, spleen, lymph nodes, bones, and teeth. Given intravenously 5–25% is excreted, chiefly in the urine; by mouth the loss is 15–50%, largely in the stool. About 75% of an oral dose is absorbed. In the average adult, 1 mC of P^{32} emits on the first day radioactivity equivalent to about 0.6 roentgen unit given by total body irradiation, or 12 roentgens during the time required for complete decay. In healthy monkeys its effect is shown by a reduction in the number of circulating leucocytes, with a lesser fall in the erythrocyte count; the lethal dose is about ten times that judged to be the equivalent of the human therapeutic dose (Scott and Lawrence, 1941).

The results of the American workers are all in close accord: in 80% of patients satisfactory remission, lasting for at least a year, is obtained; in about 20% the result is

poor or treatment has to be abandoned because of a precipitous fall in platelet or leucocyte count. These last haematological complications are rare, and fatal in less than 1%. Remission does not, of course, imply more than restoration of a normal blood picture and freedom from true polycythaemic symptoms; insufficient time has elapsed to know whether patients receiving P^{32} live longer than those treated by other methods.

There is little doubt that acute myeloblastic leukaemia occurs more commonly after the use of P^{32} . The incidence of chronic myeloid leukaemia remains the same, and may perhaps be regarded as one normal termination of the polycythaemic process. The figures in Table II include patients dying of both forms. Even so, the increase is unlikely to be due to chance; if only the acute variety is included the increase is undoubtedly significant. In one paper reports of 453 patients treated with P^{32} were reviewed, of whom only 40 (8.8%) had died; yet of these deaths, 12 (30%) had been due to acute myeloblastic leukaemia (Wiseman *et al.*, 1951).

The present series is so small compared with those from America that detailed analysis would be impertinent. Of 35 patients seen during the past five years, only 20 were treated with P^{32} ; of these, 16 have been observed for more than a year. In 13 patients (80%) satisfactory remission lasting a year or longer followed treatment; one of the treated patients has died from calculous pyelonephritis.

The technique employed has been developed with Mr. I. G. Williams, Director of the Radiotherapeutic Department at St. Bartholomew's Hospital, and closely follows those described by other authors. The initial erythrocyte count is reduced to 6,000,000 per c.mm. and the haematocrit reading to 55% by daily venesections, not exceeding 1,000 ml. in volume; patients have been bled of as much as 6,000 ml. in a week without ill effect. After venesection P^{32} is given intravenously in doses varying from 3 to 5 mC; the dose is judged by the initial erythrocyte, leucocyte, and platelet counts and by the size of the patient. Patients are seen at intervals of six weeks, and no further P^{32} is given for at least two months; further venesection is avoided. Few patients have required a second dose. A leucocyte count below 5,000 per c.mm. or a platelet count below 150,000 per c.mm. has been taken to contraindicate this form of treatment (Figs. 2 and 3).

FIG. 3.—Polycythaemia vera in a man aged 36. Unsatisfactory control with nitrogen mustard, followed by venesection and radioactive phosphorus. Further treatment with radioactive phosphorus was withheld because the platelet count fell to 90,000 per c.mm.

Conclusion

Our experience, although diminutive, has confirmed the published opinions that radioactive phosphorus offers the most convenient means of controlling the haemopoietic exuberance of polycythaemia rubra vera. In 80% of patients the blood count is restored to normal for at least a year, and the symptoms immediately attributable to its previous perversion are relieved; the remainder are either resistant to this form of treatment or show leucopenia or thrombocytopenia sufficient to make it dangerous.

Acute myeloblastic leukaemia is a more common termination in those given P^{32} than in those not so treated. The size of this risk remains to be assessed, and it will be some years before we can be certain that the mean survival is increased or the incidence of vascular and other complications lessened by treatment with radioactive phosphorus.

OBSERVATIONS ON PROGNOSIS IN HYPERTENSION

BY

A. W. D. LEISHMAN, D.M., F.R.C.P.
Consultant Physician, United Sheffield Hospitals

Lumbo-dorsal sympathectomy for hypertension is no longer a novelty, although in this country experience of this method of treatment is perhaps only now maturing. Reports of success from this operation have been criticized by Platt and Stanbury (1950) on the grounds that the prospects of many of the patients chosen for operation may well have been favourable in any case. Such criticism, indeed, cannot easily be refuted, since it exposes an unfortunate gap in our knowledge.

Follow-up studies such as those of Janeway (1913), Blackford, Bowers, and Baker (1930), and Bechgaard (1946) have helped to give us a fair conception of the overall prognosis in hypertensive disease, yet probably most of us would agree that, though we could recognize the malignant type of case and perhaps the obviously benign case, we are seldom in a position to predict with any confidence the future of a hypertensive patient, at least at the first examination. So long as we lack this facility unnecessary operations may be inflicted upon hypertensive patients, while in others the decision to operate may well be left too late. It seemed that this situation could be remedied only by acquiring a wider experience of short-term prognosis in hypertension, and this was the object of the present study.

The observations were begun in 1946 at a clinic for hypertensive patients. In addition to the selection of cases for sympathectomy it was proposed to follow the progress of every patient by full examination at regular

intervals; the hope being that when eventually each individual course or fate came to be related to the original clinical findings these would establish the guiding principles by which even at the first examination a hypertensive patient's future might be predicted.

Patients were not accepted for this study unless their diastolic pressure was 100 mm. Hg. or above (the systolic pressure has been largely ignored), or if their age exceeded 60; later, with interest becoming centred on the younger group, the age limit was lowered to 50. The period of observation ranged between two-and-a-half and five years and the patients were examined at intervals of twelve months, six months, and in a few cases three months, according to the severity of their disease. The clinical examination and investigation were strictly standardized, and a progress sheet incorporating the main features in graph form was maintained for each patient.

Since blood pressures were often found to differ considerably in the two arms, the average of a number of readings in both arms was recorded, the final figures being taken after 20 minutes' undisturbed rest. The blood pressure was also taken with the patient standing, and in the leg as well at the first examination, lest coarctation of the aorta be missed. Retinal changes were classified in the conventional five grades as initiated by Wagoner and Keith (1939): grade 0, normal; grade I, spastic retinal arteries with or without variations in calibre; grade II, compression of veins at arteriovenous crossings; grade III, the presence of exudate or haemorrhages; and grade IV, papilloedema. The investigations included intravenous pyelography; 6 ft. (1.8 m.) chest x-ray film for record of heart size in terms of cardio-thoracic ratio; 12-lead electrocardiography; chemical, microscopic, and culture examination of urine; urea-clearance test; modified urine-concentration test; and standard blood biochemistry.

The review is based on the study of 151 hypertensive patients (93 women, 58 men) who fulfilled the necessary criteria. These were first examined during the period October, 1946, to June, 1949; they were treated conservatively, and their fate or condition was known at the end of 1951.

Mortality

During the period of observation 51 patients (34%) died as a consequence of hypertension. The death rate for men alone was 44%: the male mortality was higher in each of the main causes of death, with the exception of cerebral vascular accidents, in which proportionately the sexes were equally represented. Even this slight difference may not be fortuitous, since Frant and Groen (1950) showed an actual preponderance of women dying from strokes.

The age at which the 51 patients died and the individual causes of death are shown in Fig. 1. As would be expected, most of the deaths occurring before the age of 45 were due to uraemia, whilst most deaths from other causes occurred in the sixth decade. The height of the diastolic pressure has obviously an important bearing upon mortality, particularly in the case of hypertensive men (see Table).

Percentage Mortality in Relation to Diastolic Blood Pressure at First Examination

	Diastolic Pressure					
	100–119 mm. Hg		120–129 mm. Hg		130+ mm. Hg	
	No.	Deaths	No.	Deaths	No.	Deaths
Men	18	1 (5.5%)	16	7 (43.8%)	24	19 (79.2%)
Women	39	4 (10.3%)	17	5 (29.4%)	37	15 (40.5%)

FIG. 1.—Age at death of 51 patients dying from hypertension. Cause of death: U=uraemia; H=cerebral haemorrhage; C.T.=coronary thrombosis; C.F.=congestive heart failure; D.A.=dissecting aneurysm.

For example, at the end of this comparatively short period of observation, only 5 men were alive out of 24 who had a diastolic pressure of 130 mm. Hg at their first examination.

Analysis of Clinical Findings

There were 100 survivors, and in Fig. 2 these have been divided into two groups according to the diastolic pressure at their first examination; in 73 it was below 130 mm. Hg and in 27 it was 130 mm. Hg or over. This chart shows the percentage incidence of certain of the main clinical features when these patients were first examined. While percentages of relatively small groups are obviously open

FIG. 2.—Data at first examination of 100 survivors.

to criticism, as a method of comparison they seem unavoidable. Since the object of this form of presentation is essentially to show trends, it was thought that on this basis they could be accepted.

It will be seen that in the severe group more hearts are enlarged, more electrocardiograms are abnormal, more retinæ show advanced changes, and there is a greater incidence of angina. On the other hand, albuminuria is no more frequent and headache occurred equally in the two groups.

Searching next for some indication of why one patient is more liable to a cerebral vascular accident than another, the presenting clinical features of 30 patients who later had strokes of one sort or another are compared with those of a group of 17 severely hypertensive patients who survived without such disasters (Fig. 3). By selecting severe cases

for comparison it was considered that any differences found would have increased significance. Despite the fact that in the former group blood pressures were not uniformly severe, there seems little doubt that these patients for the most part had the more advanced disease: not only were there more enlarged hearts and abnormal electrocardiograms among the patients who developed cerebral vascular accidents, but the incidence of retinal changes of grades III and IV and of true albuminuria was also notably higher.

A similar clinical analysis of the patients destined later to die from uraemia is presented in Fig. 4. It will be seen that little more than half of these patients had diastolic pressures in the severe range when first examined, and that enlarged hearts and abnormal electrocardiograms were the exception. Hypertensive headache was almost universal, but the outstanding feature of this group is the remarkable frequency of advanced retinal changes and of true albuminuria. No less than 90% of the cases had retinal changes graded as III or IV, and 75% had albuminuria in excess of a trace.

If now Figs. 2, 3, and 4 are considered together some interesting trends can be recognized. For example, the incidence of severe retinal changes (grades III and IV)

FIG. 3.—Comparison, at first examination, of 17 patients with severe hypertension who have had no cerebral vascular accident with 30 patients (13 survivors) who have had cerebral vascular accidents.

and of true albuminuria when related to the four groups of patients (Fig. 5) shows a remarkably progressive pattern. The parallel behaviour of these distinct features with its suggestion of a single pathological process should also be noted.

Enlarged hearts and abnormal electrocardiograms show a similarly progressive incidence in three of the groups of patients. These changes, however, were not a feature of the fourth group who died from uraemia; this is not surprising, for many were young and their disease was probably of relatively short duration. While from these figures it may be inferred that a high diastolic pressure increases the chances of developing an enlarged heart or an abnormal

FIG. 4.—Clinical analysis of 20 patients subsequently dying from uraemia.

electrocardiogram, other factors are clearly involved, for it will be seen that these changes were encountered most often of all in a group (30 patients who developed cerebral vascular accidents) in which severe blood pressures were not consistently found.

Thus far, at least one conclusion seems inescapable: that regardless of the height of the blood pressure the stage which the hypertensive disease has reached may best be judged on the presence or absence of these four clinical features—

namely, advanced retinal changes, albuminuria in excess of a trace, cardiac enlargement, and abnormality of the electrocardiogram.

Secondary Hypertension

A primary cause was possibly responsible for the hypertension in 21% of the 151 cases in this study (and 25 others submitted to sympathectomy). In all but three cases the primary cause was renal; the exceptions being re-

spectively cases of pheochromocytoma, Cushing's syndrome, and periarteritis nodosa. A primary cause was recognized in 32% of the fatal cases, but, rather surprisingly, of the 20 patients dying from uraemia only 7 at most were thought to have primary renal disease.

Familial Incidence

Inevitably any estimate of the familial incidence of vascular renal disease which relies upon information supplied by the patients themselves is likely to be inaccurate. But, making every allowance for this, the figure of 35% obtained in this group seems surprisingly low. A familial tendency, however, has not appeared to influence prognosis, for among the fatal cases the incidence was no higher, and it was perhaps rather surprising though comforting to find that, so far as the 15 deaths from strokes were concerned, history had repeated itself in only three instances.

Obesity and Prognosis

Obesity and hypertension have proved a favourable combination, for 50% of the 100 survivors were overweight, compared with 14% of the patients who later succumbed. Yet apparent objective improvement may follow substantial weight reduction. It was found, for example, that 11 patients out of 18 showed an average fall in diastolic pressure of 17 mm. Hg after reducing their weight by 21 to 56 lb. (9.5 to 25.4 kg.); in seven cases the heart appeared to decrease in size as well. Though at first sight a paradox, the probable explanation is as Wood (1950) suggests, that obese patients are not as severely hypertensive as they appear; certainly the benign course pursued by these patients despite high diastolic pressures would support this view. The exaggerated sphygmomanometer reading obtained in a fat arm seems likely also to account for the apparent fall in blood pressure after weight loss; and even reduction in size of the cardiac silhouette does not necessarily indicate objective improvement, since loss of abdominal fat with lowering of the diaphragm will of course alter the position and contour of the heart.

Progress of Surviving Patients

At the end of the observation period three-quarters of the 100 survivors were still leading unrestricted lives, but in at least 60% there was evidence that the disease had advanced. This was shown mainly by enlargement of the heart, deterioration of the electrocardiogram, or advance in retinal grading; blood pressures showed little tendency to rise. Albuminuria to the extent of a trace or light cloud made its appearance in the urine of more than half of the cases with severe hypertension, and here also there was a tendency for the specific gravity of the urine to become fixed. Broadly speaking, however, the severe cases behaved little differently from the milder ones, with the exception that cerebral vascular accidents occurred six times more often among the former.

Discussion

Hypertensive disease must be regarded as inevitably progressive, but the rate of progress, and therefore the prospects, of each patient are infinitely varied. Prognosis is essentially concerned with estimating the rate of advance. A full study of each hypertensive patient along the lines adopted in this investigation will reveal the extent of the damage already caused by the hypertension, and if this is then related to the patient's sex, age, and build, and above all to the height of his diastolic blood pressure, it should generally be possible, even when first seen, to assign a case to one of two categories: benign hypertension or "accelerated" hypertension.

Benign or Slowly Progressive Hypertensive Disease

The patients in this group, fortunately the largest in the hypertensive community, are likely for the most part to survive at least to 65. The most common cause of death is from congestive failure (Goldring and Chasis, 1944); uraemia is extremely rare except as a complication of heart failure, and cerebral vascular accidents are not to be expected until a reasonably advanced age. It is true that on occasion a patient who initially appears to qualify for this group will unexpectedly develop signs of an accelerated process, though this seems to be uncommon: within the period of this study not more than two patients from the 100 survivors appeared to alter course in this manner.

Recognition of this form of hypertensive disease presents little difficulty, for most of the patients

diastolic blood pressures consistently nearer 100 mm. Hg than 120 mm. Hg; but, since many of them are obese, some allowance for this must be made when higher pressures than these are recorded. Retinal changes observed in these cases never exceed grade II. The urine rarely contains more than a trace of albumin, and loss of concentrating power is the only indication of impaired renal function. The heart enlarges progressively, but the electrocardiogram as a rule becomes abnormal only when the enlargement is considerable (Leishman, 1951).

"Accelerated" Hypertensive Disease

At the opposite end of the scale the most rapid form of the disease, which usually terminates in uraemia below the age of 45, is also easy to identify. Unfortunately, however, such cases are often encountered only in the pre-terminal phase, when symptoms such as failure of vision compel attention for the first time. The age, the advanced character of the retinal changes—that is, grade III or IV—and the presence of a dense cloud of albumin distinguish this type of hypertensive case from all others. Most of these patients are men, and they are rarely, if ever, obese. Diastolic blood pressures tend to be high, of the order of 130 to 150 mm. Hg, though this is not invariable. At the first examination renal function may have failed to the point that urea retention is already established, but so rapid is the disease process that the heart, on the other hand, may have enlarged little and may still be maintaining good function. It seems a rather profitless endeavour to attempt to decide whether a case of this character is primarily due to renal disease or not. Indeed, the only practical question is whether or not the disease is too advanced for sympathectomy.

Malignant hypertension is still regarded in some quarters as a disease of its own unrelated to other forms of hypertensive disease. In the light of clinical experience, however, this seems improbable, for there is no sudden transition between the clinical picture conventionally described as "malignant" hypertension and that of other cases of longer survival which run an abnormal and unfavourable course. It seems more likely that the difference is not in the nature of the vascular disease but rather in its speed of development, and the one clinical type therefore merges gradually with the other. In its most rapid form the kidneys are quickly overwhelmed and death is from uraemia, but if the tempo is slower the kidneys survive and time allows other forms of disaster to overtake the patient. However, the most convincing evidence in favour of a single disease process comes from experience of sympathectomy for hypertension, for there is no doubt that even the malignant form of the disease can on occasion be arrested by sympathectomy.

One result of this five-year study is to suggest that, given the opportunity of examining hypertensive patients before they reach the age of 50, it ought to be possible to identify not only the malignant type of case but also this other type which, while not rapidly fatal, is nevertheless unlikely to survive, at least without incapacity, much beyond the age of 60. The commonest interrupting factor in the less rapid though unfavourable case is of course a cerebral vascular accident, and by the age of 60, or scarcely beyond, about one-fifth of the patients in this study had experienced some type of stroke. Others developed premature congestive failure either as a consequence of coronary thrombosis or independently of this. The three deaths from uraemia at a relatively late stage were in each case associated with cardiac failure.

While, of course, we are here on less familiar ground, there seems to be some chance of foreseeing the possibility of these disasters. In the first place, as a generalization it seems certain that, regardless of all other features of his case, a male of average build with diastolic blood pressure of the order of 130 mm. Hg or above has an unpleasantly slender chance of surviving unscathed to the age of 60. Coronary thrombosis can scarcely be foreseen, except that

the risk of this is obviously greater in a patient already anginal, but the premature development of congestive failure may perhaps be anticipated if the heart has early become enlarged or, on the other hand, if the strain pattern has appeared in the electrocardiogram before enlargement of the heart is obvious (Leishman, 1951).

The fate of a hypertensive patient seems to be largely determined by vascular changes which are still imperfectly understood. Oedema of the optic nerve, exudation and haemorrhage into the retina, and leakage of albumin into the urine are recognized as sinister developments; all of these suggest loss of vascular integrity, yet experience of sympathectomy has shown that these changes are reversible. It is not unreasonable, therefore, to assume the development of a biochemical lesion, possibly from anoxia, or perhaps owing to some other metabolic poison. The observations here reported have suggested that the speed with which these vascular changes develop is principally governed by the height of the diastolic pressure. The critical level, indeed, appears to be in the neighbourhood of 130 mm. Hg (as recorded in an average-sized arm), and with pressures at or above this figure the process is likely to accelerate.

While the particular liability of hypertensive patients to cerebral vascular accidents is presumably a further expression of this vascular vulnerability, it is not of course suggested that a stroke is likely to occur only when the retina shows advanced changes and the urine contains much albumin. Examination of the patients who subsequently suffered cerebral vascular accidents at a premature age has, however, generally indicated that all systems were reacting unfavourably. The impression has often been gained that changes which in a benign case might take 10 to 15 years to develop have here appeared in half that time, and for this reason the designation "accelerated" hypertension seems appropriate for this form of the disease.

Conclusions

The character or severity of a hypertensive patient's symptoms, other of course than those which point to cardiac or renal failure, give little clue to his subsequent fate. Headache, for example, has occurred as often in mild as in severe cases. Again, it might well have been expected that the transient cerebral attack ascribed to "angiospasm" would prove to be a curtain-raiser for the subsequent full-length drama of a stroke; but this has not been the case, and the incidence of such cerebral episodes was no higher among patients who subsequently had strokes than in those who did not. Since in addition neither a family history of hypertension nor the existence of a renal basis for the hypertension appears to influence prognosis unduly, assessment of a hypertensive patient must rest fundamentally upon objective findings.

Early recognition of the accelerated form of hypertensive disease is particularly desirable, since it is in this type of case that sympathectomy has most to offer, and operation performed in time may completely transform its character. Appropriate cases, however, will not be selected for sympathectomy unless the practice is adopted of submitting every hypertensive patient under the age of 50 to a systematic assessment with the object of establishing how far the disease has already progressed, for only by relating this to the age of the patient can it be decided whether or not the speed of advance has been excessive.

Summary

The selection of appropriate hypertensive cases for lumbodorsal sympathectomy presents difficulties which can be resolved only by a wider knowledge of prognosis in this disease.

In the hope of acquiring this knowledge 151 hypertensive patients below the age of 60 have been studied by regular examination over periods ranging from two-and-a-half to five years.

During the period of observation 51 patients died as a result of hypertension, giving a mortality rate of 34%. The mortality for men alone was 44%. The height of the diastolic blood pressure had an important influence on the mortality rate.

A familial tendency has not appeared to prejudice a hypertensive patient's prospects, and the existence of a primary cause for the hypertension had only a slight adverse influence.

It is probable that the combination of obesity with hypertension appears favourable only on account of the misleading sphygmomanometer reading.

The progress or fate of these patients has been related to the main clinical features which presented at their first examination.

It is suggested that the stage reached by the disease can best be judged on the presence or absence of four features—namely, advanced retinal changes, albuminuria in excess of a trace, cardiac enlargement, and abnormality of the electrocardiogram.

If the present stage of the disease is recognized the rate of its advance can be estimated, and thus to a large extent the prognosis may be foreshadowed.

Even at the first examination it should generally be possible to classify the type of hypertensive disease as "benign" or "accelerated."

Sympathectomy is principally justified in patients with the accelerated form of hypertensive disease.

PULMONARY EMPHYSEMA TREATED BY PNEUMOPERITONEUM

BY

R. D. C. BRACKENRIDGE, M.D., F.R.F.P.S.
Senior Medical Registrar, County Hospital, Whiston, Lancs

AND

A. THELWALL JONES, M.D., M.R.C.P., D.P.H.
Assistant Physician, United Liverpool Hospitals
Senior Consultant Physician, County Hospital, Whiston

Emphysema is a rather vague appellation given to patients suffering from dyspnoea, cough, and in some cases congestive cardiac failure. The term usually means the chronic hypertrophic vesicular emphysema with the "large lungs" described by Sir William Jenner.

A severe disability results from progressive dyspnoea, and all clinicians recognize the common clinical features of a life made wretched and too often hopeless. The breathless existence of the patient is prolonged to some extent by the control by antibiotics of episodes of acute pulmonary inflammation.

Emphysema occurs more commonly in men than in women, and this incidence seems pronounced enough to raise the suspicion of an occupational factor. There is no conclusive evidence on this point, but the inci-

dence does not seem to be higher in occupations where "blowing" is a feature. The effect of hard manual work is doubtful, but the importance of attacks of bronchitis and the effect of a chronic cough is recognized. Asthma is also recognized as an important predisposing factor, and bronchospasm in childhood may be followed by years of good health to be succeeded by the development of emphysema.

The essential pathological feature is a loss of elasticity in the lungs, which are voluminous but not truly distended. The lungs are pale, and the blood is supposedly pressed out of the capillaries. The alveolar walls are atrophied, bullae develop, and the intrapleural pressure is raised. Expiration is thus impaired, being largely a passive process produced by recoil of the elastic tissues of the lung. The changes result in an inability to ventilate the lungs, and the oxygen saturation of the arterial blood falls to 85%. The carbon dioxide in the blood and alveoli rises and the patient is unable to compensate by increasing the pulmonary ventilation. The inspired air tends to be drawn into avascular and dilated alveoli which form a large pathological dead space.

The clinical picture in the established case is one of misery. Dyspnoea is caused by the increased blood carbon dioxide and cyanosis is largely central. Polycythaemia is fairly common and clubbing of the fingers is sometimes present even in uncomplicated cases. The movement of the chest is poor and expansion often less than 1 in. (2.5 cm.); the antero-posterior diameter is widened and the shape sometimes "barrel"; the accessory muscles of respiration are fully employed; and hyperresonance obscures the hepatic and cardiac dullness. Air entry is poor, rhonchi and rales are widespread, and bronchospasm is often present.

Points in Diagnosis

Christie (1944) and others have stressed the importance of associated conditions. The diagnosis is not to be based on isolated symptoms and signs: it is established by the development of insidious dyspnoea on exertion which is not due to bronchospasm or left ventricular failure, together with some of the characteristic signs, and chronic bronchitis or asthma. The long duration and seasonal aggravation of the dyspnoea distinguishes it from cardiac dyspnoea, and there are no nocturnal attacks unless asthma is present. X-ray features are not diagnostic, but several abnormalities are common. Whitfield *et al.* (1951) found that the most constant radiological abnormalities were depression and flattening of the diaphragm, with poor respiratory excursion, the relative brilliance of the lung bases, and the translucency and area of the retrocardiac and anterocardiac windows. The ribs are widely separated and transversely placed, and there is rotation and elongation of the heart shadow associated with prominent pulmonary arteries.

In many cases of emphysema associated with severe dyspnoea it is difficult to determine and assess the influence of myocardial failure. McMichael and Sharpey-Schafer (1944) showed that the cardiac output is normal or increased in cases of heart failure secondary to lung disease. Cardiac catheterization in cases of emphysema reveals that the right ventricular systolic pressures are normal but become raised with the development of cardiac failure. The pressure returns towards normal with recovery from failure, proving that the pulmonary hypertension cannot result solely from fixed anatomical changes in the vascular bed of the lungs (Mounsey *et al.*, 1952).

The clinical details of the cases under review are given later, but the electrocardiograms do not seem to help in diagnosing or in selecting cases. Seven cases had normal electrocardiograms, one case had cor pulmonale, and one had right axis deviation, and no difference was apparent

in the electrocardiograms taken before and after the institution of treatment by pneumoperitoneum. The criteria for the diagnosis of chronic cor pulmonale were taken from Katz (1946).

In 40 consecutive cases of emphysema admitted to the County Hospital, Whiston, the electrocardiograms were interpreted as follows: normal, 20; cor pulmonale, 2; right axis deviation, 6; left axis deviation, 6; myocardial insufficiency, 6.

The above brief review of the aetiology and diagnostic features of emphysema provides a basis for consideration of methods of treatment. A loss of lung elasticity is the basic disability, and this seems to be progressive and uninfluenced by treatment.

The correction of abnormalities in the nose and sinuses, postural drainage, and the control of infection by antibiotics are helpful. A cough can be reduced sometimes by sedatives; ephedrine relieves bronchospasm; and oxygen is a successful measure of therapy, especially in the presence of congestive failure, when the usual treatment is given. In spite of these measures numbers of severe cases are improved but little, and dyspnoea renders life so intolerable that any means of giving relief is to be welcomed.

Treatment

The treatment of pulmonary emphysema by pneumoperitoneum was introduced by Reich (1924) and used by Monaldi (1937) in the treatment of asthma. Sisti (1936), Piaggio-Blanco and Sayagues (1938), and Rubin and Gass (1948) have also reported on the use of pneumoperitoneum in asthma. New interest was aroused in the use of pneumoperitoneum in a preliminary report by Furman and Callaway (1950), who studied its effect on seven emphysematous patients, five of whom received impressive symptomatic relief.

The rationale of pneumoperitoneum is to increase the intra-abdominal pressure enough to cause elevation of the diaphragm during expiration and yet not to impede its contraction during inspiration. Increased excursion of the diaphragm is thus obtained, with consequent improvement in pulmonary ventilation.

Other better-known measures in use have a similar rationale—namely, breathing exercises and the use of an abdominal binder, advocated by Christie (1934), Gordon (1934), and Alexander and Kountz (1934); but with neither of these methods does the elevation of the diaphragm compare with that obtained in pneumoperitoneum.

Nine cases of severe pulmonary emphysema were selected for treatment by pneumoperitoneum and have been studied for varying periods.

The patients were selected because of their severe disability. As a preliminary, active bronchial infection was treated with antibiotics to which the organisms in the sputum were sensitive, after which the following control procedures were carried out: (a) the diaphragmatic excursion in full inspiration and expiration was measured radiologically; (b) the vital capacity was measured on a "British" Benedict spirometer, the readings being taken at three seconds and also with no time limit; the three-second reading was used by Furman and Callaway (1950) because, given enough time, an emphysematous subject can record quite a high vital capacity by prolonged muscular effort; (c) haemoglobin and red cell count; and (d) electrocardiogram.

It was also intended to record the intrapleural pressures before and after treatment, but experience of this procedure on the first two patients, who were already orthopnoeic, was so alarming that it was abandoned. The above investigations were repeated at various intervals during treatment.

The pneumoperitoneum was induced with a Kjer-Petersen needle, the point of entry being roughly midway between the umbilicus and the anterior superior iliac spine, in either the right or left side: 400 c.cm. of air was given initially, and the volume was increased gradually twice a week until

800 to 1,000 c.cm. could be given without discomfort. Thereafter, refills were given at weekly or two-weekly intervals. When the pneumoperitoneum was established the final intra-abdominal pressure usually lay between 9 and 12 cm. of water.

Complications

Minor degrees of ascites occurred, and in one case existing inguinal herniae were aggravated. Abdominal discomfort was complained of by a few patients for the first 24 or 48 hours after a refill, and was usually caused by injecting too much air, but one patient (Case 6) had persistent abdominal pain, which led to the abandonment of treatment. The proper amount of air for the individual patient can soon be determined.

Free abdominal fluid was detected clinically during the course of treatment in four patients. This seemed to cause no inconvenience except for the splashing noise as the subject turned over in bed or stooped to tie his shoe-lace.

Other complications of pneumoperitoneum are listed by Banyai (1946), and include air embolism, mediastinal emphysema, subcutaneous emphysema, umbilical and scrotal pneumocele, aggravation of existing herniae, and accidental perforation of the intestine. The latter is extremely rare, and is an unlikely complication unless a loop of bowel is fixed to the anterior abdominal wall by adhesions.

Results

Of the nine patients treated by pneumoperitoneum, six have stated that they have obtained definite benefit. This was mainly shown by the disappearance of dyspnoea and an increase in the amount of exercise which could be taken. Three patients obtained no benefit after three months' treatment.

Vital Capacity.—The changes in vital capacity are recorded with the individual case histories. On the whole there is a significant increase during treatment, but not so striking as that reported by Furman and Callaway in their patients.

Diaphragmatic Excursion.—The range of movement of the diaphragm between inspiration and expiration was measured radiologically on a film taken by the double exposure technique (see Table).

Diaphragmatic Excursion

Case	Before Treatment		After Treatment	
	Right Side (cm.)	Left Side (cm.)	Right Side (cm.)	Left Side (cm.)
1	0.8	0.9	2.1	1.0
2	0.8	0.9	2.7	2.6
3	0.6	0.9	2.4	3.0
4	1.0	0.5	3.2	3.7
5	1.8	1.2	2.8	3.0
6	2.3	2.6	2.1	1.6
7	0.2	1.5	2.1	3.0
8	2.1	2.1	2.3	2.5
9	0.3	0.5	3.0	3.2

Haemoglobin and Red Blood Cells.—No significant alteration from the original levels of haemoglobin and the red-cell counts could be demonstrated in any case after treatment by pneumoperitoneum had been established.

Case Histories

Case 1.—A man aged 45 had had asthmatic attacks for 17 years. He developed pneumonia two years ago, which further aggravated his poor exercise tolerance. His convalescence was prolonged and he has remained very cyanosed since. Before beginning pneumoperitoneum treatment he rarely ventured out of his house. There has been no congestive cardiac failure. His blood pressure was 110/80 mm. Hg. A pneumoperitoneum was induced on October 24, 1951, and was maintained with fortnightly refills of air varying between 800 and 1,000 c.cm. There was evidence of a small amount of free abdominal fluid

about four months after treatment began, but this disappeared spontaneously in six weeks. His vital capacity before treatment was 2,300 c.cm. and at three seconds 1,300 c.cm. Seven months later the readings were 2,650 and 1,900 c.cm. respectively. Although still cyanosed, he could get about for walks in good weather, and maintained that he could not do without his refills.

Case 2.—A man aged 57 dated his incapacity to an attack of pneumonia seven years previously, since when he has suffered shortness of breath, sufficient to cause him to give up all work. His case notes show, however, that he had been subject to winter bronchitis for several years before that. Before treatment he was completely incapacitated, and even slight exertion in the house made him breathless. He has never had congestive cardiac failure. His blood pressure was 150/100 mm. Hg. A pneumoperitoneum was induced on October 24, 1951, and was maintained with refills of 800 c.cm. of air every fortnight. The vital capacity before treatment was 2,400 c.cm. and at three seconds 1,150 c.cm. During treatment the vital capacity has averaged 2,600 c.cm. and at three seconds 1,250 c.cm. Ascites developed about

five months after treatment began, but was negligible in amount and disappeared spontaneously. Improvement in exercise tolerance was remarkable in this patient, so much so that he developed intermittent claudication of the right leg two months after the beginning of treatment.

Case 3.—A man aged 65 had suffered from bronchitis for many years, and had severe pneumonia two years ago, after which congestive cardiac failure developed. Convalescence was prolonged, and he was

always extremely breathless, even at rest, and his ankles became swollen in the evenings. His blood pressure was 155/80 mm. Hg. An x-ray film confirmed the presence of gross emphysema. A pneumoperitoneum was induced on December 14, 1951, and was maintained with an average of 800 c.cm. of air every fortnight. The vital capacity before treatment was 1,900 c.cm. and 1,750 c.cm. at three seconds. During treatment the readings were 2,150 and 1,500 c.cm. respectively. This patient admitted to no improvement during treatment, and he continued to show signs of mild congestive cardiac failure. The pneumoperitoneum was abandoned four and a half months after it was begun.

Case 4.—A man aged 73 had suffered from chronic bronchitis and shortness of breath for 27 years. Since 1946 he has been an inmate of the chronic sick section, and could move only short distances with help. He was orthopnoeic and extremely cyanosed. An x-ray film of the chest confirmed the presence of gross pulmonary emphysema with practically no diaphragmatic movement. No episodes of congestive heart failure had been reported during his eight-year stay in hospital, but he was confined to bed most of the day. His blood pressure was 140/80 mm. Hg. A pneumoperitoneum was induced on December 14, 1951, and thereafter refills of 500 c.cm. of air were given once a week. The vital capacity before treatment was 1,500 c.cm. and with a time limit of three seconds 850 c.cm. The

readings two months later were 1,450 and 1,000 c.cm. respectively. There was no subjective or objective improvement in this case; he remained bedridden and very dyspnoeic, and, as the intra-abdominal pressure rose, bilateral inguinal herniae became aggravated, and treatment was abandoned after nine weeks.

Case 5.—A man aged 60 gave a 16-years history of shortness of breath and attacks of bronchitis. He contracted a severe suppurative pneumonia a year ago, which resulted in some fibrosis in the right upper lobe. Breathlessness became notably worse after this episode, but he could walk slowly for about half a mile. He has never had congestive cardiac failure. His blood pressure was 150/90 mm. Hg. A pneumoperitoneum was induced on January 14, 1952, and thereafter refills were continued every fortnight, the average volume of air given being 700 c.cm. A moderately large ascites developed ten weeks after the start of treatment but seemed to cause no discomfort. The fluid was turbid, containing polymorphonuclear cells, and a growth of a coagulase-negative staphylococcus was obtained. The fluid disappeared within a week after the patient was put to bed

and given a course of penicillin. The vital capacity before treatment was 1,500 c.cm. and with a time limit of three seconds it was 1,250 c.cm. These figures became 1,950 and 1,500 c.cm. respectively two months after the start of treatment. Improvement in exercise tolerance was moderately good.

Case 6.—A man aged 54 had remained well up to six years ago, when attacks of bronchitis and asthma developed. These attacks became more frequent, and after an attack of pneumonia one year ago his dyspnoea was much worse. For some time before admission to hospital he had been severely incapacitated and confined to his home. He was cyanosed and orthopnoeic, and an x-ray film of his chest revealed gross emphysema. It was evident that the severity of his dyspnoea was due in part to bronchospasm. There was no history suggestive of congestive heart failure. His blood pressure was 120/70 mm. Hg. A pneumoperitoneum was induced on January 14, 1952, and after it was established refills averaging 700 c.cm. were given once a fortnight. The vital capacity before treatment was 2,000 c.cm., and at three seconds 1,150 c.cm. Two months later, during treatment, the figures had not changed appreciably, being 1,850 and 1,100 c.cm. respectively. There seemed to be much improvement in exercise tolerance during the initial stages of treatment in hospital, but after discharge the attacks of asthma returned and he relapsed into his previous dyspnoeic condition. After persisting with the pneumoperitoneum for three months it was considered that there was going to be no improvement, and treatment was discontinued.

Case 7.—A man aged 47 had been troubled with shortness of breath and asthmatic attacks for the past 17 years. He was admitted to hospital two years ago, having sustained a spontaneous pneumothorax on the right side, presumably due to rupture of an emphysematous bulla. His exercise tolerance had become very poor during the past four years,

FIG. 1.—Case 3. Diaphragmatic excursion before treatment.

FIG. 2.—Case 3. Diaphragmatic excursion during treatment with pneumoperitoneum.

FIG. 3.—Case 4. Diaphragmatic excursion before treatment.

FIG. 4.—Case 4. Diaphragmatic excursion during treatment with pneumoperitoneum.

and he could walk only a few yards without becoming breathless. An x-ray film of the chest showed the typical features of emphysema. There has been no congestive cardiac failure. His blood pressure was 140/90 mm. Hg. A pneumoperitoneum was induced on January 14, 1952, and subsequent refills have amounted to 900 c.cm. a fortnight. A small amount of free peritoneal fluid was detected ten weeks after the start of treatment, but this disappeared spontaneously two weeks later. The vital capacity before treatment was 1,900 c.cm. and with a time limit of three seconds 1,030 c.cm. These figures had improved two months later to 2,100 and 1,300 c.cm. respectively. The improvement in general well-being and exercise tolerance was most gratifying. He can walk about outside with less dyspnoea than previously and he also sleeps more comfortably owing to improved breathing.

Case 8.—A man aged 52 was admitted to hospital in April, 1952, because of severe breathlessness and cough. He gave a history of having had chest trouble for 20 years, including frequent attacks of bronchitis, and hay-fever. His breathlessness was such that he was able to climb a flight of stairs at home only once a day, and even that amount of exertion disabled him for fifteen minutes. There was no history suggestive of congestive cardiac failure. His blood pressure was 160/80 mm. Hg. An x-ray film of his chest confirmed the presence of marked pulmonary emphysema. The vital capacity was 1,750 c.cm., and the reading with a three-seconds limit was the same. After induction of a pneumoperitoneum on April 21, 1952, refills were carried out twice a week while in hospital and then fortnightly after discharge, an average of 700 c.cm. of air being given. The vital capacity during treatment became 1,900 c.cm. and with a time limit of three seconds 1,500 c.cm. Symptomatic improvement was good; he was able to take much more exercise than before admission to hospital, and his exercise tolerance continued to improve.

Case 9.—A man aged 46 first noticed that he was becoming breathless on exertion when he was 22. He continued to work at a cotton mill, but his cough and dyspnoea became worse and he had to give up all work in 1941. He

has had pneumonia three times, the worst attack being in 1936. Before treatment he could walk about half a mile very slowly and with a great deal of effort. He does not give a history suggestive of congestive cardiac failure. His blood pressure was 130/90 mm. Hg. An x-ray film of the chest confirmed the presence of pulmonary emphysema with very little diaphragmatic movement. A pneumoperitoneum was induced on April 29, 1952, and while in hospital refills were given twice

weekly until it was established. An average of 800 c.cm. of air was given once every two weeks as an out-patient. The vital capacity before treatment was 1,450 c.cm., and with a time limit of three seconds 880 c.cm. Seven weeks after the start of treatment the readings had become 1,950 and 1,200 c.cm. respectively. He has improved tremendously; his exercise tolerance is better than previously and he can walk longer distances without becoming so breathless.

Discussion

After several months' experience of this particular treatment it was possible to select more accurately the type of case that would derive benefit from it, and exclude those showing certain features now known to be contraindications. The latter may be best illustrated by the three cases which showed no improvement. Case 3 had signs of congestive cardiac failure for two years before treatment was instituted; this was not gross, and was manifest by congestion of the veins in the neck, some swelling of the ankles after exercise, and a little engorgement of the liver. Case 4, practically bedridden for six years in the chronic ward because of exertional dyspnoea and considered to have myocardial failure, made no response to treatment. We believe that any benefit which pneumoperitoneum might have is not enough to overcome the effects of established failure of the myocardium.

A feature of Case 6 was the frequent attacks of severe asthma. Despite the favourable reports on the treatment of asthma by pneumoperitoneum made by others, we found that it had not the slightest effect; in fact, the violent muscular efforts during an attack of asthma seemed to cause considerable pain in the abdominal muscles, which were already stretched by the pneumoperitoneum. We would exclude those cases, therefore, in which asthma is a marked feature.

The emphysematous subject is particularly liable to attacks of bronchitis, which have the effects of almost complete disablement. Several patients under treatment with pneumoperitoneum developed bronchitis during the winter months, and we found that any good effect of the treatment was nullified until the infection was controlled and the sputum again became scanty. Some of the fluctuations in the vital capacity might be explained by the presence or absence of bronchitis at the time the records were made.

On the other hand, it is necessary to examine why there was no great increase in the vital capacity in our patients despite the fact that the diaphragmatic excursion had been improved.

Banyai (1946) found that in a group of tuberculous patients undergoing pneumoperitoneum treatment the vital capacity showed an average decrease of 14.7%, while Furman and Callaway reported a dramatic increase in vital capacity in their emphysematous patients—two, indeed, having double their pre-treatment values.

Meakins and Christie (1934) pointed out that, whereas the normal functional residual air amounted to 35–40% of the total lung volume, in severe emphysema the figures might reach 70 to 80%. And, since the vital capacity is also reduced, the resting tidal air and vital capacity may approach equality.

We think that in those of our cases in which the exercise tolerance improved and yet was not reflected in a greatly increased vital capacity the effect of the improved function of the diaphragm was to decrease the residual air in proportion to the total lung volume, thus allowing improved aeration.

Antispasmodics such as ephedrine and aminophylline were found to be a valuable adjunct to pneumoperitoneum in cases in which there was a tendency to bronchospasm. In patients who are not subject to such attacks ephedrine is probably of little value, since Whitfield *et al.* (1950) showed that this drug produced no alteration in the subdivisions of lung volume in emphysematous subjects without bronchospasm.

Finally, the psychological effects of a new form of treatment on patients who have been incapacitated for years must be remembered. There is no doubt that the enthusiasm of the operator is often reflected in the patient, at least during the first few weeks, and certainly many of the glowing testimonials from some of our patients could be attributed to this. After due allowance has been made for this, however, we believe that there has been a genuine

improvement in most of the cases treated by pneumoperitoneum, which warrants its use in a larger series of patients.

A pneumoperitoneum may be continued indefinitely, refills being given at weekly or, more usually, fortnightly intervals, although in Reich's experience the high position of the diaphragm was maintained for long periods after the pneumoperitoneum was discontinued. This he attributed to the fact that during treatment the patient performed an unconscious respiratory exercise, relaxing the diaphragm and contracting its antagonists, the abdominal muscles, and continued to do so without the aid of a pneumoperitoneum.

Summary

A brief review of pulmonary emphysema and methods of accepted treatment is given.

The progressive nature of the disease and the misery which is the lot of those severely affected warrant exploration of all new avenues of treatment.

Nine severe cases of pulmonary emphysema treated by pneumoperitoneum are presented, with results encouraging enough to justify further study. The rationale of pneumoperitoneum is to increase the intra-abdominal pressure sufficiently to cause elevation of the diaphragm during expiration, and yet not to impede its contraction during inspiration. Increased excursion of the diaphragm is thus obtained, with consequent improvement in pulmonary ventilation.

The vital capacity was increased in seven cases and the excursion of the diaphragm, measured radiologically, was improved in all cases. No improvement was evident in two cases with a history of congestive cardiac failure and in one case with asthma.

In his preface to the annual statistical report of the Middlesex Hospital for 1952, Colonel the Honourable J. J. Astor, chairman of the board of governors, points out that, while in the past the main function of the report was to persuade the public to subscribe to the hospital's funds, its present task "is to say whether public money, assigned by Parliament for the upkeep of their hospitals, has been used to the best advantage." During the year under review there were 633,000 out-patient attendances at the hospital and its constituent institutions, compared with 582,000 in 1951. The physiotherapy clinic accounted for 219,000, of whom 10,000 were new patients; 117,000 attended the rheumatism clinic, and 40,000 attended for radiotherapy. In-patients numbered 14,800, a slight increase on the previous year. Good progress is reported in converting Latimer House, acquired in 1951 to serve as an institute of clinical research and experimental medicine, and the institute will be in action later this year.

SENSITIVITY STUDIES ON SHIGELLA SONNEI

BY

G. B. FORBES, M.D.

Pathologist, Kent and Canterbury Hospital

This report concerns a study of the antibacterial activity of streptomycin, chloramphenicol, aureomycin, and terramycin against *Shigella sonnei*, together with observations on the suitability of these antibiotics for the treatment and control of Sonne dysentery.

Seventeen representative strains of *Sh. sonnei* were collected from separate outbreaks and isolated cases of Sonne dysentery which occurred in East Kent and Hertfordshire. The identity of the strains was confirmed by biochemical tests and agglutination to titre with specific typing serum. In addition the strains were grouped according to their bacteriophage reactions (Hammarström, 1947) and fermentative behaviour towards xylose (Bojlen, 1934) to ensure that the collection included a variety of types. Dr. Mayr-Harting, of Bristol, kindly performed the bacteriophage tests, and found that most strains belonged to phage type 3, a type commonly encountered in this country (Cooper and Mayr-Harting, 1951); five other phage types were represented (Table I). One of the strains fermented xylose; the others were xylose-negative and gave the usual biochemical reactions of strains isolated in this country (Carter, 1937).

TABLE I.—Xylose Fermentation and Bacteriophage Reactions

Strain	Xylose Fermentation	Phage Type
1, 2, 4, 7, 8, 9, 10, 11, 14, 15, 16, 17	—	3
3	—	85
5	—	32
6	—	66
12	—	23
13	+	? 17b

In-vitro Experiments

I. Tube Sensitivity Tests

Method.—Graded concentrations of each antibiotic were prepared in nutrient broth and tubed in 1-ml. amounts; 0.02 ml. of 1:100 dilution of an overnight broth culture of each strain was added to the appropriate set of tubes, which were then incubated at 37° C. The lowest concentrations of antibiotic required for growth suppression as judged by complete absence of turbidity and bacterial deposit were noted after 12, 18, 24, 36, and 42 hours' incubation.

Results.—The results of these tests, expressed as the average sensitivity of the 17 strains to each antibiotic, are given in Table II. It will be seen that the end-points increased progressively with prolongation of the incubation period beyond 12 hours. With the more stable antibiotics (streptomycin, chloramphenicol, and terramycin) the inhibiting concentrations rose slightly, to give readings at 42 hours approximately twice as high as those obtained at 12 hours.

TABLE II.—Mean Sensitivity of 17 Strains After Varying Periods of Incubation

Antibiotic	Hours' Incubation				
	12	18	24	36	42
Streptomycin	4.94*	6.23	7.29	7.76	8.47
Chloramphenicol	5.52	7.41	7.88	8.47	8.58
Aureomycin	1.01	2.00	4.00	7.53	9.06
Terramycin	2.06	2.94	3.76	3.88	4.35

* Minimal inhibiting concentration in µg./ml.

In the case of aureomycin, which is notoriously unstable at 37° C., there was a ninefold increase during the period of observation. In fairness to aureomycin, the readings obtained after the shortest workable incubation period—namely, 12 hours—were regarded as being most suitable for comparative purposes. These results are set out in Table III,

TABLE III.—Range of Sensitivity of 17 Strains After 12 Hours' Incubation

M.I.C. at 12 Hours (µg./ml.)	Streptomycin	Chloramphenicol	Aureomycin	Terramycin
8	4	7		1
4	13	9		15
2		1	1	1
1			12	
0.8			4	
Range	4-8	2-8	0.8-2	1-4

and may be summarized as follows: (1) all strains were naturally sensitive to all four antibiotics, being inhibited by 8 µg./ml. or less; (2) the strains exhibited a narrow range of tolerance to each of the four antibiotics; (3) on a weight-for-weight basis aureomycin and terramycin were slightly more effective as growth inhibitors than streptomycin and chloramphenicol.

II. Mode of Action of Antibiotics

Tests were carried out in order to compare the speed and mode of antibacterial action of the four antibiotics on *Sh. sonnei* in the presence of faecal matter.

Method.—A gramme of faeces from a healthy subject was suspended in physiological saline and the suspension distributed in four equal amounts. The specimens were seeded with approximately 100,000 *Sonne* organisms, and, after thorough shaking with beads to ensure an even distribution of the organisms, 0.02 ml. was withdrawn from each specimen and subcultured on plates of desoxycholate medium. The antibiotics under test were then added to the inoculated specimens, so that each specimen contained one of four antibiotics in a strength of 10 µg./ml. in one experiment and 500 µg./ml. in a second experiment. The specimens were incubated at 37° C., and at hourly intervals up to eight hours, and again at 24 hours, subcultures were made as described above. After overnight incubation the subcultures were examined and colonies of *Sh. sonnei* were identified and counted.

Results.—The results of these experiments are given in Tables IV and V. At a concentration of 10 µg./ml. streptomycin exerted a bactericidal action on *Sh. sonnei*, killing all organisms in less than five hours, while the other antibiotics were essentially bacteriostatic in their mode of action. At

a concentration of 500 µg./ml. streptomycin, aureomycin, and terramycin were highly bactericidal, killing all *Sonne* organisms within one hour. Chloramphenicol effected a reduction in the population of *Sonne* organisms, but a number remained viable while in contact with 500 µg./ml. for as long as eight hours. These experiments were repeated several times with close reproduction of results. The tests were also carried out using nutrient broth in place of the faecal suspension, and again the results were comparable, although terramycin in this medium was slightly less bactericidal at the higher concentration.

III. Acquisition of Resistance

Method.—Sensitivity tests were carried out on three strains by the conventional tube-dilution technique as described in experiment I. After 18–24 hours' incubation at 37° C. the highest concentration of antibiotic which permitted distinct visible growth was noted, and the culture at this end-point was used to inoculate a fresh set of concentrations on a slightly higher range. This procedure was repeated daily for eight consecutive days.

Results.—*Sh. sonnei* acquired resistance to streptomycin more readily than to the other antibiotics. The rate of acquisition of resistance, however, varied not only with different strains but also when the tests were carried out in duplicate on any one strain. But at least it can be stated that the lowest increase in resistance to streptomycin (a 64-fold increase) was equal to the highest rate of increase acquired to the other antibiotics. The strains developed an eightfold increase in resistance to both aureomycin and terramycin, and the results of repeat tests were quite consistent. Chloramphenicol did not favour the development of resistance to the same extent as streptomycin, the average increase on testing three strains being $\times 35$. Typical patterns of the development of tolerance to each of the four antibiotics are given in the Chart.

Clinical Experience with Streptomycin

Of the four antibiotics, only streptomycin has been used in enough cases of *Sonne* dysentery to allow an assessment of its clinical value.

Sixteen acute cases and one carrier were treated with this antibiotic in a dose of 0.5 g. twice daily for two to three days. The drug was given orally, mixed with flavouring agents.

Clinical cure was achieved within 24 hours of beginning treatment in all acute cases, and bacteriological cure, as judged by repeated negative stool cultures (an average of 4.3 per patient), was prompt and complete in all but one case. A sample of faeces from this patient yielded four colonies of *Sh. sonnei* on the sixth day after treatment.

although two earlier post-treatment specimens had been negative. Three subsequent specimens from this patient gave negative results. No case relapsed clinically or bacteriologically during the follow-up period, which in some cases was as long as six months.

In addition, two cases of *Sonne* dysentery which relapsed one week after treatment with a sulphonamide were promptly cured clinically and bacteriologically with streptomycin. Another patient was treated with chloramphenicol for five days, with good clinical response, but a very heavy growth of *Sh. sonnei* was obtained from specimens of faeces sent during treatment and on the day after treatment. Streptomycin was then given, and the infecting organism disappeared from the faeces within 48 hours.

A female member of the staff of a residential nursery was found to be a symptomless carrier of *Sh. sonnei* during investigations following an outbreak of *Sonne* dysentery which had occurred in the nursery two months earlier. She was sent on leave, and a specimen of faeces submitted to this laboratory confirmed that *Sonne* organisms were being excreted in very large numbers. Streptomycin was given orally for two days, and three post-treatment specimens of faeces received at weekly intervals were negative for *Sh. sonnei*. The patient returned to work, and a specimen submitted five months later was again free of *Sonne* organisms.

Discussion

Specific treatment in *Sonne* dysentery should aim not only at effecting a prompt clinical cure but also at rapidly clearing the intestinal tract of *Sh. sonnei* in order to reduce the period of infectivity to a minimum. As the disease is usually mild and of short duration, it is difficult to assess the value of specific remedies on the basis of clinical response alone; the rate and completeness of clearance is probably a more reliable index of therapeutic efficiency and adequate control. The sulphonamides, particularly sulphadiazine and the poorly absorbed sulphonamide preparations, are of undoubted value in the management of bacillary dysentery, but *Sonne* organisms often persist or reappear in the faeces during convalescence (Fairbrother, 1944). Moreover, in certain parts of the world, for example Japan, the majority of strains of *Sh. sonnei* are naturally resistant to sulphonamides (Tateno, 1950).

Oral therapy with antibiotics is an obvious alternative to sulphonamide medication in *Sonne* dysentery, and the experiments described above help to predict which antibiotics are likely to be most useful in this disease.

Welch (1950) assayed the faecal excretion of chloramphenicol, aureomycin, and terramycin after the oral intake of 1 g., and obtained levels of approximately 500 µg. per gramme of faeces with each antibiotic. Streptomycin, which is not absorbed from the bowel, was found in even higher concentrations in the faeces (at least 9,000 µg./g.) by Zintel *et al.* (1945). These levels greatly exceed the concentrations which were required to inhibit the growth of all 17 strains of *Sh. sonnei* used in this study, and from this it is apparent that all four antibiotics are potentially effective in the treatment of *Sonne* dysentery. However, streptomycin, aureomycin, and terramycin were found by experiment to exert a rapid bactericidal action at concentrations obtainable in the faeces following oral administration, and in the case of streptomycin the lethal effect was evident when the concentration in the faeces was reduced to 10 µg./g. It is likely, then, that these three antibiotics, especially streptomycin, would effect a complete and permanent eradication of *Sonne* organisms from the faeces of clinical cases. On the other hand, chloramphenicol exerted only a weak bactericidal action at a concentration of 500 µg., and in theory it should be less efficient at ridding the faeces of *Sonne* organisms.

The efficacy of streptomycin in *Sonne* dysentery has been confirmed by clinical experience, both in the present study and by others, notably Ross *et al.* (1949). In fairness to chloramphenicol it should be added that Ross *et al.* (1950) obtained equally good results with this antibiotic, and it

would seem that the theoretical objection to chloramphenicol mentioned above is probably not of significance in clinical practice.

Certain other factors would influence one in favour of streptomycin for the routine treatment of *Sonne* dysentery. It is relatively cheap and is readily available. It is non-toxic when taken by mouth, and, unlike chloramphenicol and aureomycin, does not irritate the gastric and intestinal mucosa—a point of some importance when treating an infection which itself produces gastro-intestinal upset. Moreover, it is palatable if flavoured, and is well tolerated by children. There are, however, two minor disadvantages peculiar to streptomycin: (1) the results of experiment III indicate that *Sh. sonnei* develops resistance slightly more readily to streptomycin than to the other three antibiotics, but it is unlikely that this disadvantage will prove of any consequence in clinical practice, since the duration of treatment will not normally exceed two or three days; and (2) an acute fulminating type of *Sonne* dysentery is occasionally met with in young children (Lewis and Claireaux, 1951), and Tatham *et al.* (1951) succeeded in isolating *Sh. sonnei* from the blood of such a case. Obviously an antibiotic which is absorbed from the bowel is to be preferred to streptomycin for the treatment of the septicaemic type of infection, or, if streptomycin is chosen, it should be given parenterally as well as orally.

Summary

Sh. sonnei was highly and almost equally sensitive to streptomycin, chloramphenicol, aureomycin, and terramycin *in vitro*, all test strains being inhibited by 8 µg./ml. or less.

All four antibiotics exerted a bactericidal action on *Sh. sonnei* in a concentration of 500 µg./ml., but the lethal effect of chloramphenicol was weak compared with the other antibiotics. Streptomycin alone was bactericidal at both low and high concentrations.

Sh. sonnei acquired resistance *in vitro* slightly more readily to streptomycin than to the other antibiotics.

Streptomycin, given orally, has proved a highly effective therapeutic agent in the management of *Sonne* dysentery.

My thanks are due to Dr. B. A. Thompson, Watford, for providing me with a few of the test strains, to Dr. A. Mayr-Harting for typing the strains, to Miss P. Reeves for technical assistance, and to the Wright-Fleming Institute of Microbiology for the supply of terramycin.

Owing to fatalities amongst children, a meeting of branch representatives of the Pharmaceutical Society has requested the Ministry of Health to give publicity to the importance of tablets and other medicines being kept out of reach of children. It was also suggested that, in addition to advertisements, the Ministry should approach the B.B.C. and television authorities to produce a documentary to educate the public in the extreme potency of many of the medicines being dispensed nowadays.

CONTACT DERMATITIS DUE TO
AMINOAZOTOLUENE

BY

R. H. MEARA, M.B., M.R.C.P.

Senior Registrar, St. John's Hospital for Diseases of the
Skin, London, W.C.1

AND

I. MARTIN-SCOTT, M.D.

Dermatologist, Luton and Dunstable Hospital, Beds

Recently we have encountered, quite independently, three cases of contact dermatitis due to the yellow aniline dye aminoazotoluene. This dye, which is readily soluble in fats and waxes, is a constituent in the red and green semi-solid inks used in a popular ball-pointed pen. It is also used in certain popular shoe polishes. We have been unable to trace any previous reference to cases of dermatitis caused by exposure to aminoazotoluene.

Case 1

A hospital nurse aged 21 suffered from an irritant rash on the ulnar aspect of both forearms, but worse on the right, for three weeks. It consisted of an irregular area of erythema with papules and papulo-vesicles. The appearances suggested a dermatitis due to something contacted during her work. When she stopped work for a week the rash improved considerably, but recurred during a period of study when she was not doing any ward work. This second attack showed similar features, except that there was a raised erythematous linear lesion on the left forearm. The patient readily remembered that this was where she had scratched herself with the point of her red-ink pen. She had been using this ball-pointed pen for about six weeks before the eruption started.

In view of these findings patch tests were done using various colours of semi-solid ink of the same make. It was found that, while the red and green inks gave a positive result in 24 hours, there was no reaction to the blue and black inks. The manufacturers of this pen kindly supplied the information that the only substance common to the red and green inks, and not used in any other of their inks, was the yellow dye—aminoazotoluene. A further controlled patch test, using 0.01% aminoazotoluene in yellow soft paraffin, gave a positive reaction after 24 hours' contact.

From these results it appeared that the patient's eruption was due to skin sensitization to aminoazotoluene. The dermatitis healed within four weeks of ceasing to use the red-ink pen, and has not reappeared.

Case 2

A clerk aged 24 stated that she had suffered from a rash on her hands for five weeks, and was advised by her doctor to stay off work. Under his care the rash disappeared in two weeks, but returned on the evening of her first day back at work. She attended hospital four days later.

On examination she was found to have a dry papulo-vesicular eruption along the ulnar border of the right hand and little finger, and on the medial aspect of the tips of her third and fourth fingers. The skin around the left eye showed slight oedema and fine superficial scaling. The clinical picture suggested a contact dermatitis of occupational origin.

It was learnt that she was in contact with green semi-solid ink and carbon paper during her work, and before the second attack had accidentally smudged some green ink on her right upper eyelid. Whilst convalescing from the first attack at home she had used without mishap a similar ball-

pointed pen containing blue ink. She had used a green-ink pen for six weeks before the initial skin eruption developed.

Patch tests to blue semi-solid ink and carbon paper were negative after 48 hours, but there was a brisk response to the green ink.

The manufacturers kindly sent a sample of the yellow dye present in green and red semi-solid inks but absent in the blue ink. The illustration shows the results of different strengths of this dye (aminoazotoluene) diluted in arachis oil and left on the skin for 48 hours. After these results a patch test of aminoazotoluene 0.01% produced a distinct erythema

after only 24 hours' contact. The patch tests, which were all controlled, did not cause any exacerbation of the original dermatitis.

Dermatitis caused by aminoazotoluene. Percentages indicate strength of dye used.

Case 3

A lady clerk aged 52 had suffered from an itching eruption of the anterior aspect of the right wrist for over a year. A few weeks before attending hospital it had spread up the forearm and also appeared on the eyelids. She had used a red-and-blue ball-pointed pen for about two years, and her work involved contact with accounts written in these same inks.

Patch tests read after 24 hours showed she, too, was sensitive to the red and green but not to the blue semi-solid ink. Subsequently a positive reaction was obtained after 24 hours' contact with 0.01% aminoazotoluene in yellow soft paraffin. This eruption cleared up 10 days after she stopped using the red ink, and had not recurred eight months later.

Special Investigations on Case 1

As this patient appeared to be extremely sensitive to this azo dye, further investigations were carried out to determine the critical levels of concentration and exposure time for the skin reaction to occur.

Determination of Threshold Concentration.—The following patch tests were done with decimal dilutions of aminoazotoluene in yellow soft paraffin. The patches were removed after 24 hours, and the sites of contact subsequently examined at regular intervals.

0.1%	..	..	..	Positive at 24 hours
0.01%	..	..	..	" " 28 "
0.001%	..	..	..	" " 72 "
0.0001%	..	..	..	No reaction noted

Determination of the Threshold Period of Contact.—Aminoazotoluene (0.1%) in yellow soft paraffin was used in each case. Patches were removed after differing periods of

Test No.	Patch Contact Time	Reactions Observed After Certain Intervals of Time Recorded in Hours					
		9	12	21	37	45	72
1	5 minutes	—	—	—	—	—	—
2	10 "	—	—	—	—	—	—
3	30 "	—	—	—	—	—	—
4	1 hour	—	—	—	—	—	—
5	3 hours	—	—	—	—	—	—
6	6 "	—	—	—	—	—	—
7	9 "	—	—	—	—	—	—
8	12 "	—	—	—	—	—	—

contact with the skin and the sites examined at regular intervals (see Table). Further investigations showed that a longer exposure time was necessary to produce a reaction when lower concentrations of the dye were used. It would thus appear that, within certain limits, there is an inverse relationship between the critical levels of exposure time and concentration.

Summary and Conclusions

Three female cases of contact dermatitis due to the aminoazotoluene component in green and red semi-solid inks are described. In each case the distribution of the rash and history of the case suggested an exogenous dermatitis, and this was proved by subsequent patch testing.

The time taken to produce epidermal sensitivity was closely comparable in the first two cases—six to eight weeks: in the third case the interval may have been longer.

A high degree of epidermal sensitivity to the dye has been shown in each case. An attempt was made to demonstrate critical levels of concentration and exposure times in Case 1.

The dye seems, however, to have a low sensitivity index, as only these three cases have so far been published, and yet about two million red and green ball-pointed pens are sold annually in Great Britain. Furthermore, in the manufacture of the ink there have been no cases of dermatitis among the 70 workers who are exposed each day.

We are indebted to Dr. W. N. Goldsmith for permission to publish Case 1, and to Dr. P. J. Hare for drawing our attention to Case 3. Messrs. Biro Swan Ltd., and their chemists, Dr. Rosin Industrial Research Co. Ltd., have been most helpful throughout the investigations, and to them we proffer our grateful thanks.

APLASTIC ANAEMIA OCCURRING
EIGHT YEARS AFTER T.N.T.
POISONING

BY

F. G. J. HAYHOE, M.D., M.R.C.P.

Lecturer in Medicine, University of Cambridge

Among the commoner clinical manifestations of trinitrotoluene intoxication are dermatitis, cyanosis, and gastritis. Toxic jaundice is less common and the incidence of aplastic anaemia is very small (Hunter, 1943). Despite the rarity of anaemia in T.N.T. workers a good many cases were reported in this country and in America during the two world wars. While most of these cases have had their onset during or immediately after a fairly long period of exposure, anaemia occasionally develops after a latent period free from exposure. Panton (1917) described the clinical onset of aplastic anaemia in a patient whose exposure to T.N.T. had ceased nine months previously. Both toxic jaundice and aplastic anaemia may develop in the same patient, and Evans (1941) reported the occurrence of aplastic anaemia nine weeks after recovery from an attack of toxic jaundice.

The present communication concerns a patient who suffered from toxic jaundice after two months' exposure to T.N.T. in 1943, and developed a fatal aplastic anaemia early in 1951.

Case Report

The patient, a man aged 45, was employed as a maintenance engineer in a large motor works. Until 1943 he had worked as a builder and his health had always been good. In that year he started work in a filling factory, taking the usual precautions in handling T.N.T. and wearing a respirator. After two months' exposure he suddenly became ill with nausea, vomiting, and constipation which lasted for three weeks. He became jaundiced and the icterus persisted for two weeks. After full recovery he was employed in other departments of the same factory for a further two and a half years. During this period he worked with ammonium nitrate for six months, with aluminium dust for six months, on machine cleaning and maintenance for four months, and with ammonium nitrate again for six months.

After the war he worked for short periods in a brewery and an ice-cream factory before joining the motor works where he had been employed for the five years preceding his admission to hospital. His duties here involved much contact with machine-lubricating oils, and early in 1951 he suffered from an occupational dermatitis of his hands which lasted for two months. At this time he began to feel tired and lifeless, and anaemic symptoms of dyspnoea on exertion, lassitude, headaches, and muscular pains became increasingly severe during the next six months.

In July, 1951, a blood count was carried out with the following result: Hb, 7.3 g. per 100 ml.; red cells, 2,200,000; white cells, 5,200 (13% neutrophils, 84% lymphocytes, 3% monocytes). The smear showed considerable anisocytosis. The patient was admitted to Bedford General Hospital under the care of Dr. J. L. H. Easton. At this time there were no physical signs other than pallor, a few petechiae on the thighs, and hepatic enlargement to about 1 in. (2.5 cm.) below the costal margin. Investigations showed a normal bleeding-time but the platelets were scanty. The stools did not contain occult blood. There was a histamine-fast achlorhydria. The plasma protein levels and hepatic-function tests were within the normal range. A sternal marrow examination revealed aplasia of red cells and granulocytes; with some 60% lymphocytes. Treatment with iron, vitamin B₁₂, and "plexan" did not produce any reticulocytosis or haematological improvement, and transfusions of 5 pints (2.8 litres) of blood were given.

On August 17 the patient was transferred to Addenbrooke's Hospital under the care of Sir Lionel Whitby. He was very pale but not jaundiced or cyanosed. There was some sacral oedema but no oedema of the ankles. Lymph nodes could not be felt. There was a diffuse purpuric rash on both legs, with occasional purpuric spots on the trunk. The sternum was not tender on pressure. There was no koilonychia or clubbing. Cheilosis, sore tongue, and mouth ulceration were absent. Hess's capillary resistance test was positive. No other positive findings were encountered; the liver and spleen could not be felt. A blood count now showed: Hb, 7.4 g. per 100 ml.; red cells, 2,400,000 per c.mm.; P.C.V., 20.4%; M.C.H., 31 γγ; M.C.V., 85 μ³, M.C.H.C., 36.4%; M.C.D., 7.1 μ; reticulocytes, 0.1%; leucocytes, 1,700 per c.mm.; differential count, neutrophils 67 (stab cells 50, segmented 17), lymphocytes 1,600, monocytes 34 per c.mm.; platelets, 1,000 per c.mm.; E.S.R., 68 mm. in 1 hour, corrected to 18 mm. in 1 hour. Bleeding time was seven minutes and clotting-time 12–20 minutes on several occasions. Clot retraction was poor. The prothrombin content was 62% of average normal (Quick's one-stage method).

A sternal marrow examination on August 20 showed that the marrow was hypoplastic, with many lymphocytes and plasma cells, occasional tissue mast cells, and large numbers of degenerate cells. The differential count figures were: neutrophil polymorphs 2.4%, eosinophils 0.6%, metamyelocytes 3.6%, myelocytes 4.2%, promyelocytes 1.4%, lymphocytes 66.8%, plasma cells 7.4%. Normoblasts 12.2% (early 1.2%, intermediate 4%, late 7%), proerythroblasts

0.4%, tissue mast cells 1.2%. The degenerate cells were not included in the differential count, but they often contained phagocytosed pigment and may have been chiefly reticulum cells.

In view of the suggested relationship between tissue mast cells and marrow aplasia (reviewed by Fadem, 1951), the possibility that the prolonged clotting-time might be due to hyperheparinaemia was considered, and it was found that the clotting-time could be returned to normal by the addition *in vitro* of a suitable quantity of protamine. Protamine sulphate was given intramuscularly to the patient in doses of 40 mg. four times daily for three days, but had no effect on the clotting-time, and was discontinued.

The haemoglobin level fell steadily at the rate of 1 g.%, every five to seven days, and there were several severe epistaxes during the first two weeks after admission. A small abscess under the chin developed, and the cervical glands enlarged, but this was controlled by systemic penicillin. Small transfusions were given at frequent intervals, but no evidence of marrow activity was evinced. The leucocyte count fluctuated between 750 and 3,000 cells per c.mm., with neutrophils from 10 to 150 per c.mm. The platelets varied between 1,000 and 20,000 per c.mm.

On September 8 a course of A.C.T.H. was started, 100 mg. daily in divided doses being given for 10 days. No effect was produced on either the clinical condition or the haematological state.

On September 22 severe frontal headache developed, accompanied by nausea and vomiting. Slight neck rigidity and a small retinal haemorrhage in the right fundus occurred, but no other abnormalities were found in the central nervous system. Within 12 hours the breathing suddenly became stertorous and unconsciousness followed. Both pupils were contracted to pin-points and did not react to light. The arms were flaccid, but with tendon reflexes still present and equal. After a short period of coma the patient's respiration failed completely and he died.

Post-mortem Examination.—A large spreading haemorrhage was found extending throughout the left cerebellar hemisphere and breaking through on to the surface. The meninges appeared normal. There was evidence of sub-mucosal haemorrhage throughout the small intestine and in the renal pelvis and ureter on the right side. The haemopoietic marrow of the femur was completely replaced by yellowish fat, and the marrow of the sternum and vertebrae was also very pale and suggestive of hypoplasia. The spleen and liver were congested and gave a positive Prussian blue reaction. Histologically the bone marrow contained very few cellular elements, and these were mostly lymphocytes and normoblasts. The liver showed a few scattered areas of large droplet fatty change, but there was no sign of fibrosis. Apart from congestion and scattered haemorrhages there were no other striking abnormalities in any organs.

Discussion

This case history presents an unusual combination of facts. There is no doubt that the patient was exposed to T.N.T. and developed a toxic jaundice in 1943, that he was later subject to an occupational dermatitis of the hands after working with machine oils in 1950, and that he died in 1951 from an aplastic anaemia. The relationship between these episodes is largely a matter for conjecture. There seems to be no known association between exposure to oil and the development of haematological disorders, and it is difficult to believe that T.N.T. could still exert a delayed effect after eight years. The most likely explanation of the circumstances in the light of present knowledge is that the anaemia was a coincidental primary marrow aplasia, unconnected in any causal way with the toxic agent to which the patient had previously been subjected. It is not impossible, however, that other cases of long-delayed anaemia may have occurred after T.N.T. poisoning and been dismissed as coincidental primary disorders, and it is hoped that this report may stimulate publication of such case histories if they exist.

Summary

The case is reported of a patient who suffered from toxic jaundice after exposure to T.N.T. in 1943, who developed an oil dermatitis in 1950, and who died from aplastic anaemia in 1951.

The possible relationship between these episodes is discussed.

I am grateful to Sir Lionel Whitby, regius professor of physic in the University of Cambridge, for permission to report this case.

HAEMOPHILIA WITH RESPIRATORY OBSTRUCTION

BY

A. C. MACDONALD, M.B., Ch.B., F.R.F.P.S.
M.R.C.P.

Senior Medical Registrar, Western Infirmary, Glasgow

J. G. ROBSON, M.B., Ch.B., D.A.

Senior Anaesthetic Registrar, Western Infirmary, Glasgow

AND

H. WAPSHAW, M.D., F.R.C.S.Ed., F.R.F.P.S.

Assistant Surgeon, Western Infirmary, Glasgow

Among the more serious hazards of the haemophilic patient's life is haemorrhage into the tissues of the mouth, pharynx, and larynx. Fortunately, this seems to be an uncommon site for bleeding to occur; indeed, we have been able to trace only 14 cases in the literature since 1910. Of these, 11 suffered from respiratory obstruction of varying degree. A survey of the records of the Western Infirmary, Glasgow, makes us wonder, however, if this is not a more common complication of haemophilia than that number of published cases leads one to believe. During the period 1936–51 34 haemophiliacs were treated: as so often happens, many had to be admitted more than once with haemorrhages at different sites, the total number of episodes being 112. Three instances of oral bleeding each associated with respiratory obstruction were found, and it was noted that blood transfusion and other medical measures were enough to bring the condition under control.

The following report concerns another case which came under our care at the same hospital. The problem that confronted us was to decide how best to combat the threat of suffocation. It was the feeling of all who saw the patient that surgical intervention was imperative, and a relief incision was made under the chin. As we hope to show, however, the maintenance of a clear airway by means of an indwelling endotracheal tube was probably the measure that really saved the patient's life.

Case Report

A youth aged 16, a known haemophiliac, was admitted to hospital on September 11, 1951. On the previous day he had complained of pain and a swelling under his tongue, and the swelling had gradually increased in extent. No injury or sepsis had been present to account for the lesion, though one molar tooth was carious and roughened.

When first examined the patient was pale, anxious, and moderately cyanosed. There was gross bleeding into the tongue, which practically filled the buccal cavity, and the submandibular and submental regions were also much swollen. At first there was only a slight degree of respiratory embarrassment, though swallowing was very difficult and his speech was painful and almost unintelligible. A haemarthrosis of the left knee was also present. The temperature was 97.4° F. (36.3° C.), the pulse 105, and the respiratory rate 22. The blood pressure was 125/70. The haemoglobin was 13 g. %.

Shortly after his admission a transfusion of fresh blood was begun, but this appeared to have little immediate effect on the local condition. The coagulation time was not estimated before the transfusion. Within three hours of admission the condition had advanced to such an extent that speech and swallowing became impossible and respiratory stridor was pronounced. The tongue had turned a deep purple colour and lay immobile, projecting between the teeth. The gums were bleeding and the cervical swelling had extended uniformly around the neck down to the level of the hyoid bone. Crepitations were heard at both lung bases.

In order to give more immediate relief a wide-bore needle was inserted in the midline below the chin into the base of the tongue. This met with no success even though the needle was moved in different directions and planes. It was therefore decided to resort to the more radical procedure, which we now describe in detail.

Operative Treatment

Premedication in the form of atropine sulphate, 1/100 gr. (0.65 mg.), was administered intravenously into the drip tubing, 10 minutes being allowed for its action.

The mouth, nose, and throat were prepared by spraying and painting with 5 ml. of 2% amethocaine hydrochloride containing 7 minims (0.42 ml.) of adrenaline 1:1,000. A well-lubricated No. 6 Magill nasal tube mounted on a Magill suction T-piece was passed blindly through the left nostril into the trachea. This tube was well tolerated, the relief to respiration being immediate. General anaesthesia was then induced with 10 ml. of 5% thiopentone and continued with nitrous oxide and oxygen, using a trace of trichlorethylene.

A vertical midline submental incision $\frac{1}{2}$ in. (1.9 cm.) in length was made. The deep fascia was incised and the base of the tongue and both submandibular fossae were explored, using both dressing forceps and a finger, but no clot or localized collection of blood was found. It became obvious that the haemorrhage was interstitial in type.

The wound was temporarily packed with gauze soaked in a solution of "thrombin topical," which controlled, for the time being at least, the bleeding from the wound margins. Penicillin tablets were then inserted and a small wick of gauze was left in. After operation the endotracheal tube was left in place, the T-piece being securely strapped to the face with adhesive plaster. An endobronchial suction catheter was passed and a large quantity of watery mucus removed. The patient made a rapid recovery from anaesthesia.

Post-operative Course

It was decided that the endotracheal tube would be better left *in situ* until the danger of asphyxia had passed. To relieve the discomfort caused thereby 2% amethocaine was sprayed down the tube from time to time during the first day. A clear airway was ensured by the passage of an endobronchial catheter, and suction was applied every 15 minutes for the first few hours and whenever necessary during the next four days. Penicillin was administered parenterally to reduce further the risk of a pneumonic complication. The patient received in all 3 pints (1.7 litres) of blood followed by an intravenous glucose drip.

During the next 36 hours the tongue became even more swollen and the question of tracheotomy was reconsidered. Dr. Gavin Young, oto-rhino-laryngologist to the Western

Infirmary, was consulted, but he advised strongly against further surgical intervention. By the second day we decided that the endotracheal tube had been in long enough, but on its removal it immediately became apparent that the patient still required an artificial airway. Accordingly, a fresh tube was inserted, again through the nose, using the same anaesthetic technique. At the same time a Ryle tube was introduced via the mouth in order to replace the infusion therapy with a gastric milk drip. Crepitations persisted at the lung bases, but no more serious chest complication supervened. A persistent tachycardia of 140 to 160 a minute gave some anxiety. The submental wound continued to ooze for seven days. The coagulation time during the post-operative period remained about eight to nine minutes (capillary tube method).

By the fourth post-operative day the patient's condition was materially improved. The swelling of the tongue had diminished to a size which permitted the endotracheal tube to be replaced by a nasopharyngeal tube. With anaesthesia as before, a cut-down No. 6 Magill tube served the purpose, and it was placed so that its end lay just beyond the back of the tongue. Some eight hours later this too was removed, as the patient demonstrated his ability to breathe with the tube occluded.

Five days later he was given a further blood transfusion, consisting of 1 pint (570 ml.) of fresh blood and 1 pint (570 ml.) of packed red cells, since the haemoglobin level had fallen to 5.7 g. % and the red cells to 1,800,000 per c.mm. Thereafter convalescence progressed satisfactorily, and by the fifteenth day the swelling of the tongue and the floor of the mouth had completely subsided. He had also fully recovered his speech, which, incidentally, betrayed no hint of damage to the vocal cords.

It must be admitted that the haemarthrosis of the left knee received scant attention, though we are pleased to report that it had absorbed fully, without impairing function, by the time the patient left hospital.

Discussion

With this emergency it is a matter of surgical importance to know whether the haemorrhage is a localized collection of blood or a diffuse extravasation among the soft tissues of the mouth and throat. The case reported was an example of the latter type. The following also describe interstitial lesions: Lesné, Powilewicz, and Récamier (1921), Voit and Paus (1933), Endicott, Mitchell, and Qvist (1942), and Edmonds (1951). It is noted that Wintrobe (1946) and Davidson, Epstein, Miller, and Taylor (1949) merely refer to the formation of a haematoma. The paper by Endicott and his co-workers (1942) should be read for an appreciation of the anatomical aspects of the problem.

Early transfusion is obviously indicated and would appear to have provided adequate treatment in 6 of the 14 reported cases, as it also did in those which we found in the past records of our hospital. Of the remainder, seven received surgical attention. Six of these patients underwent tracheotomy, four of them dying (Lesné *et al.*; Voit and Paus; Endicott *et al.*; Edmonds). The two patients who recovered (Baird and Fox, 1943; Fox, Spencer, and Tocantins, 1946) caused considerable anxiety in the post-operative period, a major concern having been a persistent ooze from the tracheotomy wound. Troutt (1931) reported a case of a patient who recovered after a local incision of the tongue. In our case the incision that was made under the chin may have afforded an outlet for the blood and serum, but it is more likely, considering the nature of the lesion, that the exploration did more harm than good. It is questionable, in fact, whether or not surgical intervention is necessary in this condition.

We agree with the recommendation of Boyd (1950) that an attempt should be made to intubate the trachea before resorting to a tracheotomy or relief incisions. He chose the oral route in his case, and apparently to good effect. In our case the lingual swelling only just allowed the passage of a laryngeal swab carrier, and laryngoscopy would have

been impossible. Nasal intubation under local analgesia does not seem to be unduly difficult in these circumstances. The precaution was taken not to give thiopentone until the respiratory obstruction was overcome. Davidson *et al.* (1949) have stated that the local swelling tends to diminish in 24 to 36 hours. The critical phase in our case lasted four days, and no deleterious effects seemed to result from intubating the trachea for that period of time. There is no doubt that the absence of chest complications was largely due to the post-operative nursing care and to the assiduous bronchial toilet.

Summary

A case of respiratory obstruction in a haemophilic patient is described. This complication was due to a spontaneous interstitial haemorrhage into the tongue and the floor of the mouth. Three other cases from the same hospital are cited.

The management of the case reported consisted of blood transfusion, a submental incision, and nasotracheal intubation.

It would seem that intubation presents certain advantages over, and may be preferable to, tracheotomy in the treatment of this medical emergency. A Magill nasotracheal tube left in place for four days caused no obvious damage to the vocal cords.

We wish to thank Dr. J. A. W. McCluskie and Mr. E. G. Gerstenberg, in whose wards the patient was treated, for permission to publish this case.

A CASE OF TALC GRANULOMA SIMULATING CARCINOMA

BY

F. BAAR, M.D., F.R.C.S.Ed.

Senior Surgical Registrar, Maelor General Hospital, Wrexham

Post-operative complications arising from the use of talc as dusting powder for surgical rubber equipment were first described by Antopol (1933). Experimental talc granulomas were produced in dogs by Lichtman *et al.* (1946), and many cases of post-operative adhesions have been attributed to the use of talc in the last decade. Mackey and Gibson (1948) described a talc granuloma which was found 13 days after laparotomy. Walker (1948) reported a death from general peritonitis following small-bowel obstruction due to talc adhesions following the repair of strangulated femoral hernia. Swingle (1948) recorded another fatal case of post-operative intestinal obstruction due to talc adhesions. Ross and Lubitz (1949) reported a similar case. Postlethwait, Mason, and Morehead (1950) also reported seven cases of talc granuloma found partly in persistently draining post-operative sinuses, partly causing intestinal obstruction, and partly present in operation scars. Kidd and Wilson (1951) described a case of recurrent intestinal

obstruction following appendicectomy at which adhesions containing crystalline material were found under polarized light. The value of modified starch as a substitute for talc has been recommended by Graham and Jenkins (1952).

The following is a report of a case of talc granuloma combined with an old-standing diverticulitis of the sigmoid colon which simulated carcinoma.

Case Report

A married woman aged 63 attended the surgical out-patient clinic on October 2, 1951, with 15 years' history of vague abdominal discomfort, constipation, some recent loss of weight, and poor appetite. She had also lately suffered from frequency and some discomfort on defaecation, together with a constant bearing-down sensation and backache. Cholecystectomy for gall-stones had been performed in Liverpool in 1946.

On examination her appearance was that of a middle-aged rather obese woman in moderately good general condition. There was a suspicion of an ill-defined mass in the L.I.F. Rectal examination revealed a fairly large, fixed, slightly tender mass in the pouch of Douglas which seemed connected with the uterus and suggested a uterine fibroid. On vaginal examination the mass seemed to lie behind and to the left of the uterus. The patient was referred to the gynaecologist, and an examination under anaesthesia was carried out on October 9, when the above clinical findings were confirmed.

Operation.—On the same day a laparotomy was carried out and a tumour was found which apparently originated in the sigmoid colon and which was densely adherent to the uterus. The affected part of the sigmoid colon was mobilized fairly easily and a provisional diagnosis of either carcinoma or diverticulitis of the sigmoid colon, leading to the formation of an inflammatory mass with subacute obstruction, was made. The colon proximal to the tumour was greatly distended. In view of the subacute obstruction a transverse colostomy was carried out with the intention of resecting the affected part of the sigmoid colon at a later date. The patient was transferred to the general surgical ward, and the colostomy was opened on October 15.

Second Operation.—On October 31 the affected part of the sigmoid colon was resected with end-to-end anastomosis. No secondaries were found anywhere in the abdomen apart from enlarged glands in the immediate neighbourhood, which were easily included in the resection.

Convalescence was uneventful and the patient was discharged from hospital on November 29 to return at a later date for closure of her colostomy. A barium enema carried out on November 22 showed the barium flowing to the colostomy without delay. The x-ray report mentioned a few diverticula in the lower pelvic colon with some inflammatory changes.

Third Operation.—The patient was readmitted for closure of her colostomy, which was carried out on February 2, 1952, and she was discharged healed and having normal bowel actions on February 21. She has been seen in the surgical out-patient clinic repeatedly since, and her condition is quite satisfactory.

Pathology

The specimen consisted of 4 in. (10 cm.) of thickened sigmoid colon with 3 in. (7.5 cm.) of normal colon on each side, together with a sector of resected mesocolon which contained several enlarged glands in the immediate neighbourhood of the tumour-affected part of the colon. The macroscopic appearance of the tumour suggested either carcinoma or Crohn's disease. The part of the colon proximal to the tumour was hypertrophic and distended. The lumen of the affected part was considerably narrowed, but the mucosa of the entire specimen seemed intact. As a third possible diagnosis diverticulitis with peridiverticulitis

probably the result of a healed perforation of a diverticulum, had to be considered. There was a good deal of inflammatory oedema present.

Microscopical Examination.—The specimen was sectioned and the provisional report stated the lesion to be of an unusual inflammatory nature. The sections showed normal colonic mucosa, oedema and fibrosis of the submucosa, considerable hypertrophy of and some collagen deposits in the muscularis, and chronic inflammatory infiltration and fibrosis of the serosa. The lesion was stated to resemble Crohn's disease.

The specimen was also sent to Professor W. D. Newcomb, of St. Mary's Hospital, London, W.2, who confirmed the inflammatory nature of the lesion. He considered it to be a granulomatous condition due to small anisotropic particles (Fig. 2), probably from glove powder. He confirmed the presence of diverticula, and the hypertrophied muscularis

FIG. 1.—Showing the granulomatous nature of the condition, hypertrophy of the muscularis, oedema and fibrosis of the submucosa, and chronic inflammatory infiltration and fibrosis of the serosa. (x260.)

FIG. 2.—The same section under polarized light (x260), the talc particles appearing as birefringent crystals.

was thought to be the result of chronic obstruction due largely to the adhesions and partly to the diverticula. Professor Newcomb reported: "There is no question that she has had some ruptured diverticula in the past which go as far as the fat round the colon. It is very interesting that some of the faecal material has gone out into the fat and has caused a foreign-body reaction rather similar to the type on the surface, but I think there are two separate conditions. She first had a diverticulitis which has largely healed and then has had a talc granuloma which has stuck the material to the uterus."

As previously mentioned, the patient had undergone a cholecystectomy in 1946, when the powder was probably introduced into the abdominal cavity. Fig. 1 shows a section through the granuloma and Fig. 2, taken under polarized light, shows the talc particles as birefringent crystals.

Comment

Talc is a hydrous magnesium silicate which can produce a pseudo-tuberculous non-caseating granulomatous lesion in the form of a chronic granuloma or foreign-body reaction. The talc particles can be seen under polarized light. The talc may originate from the outside of gloves, from perforated gloves, or from rubber drains which had been powdered with talc for autoclaving. The particles are visible under the polarizing microscope as birefringent crystals.

The lesions described in the past have been post-operative adhesions which have caused obstruction, tumour masses which have simulated carcinoma, Crohn's disease and tuberculosis, persistently draining sinuses, or single or multiple masses in operation wounds. Periods of years may elapse between talc contamination and the production of symptoms, but Mackey and Gibson's talc granuloma was found 13 days after laparotomy. Cornstarch is now recommended in various modified forms as a dusting powder for use on surgical gloves and drains.

Summary

A case of talc granuloma following cholecystectomy, combined with diverticulitis of the sigmoid colon, and simulating carcinoma, is described. The various lesions which can follow the use of talc as dusting powder for surgical rubber equipment are discussed.

I wish to thank Mr. R. S. Ninian for permission to treat and publish this case, Professor W. D. Newcomb for the interpretation of the microscopical sections, and Professor J. Gough for the preparation of the photomicrographs.

The London fog of December, 1952, and the initiation of the second smokeless zone in this country (in Central Manchester) are two points noted in the 1952 Annual Report of the National Smoke Abatement Society which is published in the Society's 1953 Year Book, now available from the offices of the Society, Chandos House, Buckingham Gate, S.W.1, price 1s. The report expresses concern at the calm acceptance of the incapacity caused by the fog, and the Society has urged the Government to undertake a comprehensive investigation into the disaster. The Year Book also contains articles on laws relating to smoke, investigation of air pollution, and domestic and national fuel policy. There is also information about the Society and its services to members, as well as a directory of organizations concerned with air pollution, and a list of recently published papers on the subject.

ISHIHARA TABLES: COMPARISON OF
THE NINTH AND TENTH EDITIONS

BY

R. A. WEALE, M.Sc., A.Inst.P.

(From the M.R.C. Group for Research in the Physiology
of Vision, Institute of Ophthalmology, London)

The assessment of the quality of isochromatic tables can only be empirical. Since their principal use, however, is for the detection of grossly colour-defective individuals who, by confusing red and green, are a danger to, and endangered by, modern traffic, a merely superficial test may provide a sufficiently valid result. But when a detailed answer is desirable, as when a certain amount of colour confusion can be tolerated, it will be found that clear-cut answers are obtained but rarely.

Criterion for Comparison

In the comparison of two different editions of the Ishihara tables it is necessary to test a given patient with both sets of tables in a random order so that the effect of memory becomes unimportant. Some sort of criterion must obviously be developed in order to evaluate the answers numerically. In the present instance, adequacy (A) and inconsistency (I), which are defined below, were chosen to compare the ninth and tenth editions of the Ishihara tables. All tables show at least one figure which the patient can or cannot read according to his colour vision. Some of them provide an alternative reading: thus Table 4 is designed to elicit the answer 29 or 70. If neither of these answers is given, and the patient reads 20 or 79 or any other number, this is considered to be a failure (F). The total number of F is subtracted from the number of tables (24, if the sample No. 1 is omitted) to yield the adequacy, A.

In itself, however, the adequacy is not a sufficient criterion. It may happen that the patient is diagnosed as normal following one table, red-green blind following another, and totally colour-blind according to a third. Again, another man may be completely red-blind by Table 22 and completely green-blind according to Table 24. Such diagnoses are not self-consistent. If, for example, the first patient gives six "normal" replies, then there are six inconsistencies (I=6), since if he were normal he would have shown it more than six times. Similarly, in the second case I=1, as one of the answers is unsuitable for an adequate diagnosis. A perfected diagnosis consequently requires A=24, and I=0—that is, all the answers must have been foreseen by the author and the 24 separate diagnoses must not contradict each other. The theoretical reason behind values of A different from 24 and values of I larger than 0 is that most colour defects are of an intermediate nature—that is, the patients are neither completely red-blind nor completely green-blind—and it is impossible to design a set of tables all of which would detect the defect. There are, moreover, individual variations in the spectral sensitivity which vitiate any attempt to standardize the tables in detail.

Results

In the present test, standard illuminating conditions were observed and 10 subjects examined. Of these, No. 1 was normal, No. 3 a deuteranope, and No. 5 totally colour-blind (a cone-monochromat, v.i.). The other defects were not identified. Patients 9 and 10, who do not occur in the accompanying Table, were also cone-monochromats and could not read any of the tables except the first. The results obtained were as shown in the Table.

The two editions thus provide equally self-consistent answers, but the later set appear to be more adequate. It is uncertain whether the difference in this respect is statistically significant.

Patient	Adequacy		Inconsistency	
	9th Ed.	10th Ed.	9th Ed.	10th Ed.
1	24	24	0	0
2	16	11	4	7
3	21	20	0	0
4	18	18	1	2
5	18	18	1	1
6	17	20	1	0
7	15	21	7	6
8	18	18	2	0
	147 (76%)	150 (78%)	16	16

Both sets of tables seem inadequate for the detection of total colour-blindness. If the patient suffers from rod-monochromatism an Ishihara test is generally superfluous because he will probably suffer also from photophobia, nystagmus, and reduced visual acuity. But such patients (not listed above) were not found to follow the Ishihara key: they were invariably successful with Tables 6 to 9. The reason for this is no doubt that the rod-monochromat's sensation of light is limited to the response mediated by the rods: this will allow blue-green figures on a background, isochromatic for the normal photopic sensitivity, to stand out as light numbers on a dark background. Although patients 9 and 10 failed on every table, patient 5 would not have been detected as being totally colour-blind had more reliable tests not been available. Again, another patient who would have been classed as totally colour-blind on the strength of the tables was found to be a protanope when tested more severely. These findings reaffirm the opinion that the Ishihara tables can be relied on to discover red-green defects: as regards total colour-blindness, however, the reliability of the answers they provide is much less.

Medical Memoranda

Congenital Syphilis of the Lungs

The following case of what is now a rare disease is reported because, despite knowledge of all the significant facts, difficulty was experienced in establishing the true nature of the lesions.

CASE REPORT

A woman aged 26 gave birth to a stillborn female infant. The mother alleged that the infant had been born some five weeks prematurely. She had had a miscarriage four and a half months after her marriage, but since that time had had one normal pregnancy and no further miscarriages. Prior to her confinement she had not attended an antenatal clinic, and it was only after the post-mortem examination on the infant had been completed that it was discovered that both the mother and father had positive Wassermann and Kahn reactions. There was no significant family history.

Post-mortem Findings.—The body was that of a female infant of 5 lb. 11 oz. (2.68 kg.) and apparently full maturity. There was gross oedema of the face, chest wall, and neck. A quantity of clear straw-coloured fluid was found in the pericardial sac. The heart was normal in structure and size. The ductus arteriosus and the foramen ovale were patent, the latter being very large and showing no valve. Both pleural cavities were full of clear straw-coloured fluid. Both lungs were atelectatic, and scattered throughout their substance were numerous globular tumours varying from about 2 mm. to 1 cm. in diameter. These tumours were yellowish white in colour, and, on section, rubbery and uniform in consistency. A number of the more superficial tumours caused bulging of the lung surface, and were quite sharply defined. The only other abnormalities discovered

were clear straw-coloured fluid in the peritoneal cavity, gross oedema of the brain, and suprarenals which were smaller than usual.

Histology.—Liver: numerous spirochaetes were seen, but the usual unicellular fibrosis was absent. Portal fibrosis, oedema, and excessive haemopoiesis were present. Pancreas, placenta, and kidneys: these appeared to be normal. Lungs: considerable numbers of spirochaetes were present in both the tumour and the non-tumour areas. A chronic interstitial pneumonia was present. In the nodules of solid tissue the bronchi showed up well and in some places the alveoli were lined with cubical epithelium.

COMMENT

The gross lesions in this case of congenital syphilis were exclusively in the lungs. Although microscopically spirochaetes were found in the liver the reaction to them appeared to be minimal in this organ. The gross lesions found at necropsy and the H. and E. sections presented a puzzling picture, and it was only the presence of spirochaetes in the sections stained by Levaditi's method which finally established the diagnosis.

The classical diffuse pneumonia alba was absent, and reference to numerous modern textbooks of pathology gave little information on discrete congenital syphilitic lesions in the lungs; they usually confined themselves to such remarks as, "Gummata may occur." The histological appearances of the tumours in this case were not those of gummata. It would seem that this form of congenital syphilitic lesion of the lungs is now so rare as not to merit description, in the standard textbook at least. However, on reading the older textbooks it is obvious that such lesions as have been described here were frequently seen by the pathologists of former days. An example of their descriptions, which tally in almost all respects with the lesions here recorded, may be quoted (Lancereaux, 1869): "The pathological product in the lungs always showed itself in the form of tumours, more or less numerous, of the size of a pea or a walnut, and these tumours were perfectly circumscribed, firm or softened at their centre and usually of a yellowish colour." Syphilis is still capable of presenting atypical lesions, and its presence must always be borne in mind when unusual pathology is encountered.

My thanks are due to Drs. R. D. Reid and A. B. Bratton for their help with the histology, to the department of pathology, Essex County Hospital, and to the Medical Director-General of the Royal Navy for permission to publish this case.

P. W. EDMONDSON, M.R.C.S., L.R.C.P.,
Surgeon Commander, R.N.

A Finger Bud

I first saw the patient, a man aged 59, warming his hands by an old-fashioned grate, fingers outstretched, with the red glow of the fire showing through them. After a pause he saw me counting and proceeded to give the following story.

The swelling started, without pain, as a small pink, smooth elevation of the skin. He has no remembrance of injury. It grew slowly, and a long time passed before it became an embarrassment to him at whist drives, before all of which he would ask his wife to bandage the finger. Finally, the point was reached when his social life was jeopardized and he determined to be rid of it. Various suggestions made by his workmates were acted on. First, he rubbed it down regularly with the business edge of a matchbox. Next he plucked a hair from a horse's tail (there is a drayman's yard of a local brewery near by) and tied it round the base of the offending swelling. Finally, acting on the advice of his 90-year-old mother-in-law, he buried a part of the meat ration (beef) at the bottom of his garden and awaited results.

One day, while the swelling was still fairly small, he accidentally cut it at its base with the edge of a tin. It bled

only a little, but afterwards its growth was fairly rapid, and it took on the angle shown in the photograph. By the time he came to the surgery (June, 1951) he had had the appendage for 10 years.

On examination the swelling was a little more than an inch (2.5 cm.) long, solid, and sausage-shaped. It was attached to the volar aspect of the middle finger, near the distal interphalangeal joint. The skin crease of that joint was obliterated, and the middle segment of the finger was thicker than that of the corresponding digit of the other hand. The grey-pink skin over it was thick and horny, particularly at its tip. In the acute angle it made with the finger the skin was dry and not infected. A small amount of painless movement was possible at the junction of bud and parent stem. A curious feature was the continuation for a short distance of the normal "whorl" pattern at its

base, but these characteristic markings rapidly gave way to a few short shallow linear creases, reminiscent of the "striae gravidarum." Although it was a cumbersome attachment the patient said he played darts and dominoes with ease.

A skiagram of the hand as a whole showed that there was no generalized or local bone disease, and that the tumour was in fact composed of soft tissue only. A tentative diagnosis of an implantation dermoid was made.

Benign tumours of the hand are uncommon. Mr. Norman Lake gives the following: lipoma and fibroma, cutaneous myxomatous cyst, implantation cyst, glomus tumour, enchondroma, exostosis and osteophyte, and osteoclastoma.

After a preliminary photograph the base of the finger was infiltrated with 2 ml. of 1% procaine hydrochloride on each side of the bone—"ring" block anaesthesia, as described so succinctly by members of the hand clinic at University College Hospital. The skin at the base of the swelling was incised elliptically; the swelling was transfixed by a ligature and retracted by the patient, using his other hand. It was seen that the tumour had a pearly white capsule. Gauze dissection was enough for its separation, and bleeding was slight. Separation of the proximal part in the substance of the middle segment gave no difficulty. Little dead space was left at the end of the enucleation, and after dusting the wound with sulphonamide-allantoin the skin edges were brought together with three interrupted nylon sutures without packing.

Healing was rapid and by first intention. The sutures were removed on the tenth day and movement at the distal interphalangeal joint became rapidly normal. Meanwhile, a section of the tumour revealed that it was a fibroma.

I thank Mr. John Hadland for the photograph; Dr. Jamison, of Watford, for his pathological report; and my senior partners, Dr. R. Fisher and Dr. D. Brown, for their encouragement.

CANADIAN SURGERY

Textbook of Surgery. Edited by H. F. Moseley, M.A., D.M., M.Ch.(Oxon.), F.A.C.S., F.R.C.S.(Eng.), F.R.C.S.(C). With foreword by G. Gavin Miller, M.D., C.M., M.Sc., F.R.C.S.(C), F.A.C.S. (Pp. 896; 460 text illustrations and 46 colour plates. £5 10s.) London: Henry Kimpton. 1952.

This fine volume has been conceived and produced for the assistance of students undergoing a five-years course in surgery at McGill University with a view to specializing as surgeons. It may be taken to represent surgical practice in Canada at the present day on the highest level. It contains an immense amount of information in a small compass and in a very compressed form, as is suitable for those for whom it was written. It is not a book for a beginner, but the advanced student will find it invaluable, since it will enable him both to expand and to classify his knowledge.

It is impossible to review in detail a work by some 30 authors, but it is at once obvious that everywhere it reaches a high level. The various subjects have been treated all on a similar plan, resulting in a uniformity and a balance which are remarkable and a great credit to the editor. The volume is profusely illustrated, and the line and half-tone drawings are superb and add greatly to its value. Each section carries a short bibliography of recent work, providing easy access to the literature.

HENRY SOUTTAR.

CHANGING HEALTH SERVICES

Trends of Opinion about the Public Health, 1901-51. University of London Heath Clark Lectures 1951. By Professor J. M. Mackintosh, M.D., LL.D., F.R.C.P. (Pp. 202. 12s. 6d.) London: Geoffrey Cumberlege (Oxford University Press). 1953.

In these lectures Professor Mackintosh, out of his long and ripe experience both as a public health administrator and as a holder of professorial chairs in two great universities, traces the rise of personal health services, the growth of National Health Insurance, the advent of the Ministry of Health, the zenith of local government, and the steps which led to the establishment of the National Health Service in Great Britain.

As one who has promoted and seen the growth of health and hospital services by enlightened and progressive local authorities, he is unable to approve of the course that subsequent events have taken. As far back as 1909 Mr. John Burns, then president of the Local Government Board, was pressed by his medical adviser, Sir Arthur Newsholme, to take legislative action not only to carry out the recommendations of the Poor Law Commission but also to establish a national health service which would link up the public health work of local authorities with specialized and general medical practice. Administratively such a service would have been logical and sound. Mr. Burns hesitated, and meanwhile Mr. Lloyd George brought in the National Insurance Act, which created an *ad hoc* central authority in the National Insurance Commission. This mistake was rectified to some extent by the merging of the Commission in the Ministry of Health in 1919.

In 1929 a great step forward was made by the passing of the Local Government Act, which made a way for the abolition of the Poor Law, enlisted the co-operation of the voluntary hospitals, and created a hospital service under the major local authorities. Some administrators hoped that, by extending the provisions of the National Insurance Act to dependants and integrating the specialist services already provided by local authorities, a national health service could be provided economically by progressive stages.

Instead, the National Health Service Act of 1946 established a national medical service in which the hospital

services and other services, hitherto administered by local authorities, were placed under regional hospital boards. Professor Mackintosh deplores this and also the creation of a special Children's Department of the Home Office. Referring to the making of separate, sometimes competing, occasionally conflicting services under local and central control, he adds: "It is hard to understand why we go on making the same mistake only to regret it when it is too late to mend."

Not everyone will agree with Professor Mackintosh's point of view, but all will appreciate the clarity and vigour with which he defends his thesis in the "Physic Act," his plea for greater attention to the preventive aspect of medicine, and the admirable literary style of these lectures.

ARTHUR S. MACNALLY.

OCULAR SURGERY

Ocular Surgery. By Hermenegildo Arruga, M.D. Translated from the third Spanish edition by Michael J. Hogan, M.D., and Luis E. Chaparro, M.D. (Pp. 936; 1,293 illustrations in text, 127 in colour. £15 6s.) London: McGraw-Hill Publishing Co. 1952.

Arruga's book first came out in his own language (Spanish) in 1946; the second edition, translated by Blum, of Geneva, was published in France in 1950; this translation into English has now appeared; and each successive edition has incorporated the advances which have appeared since the publication of its predecessor. The translations of this work indicate its unusually large appeal to ophthalmologists all over the world.

The plan adopted is not a comprehensive description of the innumerable types of surgical procedures and their minor variations; rather, the author confines his attention to those techniques which he himself considers best and which have been adopted by most leading ophthalmologists. The whole of ophthalmic surgery is systematically discussed, each section being of a standard so high that it is difficult to distinguish any one as outstanding. The section on the surgery of the eyelids includes not only an account of operative procedures for all the ordinary conditions so familiar to ophthalmologists, but also a useful account of plastic surgery of the lids. In the section on the cornea the various techniques for corneal grafting figure largely, and there is a more than usually interesting discussion on the technique of tattooing corneal scars in various colours. The chapter on the lens is a classic. As would be expected in a book written by Arruga, the discussion of detachment of the retina is lucid and elaborate, and in the section on the surgery of glaucoma, in addition to a description of the standard operations with their many variations, a most useful feature is the attention paid to the difficulties and complications which may arise. In the chapter on the surgery of the muscles the description of the numerous mechanical techniques which may be adopted is made interesting by the space given to the theoretical considerations which should determine the choice of the many techniques available. The author fully discusses that most difficult surgical problem, the treatment of intraocular foreign bodies.

Each section is written with great clarity, and the excellent illustrations make the descriptions in the text so clear that even readers who have little acquaintance with ophthalmic surgery can readily follow every step in the most elaborate operations. The descriptions of the minutiae in technique, and of the difficulties expected and unexpected which may arise, provide the best index of the vast experience and unusual surgical skill of the author. The book is extremely well produced, the illustrations are lavish and excellent, and the translators are to be congratulated in carrying out a responsible task with great fidelity to the original text without sacrificing the rhythm of the English language. It is a book which should be read and studied by anyone who practises ophthalmic surgery.

STEWART DUKE-ELDER.

MODERN TREATMENT

Modern Treatment Year Book 1953. Edited by Sir Cecil Wakeley, Bt., K.B.E., C.B., LL.D., M.Ch., D.Sc., F.R.C.S., F.R.S.Ed., F.R.S.A., F.A.C.S., F.R.A.C.S. (Pp. 348; illustrated. £1 1s.) London: Baillière, Tindall and Cox. 1953.

This book contains 38 articles by different contributors on a variety of subjects. The general practitioner is interested in three kinds of treatments: first, those he will carry out himself; secondly, those applied by specialists; and, thirdly, a group which overlaps the first and second according to the severity of the disease and the temerity of the practitioner. In which group a particular patient is placed depends largely on the judgment of the practitioner, so that he has not only to learn modern methods but also to pass judgment on them.

First, his own practice will be improved by reading Sir Cecil Wakeley ("Modern Treatment of Hydrocele"), Dr. Douthwaite ("Medical Treatment of Peptic Ulcer"), Dr. Gwyn Griffith ("The Modern Treatment of Rheumatic Fever"), and Dr. Thomas ("The Modern Treatment of Eczema").

Secondly, Mr. Stallard ("The Treatment of Glioma Retinae"), Mr. Barrett ("The Treatment of Carcinoma of the Bronchus"), and Dr. Phyllis Wade ("Modern Treatment of Cancer of the Thyroid") show the possibilities and limitations of surgery and radiotherapy in these conditions. Professor Strachan ("The Investigation and Treatment of Carcinoma of the Body of the Uterus") is refreshingly forthright in his opinion of the limitations of the general practitioner in this disease.

In the third group it is interesting to note how specialists differ about the proper range of the general practitioner. Whereas Mr. Ross Smith ("Treatment of Fractures of the Knee-joint") is prepared to leave quite serious injuries of the knee to the general practitioner, Mr. Plewes ("Modern Principles in the Treatment of Fractures") would bring his fracture clinic into the factories.

Obstetrics and gynaecology are well served, especially the treatment of infertility, although no one is willing to tackle artificial insemination very firmly. In this specialty I liked best Mr. Linton Snaithe ("Modern Views of Treatment of the Menopause"). He treats the woman's mind as well as her hormones. Dermatology is not neglected. It is noticeable that here old methods are replacing new.

There are plenty of good illustrations and photographs. Reproductions of x-ray negatives are clear, of positives indistinct. I wonder why the negatives are not always used.

C. W. WALKER.

DENTAL ANAESTHESIA

A Manual of Dental Anesthesia. By Professor W. Harry Archer, M.A., D.D.S. (Pp. 192; 146 figures. £1 7s. 6d.) Philadelphia and London: W. B. Saunders Company. 1952.

The first half of this book, devoted to local analgesia, is admirable. The bold illustrations and the text have that stamp of the master which makes their meaning clear and their teaching helpful. The remaining 66 pages on general anaesthesia bear evidence of wide reading, but lack the touch of authority.

This second section opens with a timely warning against playing the dual role of dentist and anaesthetist, but Dr. Archer then appears to overlook the dangers of a dental surgeon advising his fellow practitioners in anaesthetic techniques which are a full-time study. Amputation has resulted only too often when thiopentone has been given by mistake into an artery instead of a vein. On two occasions the author injected it inadvertently into an artery, producing characteristic pain: "The injection of the anaesthetic solution was stopped and the pain disappeared. When a moment or two later a few more cubic cm. were injected, the same pain was provoked." Curare and thiopentone have been used on occasions by experienced anaesthetists to relieve laryngospasm. The suggestion that these drugs

might be of value to dentists for the same purpose is asking for trouble. In Britain the anaesthetist will read with surprise, and the dental surgeon with concern, the nine pages of tests to which the patient should be subjected before being anaesthetized for a dental operation. Many of the views on general anaesthetics in this book are out of date, and some of the practices advocated cannot but be dangerous in the hands of the average dental surgeon.

R. R. MACINTOSH.

ALLERGIC DISEASES

A Manual of Clinical Allergy. By Professor John M. Sheldon, M.D., Robert G. Lovell, M.D., and Kenneth P. Mathews, M.D. (Pp. 413; illustrated. £2 2s. 6d.) Philadelphia and London: W. B. Saunders Company. 1953.

This illustrated manual reflects the outlook and methods used in the allergy clinics of the University of Michigan, Ann Arbor. It is not an ordinary textbook of allergic diseases, and not much space is devoted to the clinical description of such diseases. As the authors state, the book is "primarily for the physician interested in devoting part of his time to the treatment of allergy patients, or in establishing an allergy practice." It satisfies this demand extremely well, and I am sure that no such physician should be without this book. There are 20 chapters and 5 appendices. Evidence of wide experience and common sense appears on every page. Almost all the chapters deal in considerable practical detail with the methods used to establish an exact diagnosis of the cause or causes of a particular allergic condition, and give a reasoned and reasonable approach to treatment. One large illustrated section is on the identification of individual pollens, fungi, and moulds.

This book is beautifully printed and produced, reasonably priced, and singularly free from typographical errors. It may be highly recommended to all doctors interested in the practical investigation of allergic diseases as a companion to clinical texts on the subject.

C. J. C. BRITTON.

Those who enjoyed Dr. Richard Gordon's *Doctor in the House* will not be disappointed by the same author's *Doctor at Sea* (Michael Joseph, 10s. 6d.). The central character is a prim young assistant in general practice who takes a job as a ship surgeon on the advice of a psychiatrist, who thought this would be the best treatment for headaches induced by the seeming inevitability of a marriage arranged by the principal's wife. The voyage of a rather seedy cargo boat to South America gives the author even more scope for picaresque adventure than the life of a medical student. The young doctor, who gradually loses his primness, and his dissolute steward are very down-to-earth descendants of Bertie Wooster and Jeeves, and such stalwart stand-bys of British humour as sea-sickness, false teeth, Christmas dinners, D.T.s, corpses, and of course sex are all given a bright and breezy new look befitting a book about the sea. Dr. Gordon's crackling epigrams, sure touch, and slightly outrageous cynicism combine to make this an uproariously funny book.

Although the name of Abraham Trembley must be known to very few to-day, during his lifetime he made some of the greatest contributions to experimental morphology. His memoir on freshwater polyps (1774) demonstrated for the first time that certain animals could be artificially reproduced by division. He was the first to make permanent grafts of animal tissue, to prove that asexual reproduction by budding occurs in animals, and to witness cell division. Biography written too close to the life of its subject suffers certain disadvantages. Such a biography was prepared by Trembley's nephew three years after his death. Since then a considerable correspondence between Trembley and Réaumur has come to light. Full use has been made of this in a new biography by Dr. John R. Baker (*Abraham Trembley of Geneva: Scientist and Philosopher, 1710-1784*. Edward Arnold, 1952. 35s.). Dr. Baker puts the discoveries of Trembley in proper perspective against present-day biological knowledge. His admiration for Trembley and his painstaking study of his life and work have resulted in a fascinating and authoritative book, skilfully written and lavishly illustrated.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MAY 23 1953

DEBATE ON THE GUILLEBAUD
COMMITTEE

Mr. Iain Macleod, Minister of Health, on Monday this week ably and convincingly defended the Government's decision to inquire into the Health Service through the Guillebaud Committee. Mr. Aneurin Bevan, in his attack on this decision, thought that the Central Health Services Council, which could act on its own initiative as well as on the stimulus of the Minister, was the right body to detect defects in the Service and advise the Minister on changes to remedy them. The Central Health Services Council could not advise the Minister to curtail the N.H.S., and this, according to Mr. Bevan, was the reason why the Minister was trying to side-track it by setting up an independent committee of inquiry. "What the Minister is anxious to do," said Mr. Bevan, "is to obtain an alibi in order to cut the Health Service." On the question of cost, Mr. Bevan made great play with the fact that where the initiative lay with the patient, that is in using the dental and ophthalmic services, the cost had gone down. The demand had begun to fall, he claimed, before the imposition of charges. But in the pharmaceutical services the initiative came from the doctor in making his prescriptions, and it was here that expenditure was going up. Mr. Bevan asserted that prescribing was too free and that general practitioners needed disciplining because they had not been as co-operative as they should have been. Another point made by Mr. Bevan was that the cost of the N.H.S. did not present the Exchequer with something that was unpredictable. The cost of the hospital services was entirely within the Minister's control; at this point Mr. Macleod observed that two-thirds of the hospital costs are governed by nationally negotiated or other agreements over which no one had control.

Mr. Macleod pointed out there were two questions to be answered: Is there anything to inquire into? and, if there is, What sort of body should make the inquiry? There was more disagreement on the second than on the first question. The first point he made against using the Central Health Services Council for this purpose was its size, consisting as

it does of 41 persons. Secondly, as all these members had special interests in the Service he did not think they were the right persons to conduct the inquiry, but that it should be done by experienced persons independent of the professions and of the political parties. He wanted an impartial assessment made. Speaking on block grants, he observed that the financial system in this country was not designed to cope with such a problem as the hospital service. The case made for the block grant was that the present system was a disincentive to wise spending in the last months of the financial year, and that there would be greater economies if hospitals were allowed to plan three or five years ahead. On the other hand, the two-thirds of the cost of the hospitals related to salaries was outside the control of the Minister and the hospital authorities, and so was something to which the block grant could not apply. Nevertheless, he said subsequently that it would not be possible to control expenditure in the Health Service until they could control manpower. At the end of 1951 there were 328,000 full-time and 90,000 part-time staff in the hospitals—an increase over 1948 of 15% and 33% respectively. "We want," said Mr. Macleod, "a national manpower policy in the hospital field." He hoped it would be possible to get more staff into sanatoria, and particularly into mental hospitals, by limiting to some extent those hospitals which were already up to general staffing ratio.

The Government, said Mr. Macleod, viewed with the very gravest concern the present cost of the pharmaceutical services. This was a part of the Health Service which was not under financial control. The average cost of prescriptions had risen from 38d. in 1949-50 to 50.5d. in 1952-3, and for his estimates for the current year he had taken the figure of 52d. The number of prescriptions in England and Scotland ran into the figure of 241 million a year. The increased expenditure was due to a general rise in the cost of ingredients, to the increasing use of new, valuable, and expensive drugs, and to the increase in the proportion of proprietary remedies, now accounting for 25% of prescriptions and in money for about half the whole drug bill. He intended to notify doctors in a month or so of the two schedules laid down by the Cohen Committee which referred to drugs of no proved therapeutic value. The Government had decided to inquire into the cost of certain proprietaries which seemed to be specially expensive. Mr. Macleod was critical of firms "who are merely wrapping up standard preparations in pretty packages and forcing them on the notice of doctors by salesmanship." The pharmaceutical industry was producing about one-third of its product for export, one-

third for the N.H.S., and roughly one-third went over the pharmacist's counter without prescription. It may be noted that Mr. Macleod paid a deserved tribute to the research done by some of the firms which had to be paid for by their proprietaries. On the effect of charges Mr. Macleod gave some interesting figures which showed that dental charges had had the effect of increasing the services given to school-children. But it seems that he has set his face against further charges, saying, "The difficulty about a policy of successive charges is that in time it must destroy the Health Service." Towards the end of his speech Mr. Macleod said: "What we want to achieve is a system whereby the Service itself has an interest in economy which is as natural and rewarding as is its interest in medical efficiency. That is the essence of the problem which the Guillebaud Committee are trying to solve."

The terms of reference of the Guillebaud Committee are so wide that they do not exclude any approach to the numerous problems that beset the N.H.S.; so wide, in fact, that the Committee's investigation could amount to that of a Royal Commission, which Colonel Stoddart-Scott advocated subsequently in the debate. But it seems certain that the Committee will look closely into the question of block grants to hospital authorities—a subject referred to in a previous leading article¹—into the needs of certain hospitals, especially mental institutions, for staff, and particularly into the cost of the pharmaceutical service. It looks as if the pharmaceutical industry will be subjected to a searching inquiry—an inquiry which may be extended to the prescribing habits of the medical profession. We suggested some twelve years ago that the industry needed some form of rationalization,² but the medical profession is deeply sensible of the great contributions made to pharmacology by a large part of the pharmaceutical industry, apart from its indispensable services in the manufacture and distribution of drugs. Mr. Bevan would of course blame general practitioners for the rising cost of the pharmaceutical service; that is the sort of thing we have come to expect from him, and he does not disappoint us. But much of the trouble is due to the fact that many patients equate a free Health Service with an abundant supply of free pills and potions. Consumer demand is still at full tide. Doctors have done their best to stem this. They will co-operate with the Guillebaud Committee and the Minister of Health in any rational attempt to introduce order where disorder is shown to exist. But the medical profession will at the same time have to watch

carefully lest any restriction should be imposed which will prevent or hinder the practitioner from prescribing what he thinks is best for his individual patient. This cannot be dictated to him.

SEXUAL REPRODUCTION IN VIRUSES

The distinctive feature of sexual reproduction in general was formerly considered to be a fusion of different types of gamete. Now it is held to consist in meiosis and nuclear fusion. The presence of sexually differentiated organs or cells is not of the first importance: the primary significance of sex lies in the opportunity it provides for genetic recombination—that is, for fresh combinations of genes. Hence any organism having mechanisms for genetic recombination between different individuals may be said to show sexual reproduction. This is the basis for the claim that sexual reproduction occurs in viruses.

In 1946 Delbrück and Bailey¹ and Hershey² observed genetic recombination in the type of virus known as bacteriophage—that is, new strains showed mixtures of characters from two parental strains. Since this discovery the evidence for a hereditary mechanism in viruses, in several respects like the chromosome mechanism of higher forms of life, has been greatly strengthened. Luria³ had previously demonstrated that viruses undergo mutation, and Hershey² showed that different mutations occurred independently at different genetic loci. Subsequently, Hershey and Rotman⁴ demonstrated partial linkage of certain phage characters. Moreover, the linkage data fitted a linear map, suggesting that certain genes in phage are disposed in a line, and that there was an interchange of genes comparable to the crossing-over that occurs between homologous chromosomes during meiosis in higher organisms. Later Hershey and Davidson⁵ established in one instance the existence of multiple alleles. Furthermore, Hershey and Chase,⁶ in a study of plaque formation by bacteria, have demonstrated that heterozygous phage particles are often produced when bacteria are infected with two virus strains differing in plaque formation.

Despite this apparently normal hereditary mechanism in viruses, there is other evidence

which conflicts. First, the heterozygotes observed by Hershey and Chase⁷ have some puzzling features: most appear to be heterozygous at only one locus, even when parental strains differ at two loci. This suggests that the heterozygotes may not be diploid, but rather haploid with the addition of one or more extra pieces of genetic material. Secondly, viruses seem to differ from other organisms in their method of multiplication. There is no evidence, from electron microscope studies or elsewhere, that virus reproduction is by binary fission. Furthermore, the finding that viruses cannot be re-isolated from host tissue for a definite time after inoculation has led to the suggestion that the virus particles break down in the host into a number of smaller units, which are then reduplicated before assembly into new virus particles. If this is in fact how the virus multiplies, then there would be abundant opportunities for recombination during mixed infections of the host. Indeed Luria,^{8,9} in order to account for certain effects of phage on bacteria, put forward a hypothesis that genes multiply independently and subsequently reassemble into virus particles. However, it now appears¹⁰ that an alternative explanation for these effects is necessary. Nevertheless, the hypothesis will explain genetic recombination in viruses. Indeed, several observations support the hypothesis that reproduction of the genetic material of viruses takes place mainly by reduplication of elements that are not yet in the form of mature virus particles, and that recombination occurs late in reproduction of the genetic material. Thus, Luria¹¹ has shown that gene reproduction in phage is exponential—that is, one gene produces x genes, each of which then produces x genes, and so on. The initial genes, brought in by the infecting virus, give rise to copies which are themselves copied, giving a clonal distribution of any mutants which may have appeared. This is in contrast to the nearly random distribution of recombinants from mixed infections.

Whatever the nature of the hereditary mechanism in viruses, it is certain that genetic interaction occurs between different strains. This is a finding of great significance, for it means that new and more virulent strains may arise whenever a host is infected by more than one strain of virus. Burnet and his colleagues Lind and Fraser found^{12,13,14} that recombination occurred when mixed strains of influenza virus were inoculated into mouse brain and chick embryo, and it seems possible that genetic interaction always follows infection with two or more strains of virus. This undoubtedly supports the suggestion made by Pontecorvo¹⁵ in 1948 that virulent influenza epidemics may arise by the simultaneous double infection of hosts by two non-virulent forms.

SURPLUS REGISTRARS

The statement of agreement reached between the Minister of Health and the Joint Consultants Committee on the subject of surplus senior registrars in England and Wales which appears in this week's *Supplement* (page 243) is good news. It is the outcome of considerable pressure upon an adamant—albeit sympathetic—Ministry by the Joint Consultants Committee ably backed up by the registrars. In fact, the measures now proposed are largely those of the Registrars Group of the B.M.A.

The Minister has authorized hospital boards to retain senior registrar posts in excess of the establishment laid down in 1951¹ for a period not beyond 1955 in cases where the retention will avoid extra staff having to be employed in other grades, and provided suitable candidates are forthcoming. Posts which are to be retained will be advertised as they become vacant. The present holders, other senior registrars whose appointments are nearly at an end, and, in certain circumstances, former senior registrars will be able to apply. The term of appointment will be for one year, but boards will be able to extend it to a second year where other employment has not been obtained by the end of the first year. Holders of these posts will still be free to compete for higher appointments, but they will do so without priority and on equal terms with other candidates. In addition to the opportunity of applying in open competition for a post which he has just vacated, there will be nothing to prevent a senior registrar from applying as at present for any other post within the training establishment. These proposals are fair, and bring to an end a long period of anxiety and uncertainty. They allow for open competition, which will be good for the hospital service, and those who lose may do so with grace and without bitterness against the politicians. Too long has the registrar establishment and the hospital service to which it belongs been the victim of *ad hoc* decisions based on political expediency. A crisis of unemployment among future consultants and a staff shortage in hospitals have been averted. The time gained should be devoted to some creative thinking undisturbed by political clamour so that eventually some order may be created out of the muddle which at present clouds the hospital service.

MUSCLE FIBRILLATION

Traditionally muscle fibrillation² has been the term used for involuntary contraction of groups of muscle fibres without actual movements of the limb, a phenomenon seen most often in patients with motor neurone disease. In 1938 Denny-Brown and Pennybacker³ suggested that fasciculation would be a preferable term, since contraction of a group of muscle fibres supplied by a single motor unit causes the involuntary contraction. The term fibrillation, they suggested, should be used for the involuntary contraction of single muscle fibres which occurs in denervated muscle and which gives a characteristic record on the electromyogram. This denervated

¹ *British Medical Journal Supplement*, 1951, 2, 47.

vation fibrillation cannot be seen through the skin, and in man the only place where it can sometimes be seen is the tongue after a lesion of the hypoglossal nerve or nucleus. Since then the two terms have been used somewhat indiscriminately, traditionists favouring fibrillation, purists fasciculation, in spite of the fact that the involuntary movement does not involve a whole muscle fascicle but only the fibres innervated by one anterior horn cell.

Clinically the most frequent cause of muscle fibrillation is chronic disease affecting the spinal anterior horn cells, of which the various types of motor neurone disease are the most common, but it may also be seen in syringomyelia and with spinal compression at the level of the compression. It may occur in acute disease affecting the anterior horn cells, as in the pre-paralytic stage of anterior poliomyelitis.⁴ Then the muscles showing extensive fibrillation are likely to be involved by paralysis within the succeeding twenty-four hours, but fibrillation does not indicate whether the muscle weakness will be slight or severe. Fibrillation may occasionally occur in diseases of the lower motor neurone with no definite pathological evidence of anterior horn cell involvement, such as polyneuritis,⁵ peroneal muscular atrophy, and thyrotoxic myopathy.⁶ But it must be emphasized that muscle fibrillation may occur without any disease of the central nervous system or of the muscles, and long-continued fibrillation in the absence of muscle wasting or weakness is usually a trivial disorder. But when it afflicts doctors it not unnaturally may cause considerable anxiety about its possible significance,⁷ and this may in itself aggravate the fibrillation.

The pathology of fibrillation is of interest. Its occurrence most frequently in chronic disease of spinal anterior horn cells suggested that it was due to some disturbance in these cells, but the old observation⁸ that physostigmine or its analogue neostigmine, which act predominantly at the myoneural junction, may cause intense fibrillation, was in favour of a more peripheral mechanism; and this theory was supported by its occasional appearance without disease of the anterior horn cells. Forster and his colleagues^{9,10} have demonstrated that it can occur when impulses from the anterior horn cells to the muscles are interrupted either by spinal analgesia or by injection of procaine into the common peroneal nerve with resultant muscle paralysis. As a final demonstration they divided the left axillary nerve in one patient with severe amyotrophic lateral sclerosis and the femoral nerve in another, and found that fibrillation persisted for about seven days after nerve section. They thus conclusively proved that conduction of impulses from the anterior horn cell to the muscle was not necessary in the production of muscle fibrillation, which they suggested originated at the myoneural

junction. These experiments show without a doubt that the source of muscle fibrillation is peripheral, and it is not at present clear why it should be such a conspicuous sign in certain disorders affecting the spinal anterior horn cells.

AN UNWISE RISK

In sending samples of drugs through the post manufacturers and distributors normally exercise the care expected of them. Some of these medicaments are toxic, especially to children, but they are usually well packed up. An exception to the rule has been brought to our notice by a correspondent, to whom samples of a new hypnotic were recently delivered by post. A small box with a transparent top and bottom containing four exceptionally brightly coloured capsules was sent to him unsolicited in an unsealed, unregistered envelope. He found it on the doormat together with an identical package addressed to a doctor who had inhabited the house some time previously. While the preparation is not a scheduled poison and can be bought over the counter by the public, it nevertheless deserves to be treated with greater respect than that. A suicidal death has been reported¹ in the U.S.A. from taking the drug (there given a different name). Certainly a gross overdose was then taken—about 12 times the recommended dose. But quite a small quantity of any such drug may constitute a fatal dose to a child aged 1 to 2 years, which is the age when the chance of dying from accidental poisoning is exceptionally high. Nor must the dispatch of these samples only to doctors' addresses be thought a sufficient safeguard, for the addresses are often out of date—as indeed in the case reported to us. Pharmaceutical firms should surely consider it a duty to seal securely the packages of potentially dangerous drugs that they send through the post, for the danger to children of medicaments that are relatively non-toxic to adults should not be overlooked.

ADOPTION

Social legislation places high in its scale of values the rights of children to a normal home life, and the practice of adoption is one of the ways by which these rights are secured. We are told in *The Golden Bough* that when Hera adopted Hercules she went through the ritual of a mock confinement, and that similar rites were in fact practised not long ago among primitive peoples when a child was "adopted." Less picturesque but doubtless safer and more orderly procedures are now laid down by the law. In this country legislation was at first resisted, for it was said that legalized adoption would encourage illegitimacy and child neglect. However, unsupervised and unregulated adoption, often associated with baby-farming, was recognized as the greater evil, with the result that after cautious deliberation and the presentation of a series of reports to Parliament the first Adoption Act was passed in 1926. The great increase in the numbers of illegitimate children and orphans during the first world war pointed

the need for official action. The more recent Acts, the last of which was passed in 1950, reflect the pressure of increasing numbers of adoptions during and after the second world war. In England legal adoptions rose from 2,967 in 1927 to 21,280 in 1946, the peak year so far, for numbers have tended to fall since then.¹

Earlier this year the Home Secretary appointed an interdepartmental committee, under the chairmanship of Sir Gerald Hurst, to consider the present laws relating to the adoption of children, and in the *Supplement* this week (p. 240) we print the memorandum of evidence which will be submitted by the Council of the B.M.A. to the committee. The views of medical men and women on this question will be received with attention, for they are in a better position than most to assess the success or otherwise of adoptions. Some of the adoption societies forbid official inquiries to be made about how an adoption is working out once the adoption order has been made, and many of the social workers employed by the courts and local authorities tend to see only the unsatisfactory results. Health visitors, of course, are also in a good position to watch the progress of adopted children, for they can visit them in the ordinary course of their duties.

There is a tendency in official circles to frown on adoptions arranged by individuals (so-called third-party adoptions) as opposed to those arranged by registered adoption societies and local authorities, but the Council of the B.M.A., while admitting there is a greater risk of failure with third-party adoptions, comes out firmly in favour of preserving this method, provided safeguards are introduced. Such safeguards should include notification to the local authority and full investigation before the placing of the child with the proposed adopters. The mother also should be under an obligation to make a request to the local authority for permission to place the child for adoption. Another recommendation contained in the memorandum of evidence is that child adoption should be controlled by the Ministry of Health rather than the Home Office, and, further, that the health committee of a local health authority should delegate to a special adoption subcommittee the responsibility of investigating cases. This of course raises the thorny question of the responsibility of the health committee *vis-à-vis* the children's committee of the local authority, and on this point the memorandum of evidence states, "It is realized that active co-operation with the local children's committee would still be essential." Another interesting recommendation is that the proposed adopters of a child should be medically examined by their family doctor, who should also give to a medical referee appointed for the purpose an opinion on their personality, probable adaptability to family life, and reasonable expectation of survival. This proposal may lead to some controversy, but it is both sensible and practicable. A final point of some importance is that a child attending the juvenile court for the purposes of the Adoption Act should not have to mix with those attending the court for other reasons.

CULDOSCOPY AND CULDOTOMY

In gynaecology, as in other fields of medicine, a carefully taken history is a first step to diagnosis, but the evaluation of the presenting symptoms may be difficult, and bimanual pelvic examination, even under anaesthesia, is not without its limitations. If there is no response to simple treatment, or if the diagnosis remains in doubt, laparotomy may be undertaken, particularly when pelvic pain persists or the possibility of an ectopic pregnancy cannot otherwise be excluded. Operation may reveal unsuspected disease or a more extensive lesion than was expected, but on the other hand no abnormality may be found. In the latter case, although the opportunity may be taken to carry out ventro-suspension of the uterus or to remove the appendix, the surgeon might well wish there were lesser procedures available whereby the uterus and appendages might be inspected. In fact, gynaecologists have performed coelioscopy by two different routes. Transabdominal peritoneoscopy, introduced by Kelling in 1902, was developed by Ruddock,¹ and Palmer,² in France, still champions its use in the study of sterility, especially in assessing whether salpingostomy is likely to be successful. In 1944 Decker and Cherry³ described the use of a special endoscope for introduction through the posterior vaginal fornix into the pouch of Douglas (cul-de-sac in American terminology), and gave the name culdoscopy to the inspection of the pelvic contents by this route. In a monograph⁴ reviewed in this *Journal*⁵ a few months ago Decker showed that if the operation is performed with the patient in the knee-elbow position the difficulties and dangers, the chief of which is perforation of the rectum, can be avoided. He found culdoscopy particularly useful in the diagnosis of endometriosis and ectopic pregnancy and in the study of infertility, and he pointed out its value for research into tubal and ovarian function.

More recently Doyle⁶ has extended this procedure into one of "exploratory culdotomy," which gynaecologists will appreciate is none other than posterior colpotomy in a new guise. After palpating the pelvic organs through the peritoneal opening, a magnifying "pelviscope" is introduced and the pelvic contents are inspected. The telescope can be removed, leaving a retractor in place through which adhesions may be cut or biopsy sections taken. According to Doyle the main indications for culdotomy are to find the cause of pelvic pain, to diagnose endometriosis, ectopic pregnancy, and ovarian neoplasms, and to study the uterus and appendages in cases of sterility. In all these cases palpation and observation through the pouch of Douglas constitute an alternative to laparotomy and may demonstrate that the major procedure is unnecessary. In contrast to Decker, whose claims are moderate, Doyle might be thought to have overstated his case. Certainly his advocacy of denervation of the uterosacral ligaments by transection for the relief of pelvic pain in dysmenor-

rhoea and dyspareunia will be challenged. Nevertheless culdoscopy, experience of which is apparently so far slight in Britain, may have something to offer the gynaecologist both in practice and in research.

THE DUTIES OF A NURSE

In the debate on the nursing services in the House of Lords last week (see p. 1172) several speakers referred to the technical work which in some hospitals was apparently thought to be within the range of duties of student nurses. Lord Amulree, for instance, thought there was a danger of getting too many nurses too highly trained, so that they would become not very good doctors instead of good nurses. The council of the Royal College of Nursing is also worried about a possible confusion between the functions of nurses and doctors, and has recently sent a memorandum to governing bodies and regional hospital boards. This draws attention to the increasing tendency for nurses, particularly in hospitals, to carry out duties which do not lie within their field of training—for instance, the giving of intravenous injections and the withdrawal of blood from veins. This may expose the nurse to the risk of charges of professional negligence, though in the opinion of the Royal College of Nursing the responsibility is the doctor's. "The only professional negligence for which the nurse should be held liable should be failure in regard to nursing procedures." Another matter of concern to the College is the practice in some hospitals of leaving it to a nurse to explain to the patient "the nature and effect of the operation" when obtaining the patient's signature on the revised form of consent. Although nurses can properly undertake part of this routine work the College believes that the doctor must at all times retain full responsibility, and should enter the type of operation on the form himself, explain it to the patient, and obtain his signature.

The performance of duties outside her professional scope also makes inroads into the time which a nurse should spend in the nursing care of the patient. Though younger nurses are often enthusiastic to undertake technical procedures, the College maintains that senior members of the profession realize the possible disadvantages and believe that a trained nurse in hospital should have more than enough to do in teaching, caring for her patients, and administering her department. Although the General Nursing Council does not control a nurse's actions when she is trained, it would deprecate the delegation of extraneous duties to ward sisters and staff nurses in nurse-training schools. Busy ward sisters, when asked by the Working Party¹ appointed to inquire into these matters whether they would welcome extra technical responsibilities if pressure of work were lessened and the element of risk removed, replied that this temptation should be resisted on account of the loss of time which they should be giving to their nursing duties.

These doubts and difficulties of the nursing profession will have to be carefully considered by the medical profession, and it will be interesting to hear the reaction of the hospitals to the Royal College of Nursing's memorandum.

ENDEMIC SYPHILIS

Endemic syphilis, which has been present in Bosnia since, and perhaps even before, the sixteenth century, is not usually acquired venereally, affects children mainly, is particularly prevalent where standards of living are low and social and economic conditions poor, and is found in rural rather than urban communities. Clinically and pathologically it differs in no important respects from sporadic venereal syphilis; though primary lesions are rare, secondary ones and gummata are common. Contrary to what has been stated, neuro- and cardiovascular syphilis do occur, though not often. Congenital syphilis is very rare, and this is explained by the fact that infection usually takes place in childhood, and by the time the patients reach adult age they are no longer likely to transmit the disease. But this is probably not the whole explanation, since it is not uncommon for a mother to be infected by her child when suckling. Efforts to eradicate endemic syphilis from Bosnia were made in 1905–11 and again in 1926–33, but they had little success. In 1948¹ an organized campaign was started under the aegis of W.H.O. The objects were to examine, both clinically and serologically, the whole population and treat compulsorily all infected persons and their contacts, to improve standards of hygiene, and to repeat the surveys at appropriate intervals. Serum was tested by the Kahn and Meinicke reactions, and the only drug used for treatment was procaine penicillin G in oil with 2% aluminium monostearate (P.A.M.). The usual dosage was 3.6 to 4.2 mega units spread over six to twelve days, and 1.2 mega units as abortive treatment for contacts. In the first survey 85% of the population was examined, and this figure rose to 95% at the second survey. The people proved co-operative. Complete eradication of the disease should be possible, but the difficulty in achieving this is due to a few infected persons remaining untreated, to the entry into the area of infected persons from outside, and to symptomless cases in the incubation period being missed. Infectious relapse is considered to be rare. Repeat surveys should in time reduce the reservoirs of infection to negligible proportions. Animal experiments and penicillin sensitivity tests showed that spirochaetes obtained from cases of Bosnian endemic syphilis differ little from those found in venereal syphilis acquired elsewhere.

Theoretically there seems no reason why any treponemal disease in any part of the world should not be eradicated by mass treatment, provided the campaigns are carefully followed up. In fact such treatment has already had great success in the treatment of yaws in Haiti, Indonesia, Thailand, and the Philippines, and in the treatment of bejel in Iraq.² The value of the follow-up is shown by the results of treating yaws in Sierra Leone, where between 1941 and 1946 mass treatment alone reduced the infection rate from 13.7 to 5.8, mass treatment plus permanent treatment facilities to 1.3, and both those plus home visits to 0.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

APOPLEXY

BY

F. J. NATTRASS, M.D., F.R.C.P.

Professor of Medicine, University of Durham; Physician, Royal Victoria Infirmary, Newcastle-upon-Tyne

The term "apoplexy" is a very general one meaning a sudden severe cerebral illness of vascular origin, and as such is a common emergency of general practice. The disaster may be due to haemorrhage ploughing up brain substance or flooding the subarachnoid space or to extensive softening resulting from arterial obstruction. Of the latter the chief causes are thrombosis and embolism, but in some fatal cases no actual block can be demonstrated, and it is probable that vascular spasm has been responsible for the damage. Limited softening causing local or general disturbances of brain function of a more insidious character are not included under the term apoplexy. Recognition of the nature of an apoplectic seizure is important from the point of view of prognosis and increasingly so from the point of view of treatment.

Generally speaking there are clear pathological and clinical differences between intracerebral and subarachnoid haemorrhage, but the distinction is far from absolute. Blood from a primary intracerebral haemorrhage often reaches the subarachnoid space from the ventricles; and haemorrhage from a surface vessel may produce its chief effects by destroying cerebral tissue.

Intracerebral Haemorrhage

The underlying pathological cause in the great majority of cases of intracerebral haemorrhage is atherosclerosis accompanied by hypertension. There is little evidence clinically of sudden increase of tension, and it is not clearly known why the arteries, so long under strain, suddenly give way. Most of the patients are elderly: exceptions are the subjects of malignant hypertension or chronic nephritis, who may be younger, and patients with aneurysms which rupture into the brain (see below).

Haemorrhage may occur in any part of the cerebral hemisphere or in the pons, rarely elsewhere; much the commonest site is into the internal capsule and the adjacent basal ganglia, an area supplied by the small perforating arteries (lenticulo-striate and lenticulo-optic) arising from the middle cerebral artery.

The accident may occur at a time of physical or emotional strain, but more often there is no known exciting factor. The patient may cry out with pain in the head or may complain of dizziness, but if such symptoms are present they are very brief. Unconsciousness may be immediate or there may be a rapid onset of hemiplegia succeeded in a few minutes by coma. The face is flushed, the breathing noisy, sweating copious, the pulse usually slow and tense; at the outset there may be vomiting. There is soon incontinence of urine and often of faeces.

Signs of the location of the lesion are often lacking in deep coma, but there may be some signs of hemiplegia. Deviation of the head and eyes may be present and is usually away from the side of the lesion; the pupils dilate as coma deepens, and more on the side of the lesion; but these indications of laterality are unreliable. Paralysis of the limbs on one side may be revealed by their greater flaccidity and by their falling more heavily when released. An extensor plantar response accompanies other signs of hemiplegia, but otherwise the plantar reflexes do not help in comatose patients. In pontine haemorrhage it is characteristic to find pin-point pupils and high fever from the onset.

Differential Diagnosis

If the whole story is known this clinical picture is almost diagnostic of a severe intracranial vascular lesion. Lumbar puncture should be performed. A small amount of blood is very commonly present from a primary intracerebral haemorrhage, and if this is accompanied by the clinical picture described the diagnosis is established and recovery virtually excluded. If the cerebrospinal fluid is clear other possibilities have to be considered. Capsular haemorrhage of lesser degree may be followed by recovery, as is known from pathological studies revealing the results of old haemorrhage, but clinically is not distinguishable with certainty from softening. Other causes of coma require consideration if the mode of onset is unknown, but are not usually difficult to distinguish. A patient suffering from head injury shows signs of shock rather than stertorous coma, or, if shock is not profound, restlessness and resistance—these apart from direct signs of injury. After an epileptic seizure the patient is often stuporous, but the problem is soon resolved by recovery of consciousness or recurrence of fits.

Persons suffering from narcotic poisoning are usually cold, with depressed respirations, the skin dry or lightly sweating; the state of the pupils may help in opium or belladonna poisoning, though not in the barbiturate poisoning so common to-day. There is usually clear circumstantial evidence. The comatose diabetic is flushed, with distinctive sighing respirations, and has abundance of acetone in the breath and urine, and sugar in the latter. Spontaneous hypoglycaemic coma is rare and paroxysmal: the latter is true of the much commoner hypoglycaemia occurring in a known diabetic under insulin treatment. Terminal uraemia may resemble cerebral haemorrhage, but is not likely to present primarily as unexplained coma, and the evidence of chronic nephritis and a high blood urea is decisive.

Patients with malignant hypertension are liable to attacks associated with sudden elevation of the blood pressure and cerebral symptoms (hypertensive encephalopathy), but the appearances are rather those of status epilepticus than of apoplexy, and the retinal and other signs of this disease are present.

Subarachnoid Haemorrhage

Symonds in 1924 reviewed 124 published cases of subarachnoid haemorrhage and showed clearly for the first time that the rupture of an intracranial aneurysm is by far the commonest cause of this form of apoplexy. Later authors have estimated the percentage due to this cause at 70 to 80. Of the remainder it is now recognized that most are due to bleeding from arteriovenous angiomas or other vascular malformations. Subarachnoid haemorrhage is common, possibly not much less frequent than primary intracerebral haemorrhage.

These aneurysms are formed by a bulging of the outer and inner coats of an artery through a developmental defect in the muscular and elastic wall. Such a defect is common in arteries, cerebral and other, without aneurysm formation, and there is little doubt that further factors involved are arterial degeneration and the strain of increasing blood pressure. This view is borne out by the age incidence. Developmental defect alone probably accounts for the occasional cases of rupture in childhood, and the condition is relatively common in early adult life, but the maximum incidence is between 40 and 60 years, little lower than that of intracerebral haemorrhage.

The majority of these aneurysms are situated on the anterior part of the circle of Willis and the vessels arising therefrom (see Figure), and receive their blood supply from the internal carotid artery; a small percentage occur further back on vessels derived from the basilar artery.

Physical strain as an immediate exciting factor is commoner in subarachnoid than in capsular haemorrhage; nevertheless, any such factor is absent in most cases. Sudden intense pain in the head is also a much more constant and dramatic initial symptom: it may be masked by almost immediate unconsciousness, but more often impairment of consciousness is less complete than in the intracerebral form, and the headache may be accompanied

Aneurysm on anterior part of circle of Willis. Reproduced from *A Textbook of Medicine*, edited by E. Noble Chamberlain, by permission of Messrs. John Wright and Sons.

only by giddiness and confusion, and often by vomiting. In the severest cases coma deepens and death follows in a few hours. Most patients make a partial recovery from the initial collapse, but continue to complain of severe headache, now tending to be occipital, and remain confused and restless. Within a few hours such a patient presents a picture of meningitis, due of course not to infection but to severe meningeal irritation by effused blood and the reaction aroused thereby. He lies curled up and resistant, groaning with pain, with neck stiffness and Kernig's sign, and the picture is completed by moderate fever. Lumbar puncture reveals a diffusely blood-stained fluid. On standing, the blood does not clot and the supernatant fluid is yellow; this xanthochromic change is not immediate but is usually present within four hours of the onset.

Such is the typical picture, but it may be modified, particularly by two factors—the rate of rupture and the situation of the aneurysm. Occasionally the onset of headache is gradual, or there may be intermittent occipital and back pains suggesting small leaks before the ultimate apoplexy. Paralysis of ocular muscles, especially of those supplied by the third nerve, may appear shortly after rupture of an aneurysm situated on or near the internal carotid artery. Local signs of brain injury may result from rupture of an aneurysm on the middle or anterior cerebral artery beyond the circle of Willis; the finding of a hemiplegia following a subarachnoid haemorrhage, which may not itself have been extensive, is strongly suggestive of the intracerebral rupture of an aneurysm, for the bursting of a primary intracerebral haemorrhage into the subarachnoid space is incompatible with recovery from coma.

Prognosis of Subarachnoid Haemorrhage

The outlook in subarachnoid haemorrhage is much less grave than in the primary intracerebral form, but the immediate mortality rate has hitherto been about 45%. Of the patients who die, about a third do so in the first 24 hours, and a further considerable proportion during the next 14 days. Great importance therefore attaches to the possibilities of surgical treatment, for the basis of these cases is a local anomaly rather than a general arterial disease.

Surgical treatment depends upon demonstration of the site of the aneurysm by arteriography; this is not always possible, and when it is possible surgical treatment is by no means always applicable. In a group of 70 cases treated by Falconer during or soon after haemorrhage the mortality rate was 17%: allowing for some probable selection of cases, this is still very impressive when compared with conservative treatment. What seems to emerge clearly is that a decision on surgical treatment is required early, not longer than a few days after the initial bleeding, as the chief role of surgery seems to be the prevention of early recurrence. The decision on method—carotid ligation and/or some form of intracranial operation—is a highly individual problem.

The matter of late prognosis is also of great importance. What happens to the 50% or more who survive an attack of subarachnoid haemorrhage even under purely conservative treatment? The most recent and largest follow-up (from 1 to 12 years later) is reported by Walton (*British Medical Journal*, 1952, 2, 802), and it shows that fatal recurrence of bleeding occurred in 20.6%, but that almost half of these recurrences took place within the first six months. Of 120 surviving patients 115 were able to pursue some useful activity, although 49 were moderately disabled. The causes of disablement include headaches, paralysis, and epilepsy, but the greatest cause is anxiety due to fear of recurrence. Walton emphasizes that after six months the patient should be encouraged to live a perfectly normal life and to do heavy work and play games if he so desires: to warn him against these things is to create anxiety without any evidence that recurrence will be prevented. With this view I am in full agreement.

Cerebral Thrombosis

Cerebral thrombosis is commoner than haemorrhage. The clinical picture of thrombosis is also much more varied; often the lesions are limited and the effects fall short of the major disturbances usually described as apoplexy. Sudden occlusion of the main trunk of the middle cerebral artery may cause loss of consciousness with appearances and course indistinguishable from those of cerebral haemorrhage. More often paralysis comes on quietly and painlessly without loss of consciousness, or is found on waking from sleep. Occasionally indications arise first of involvement of branches of the cortical division: thus an aphasia of motor or sensory type may occur first, or attacks of Jacksonian epilepsy, to be followed in the course of a few hours or days by hemiplegia as the thrombosis spreads to the main trunk. The paralysis is more severe in the arm than in the leg, since the leg area of the cortex has an additional blood supply from the anterior cerebral artery.

Cerebral thrombosis has a much lower immediate mortality than haemorrhage. Repeated strokes are due to thrombosis—or possibly to arterial spasm—and a final stroke is often due to haemorrhage into a softened area. There is always this danger of sudden termination, but most patients survive and are left with paralysis of varying degree. As is well known, a proportion of such patients recover completely.

While, as in cerebral haemorrhage, the middle cerebral is the artery most commonly involved, major disturbances of apoplectic type may arise from occlusion of other vessels. The picture of anterior cerebral thrombosis may be distinguishable by the character of the hemiplegia, which affects the leg more than the arm, and by the presence of sensory loss of cortical type. Occlusion of the posterior cerebral artery seems mostly to arise insidiously: its main manifestation is partial or complete blindness on the opposite side, but it may be accompanied by transient paralysis or aphasia. Sudden softening of the brain stem gives varied and alarming symptoms, including paralysis of speech and deglutition, and intense vertigo from involvement of labyrinthine and cerebellar fibres; nevertheless, recovery is often satisfactory.

Cerebral Embolism

These cases are not usually difficult to recognize, as the source of an embolus is apparent in the heart. Mitral stenosis, especially with auricular fibrillation, is the common lesion. Subacute bacterial endocarditis may give rise to embolism causing either an uncomplicated hemiplegia or a mycotic aneurysm of which the first manifestation is a subarachnoid haemorrhage. Detachment of intramural clot following myocardial infarction is an occasional cause of cerebral embolism.

The main clinical feature suggesting embolism is the absolutely sudden onset without premonitory symptoms. As with thrombosis, consciousness is retained unless the occlusion is unusually large; if unconsciousness occurs the prognosis is correspondingly grave.

General Treatment

The aim in comatose patients is to maintain the best conditions for possible recovery. To this end care of the skin endangered by pressure, by soaking with urine, or by burning with hot bottles is important. Special care should be taken to see that apparent incontinence is not retention with overflow; if this is the case catheterization may be needed, with prophylactic sulphonamide. Most patients recover consciousness or die before nutrition becomes a problem. In subarachnoid haemorrhage, the intense headache calls for morphine with such frequency as is judged necessary; as the often protracted illness proceeds, milder analgesics should be substituted. It is justifiable to repeat lumbar puncture if pain is unusually persistent, but it does not always give relief. Rest in bed for several weeks is indicated after a haemorrhage.

While it is of little use moving helpless patients from bed to chair, it is a mistake to keep patients with cerebral thrombosis in bed for any longer than is necessary. It is most important that from the earliest days simple and full passive movements of all parts of the paralysed limbs are made, and unless instruction to do this several times daily is given to the relatives painful contractures develop which greatly impede restoration of function.

Next Refresher Course Article.—"Treatment of Accidental Poisoning," by Professor John Glaister.

The birth of a new kind of chemistry is heralded by Professor C. D. Darlington, F.R.S., in a special supplement to *Heredity*, 1953, volume 6, which records a symposium on chromosome breakage held at the John Innes Horticultural Institution last year. The breakage of chromosomes is of outstanding interest to biologists, because it is a nuclear change that can be studied microscopically and in relation to its effects on the organism. Its causes can also be subjected to experimental investigation. These include various chemical treatments and ionizing radiations, of which latter, as Professor Darlington says, "atomic radiation is in some danger of becoming the most important." He goes on to say that chromosome breakage "is the most effective experimental agent of the death of cells. It is therefore the chief means of cancer treatment. It is also, as a spontaneous event, characteristic of many types of tumour development. Jointly with gene mutation, it is, although we are still only beginning to understand their connexion, the agent of all genetic and evolutionary change." The new kind of chemistry he sees is one in which the actions of very large molecules in the cell—the nuclear structures—can be observed directly by means of a microscope. This symposium contains 23 papers on many different aspects of the experimental and natural breakage of chromosomes. It is published by Oliver and Boyd (45s.).

Reports of Societies

LABORATORY FACILITIES FOR THE GENERAL PRACTITIONER

A joint meeting of the Sections of Pathology and General Practice of the Manchester Medical Society discussed "Pathological Facilities for the General Practitioner" on May 13.

Dr. F. B. SMITH (Kendal), in opening the discussion, said that a service in clinical pathology should be available to the family doctor. The general practitioner was the first person on call to the sick, and he had a clear right to the assistance of those of his colleagues who could help him with techniques beyond his own compass. Dr. Smith said that he had practised clinical pathology for more than thirty years in departments that had also served family doctors, almost entirely in combined urban and rural areas. Family doctors had provided 15 to 20% of his work, which was rather less than he had expected, but they had valued the service and did not wish to be without it. A proper co-operation of pathologist and family doctor could reduce the pressure on both other services and bed-space provided by hospitals. But, to be effective, the pathologist must have had a sound training in clinical medicine; he must keep in constant contact with family doctors, and must maintain close touch with current advances in pathology. This would reduce abuse of the facilities offered.

The Advantages

Dr. MILES PARKES (Crewe) spoke from the point of view of the general practitioner who accepts ultimate responsibility for the patient. The medical student was trained to use laboratory facilities, but if he was denied these when he entered general practice he became a mere signpost to the nearest overloaded out-patient department. The cases with which the general practitioner needed the pathologist's help could be grouped together as those which for the safety of all must be nursed in hospital—typhoid, diphtheria, tuberculosis; those which, with a satisfactory domestic situation, could and should be nursed at home, such as septic throats (where with certainty in diagnosis blunderbuss therapeutics could be avoided), intractable diarrhoea and bladder infections, glandular fever and pyrexias of unknown origin; and those cases not yet bedfast which need not encumber hospital out-patient departments—for example, anaemias, disorders of metabolism, etc. Patients requiring treatment with drugs such as the anticoagulants and "butazolidin" could be given domiciliary treatment, granted adequate laboratory control. In the maternity service no woman should approach delivery without her blood state being known.

The provision of laboratory facilities would maintain the interest of general practice and relieve pressure on hospitals, and it would be cheaper than providing more beds. It was said that the facilities would be abused, but the greatest present abuse was the amount of treatment that had to be given as a result of guesswork, brilliant though that guesswork might often be.

Outline of a Service

Professor FRASER BROCKINGTON (Manchester) thought that the chief need was for a direct relationship between the general practitioner and the pathologist. This would allow the fullest development of pathological services consistent with economy. Misuse, which might easily ruin such a scheme, was less likely when the pathologist consulted directly with the general practitioner in the use and interpretation of tests. Properly used, pathology in general practice was bound to effect a saving in hospital accommodation.

The second most important need was for this general-practice pathology to be done in fully equipped and staffed

laboratories. Health centres could with advantage have side rooms, but it was important that any side rooms or health centre units should be attached to and part of the main pathological unit. The exact location of the main laboratory was not of paramount importance, given good transport; it was probably most conveniently sited in the grounds of a hospital.

The third most important need was for unity between public health and clinical pathology. This was of universal application, but from the viewpoint of the general practitioner it had special meaning. An extension of the present tendency to link together the different types of laboratory would help in the development of general-practice pathology along logical lines.

The fourth consideration concerned the mode of contact between general practitioner and pathologist. This should not entail the visiting of patients by the pathologist. Consultation should be at laboratory level, for it was always time-consuming. General-practice pathology would be difficult to develop sufficiently with patient lists of more than 2,000–2,500. The general practitioner who wanted to do research (in which pathological techniques were often indispensable) should have the pathologist readily available for advice and guidance. In short, Professor Fraser Brockington thought that pathology in general practice would raise general practice to higher levels and economize in hospital care, but as a mere technical aid general-practice pathology would not be good. The secret of success lay in securing a direct and personal relationship with the pathologist, who must be regarded in any such scheme as a member of the "home-care team."

The Difficulties

Dr. T. BLENCH (Manchester) said that some of the difficulties now were due to the wide horizons: it was impossible for one person to be completely comprehensive. The general practitioner was the pathologist to the family and had to label the disease. He would like to know when this general pathology became a specialty.

Dr. J. G. O'SULLIVAN (Manchester) was sure that the advice and help of the pathologist were most needed and could best be obtained in the laboratory and not at the bedside. Costs could be kept down by the general practitioner taking the specimens necessary for the required tests, but time and expense could also be saved if specimens could be sent to one laboratory rather than to several laboratories, as might occur now. A simple set of instructions on the methods of collecting specimens for the tests would be most helpful to the general practitioner.

Dr. R. W. FAIRBROTHER (Manchester) said that, while all agreed that a pathological service for the general practitioner should be developed, the need for accuracy in the investigations necessitated a first-class laboratory service and personnel. At the present time the laboratory service was grossly inadequate, for there was a shortage of adequately trained pathologists and technicians, of facilities and money for development. These deficiencies could not be remedied easily, for the hospitals also suffered from them besides being affected by the latest "cuts" and having other greater priorities. The hospital pathologist must obviously devote his services primarily to the hospital demands. He thought that the College of General Practitioners should make urgent and repeated demands for this service.

Dr. MILES PARKES (Crewe) said that the most highly organized section of the profession—the general practitioners—was continually presenting the problem to the Minister, who was unfortunately restrained by the financial controls.

Dr. J. I. McKANE (Pendleton) referred to the successful debut recently of the pathology service to general practitioners in Salford. This now enabled simple pathological investigations to be done. He thought that in consequence fewer patients were being referred to hospital. Dr. G. J. CRAWFORD (Salford) said that with his new laboratory the new service was meeting all the demands made upon it so far, but they were receiving only about 30 requests per week.

Correspondence

Registration of Medical Auxiliaries

SIR,—The need for a reasonable guarantee that those who profess to look after the health of the people should have received an adequate training and attained a sufficient qualification has led to the statutory registration of doctors, dentists, nurses, and midwives, but this guarantee is still lacking in the case of the increasingly important group of medical auxiliaries. In 1936, largely on the initiative of the British Medical Association, the Board of Registration of Medical Auxiliaries was formed to undertake the keeping of a register on a voluntary basis. Since that time the Board has helped to maintain the necessary standards, though the defects of a voluntary registration have been apparent.

Four years ago the (then) Minister of Health set up a series of committees to "consider the supply and demand, training, and qualifications of certain medical auxiliaries in the National Health Service and to make recommendations." These committees issued their reports two years ago. One of the recommendations, agreed to by the majority of every committee, was the setting up of a statutory body, under the aegis of the Privy Council, one of whose functions should be "the maintenance of registers of medical auxiliaries qualified for employment in the National Health Service." It was thought that this machinery could be established on a more representative basis than was possible within the confines of a Government department.

On March 19 this year the present Minister of Health announced in the House of Commons that "there is insufficient agreement on fundamental matters to proceed with statutory registration on the lines proposed in the reports," and he added that it was proposed to make regulations prescribing the qualifications for medical auxiliaries for the purpose of employment in the National Health Service. We must hope that this is but a temporary expedient and but a prelude to the establishment of a statutory register, but we have no guarantee of this. Meanwhile it behoves everyone concerned carefully to scrutinize any regulations which may be issued so that no lowering of standards may result, and constantly to keep in mind and to press for the establishment of a statutory register which would bring medical auxiliaries into line with the other professions which deal with the maintenance of health.—I am, etc.,

London, N.W.3.

ZACHARY COPE.

The Premenstrual Syndrome

SIR,—The articles on premenstrual tension in the *Journal* of May 9 are of very great interest. In 45 consecutive cases of migraine in women of the child-bearing age I found that attacks occurred in the premenstrual phase in 16, at the onset of the menses in 7, and after the onset of the menses in 5. The others had attacks of migraine precipitated by other factors which were not obviously related to the menses. Some evidence that migraine is associated with disturbance of sodium metabolism was given by Dr. Dorothy Adams Campbell and myself and Miss Eva M. Tonks in the *Journal* of December 15, 1951 (p. 1424). The other factors which will precipitate migraine, such as tension states, physical fatigue, and infections (after the acute stages), will all exacerbate symptoms of premenstrual tension, and should be taken into account in the treatment.

In the migraine clinics of the Birmingham Eye Hospital premenstrual migraine is treated with diuretics such as ammonium chloride, urea in large doses, and with either ethisterone or with methyltestosterone in the doses given by Dr. Linford Rees (*Journal*, May 9, p. 1014). The tendency to relative hypoglycaemia and hunger, which incidentally can also precipitate true migraine, can be dealt with to some extent with a high protein diet.

I feel that further study of these questions will give valuable information as to the nature of the essential

constitutional background of many of those complaints which are labelled as being "psychosomatic."—I am, etc.

Birmingham.

K. M. HAY.

SIR,—Dr. Raymond Greene and Dr. Katharina Dalton (*Journal*, May 9, p. 1007) suggest that water retention may be the link between the menstrual period and attacks of migraine, bronchospasm, nasal congestion, "rheumatic" pains, and various dermatoses. Two dermatoses which commonly flare up at period time are rosacea and neuro-dermatitis. When this list is reviewed it will be seen that all the disorders named belong to the "stress disorder" group, and their association with emotional tension is well established. Thus it may be that the period sets off attacks of these disorders only when it provokes conflict and emotional excitement. It is a familiar clinical observation that a woman who has migraine attacks each month will lose them when her conflicts over sex feeling and the female role in life are dealt with by psychotherapy. The same is true of vasomotor rhinitis, tension pain (Hench's "psychogenic rheumatism"), and the stress disorders of the skin. Water retention, of itself, could not be the whole explanation of these cyclic reactions. It is, perhaps, one of the mechanisms through whose agency mental tension effects physical changes.—I am, etc.,

London, W.1.

DESMOND O'NEILL.

SIR,—I am most interested in the two papers in the *Journal* of May 9 on the premenstrual syndrome and its treatment, because the condition is a personal problem and my solution to it is different from that given by Drs. Raymond Greene and Katharina Dalton (p. 1007) and by Dr. Linford Rees (p. 1014).

In my own case premenstrual tension became increasingly incapacitating from about the age of 20. It lasts 10–14 days and is at its height in the last seven days. In addition to the general anxiety and depression there are outbursts of irrational irritability occurring most frequently in the early morning during sleep, which is interrupted by them. When these outbursts occur in the daytime they are preceded, and sometimes followed, by various distortion phenomena, feelings of unreality, etc. Some years ago depression became so marked a symptom that advice was sought, and dextroamphetamine sulphate, 15 mg. daily, was prescribed. This was effective in relieving depression and anxiety, but after 10 days produced an outburst so violent that the treatment was considered dangerous and discontinued. Pregnancy affords protection from all symptoms from the fourth month to almost two years after confinement.

Within recent months I have been interested to notice the increase in weight from ovulation to menstruation and the sharp decrease of 2–3 lb. (0.9–1.35 kg.) immediately after menstruation. Before I realized the cyclical nature of the increase I started a dietary regime and took 0.25 mg. dextroamphetamine sulphate to reduce appetite. The increase in weight is unaffected by this (despite reduced food intake), but the other symptoms—irritability, anxiety, depression—are, and the half-tablet is now taken daily from ovulation to menstruation.

I would be interested to know if other doctors have used this drug for this condition. It would seem to have none of the unpleasantness of the dehydration regime, and in this very low dosage none of the disadvantages of the hormone treatment. I would also like to know if the outbursts of irritability have been encountered by other doctors. It has been suggested by a psychiatrist friend that these are similar in nature to the so-called psychomotor attacks of epilepsy.—I am, etc.,

WOMAN DOCTOR.

SIR,—In the "Premenstrual Syndrome," by Drs. Raymond Greene and Katharina Dalton (*Journal*, May 9, p. 1007), it is stated that the condition is due to abnormal deviation of the oestrogen/progesterone ratio. One can only ask how such a ratio can be considered abnormal if it admittedly occurs in nearly half the population. If it be conceded

that the "abnormal" ratio is indeed the "cause" of the undoubted symptoms, one again asks what is the real cause of the "cause"? Is it an indictment of our present way of life?—I am, etc.,

Ilford.

R. N. C. SMITH.

Subcostal Pain Following Controlled Respiration

SIR,—Dr. T. T. Currie (*Journal*, May 9, p. 1032) should not dismiss so lightly the transient excitation produced by succinylcholine as a cause of the chest pain which sometimes follows its use. If he will take the trouble to have himself injected with 10 or 15 mg. of the drug I think he will find, as I did, that the muscular contractions which precede paralysis can be quite painful and leave a feeling of stiffness which lasts a day or two; mine was chiefly under the sternum and in the back of the neck. As the amount of twitching seems to vary with the speed of injection he may help his patients by giving succinylcholine slowly.

The two patients who had pain but no succinylcholine must be explained otherwise; by all means let Dr. Currie inflate with less vigour, but I doubt if this alone will eliminate the complaints. It will be interesting to know.—I am, etc.,

London, W.C.1.

CYRIL SANGER.

Long-delayed Rupture of Spleen

SIR,—Mr. C. G. Attenborough (*Journal*, February 14, p. 380) gives an interesting account of two cases of long-delayed rupture of the spleen, and refers to the arrest of haemorrhage by perisplenic haematoma. This was the commonest means of arrest of haemorrhage found at operations or necropsy in my experience when I practised general surgery in India, where rupture of the spleen is a common emergency. It is usual to find a damaged spleen surrounded by clots while the blood which is free in the peritoneal cavity remains fluid.

In 1945¹ I published a case of a very grossly damaged spleen in which haemostasis was complete in a patient who had succumbed to other injuries. Haemorrhage which is delayed a few days indicates failure of efficient clotting, while long-delayed haemorrhage is due to autolysis of the clot, and therefore comes within the category of secondary haemorrhage. I have never seen a case where the rupture of a subcapsular haematoma was an obvious explanation of delayed bleeding, and this phenomenon, if it occurs at all, must be uncommon, and it is difficult to imagine that "tamponade" by slippery serous-covered structures such as omentum or stomach can be an important feature favouring cessation of bleeding.—I am, etc.,

Melbourne.

Test Strips for Dry Sterilized Syringes

SIR,—Failure in the human element in a syringe service may result in the occasional issue of unsterile syringes. This is especially liable to occur in hospitals where the syringe service is too small to warrant the use of a special department and staff, and where it is run as a subsidiary function of the theatre or laboratory. Having experienced two local infections probably due to contamination introduced by syringe or needle (one a chronic muscle abscess, the other a thrombophlebitis), the need was felt for a device to ensure that every syringe and needle had been heat-treated.

The following simple test strip has been in use in this hospital for over five months, during which time it has on several occasions indicated inadequate sterilization or omission of sterilization. Filter paper is soaked in saturated sodium bicarbonate solution and dried at gentle heat. A dried strip is added to each syringe and needle assembly. After a few minutes at 160° C. the strip assumes a brown colour. While the colour change does not prove adequate sterilization, it does indicate that the syringe has been subjected to a sterilization procedure. Inadequate sterilization

has on occasions been found to be due to uneven heat distribution in a well-filled sterilizer. The sterilizer thermometer has at such times given a fallacious sense of security. The strips have been found satisfactory after three months' storage.—I am, etc.,

Penzance.

T. D. S. HOLLIDAY.

Importance of Post-mortem Examinations

SIR,—The importance of post-mortem examinations, not only for research but also especially for raising the standard of medical practice, has been stressed by the late Dr. C. O. Hawthorne (*Journal*, 1935, 1, 616) and others, but is still not sufficiently appreciated.

The National Health Service could, without much cost, provide facilities for post-mortem examinations on patients dying at home and thus help the general practitioner to improve his education and efficiency as well as enlist his co-operation for clinical research. After decease of any patient the doctor in charge should, with consent of the relatives, be able to arrange for admission of the body to the nearest hospital, or any hospital where the patient may have been under treatment. Transport could be by ambulance and further procedure as if the patient had died in hospital. The doctor should receive a full report on the necropsy and perhaps also a small fee for attendance.

If the necessary facilities were granted, a good deal of propaganda would certainly be required to bring their importance to the notice of the medical and lay public before necropsies cease to be an exception and become the rule—as they should be.

The rapid introduction of new and potent remedies makes careful check on our failures more than ever necessary, and the general practitioner must be enabled to obtain the true facts for his own enlightenment as well as for the progress of medical research.—I am, etc.,

London, W.1.

F. E. LOEWY.

The Metric System

SIR,—I had intended to take no further part in this correspondence, if only because none of the points made in my letter in the *Journal* of March 14 (p. 619), wherein I ventured to criticize Dr. C. Langton Hewer's letter (*Journal*, February 21, p. 450), were answered by him. Further, I thought that a chuckling silence was the best possible retort, as well as the most space-saving, to his highly entertaining final paragraph. However, having been soothed by Dr. Langton Hewer, I have again been roused into protest by Dr. J. W. Shackle (*Journal*, April 18, p. 887), who, after a mystifying reference to goose and gander, accuses me of saying that "we are wickedly inaccurate in talking about 'ccs.'" I challenge him to find any such statement by me at any time or in any place. What I did insist was that the issue as between cc. and ml. had nothing whatever to do with that between the metric and any other system of weights and measures. Dr. Langton Hewer presumably now agrees, because he is silent on the matter.

Apparently Dr. Shackle does not, for he goes on to ask that I should tell him "what is the exact difference between a 'cc.' and a 'mil.', and whether the difference is enough to be of the slightest significance." I propose to do nothing of the sort, for two good reasons. The matter was given detailed discussion from 1924 to 1929; any good scientific library must contain the publications in which the difference was explained. One reference is to an article called "The Millilitre" in *Nature* (1929, 124, 622). Those of us with a scientific training have always preferred to use the more, rather than the less, precise of the two units, even when the difference had no practical effect, for this helped to inculcate in ourselves good habits against the occasions when the difference did really mean something—for example, in some microchemical work.

As to Dr. R. A. C. Herron (*Journal*, April 25, p. 938), why does habitual usage prevent his saying "half, or 0.5 mg.," instead of "nought comma nought nought nought five" gramme, without making confusion worse confounded?

I have seldom heard such nonsense. And, to use his own dialectical technique, who indeed would argue that the difference between (a fig for his "mental pictures") 0.45 and 0.65 mg. is not more quickly appreciated than that between 1/150 and 1/100 gr.? If Dr. Herron is still confused by "those damned dots" I would suggest that he ought to find it no more difficult to remember the difference between 1/24 and 1/16 mg. than that between 1/150 and 1/100 gr. Dr. Herron has managed to introduce yet another red herring into this discussion by implying that the use of fractions is incompatible with the adoption of the decimal system. Since when? Has he never heard pharmacists talk of one-tenth of a mg. or a quarter of a gramme, or himself never referred to the running of a half-kilometre race? The amusing end to Dr. Langton Hewer's last letter is, need I point out, an impish exploitation of the same fallacy, to be welcomed on the grounds of its impishness, but hardly as a serious contribution to this discussion. Not, as he would say, for 0.00027 hr.—I am, etc.,

London, N.W.3.

A. L. BACHARACH.

SIR,—I can assure Dr. C. Allan Birch (*Journal*, May 9, p. 1049) that I am acutely aware of the origins of "mils." and "cc.s" and of the highly pedantic distinction between them. A matter of some five—or is it six? (there, how easy to be wrong in this system)—places of decimals. How well Dr. W. Edwards (*Supplement*, May 9, p. 217) describes the metric system as "designed for those who can only count on their fingers."

Dr. Birch counters the dangers of the misplaced dot with those of the malformed drachm sign. I hold no brief for this sign, which I have always thought idiotic, but errors in this are surely safeguarded by the dispenser. For this sign indicates the dose, and the dispenser is trained to know when this is poisonous. If it is excessive he should (a) look for an exclamation mark after the dose, or (b) ring up the doctor and verify the amount. Errors with the decimal point, however, more commonly occur when the dispenser is making up the bulk medicine, neglecting to make a rough check to establish the position of the point—a horribly easy mistake to make during rush hours. I can think of two deaths as a result of such errors in making up thallium for depilation; and an anaesthetist was mulcted in heavy damages because he followed out exactly the directions in an expert's paper but had not seen a correction made a week later altering the position of a decimal point and reducing the dose by a tenth.

But an additional point about the old system is that it was adjusted to allow the patient to measure his dose in teaspoons, dessertspoons, or tablespoons. Must every family now purchase measures graduated in "mils."?—I am, etc.,

London, W.1.

J. W. SHACKLE.

Controlled Hypotension in Neurosurgery

SIR,—Dr. David Aserman's article on controlled hypotension (*Journal*, May 2, p. 961) raises several controversial points. First, let me protest most vehemently against the technique being labelled a "form of anaesthesia," which it most certainly is not. Hypotension can be produced with one of the hexamethonium drugs, supplemented if one wishes with procaine amide, in almost anyone without any nearer approach to anaesthesia than the syncope that is likely to happen if the victim sits up too quickly.

Dr. Aserman admits the possibility of cerebral anoxia, but distinguishes it from the interesting condition he has described and which he has named "retractor anaemia." In fact, these two conditions obviously spring from the same evil—inadequate pressure in the intracranial arteries. The only difference between the conditions is that the former has more or less general effects and the latter has more or less local effects. What is certain is that cerebral anoxia, whether local or general, can produce both physical and psychical sequelae. One wonders how many of our enthusiastic bloodless phlebotomists are carrying out properly controlled investigations, which of course must include

not only the incidence of the immediate mortality (investigation of this has provided sufficient material for some papers already published) and the almost immediate morbidity (investigations sufficient for all other articles published so far), but it must also include investigations of the quite possible remote psychic affects causing various behaviour changes. Dr. Aserman is batting on a good wicket, as he is able to say that the results of anoxia "may possibly have been masked by surgical trauma." The surgeon also seems to be in an enviable position. But it seems somewhat unscientific that a brilliant operation may have been ruined by the anaesthetist or a brilliant anaesthetic may have been ruined by the surgeon and no one is quite sure of the real answer.

No doubt controlled hypotension has its place in surgery, and it would seem that in intracranial surgery its immediate advantages considerably outweigh its immediate dangers, but let us hope that somewhere someone is really investigating the very possible and quite likely horrific remote consequences of the cerebral anoxia caused by this technique.—I am, etc.,

Chesterfield.

H. E. POOLER.

SIR,—I have some experience of arteriotomy for hypotension in neurosurgery, and was therefore particularly interested to read Dr. David Aserman's article (*Journal*, May 2, p. 961) on the use of hexamethonium and procaine amide in this field.

Dr. Aserman mentions that during an operation for removal of a meningioma a big vessel was accidentally opened and a profuse and rapid loss of blood resulted. The condition of the patient was fairly satisfactorily maintained by rapid replacement of blood and levelling of the table. I have had a similar experience during arteriotomy, when severe haemorrhage accompanied the fractional removal of a meningioma in an otherwise bloodless field. Control of the blood pressure was easily retained by intra-arterial transfusion of the blood already removed from the patient, followed by stored blood. It seems probable in this type of case that permanent loss of blood pressure control may follow haemorrhage during methonium hypotension, in spite of a faultless technique; whereas the ease with which intra-arterial transfusion can be performed in arteriotomy is a safeguard, and surely one of the great advantages of this method. Is it Dr. Aserman's view that in the "failures" he mentions bleeding is more severe than if the methonium drugs had not been used?

Unless the "convenience" of the surgeon is regarded as an indication for hypotension, the technique is only occasionally required, for in the majority of neurosurgical cases cerebral congestion can be avoided by strict attention to the essentials of this branch of anaesthesia—a perfect airway, adequate spontaneous respiration, and correct posture.—I am, etc.,

London. E.C.1.

ROBERT I. W. BALLANTINE.

Modification of the Foley Catheter

SIR,—Mr. Paul Houghton (*Journal*, May 2, p. 994) may be interested to know that the three-way Foley catheter, for which he makes a plea in the final paragraph of his letter, already exists as Alcock's modification of the Foley catheter, and is marketed by William Warne & Co., Ltd.—I am, etc.,

Barnet.

V. J. DOWNIE.

Endemic Goitre

SIR,—Repetition does not make a statement true. Sir Charles Harington's quotation from a memorandum of the Medical Research Council and Kimball's retelling of the results of the Akron experiment referred to in your annotation (*Journal*, March 21, p. 665) do not nullify the criticisms of both of these that have been made by me and by others.¹ The facts are as follows.

Goitre has never been produced by simple deprivation of iodine: whenever purified foodstuffs were used, with the greatest possible exclusion of iodine, no goitre was pro-

duced.² The postulated differences in the content of iodine in soils, water, and food between goitrous and non-goitrous regions have not been established. Noteworthy exceptions are to be found in South Africa³ and in Danzig.⁴ (Several authors have listed Danzig as goitre-poor, whereas it was precisely the high incidence of goitre in iodine-rich Danzig that led Liek to deny the "iodine-lack" hypothesis in the very paper from which his data have been erroneously copied.) Diminutions in the incidence of goitre more marked than those reported by Kimball, without any known change in iodine intake and without any reason for supposing that there had been any, have been reported.^{5,6,7} In many places there was complete disappearance of goitre, with, in some, reappearance after a lapse of 50 years or more. Epidemics of goitre have been observed repeatedly, and are still being reported.^{10,11} Goitre was not reported in England until the eighteenth century and in the Americas and in New Zealand until after the coming of white men, and in most of Africa, including Egypt, until quite recently.¹² The information regarding all of these is sufficiently extensive to enable us to conclude that goitre was unreported because it was absent.

Anyone who studies the history of goitre with an open mind will, I believe, come to the conclusion that the disease is due to a biological agent, and that such prophylactic or curative effect as iodine may have is due to a pharmacological action and not to its making good a nutritional deficiency.—I am, etc.,

New York.

Nicotinic-acid Deficiency

SIR,—I am greatly interested in Dr. Jonathan Gould's letter (*Journal*, April 25, p. 935), which followed Dr. G. H. Collins's case note (*Journal*, March 28, p. 731), and welcome the broader application of the use of vitamins in confusional states, a therapy used successfully since 1939.¹

Everyone will agree with Dr. Gould that the parenteral use of nicotinamide is to be preferred to nicotinic acid, not only because it is not associated with the unpleasant vasodilator effects of the latter, but also because of its quicker action. I am also in complete agreement with him that deficiency of one single member of the B group of vitamins is improbable even if the symptoms and signs are highly suggestive of nicotinic acid or another single vitamin deficiency. I find, however, some difficulty in accepting Dr. Gould's "mixed barrage of vitamins" and also in considering the vitamins "as metabolic reagents having metabolic cycles of their own."

Dr. Gould was most successful in using intravenously 1,000 mg. aneurin (better thiamin), 200 mg. nicotinamide, 200 mg. pyridoxin, and 1,500 mg. ascorbic acid in 10% dextrose solution, but it is interesting that Dr. V. P. Wordsworth (p. 935) had in a case of an admittedly mild alcoholic intoxication dramatic results within three minutes after intravenous use of only 100 mg. pyridoxin. Moreover, intravenous application of only 30 mg. of thiamin in a case of Wernicke's encephalopathy was found to be sufficient for the patient to regain consciousness and to abolish temporarily most of the neurological signs.² While intravenous application of high doses of vitamins are certainly advisable in severe cases at first, the continuation of the treatment by intramuscular route is not only more efficient owing to the slow excretion but also less fraught with danger.

It is to be expected that in the near future the advocated "mixed barrage of vitamins" will be used on a large scale in psychiatric practice. Whilst I would welcome this step, I may perhaps be allowed to make two comments. First,

large doses of a single vitamin, especially of the B group, or an unbalanced mixture of these vitamins may easily precipitate latent deficiencies of other vitamins and may cause most unpleasant side-effects.³ In my limited experience Dr. Gould's formula could be better balanced by reducing the amount of thiamin and by adding at least 50 mg. of riboflavin to the mixture. Secondly, it should be borne in mind that untoward effects like anaphylactic reactions with circulatory collapse, occasionally followed by death, have been described after intravenous application of several members of the B group of vitamins, especially if massive doses were given repeatedly.⁴—I am, etc.,

Trichlorethylene in Labour

SIR,—I have read the letter of Dr. R. P. Robertson (*Journal*, April 18, p. 884) on this subject with interest. I can confirm from my own experience that his routine of pethidine, followed by gas and oxygen and later by trichlorethylene, is most satisfactory for analgesia in normal labour.

I differ from him, however, in the use of chloral. I have not found pethidine a substitute for chloral by any means, and think that the old-fashioned "mother's mixture" still has a valuable place in the early stages of labour. It allays anxiety and is well tolerated if bromide is not mistakenly added to it. Moreover, it never stops the labour pains. My experience of pethidine, when used before the pains are coming at regular intervals of not more than five minutes, has been that it stops the pains just as effectively as morphine used to do. Consequently, I have found that sufficient comfort can be obtained by one or two doses of chloral mixture, so that I rarely need to give pethidine until the cervix is two or three fingers dilated and well taken up. Others may not agree that any analgesic is necessary before this stage, but, as niggling pains can and do last as long as 24 hours and prevent the patient resting, I feel it is helpful to secure a few hours' sleep then without the risk of arresting the progress of labour.—I am, etc.,

St. Asaph, N. Wales.

A. H. HOLMES.

Reduction of Post-operative Pain

SIR,—We must be grateful to Mr. D. Lincoln Lewis and Dr. W. A. L. Thompson (*Journal*, May 2, p. 973) for their reiteration of the principle that when a pain arises from a localized area and gives rise to reflex complications it is more logical to relieve it by blocking the afferent nervous pathway than by administering analgesic drugs which act systemically and so depress other vital functions. Although apparently simple, the method described involves the administration of three-hourly injections over a period of three days—that is, up to 24 injections into each of two tubes—which must be very time-consuming to the nursing staff and disturbing to the patient, apart from the risk of introducing infection. The result that "all the cases had considerable relief from pain a few minutes after the injections were given" implies that even with three-hourly injections pain returned before the next dose was due.

At the cost of adding five minutes to a two-hour operation, a more continuous analgesic effect can be obtained by the use of depot anaesthetic solutions which make unnecessary any subsequent disturbance of the patient, his wound, and the nursing staff. At least two effective preparations have already been described by the writer¹ and Rutter²: "efocaine" (1% procaine base and 5% butyl p-aminobenzoate in glycols) and Rappaport's solution (2% benzocaine base in 40% urethane in water). Both act by precipitating the anaesthetic base at the site of injection. This crystalline deposit exerts a prolonged analgesic effect which may last for up to three weeks or more. The solvents are strongly hypertonic and should not be injected superficially or into inflamed tissues, as an osmotic reaction will result, as described by Howell (*Journal*, April 4, p. 285).

although this has no permanent ill effects. I have used up to 20 ml. after 46 upper abdominal operations without unfavourable reactions.

The technique is all-important, because once the anaesthetic has precipitated it does not diffuse appreciably. More effective than infiltration into the wound or on each side of it is an intercostal block of the seventh to the eleventh thoracic nerves, carried out posterior to the midaxillary line so as to include the lateral cutaneous branches. At least 1.5 ml. must be injected into each space, and if the incision is near the midline both sides must be injected. Although accurate intercostal nerve-blocking requires a little practice, the results are most rewarding. For instance, following repair of perforated peptic ulcers, 11 patients required between them a total of only six injections of analgesics. Breathing is easier, cough is free, and even chronic bronchitics comment on how little their chests trouble them. It would appear that these depot solutions, or others based on similar lines, hold more promise than the use of water-soluble salts, which have only a transient effect and so require tedious or cumbersome methods of administration.—I am, etc.,

London, W.1.

Magic, Medicine, and Religion

SIR,—Sir Sydney Smith (*Journal*, April 18, p. 847) is to be congratulated on his masterly analysis of such various therapeutic methods as medicine, magic, and religion throughout the ages. His conclusion that "all of them are directed towards the restoration of the harmonious relationship in the functions of the body through the removal of some source of disharmony in the mind" is most apt in this present age not peculiarly noted for its equanimity or serenity.

It is unfortunate that the main thesis is marred, but by no means invalidated, by references to the mediaeval period which are inaccurate. These inaccuracies are not singular, but in a letter to the editor it seems more advisable to correct the most important of them—that is, the statement that science was discouraged by the Roman Catholic Church. This statement is not supported by either the teaching or the practices of the Church in those days. The Church's attitude to science is best summarized by the writing of Cardinal Borromeo, who officially interrogated Galileo at the time of the controversy over the Copernican theory. He wrote as follows: "I say that if a real proof be found that the sun is fixed and does not revolve round the earth, but the earth round the sun, then it will be necessary very carefully to proceed to the explanation of the passages of Scripture which appear to the contrary, and we should rather say that we misunderstood these than to pronounce to be false that which is demonstrated." Thus to reconcile the interpretation of Scripture with a really demonstrated and proved fact of science is surely no discouragement of the sciences. In practice also the Church encouraged and patronized the physical sciences, for was not the university of Bologna, the first of the universities as we know them, founded under papal charter?

It is difficult in a short letter to expound on these historical problems, so I would recommend to Sir Sydney a recent book on the history of science from A.D. 400–1650. It is entitled *Augustine to Galileo*, by A. G. Crombie, of the department of history and philosophy of sciences, University College, London, and is a more serious study than the popular bibliography quoted by Professor Smith.—I am, etc.,

Dublin.

J. BARNES.

SIR,—May I make a short comment on references to Christian Science in the report of the Finlayson Memorial Lecture by Sir Sydney Smith (*Journal*, April 18, p. 847)?

In the lecture Christian Science treatment appears to be identified with mental suggestion. But the method of Christian Science treatment is essentially that of prayer.

based on a spiritual understanding of the nature of God and His creation. The discoverer and founder of Christian Science, Mary Baker Eddy, indicates this in the first sentence of the Christian Science textbook, *Science and Health with Key to the Scriptures*: "The prayer that reforms the sinner and heals the sick is an absolute faith that all things are possible to God—a spiritual understanding of Him, an unselfed love."—I am, etc.,

London, W.C.2.

COLIN R. EDDISON.

SIR,—Many years ago when I began research about ancient Egyptian medicine I went to see Sir Gaston Maspero—the greatest Egyptologist—and asked him his opinion of the subject. He gave it readily. It was: "What the ancient Egyptians knew about medicine is not worth knowing." I am now in entire agreement with that authoritative statement. Yet we frequently see eulogistic statements concerning their "wonderful knowledge" based largely on myths and legends.

I cannot now go fully into the matter, but I would like to draw attention to a few statements made by my old friend the illustrious Sir Sydney Smith (*Journal*, April 18, p. 847) under the above heading. With regard to the Ebers Papyrus he makes the extraordinary statement that it shows a "remarkable standard of knowledge." It does nothing of the sort. Every ache and pain is subject to supernatural influence, and disease was held to be caused by entry into the body of evil spirits who produced psychological changes according to their malignity. No serious attempt was made to define a disease, or to describe it as a separate entity. It is merely a haphazard collection of recipes mingled in an indescribable hodge-podge. All this looks ludicrous, and much popular writing based on such translations has professed to give us some account of Egyptian medicine—without value and very misleading.

Now as regards the Edwin Smith Papyrus, we are told by the eminent jurist that it indicates a "fairly high degree of medical knowledge." It is a surgical treatise and deals in a "common-sense way" with fractures and other lesions of traumatic origin, but is in no way an improvement on the methods employed by the witch-doctors and fiki at the present day. In the treatise, to be sure, great emphasis is laid on the state of the pulse and the origin of sepsis, of which condition they must have had wide experience, as hygiene is not mentioned—indeed, they had no word to signify cleanliness. Fractures of the skull were naturally very frequent. A puncture of the skull is likened to "a broken hole in a pottery jar." Yet there is no mention of trepanning, although this operation was practised by other ancient peoples, especially the Chinese, and this omission is quite sufficient in itself to prove that the treatise does not display a "high degree of medical knowledge." Instead the routine treatment for head injuries was fresh meat for one day followed by grease and honey.

There are other serious defects which cannot be discussed now. In the treatise there are 48 cases, 14 of which were left untreated, and there is no indication to show the final results in those treated. Yet Professor Breasted, the translator, in his grossly exaggerated eulogism suggests that the papyrus should be considered the standard work and all the other papyri scrapped. He even "hazarded a guess," according to Sydney Smith, that the original work was by Imhotep himself. But there was more. In his exaggerated enthusiasm for the papyrus the professor seems to consider the claims of the immortal Hippocrates as secondary to "our scientific surgeon," and makes the remarkable statement that the Hippocratic school was far more interested in the human body when it was sick than when it was well, and furthermore was evidently more inspired by a desire for knowledge than by the hope of curing the patient. Such exaggerated and erroneous statements should be considered when we come to consider the value to be placed on the claims made by him as translator on behalf of his "scientific surgeon." In extenuation it might be said he was a layman writing on a medical subject.

Lastly, I wish to refer briefly to Imhotep, whom Professor Smith considers "the earliest physician we know by name," as many others do also. There is not the slightest evidence in support of this claim. We know nothing of his early history, of his birthplace, or his childhood, or of his appearance in the flesh. There is no record of any sort in support of his medical qualifications. His name does not appear in the medical papyri, in any of the ancient monuments or texts, and even in the Theban recension of the *Book of the Dead*, although in certain aspects the god (for he was a god) had a funerary character; neither is he mentioned by any of

the contemporary sages, many of whose sayings survive. The omission of his name in connexion with any work or discovery or text is very remarkable when we know the names of many others who have been associated from the very earliest times with the practice of medicine.

At the International Medical Congress in Cairo in 1934 I read an exhaustive paper on Imhotep. The paper can be seen in the form of a pamphlet at the Wellcome Historical Medical Museum by anyone interested in this controversial subject.—I am, etc.,

Englefield Green, Surrey.

T. GERALD GARRY.

Treatment of Threadworms

SIR,—I was interested to read the letter of Mr. W. Ivon Hayes (*Journal*, February 28, p. 510) about threadworms and the means of eradicating them by altering diet.

It may be of interest to report a case of an adult female who had had threadworms practically all her life. She reported that her faeces were sometimes "alive with worms." She suffers from rheumatoid arthritis and has a very bad sinusitis. At one time she was given a course of aureomycin. She reported to me that since that course she has never seen any sign of threadworms, nor has she had any symptoms suggesting their presence. I do not know whether aureomycin would interfere with the life cycle of the threadworm, or whether the antibiotic in some way affected its food supply by altering the bacterial flora in the large bowel. So far as I know, there was no alteration in diet in this case.—I am, etc.,

Melbourne, Australia.

FRANK MAY.

Uterine Tension

SIR,—Green *et al.*¹ have advanced the theory that ischaemia of the uterus is a major aetiological factor in eclampsia. According to them pre-eclampsia shows a rise in plasma pentose levels. The substance derived from muscle adenosine is a result of muscle ischaemia, and the uterus was the only site for such a change. Increased uterine tension must be associated, and I expressed the opinion² that the data must prove of great value in support of the thesis that increased uterine tension was responsible for the toxæmic syndrome.

Now Corner and Csapo (*Journal*, March 28, p. 687) have shown that the isometric tension of the myometrium is related to the actomyosin content therein, and that the myosin component breaks the terminal phosphate linkage of adenosine triphosphate present in the muscle releasing adenosine. Thus adenosine comes to provide as well an indirect measure of the isometric tension of the myometrium. The levels of actomyosin in the various periods of pregnancy bear relationship in time to the incidence of toxæmia. Uterine ischaemia (Green) and uterine tension (Corner) are both referable to adenosine production evidently, and become equivalent.

There is a further advance. Arising from these fresh researches is the relationship of the potassium-sodium ratio to the isometric tension of the myometrium. A potential avenue for therapeutics is thereby provided. The practical value of the utero-renal reflex (Franklin³) and the Trueta mechanism cannot fail to emerge.—I am, etc.,

Salisbury, S. Rhodesia.

The Judet Operation

SIR,—I would agree with Mr. A. Webb-Jones (*Journal*, April 25, p. 935), that pain does recur in certain cases following the Judet operation for osteoarthritis of the hip. His explanation for this is not, however, satisfactory. To suggest that the recurrence of pain is due to mechanical wear resulting from the fact that no prosthesis accurately matches the removed head is to ignore the fact that when the same

operation is carried out for subcapital fracture of the femoral neck the results, as regards freedom from pain, are uniformly good. Mr. Webb-Jones stresses the painless range of movement in these latter cases, although the same incongruity between the bearing surfaces must be present as when the operation is done for osteoarthritis.

In osteoarthritis of the hip the disease process affects not only the articular surfaces but also the capsule and peri-articular structures, and from the evidence available it would appear to me that herein lies an important cause not only of the pain which may recur but also of the limitation of movement which may persist despite operation.

Mr. Webb-Jones does well to draw attention to the fact that indifferent results can follow the Judet operation. But, if there is no reason for complacency, still more is there none for despondency. While far from being the final solution, it does, I think, represent an advance. To go back to displacement osteotomy for osteoarthritis must surely be a retrograde step.—I am, etc.,

London, W.1.

T. M. HENNEBRY.

Litigation Against Doctors

SIR,—Now we have seen the National Health Service Act and Legal Aid and Advice Act in action, many are wondering about the future of medicine. The State-treated patient can so easily become the State-aided plaintiff; costs mean nothing to him, and he can readily use or abuse both these Acts, as is shown by the increasing litigation against all medical practitioners on allegations of negligence in treatment, with and without just cause. If clinicians are forced to cover themselves against all possible criticism, and are obsessed with this need, then indeed we will become careful Civil Servants, and good clinical medicine will die and with its passing the cost of the Health Service will become prohibitive. Are the minority of our patients going to force us into this approach to medical practice?

But the matter does not end there. As I write I have before me a letter from the secretary of a hospital management committee: "The points raised in your letter," he writes, "are of extreme importance to the hospital management committee, who are the ultimate authority held responsible for any matter concerned with the treatment of patients and the legal consequences thereof." Is this really true? Have consultants, in their contract of service to the national hospitals, really handed over their responsibilities in the treatment of their patients to lay committees, the large majority of whose members have no medical experience at all? Is this the meaning of the National Health Service Act? My legally minded surgical colleagues tell me that there is a world of difference between a contract for service (which we believe we have agreed to) and a contract of service (which apparently some believe we have signed). The Hon. Justice Hilberry summarized the distinction in this way: "... In a contract for service the master can order or require what is to be done, while in the other case (a contract of service) he can not only order or require what is to be done but direct how it shall be done."

If the real objectives of the National Health Service are to be achieved, then the individual members of the profession must carry the full weight of their clinical responsibility and pass no part of this responsibility to any lay committee, nor share it with them. Yet can it be clearly stated now that our contract is for service? If this is so, have we any guarantee that some future negotiating body or some future legislation without negotiation will not change this apparently important little word?

Concerned as I have been for many years in the treatment of accidents, I am well aware that this field of surgical practice is open to litigation. The injured often do not honestly understand why they should suffer a permanent disability or a lengthy convalescence. Was the splint left on too long, taken off too early? Was it too loose or too tight? Why, after a week's effort to save a limb, was it eventually necessary to amputate it? Was this the surgeon's fault, or the house-surgeon's, or the nurse's? "Well," says the minority, "it will cost nothing to find out, and there may be a good financial return if the hospital did make a mistake."

And so litigation is started. The hospital case notes are called for, and, because by law they are the "property of the Minister," they can be, and to my knowledge have been, impounded by the Minister's lay officers, and the surgical staff as a consequence have been unable to

examine them. Often the case is defended jointly by a regional board and a hospital management committee. Perhaps the plaintiff succeeds and a member of the medical staff, in the judgment of the Court, has, in fact, been negligent. So a regional board and a hospital management committee can now claim damages against the unfortunate doctor, for such is the law. Medical men now find themselves open to attack not only by their patients but by their hospital authority.

Is it any wonder that there is now a great shortage of junior medical men applying for appointments to the casualty departments of all hospitals of this country, and is there any likelihood, if these conditions continue, that inadequately staffed casualty departments will attract medical men in the future? The situation is about as serious as it could be, for to the 1,000-odd hospitals of this country over 1½ million accident cases go for treatment each year. The organization generally available for treatment of accidents in our hospitals is already poor, but over it a medico-legal cloud has cast a very dark shadow.—I am, etc.,

Birmingham.

WILLIAM GISSANE.

SIR,—Your medico-legal correspondent stated that the judge in cases of malpraxis weighed up the evidence of the medical experts on the two sides before giving judgment. I know of two cases, and there must be more, in which the plaintiff was awarded damages without medical evidence to support his claim, the judge making up his mind on his own on the question of the exercise of skill, care, and diligence.

It is this new development which agitates us all.—I am, etc.,

London, W.1.

A. DICKSON WRIGHT.

The Floating Spleen

SIR,—In the *Journal* of August 23, 1952 (p. 446), Dr. H. W. Wyile reported a case of a movable spleen. I should be glad if you would afford me the space to report on a case I had in British Honduras in 1949.

A Maya Indian woman, of about 55 years, came to the out-patient department complaining of discomfort and pain for a period of years in the left hypochondriac area and inclined to become more severe. As the patient was slim it was not difficult to detect in the left iliac fossa a swelling which could be moved fairly freely in any part of the left abdomen up to the costal margin. The diagnosis made by my colleagues varied from a pedunculated fibroid to a floating kidney. I, too, thought the swelling to be a movable kidney.

A laparotomy was done, using an upper midline incision, and I was easily able to bring into view the swelling, which was a spleen about four times the normal size. Its removal proved quite a simple matter. Ligation of the long pedicle between two clamps was all that was necessary. On section the lymphatic tissue was permeated with areas of cystic degeneration. I think I am right in stating that a movable spleen is a rarity in the surgical field.—I am, etc.,

Tumatumari, British Guiana.

A. H. BARTLEY.

Flood Appeal

SIR,—No doubt it will be of interest to all members to know that as a result of our recent appeal to the Essex Branch of the Association we raised a sum of £486 18s. 10d. Generous as our subscribers were, this amount would have been quite inadequate for the needs of our fellow practitioners in distress, and we owe a great deal to the assistance of the Sir Charles Hastings Fund, which enabled us to fulfil all the demands made upon us.

Our fund is now closed and the whole amount subscribed has been used for the purpose intended. May we, through you, Sir, once again offer our grateful thanks to all who subscribed?—I am, etc.,

Westcliff-on-Sea.

G. T. FOSTER-SMITH,
Honorary Treasurer,
South-east Essex Division.

POINTS FROM LETTERS

Unit System of Prescribing

Dr. DAVID HALER (London, W.1) writes: I was very intrigued to read Dr. Bruce Williamson's suggested unit system of prescribing (*Journal*, March 14, p. 620). It was perhaps a little unfortunate that this important letter became embedded into a discussion on the metric system. I am sure that this has led to the overlooking of this important contribution. Speaking as a practitioner of more than 20 years' experience, and one with considerable experience of a coroner's work, I would like to add my plea to the adoption of some such system as that advocated by Dr. Bruce Williamson. I am sure that students in general would also welcome such a simplification of the burden of learning that they have to carry.

The Medical Practitioner and the Law

Dr. HENRY CHURCHILL (London, N.W.8) writes: It is not difficult to find a professional expert witness who, after the event, will say: "Yes, I would have operated at once" (although sometimes we know he is not really such a bad surgeon as that), but it is not easy to find an expert who has a big enough and convincing enough witness-box personality to say, and get away with: "I don't know what would have been my line of treatment, because I was not there." Might the judge have sitting with him a medical assessor of his choice, from a panel? The panel could be formed from a representative selection approved by the whole profession, possibly nominated by the Royal Colleges. One can think of quite a number of names which should be acceptable. The alternative, it seems, is an increasing expense in every kind of investigation and consultant opinion as an additional insurance. This the country simply cannot afford.

Magic, Medicine, and Religion

Dr. GEORGE V. BOYLE (Glasgow) writes: I have read Sir Sydney Smith's Finlayson Memorial Lecture on magic, medicine, and religion (*Journal*, April 18, p. 847) with amazement. . . . Professor Smith states that the Roman Catholic Church in the early centuries discouraged science, etc. In all fairness why does he not mention that in the Middle Ages 81 universities were founded by the Catholic Church, mostly by papal authority? The chief among these were Oxford, Cambridge, Glasgow, Paris, Vienna, Bologna. Where would science be without the work of the following Catholic scientists: Schwann (histology), Müller (physiology), Vesalius and Fallopius (anatomy), Copernicus and Laplace (astronomy), Ampère, Volta, Lavoisier, Galvani, Foucault, Roger Bacon, H. Fabre, J. Fabre, Gutenberg (inventor of printing), Roentgen, Agricola, Marconi, and the man to whom medicine must be for ever grateful, Pasteur, who died embracing his crucifix? Again he states that radio and television are outstanding examples of things "accepted as commonplace today" which "would have been considered miraculous not so many years ago." By whom, and why? The results of giving thyroids to cretins, quinine for malaria, and opium for pain would have appeared miraculous 100 years ago. Maybe our ancestors knew that a miracle is a supernatural event, a sensible (that is, perceived by the senses) fact, extraordinary and divine (Tanqueray, a theologian), or, as the *Oxford Dictionary* states, an event due to supernatural agent, act of supernatural power. The Medical Bureau at Lourdes, which has thousands of medical men as members, openly invited doctors from every country in the world to visit Lourdes and offered every facility to enable them to inquire fully into the complete history of the cases recorded as miraculous cures. Hundreds of these cases are recorded and none have ever been proved to be false.

Dosage of Penicillin

Dr. W. A. BELLAMY (Aylesbury) writes: Most therapeutic agents appear to have a standardized dose which has remained constant for years. Not so penicillin. I am not at all sure that the enormous doses given now produce better results than the smaller ones given seven years ago, but I presume that the pathologists will refute this by statistics on blood concentrations. I have recently been advised to give a patient (now up and about, convalescent from pneumonia, with one slight relapse) 4 million units twice a day for 28 days. My own experience, for what it is worth, is that cases treated in practice (and many of the authors of refresher courses for general practitioners will be amazed to learn that cases are treated in general practice), cases of pneumonia, acute otitis media, carbuncles, cellulitis, tonsillitis, whitlows, etc., do very well, at all ages, on 1 million units, twice a day intramuscularly for five or six days. I get nothing like the same results with penicillin by mouth.

Obituary

E. D. PULLON, M.D., F.R.C.S.Ed.

Dr. E. D. Pullon, of Christchurch, New Zealand, died suddenly at his home from coronary thrombosis on April 23 at the age of 62.

Edwin Douglas Pullon was the second son of the late Dr. Henry Pullon, of Huddersfield, and was educated at the Leys School, Cambridge, and Edinburgh University, where he had a brilliant career, the promise of which was belied to a considerable extent by ill-health, which was the prime reason for his going abroad. At Edinburgh he took the B.Sc. degree and then graduated M.B., Ch.B. with first-class honours in 1912, later proceeding to the M.D., with gold medal for his thesis, in 1920. After qualification and the usual resident appointments he went out to South Africa on account of his health, and lived in Capetown, being appointed assistant professor of anatomy at Cape University in 1914. On the outbreak of the 1914-18 war he joined the South African Medical Corps and served in the German South-west African Campaign with the rank of major. He returned to Capetown in 1917 as assistant Government bacteriologist and then came back to Edinburgh for a time, worked at his M.D. thesis, and took the diploma of F.R.C.S.Ed. in 1922. Leaving Edinburgh again, he went out to New Zealand, his wife's home country, and settled in practice in Christchurch, where he served as assistant surgeon on the staff of the Christchurch Hospital. Ill-health still haunted him, but after recovery from a long illness he took a great interest in the activities of the New Zealand Branch of the British Medical Association and its campaign against the Government's social security proposals there. In 1947-8, when he was chairman of the Canterbury Division of the Association, he represented the South Island on a joint committee of four members in consultation with the New Zealand Government. These discussions were presided over by Judge Cleary, and it was through adoption of the Cleary Report that Section 8 of the Social Security Act of 1941 was repealed, the civil rights of the medical profession being thus reinstated at last. Dr. Pullon had always advocated the "refund system" of payment for medical practitioners, which enables a direct relationship to exist between patient and doctor. At the time of his death he was actively engaged on the executive council of the New Zealand Branch of the B.M.A.

Dr. Pullon came of a family of musical enthusiasts, wrote music and played the piano in his youth, and all his life took the greatest pleasure in music and the theatre. He missed the theatre very much in New Zealand, but loved entertaining touring companies there, whether they were Gilbert and Sullivan, Shakespearean, orchestral, musical or otherwise, and his house was always filled with travelling celebrities of one kind or another. Only a few weeks before his death he had been entertaining Anthony Quayle and the Stratford-on-Avon players. Like so many of his colleagues in New Zealand, he was a great Edinburgh enthusiast and never missed visiting his alma mater when he came to Britain. Dr. Pullon had a most unselfish, charming, and altogether delightful personality, and will be greatly missed. He was twice married, and leaves a widow and four children, with whom he had enjoyed a gracious, full, and understanding family life.—R. S. S.

Sir ROBERT G. ARCHIBALD, C.M.G., D.S.O., M.D.

B.N.S. writes: A wide circle of friends will have heard with sorrow of the death of Sir Robert Archibald, whose obituary notice was published in last week's *Journal* (p. 1112). Long before the end of the thirty years he spent in the service of the Sudan Government "Archie" had attained a unique position in the community. Living in Khartum, the clearing-house of the Provinces, he came into contact sooner or later with everyone who served in the Sudan. To few men is it given to become so universally admired and respected as he was, and to be so warmly regarded by all who knew him intimately. And no man ever more richly deserved the popularity he enjoyed or made less conscious effort to achieve it. It was the homage willingly paid to a wise and gifted man, endowed with great charm, good manners, a genial sense of humour, and a hospitable nature. The knighthood bestowed on him towards the end of his career in the Sudan was a fitting reward for a life of selfless devotion to duty. He was a tireless and most conscientious worker in his chosen field of medicine, and the services which he rendered as director of the Wellcome Tropical Research Laboratories in Khartum were of inestimable value to the Sudan, where his name will long be remembered and honoured. Absorbed though he was in his work, he still found time to play his part in the social life of Khartum. He was fond of all games and sports such as tennis, golf, fishing, and shooting, and loved nothing better after the day's work was over than one of those unforgettable evenings duck shooting on the Nile.

Dr. CHARLES A. MACKENZIE died at Winnipeg on April 6 at the age of 83. Born in Ontario, he was educated at Upper Canada College and graduated in medicine at McGill University in 1899. Going to Winnipeg, he served for many years as chief medical officer of the Canadian Northern Railway (later incorporated into the Canadian National Railway), of which his uncle, Sir William Mackenzie, was a founder. In 1930 he was president of the Manitoba Medical Association, and as such was the official host for the British and Canadian Medical Associations which held a joint meeting at Winnipeg in that year. He was a close friend of Dr. W. Harvey Smith, who served as President of the British Medical Association in 1930, and with Dr. Harvey Smith he was largely responsible for the erection of the Medical Arts Building in Winnipeg, owned and operated by the tenant doctors and dentists. For 25 years, from its opening in 1923, he acted as president of the building and administered its finances with singular ability.

The sudden death of Dr. W. A. MAGILL on April 22 at the age of 72 came as a great shock to his patients and friends. William Arthur Magill was born on April 1, 1881, and was educated at the Methodist College and the old Queen's College, Belfast. His parents intended him for the Church, but after matriculating at the former Royal University of Ireland he took up the study of medicine and was a prize-man at Queen's and an exhibitor at the Royal Victoria Hospital, Belfast. He qualified by taking the Scottish triple qualification in 1904, and then, before starting in general practice in Belfast in 1909, he was an assistant in Yorkshire and Portsmouth. At Belfast, where he soon built up a large practice, he was a keen and extremely conscientious worker, and his quiet and kindly manner endeared him to his patients and professional colleagues. He died in harness, as he hoped he would. Outside his profession his main interest was reading. He had a good knowledge of six or seven modern languages, and kept up his knowledge of Latin and Greek. He was also fond of motoring and gardening. His wife, formerly Miss Constance Spence, of Douglas, Isle of Man, predeceased him a short time ago, and he is survived by a son and daughter.—W. R. E. W.

Dr. A. E. THOMPSON, who died at Birkdale, Southport, on April 15 at the age of 82, had previously been in practice for 49 years at Barrow-in-Furness, where he was well known and greatly liked. He retired to live at Birkdale in 1949. Arthur Edward Thompson was born on April 21, 1871, and was educated at the University of Durham, where he was a student of outstanding merit. He gained the Charlton Scholarship and first-class honours in medicine in 1893, the year in which he graduated M.B., B.S., and three years later he took the degree of bachelor of hygiene. His first appointment was that of assistant visiting surgeon to the Newcastle-upon-Tyne Dispensary, but the war in South Africa at the turn of the century saw him on active service as a medical officer, and he became assistant district surgeon at Estcourt, in the Natal Province. When he returned to this country he settled in practice at Barrow-in-Furness, becoming known as "the doctor on the motor-cycle," a mode of transport he used for many years, and his quiet, friendly manner and cheery word endeared him to all. A member of the British Medical Association for fifty years, Dr. Thompson was honorary secretary of the Furness Division in 1922, and president of the North Lancashire and South Westmorland Branch in 1926-7. A staunch churchman, he was a regular attender at divine service until three weeks before his death.

Dr. A. N. FELL, one of the best-known medical practitioners in North-east Essex, died at his home at Colchester on April 19 at the age of 75. Alfred Nolan Fell was born at Nelson, New Zealand, on January 17, 1878, and was educated at Nelson College and at Otago University, continuing his studies at the University of Edinburgh, where he graduated M.B., Ch.B. in 1902, proceeding to the M.D. in 1906. In 1905 he became a Member of the Royal College of Physicians of Edinburgh, a distinction which he relinquished when he settled in general practice at Colchester in 1907, because at that time Members of the College were forbidden to dispense their own medicines. It was characteristic of the man to practise medicine as he thought best. In recent years he was reinstated at Edinburgh, an honour which modesty prevented him from mentioning even to his closest friends. After graduation Dr. Fell held house appointments at the Royal Infirmary, the City Fever Hospital, and at the Corstorphine Convalescent Hospital, Edinburgh. His distinguished academic career was matched by his brilliance as a Rugby footballer and as champion "miler" of the Scottish universities in 1901-2 and of Edinburgh University in 1901-2-3. While at Edinburgh he built up and led one of the finest Rugby sides in the history of the game. The record of his first season as captain read: matches played, 16; won, 15; drawn, 1; points for, 425; points against, 6. He was "capped" for Scotland in 1901, 1902, and 1903, and only injuries prevented him from playing in the two following years. He was the great wing three-quarter of his day, with a tremendous swerve and speed and a determined dash for the line. He retained a keen interest in the game until his death, and was the first president of the Colchester Rugby Club. As a past president of the Colchester Medical Society and through his long membership of the Essex Panel Committee Dr. Fell exerted a valuable influence on the general-practitioner services throughout the country—an influence he exerted also as a member of the British Medical Association. He was honorary secretary of the North-east Essex Division from 1915 to 1917 and again in 1920-1; honorary secretary of the Essex Branch from 1921 to 1924; chairman of the North-east Essex Division in 1927-8; and president of the Essex Branch in 1930-1. In 1918-19 he served as a temporary captain in the R.A.M.C. in Macedonia, Bulgaria, Serbia, and in the Caucasus.

We are indebted to Mr. RONALD REID for the following appreciation: The death of Dr. A. N. Fell will be lamented by all who knew him, for he was beloved and respected, and his patients were his friends. To many of his colleagues who have witnessed the changing scene in medicine it is like the end of an era, for he was one of the great general practitioners. Not

only was he highly skilled in his profession and devoted to the welfare of his patients, but he was a man of great wisdom and kindness, a true family doctor and adviser. In him, character, education, and experience were blended and matured to a degree not often encountered in the world of medicine to-day. He was a man of high ideals and modest to the point of self-effacement; at first meeting his sensibility might make him seem austere and distant, but suddenly his kindness and impish sense of humour would break through, and the warm smile and the twinkle in the eye would show the real man below the surface. He had a liberal outlook on life, for his interests were not confined to medicine, as those who were privileged to sail in the family yacht will remember. He was one of those rare human beings who had an innate knowledge of what is right and enduring; his self-discipline and his determination carried him through life as they carried him through the opposing team on the football field fifty years ago. When still in active practice he learned that he had not long to live. Pondering on the prospect of retirement, he remarked, "I shall play to the final whistle"; and that is exactly what he did. He will always be remembered for his devotion to ideals, his courage, and his humanity. He leaves a widow, three sons, and a daughter; another son died of wounds in North Africa in 1942.

Medico-Legal

ACTIONS FOR NEGLIGENCE

[FROM A SPECIAL CORRESPONDENT]

Anxiety undoubtedly exists among members of the medical profession because, as the medical correspondent of the *Daily Telegraph* has put it,¹ "what is classed as negligence is not negligence as understood by them." He submitted that some legislation was necessary to clarify the position. This was followed by a letter from Dr. R. W. Cope,² who stressed the fact that accidents do occasionally follow "simple procedures when there has been absolutely no evidence at all of any careless or ignorant practice carried out by the operator and the nursing staff concerned." He supported the desire for new legislation and suggested a Select Commission.

The law concerning the liability of a professional man has not changed. His duty is, as it has always been, to bring to bear upon all his professional activities the degree of skill and care possessed by an ordinarily competent practitioner of comparable standing to himself. Judges have repeatedly stressed that he does not, in the absence of very special circumstances, guarantee either the success of his treatment or the perfection of his technique; but he is liable for the consequences if he fails to apply that skill and care defined above. While the law has not changed, its application by judges and juries in individual cases in recent years has revealed a trend to the disadvantage of the doctor and the hospital.

Discovering the Facts

In the first place the judge (and jury, if there is one) has to discover the facts. Often there is a direct conflict between the witnesses on vital points—for example, on whether some particular examination was carried out. Every system of law has to provide a machinery for ascertaining the truth in such a case, and ours is the familiar procedure whereby witnesses give their evidence orally and are questioned. No better has yet been devised, nor is likely to be. The judge then makes up his mind about whom he believes. If the evidence of the doctor does not impress him, he will not believe his version of the facts: so with the patient and his witnesses. More cases are won or lost on this score than on any other. It is seldom that one can discover from reading a newspaper report whether any witness has been believed or not: and it is obviously fruitless to criticize a verdict that there has—or has not—been negligence without

knowing what the judge believed to have happened. Only after he has resolved the facts can the judge decide whether there has been negligence, and in reaching this conclusion he is guided by the views of the expert witnesses called. Again, when there is conflict between the expert witnesses, it is for the judge to choose the one whose views he accepts.

Lord Justice Denning is reported to have said³ that before the National Health Service Act the courts had been "very kind" to voluntary hospitals. The report suggests that Lord Justice Denning was implying that the great increase both in the number of cases brought against hospitals, and the number of successful cases, was at least in part attributable to the application of the strict rule of law to those cases now for the first time. It is the writer's view that this is a part only of the truth, and some additional suggestions are hazarded below.

The Changing Times

The taking over of hospitals under the National Health Service has brought about a radical change in the whole attitude of the patient towards hospitals. Many in the past have grumbled if they were not treated at hospital in every way as they would have wished, but yet respected the hospital and its staff. Some of this respect has now gone. With it has gone an inherent unwillingness on the part of patients and their legal advisers to institute proceedings against local hospitals. The attitude nowadays is that they are suing the "State." The jury, too, are members of the public, and, just as the patient is less hesitant to allege negligence, so are they less hesitant to believe it.

The passing into law of the Legal Aid and Advice Act, 1949, has made it possible for many people to bring actions which they could not previously have afforded. Who can blame a plaintiff for instituting proceedings in respect of injuries which he had undoubtedly received, when he thinks, as many do, that he is suing the State at the State's expense?

The public has in every aspect of life become increasingly "compensation-minded." It is not only claims against doctors and hospitals which have increased. There has been a steady rise in the number of all classes of case in which damages are claimed for personal injuries, whether these are sustained in road traffic accidents, at work, or otherwise. Many readers will remember in this connexion the increase in their motor insurance premiums.

The law of negligence has been seriously affected by the internal combustion engine. The lay public do not usually realize that a very high proportion of the time of the civil courts is taken up with claims for personal injury arising from road traffic accidents, and it is inevitable, therefore, that the influence of these cases on the law of negligence should have been marked. In most Continental countries a motor vehicle is treated as inherently dangerous, and if a driver injures someone it is for him to show that he was not negligent if he is to escape liability. In England this is not the law: the burden of proof of negligence is on the plaintiff, but if he can show that the driver has made an error the court will then hold that there has been negligence unless the driver can disprove it. Day after day, therefore, judges and barristers are concerned with cases in which error and negligence are closely approximated. It is hardly surprising that when they deal with another type of negligence case their application of the law will be influenced by this state of mind. Twenty-three years have passed since third-party insurance for motorists became compulsory: it will be seen, therefore, that this factor has had enough time now to have a significant effect.

New Potential Dangers

To venture on more controversial fields: few will deny that medicine and surgery have developed apace since, say, 1939. It is by no means impossible that this development has outstripped the improvement in the teaching of medical students and young doctors. To-day the practitioner in all spheres has a much wider and potentially more dangerous

range of treatment than his colleagues of 15 years ago. There is therefore much more scope for the occurrence of "inadvertent" results, which are really only the logical consequences of some procedure adopted by the doctor which he has not foreseen or been taught to avoid. The smallest mistake is now harder to retrieve or to counter than formerly, and its consequences are apt to be much more dire to the patient.

In medicine, as in all walks of life, there have always been a few who are careless. It would be surprising, after a world war and a social and medical revolution, if those inevitable few were not slightly less few. Nor would it be surprising if the very newness of the N.H.S. had put a few such people into the wrong jobs or had failed to weed them out. The newness of the N.H.S. organization appears in some cases to have also contributed to this problem in another way—namely, that the hospital machine has not always worked with complete smoothness. Situations of doubt and difficulty have arisen in which mistakes (mostly of inexperience) have been made.

The cause of the present circumstances lies not in the law but in its application, and its cure in the social and not the legal field. There can be no justification for the medical profession to ask for special protection beyond that which the law gives to others. What need is there for a Select Commission? If doctors continue to do their best at all times, if they uphold the traditions of the past, if they can manage to do their work without looking over their shoulders at the law, secure in the support of their defence organizations, the causes which are tilting the scales against them will vanish in time and the equilibrium will be restored.

Medical Notes in Parliament

INQUIRY INTO HEALTH SERVICE

The National Health Service was debated on May 18 on a Vote for the Civil Estimates.

MR. ANEURIN BEVAN said that the Opposition took the gravest view of the decision of the Minister of Health to appoint a committee of inquiry into the Service. Why had not the Minister made use of the Central Health Services Council, which had an unsurpassed pool of knowledge?

The terms of reference made it clear why the Minister had not used the council. It would not be possible for the council in its own terms of reference to advise the Minister on the limitation of the Service. It would only be possible for them to advise on any defect in the administration and on any changes that should be made to repair those defects. The Minister was setting up an independent committee not because he was anxious to improve the administration but because he was anxious to obtain an alibi to cut the Service.

Stiffer Discipline

Demands on the Service in the two sections—dental and ophthalmic—where the patient initiated the expenditure had already begun to decline before charges were put on. The pharmaceutical side of the picture was slightly different. This was where the initiative on the expenditure lay mainly with the doctor. It was the doctor who, by his prescription, attracted money from the Exchequer. Here the expenditure had been and still was going up in spite of the prescription charge. But in this case there was disciplinary action open to the Minister, and there were administrative pressures which might be increased more severely than they had been. It surely was a reflection on the medical profession that in the case of "dextrodine" £400,000 was spent on it last year when the equivalent in the official formulary would have cost only £158,000. It was a reflection on the doctors, and what was required was not action to penalize the patient, who was not responsible, but to make an investigation into the profits made by the big drug houses and to stiffen more severely the discipline over the general practitioners.

The hospital organization should be looked at from the point of view of the treatment of the chronic sick with a view to relieving some of the charges on the hospitals.

Minister's Reply

MR. IAIN MACLEOD, Minister of Health, said that two questions in relation to the inquiry had to be decided: Was there anything to inquire into, and, if so, who should undertake it? On some matters within the area of dispute he wanted advice, though he agreed that the decisions could be taken only by the House of Commons. One matter was the block grant. It was one view that the central accounting system of this country was never designed for the burden the Health Service had put upon it in the management of several thousand hospitals. That money unspent at the end of the financial year had to be returned was not an incentive to wise spending in the last few months of the year. By planning three or five years ahead, the hospitals could make great economies.

Ambulances were a hospital service in Scotland and a local authority service in England. Which system was the better? There was the immensely difficult problem of fitting national wage negotiations into the intensely human and personal hospital service. If savings could be effected without loss of efficiency, should not a hospital get the benefit of that economy? Had local authorities found their right role in the Health Service? There was a good case for some investigation after five years.

Then came the question of who should undertake it. Mr. Bevan had suggested the Central Health Services Council, but it was because that council was representative of all the interests in the Service that he did not regard it as the right body to undertake the inquiry. He desired an independent view from independent-minded people.

The case that there was something to be inquired into was unanswerable. Expenditure in the Health Service field could not be controlled unless man-power was controlled, because salaries and wages accounted for two-thirds of the cost of hospitals, and hospitals accounted for nearly two-thirds of the cost of the scheme. At the end of 1951 there were 328,000 full-time and 90,000 part-time staff in hospitals, an increase of respectively 15% and 33% over 1948. They must try to relate the numbers employed to the service obtained, and he hoped that as an outcome of the review more staff might be available for the hospitals and sanatoria which at present were in the greatest need.

Concern about Prescribing

The Government viewed the present cost of the pharmaceutical services, as did their predecessors, with the gravest concern. It was the only part of the National Health Service that he could not claim as under financial control at the present time. There had been a steady increase in the numbers of prescriptions, which were now running at the rate of 241 million a year in Great Britain. The average cost of a prescription had climbed from 38d. in 1949–50, to 40.5d., 47d., and 50.7d., and he had made an estimate of 52d. for each prescription for this year. This rise was due to a general rise in ingredient costs, though that was flattening out, and to the increasing use of new, valuable, and expensive drugs and to the important increase in the proportion of proprietaries. Before the Service came in the proportion of proprietaries was 6%. In 1949 it was 15%, and it was now 25%, which accounted for about half the drug bill; and the whole of the amount he had to pay out, taking into account the hospitals, was about £60m.

He was going to invite doctors in a month or so not to prescribe the drugs which Sir Henry Cohen's committee had referred to as not of proved therapeutic value. That would help the situation, but the biggest problem was that no fewer than 4,000 proprietaries came in the categories in which the Cohen committee advised they were not superior to standard proprietaries but which they thought ought to be prescribable subject to satisfactory price arrange-

¹ *Daily Telegraph*, March 16.

² *Ibid.*, March 19.

³ *The Times*, March 19.

ments being made. The problem that confronted him was what should be done. It was not a new problem. The House was recommended to take action over proprietaries first in 1914, and many efforts had foundered in the past. There was a genuine case for many of the firms, but the trouble was that there were firms who were merely wrapping up standard proprietaries in pretty packages and forcing them on the notice of doctors. And the difficulty was to distinguish between the two so that he would not harm the export industry or research, which had brought such splendid advances in chemotherapy, and to get rid of those firms that battered on the Service.

There were various possible approaches, but the Government had decided in the last few days to start a number of cost investigations—as many as they could undertake—into the cost of manufacture of certain of these proprietaries that seemed, at first sight, especially expensive. (Cheers.) He hoped it would yield substantial savings, and he intended to circulate doctors with the names of those proprietaries concerning which the Government was unable to reach satisfactory agreements on price. This action should not be taken to be the end of the story, and he did not rule out more drastic measures if this should fail.

Charges to Patients

As a result of the 1s. charge for prescriptions there was a drop of 14% in the first month. That came down, until in September the deterrent effect was ½%. In the three months at the turn of the year December, January, and February, the number of prescriptions dispensed was running at about 12% above a year before, even though the 1s. charge was on. It was true there was fog, floods, and 'flu, and it was quite impossible to make any valid comparison from year to year unless one looked at the sickness figures of the Ministry of National Insurance. The past year had been one on which it was genuinely almost impossible to draw conclusions. But when he calculated his Estimates he had put down a deterrent figure of 6% for the coming year. Whether it would be right or wrong he could not tell, and it depended more than anything on whether there would be an epidemic year or not.

The main problem was how to meet the thrusting needs of the hospital service. Last year the hospitals under-spent by £14m. owing partly to the Government's requests to them not to over-spend. In this year's Estimates the Government had provided £15,250,000 for extra expenditure. Stocks carried by hospitals amounting to £21m. in March, 1952, were being reduced by £3m., which was additionally available to hospitals for the coming year. Cash balances were being reduced by £2m., and, adding these figures to the £15,250,000, there was provided £20m. over the out-turn for last year for the hospitals. With this £20m. he could maintain the Service, bring into full use the developments that had been finished recently, and provide for modest future development.

The policy of successive charges would in time destroy the Service. The Government had shunned a further step down that road. A "hotel charge" had never been discussed either by himself or his colleagues at any stage. It might be that they were at the end of charges; he did not know, but at least a halt had been called. He had tried, as he had shown in his Estimates, to hold the line, but many of the things he had done could not be repeated year after year. What they wanted to achieve was a system by which the Service had an interest in economy which was as natural and rewarding as was its interest in medical efficiency. They were right to review the Service, and the Guillebaud committee was the best method of carrying out the investigation.

Due for Review

Mr. F. MESSER said that the Service was due for review. Consultants who were members of teams of full-time consultants were now leaving to become sessional consultants. Travelling time was taken into account as part of the session, and they got income-tax allowances on all expenses.

Among them were men now getting £2,000 or £3,000 a year who would have been lucky in the old service if they ever got £1,500. Surely there was a field for investigation.

Dr. S. JEGER said that the poor general practitioner had been the whipping-boy for what had been described as "unnecessary expenditure." It was true that some doctors, either through ignorance or malevolence, were not playing the game, and he had heard of one who prescribed a pound of cotton-wool a week for his barber, who used it round the necks of his customers. But some patients did not feel happy unless they were getting bottles of medicine to pour down their throats, which was one of the consequences of establishing a vested interest in patients.

Commander GALBRAITH, Under Secretary, Scottish Office, said that the Guillebaud committee would be able to study the merits of whole-time and part-time service but it would not be dealing with rates of pay. The differences between the English and Scottish services were in matters of administration, but so far as those differences had a bearing on expenditure it would be of advantage to have them reviewed.

An Opposition motion to reduce the Vote by £5 was defeated by 293 votes to 268.

NURSING DUTIES

The hospital nursing services were debated in the House of Lords on May 12. Opening the debate Lord CROOK founded his case on the recent report of the Nuffield Provincial Trust and the evidence produced by its job analysis of the great misuse of nursing skill. He asked, in effect, for urgent Government consideration of the report and the adoption of as many as possible of its recommendations.

Lord MORAN thought it was generally agreed that they could not look for any great increase in the numbers of nurses in the future, and therefore attention must be concentrated on making the best use of existing numbers.

Nursing Orderlies

He hoped the nursing profession would give careful attention to the use of the orderly. If an orderly was trained for a year he would be a most useful pair of hands. If there were enough trained nurses, they should be taken to the bedside; but in the present scarcity there was no option but dilution of the nursing profession.

Lord AMULREE supported the idea that some form of dilution was the only way out. The danger seemed to be that too many nurses were being trained to too high a standard. It had always seemed to him a pity to make the trained nurses' standard too high. The nurse so trained looked for an administrative job. No other would give her an increased salary.

Lord HADEN-GUEST regarded "inevitable dilution" as a defeatist argument. There was already far too much dilution in the nursing profession.

Need to Reorganize

Lord WOOLTON replied to the debate. He said there were some good points in the picture. The nursing force had increased by two and a half times in the past 50 years, so some progress was being made. The demand had increased even more, but that was also a sign of progress—more care was being taken of the sick. He gave an assurance on the Nuffield report. It was received by the Minister of Health at the beginning of April, and the advisory committee met on April 29 to consider it. The Minister was anxious that no time should be lost. He endorsed the importance given in the Nuffield report to the need for reorganization of hospital services. He had been horrified to find, in talks with the nurses, that promotion went in the line of administration. At the time he was thinking very little of administration. It was a great pity if highly trained nurses were having to do clerical work, which involved an entirely different capacity and attitude of mind. The things that ought to be looked at were what reorganization could be obtained in personnel employed in administration and also in the fuller use of orderlies.

ANTIBIOTICS BILL

The Therapeutic Substances (Prevention of Misuse) Bill was discussed by the House of Commons on Second Reading on May 13.

Mr. IAIN MACLEOD explained that the purpose of the first of the two clauses was to extend the scope of the Penicillin Act, 1947. It was right to ask for powers to make regulations, similar to those made under the 1947 Act, in respect of any substance which appeared to him and the other Health Ministers to be capable of causing danger to the health of the community. Isoniazid was the drug which had given rise to Clause 1. It was necessary they should consult the Medical Research Council, and questions had been raised whether he would also consult the manufacturers and other interests affected. He stated that there would be such consultations, provided it was understood that the final decision must be taken on medical grounds.

Clause 2 was popularly known as the "penicillin for pigs" clause. It had been found by experiment in the United States that minute quantities of antibiotics put into the feedingstuff could have a most remarkable effect in encouraging the growth and fattening of pigs. The first consideration was whether this could have any ill effects on human beings who would eat the meat produced, but he was assured by the Agricultural Research Council that there was not the slightest danger of this happening. The other danger which was being guarded against was the possibility by this wider use of antibiotics of a black market in penicillin, but the Government would take steps to ensure that the antibiotics were used in such a way that they could not be extracted and used for self-medication.

At the moment it was proposed to apply these regulations only to penicillin, since that was the only substance of this class of which there were satisfactory quantities, but it was possible that in the future aureomycin and perhaps terramycin would be manufactured in sufficient quantities in this country if they were suitable for use in the same way. He would consult the Agricultural Research Council and, if necessary, the Royal College of Veterinary Surgeons.

Danger of Sterility

Captain J. A. L. DUNCAN, a member of the council of the Royal College of Veterinary Surgeons, said that the use of such drugs for fattening pigs for slaughter might be all right, but farmers should be warned that if they were used for feeding pigs for breeding there was a danger of loss of fertility. The same applied to cattle and sheep for breeding. He sought an assurance that the Royal College of Veterinary Surgeons would be consulted.

Mr. G. R. H. NUGENT, Parliamentary Secretary to the Ministry of Agriculture, gave the assurance that there would be consultations with the College on many matters, and that these were already in progress on the drafting of the regulations.

The Bill was read a second time.

Synthetic Detergents Investigation

Mr. H. MACMILLAN, Minister of Housing and Local Government, announced on May 18 that he had appointed a committee "to examine and report on the effects of the increasing use of synthetic detergents and to make any recommendations that seem desirable, with particular reference to the functioning of the public health services." Its chairman is Sir Harry Jephcott, F.R.I.C., chairman and managing director of Glaxo Laboratories. Among its 17 other members are the following medical men: Dr. N. R. Beattie, principal medical officer, Ministry of Health; Professor J. C. Cruickshank, professor of bacteriology as applied to hygiene at the London School of Hygiene and Tropical Medicine; and Lieutenant-Colonel E. F. W. Mackenzie, director of water examination, Metropolitan Water Board.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending May 2 (No. 17) and corresponding week 1952.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

Vital Statistics

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1944-52 are shown thus -----, the figures for 1953 thus ————. Except for the curves showing notifications in 1953, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Week Ending May 9

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,387, whooping-cough 3,461, diphtheria 22, measles 9,809, acute poliomyelitis 38, dysentery 729, paratyphoid fever 14, and typhoid fever 1.

Infectious Diseases

The largest variations in the number of notifications of infectious diseases in England and Wales during the week ending May 2 were decreases of 2,979 for measles, from 13,731 to 10,752, and 132 for acute pneumonia, from 681 to 549, and increases of 167 for whooping-cough, from 3,206 to 3,373, and 92 for scarlet fever, from 1,047 to 1,139.

The largest falls in the incidence of measles were 267 in Yorkshire West Riding, from 1,317 to 1,050; 256 in Surrey, from 736 to 480; 210 in London, from 629 to 419; and 204 in Warwickshire, from 528 to 324. The largest fluctuations in the trends of whooping-cough were a rise of 46 in Kent, from 85 to 131, and a fall of 48 in Lancashire, from 497 to 449. Only small variations were recorded in the local returns of scarlet fever. 13 cases of diphtheria were notified during the week, 12 fewer than in the preceding week.

29 cases of acute poliomyelitis were notified—15 fewer for paralytic and 3 more for non-paralytic cases than in the preceding week. The largest returns were London 5; Southampton County 4 (Portsmouth C.B. 3); and Middlesex 4.

A rise in the notifications of dysentery from 419 to 466 was recorded during the week. The largest centres of infection were Lancashire 114 (Liverpool C.B. 35, Preston C.B. 22, Manchester C.B. 17); Middlesex 70 (Edmonton M.B. 26, Southgate M.B. 13); Essex 35 (West Ham C.B. 12); London 34 (scattered through 12 boroughs); Bedfordshire 28 (Bedford M.B. 17); Yorkshire North Riding 26 (Middlesbrough C.B. 26); Norfolk 23 (Great Yarmouth C.B. 21).

Smallpox in the North Country

The number of confirmed cases reported up to noon, May 19, is 30, including 8 deaths. No new cases have been reported since last week. Although the period of surveillance of known contacts is almost expired, the need for special vigilance must continue for a longer period, because the source of infection of 4 cases which occurred two to five weeks ago is uncertain.

In its first large-scale effort to raise funds for promoting various projects, the National Spastics Society is offering Coronation seals for sale at 1d. each. So far 2,250,000 seals, which show a picture of Westminster Abbey, have been printed for distribution. Supplies of seals may be obtained from the Appeals Secretary, National Spastics Society, 44, Stratford Road, London, W.8.

Medical News

The Committee of Inquiry on the Rehabilitation of Disabled Persons which was set up by the Minister of Labour and National Service, the Minister of Health, and the Secretary of State for Scotland, under the chairmanship of Lord Piercy, is now ready to receive evidence from interested persons and organizations. Those intending to give evidence should give notice as soon as possible to the joint secretaries of the committee (32, St. James's Square, London, S.W.1), with a memorandum of the views they wish to present.

Courage Laboratories of Ophthalmology.—At the Royal Eye Hospital, London, on May 13, Mrs. M. V. Courage laid the foundation stone of new laboratories which are to be known as the Courage Laboratories of Ophthalmology. They will be used for clinical research under the direction of Professor Arnold Sorsby. The Bishop of Kingston (The Rt. Rev. F. O. T. Hawkes) reminded those present at the ceremony of the large amount of good work which the firm of Courage and Company, Limited, had done for the Royal Eye Hospital: a few years ago they presented a nurses' home at Surbiton, and now they had come forward with the necessary funds to build these laboratories in the hospital precincts. The research department of the Royal Eye Hospital had been in existence for ten years, and immense benefit was hoped for with the new facilities which the laboratories would provide.

Chelsea Clinical Society.—The Annual Dinner of the Chelsea Clinical Society was held at the South Kensington Hotel on May 12 with the president, Mr. Eric Steeler, in the chair. The toast of the Society was proposed by the Very Reverend Archimandrite James Virvos, Provost of the Greek Cathedral, who engagingly found a similarity between the present dinner and the feasts of good fellowship which were facilitated by the nature of the Greek vineyards in the time of Hippocrates. There was much in common between the two civilizations of Greece and Britain. His ancestors, the Archimandrite continued, had deified Asklepios, whose daughter was Hygieia. Greece became the cradle of the scientific development of medicine, and in early Greece the doctor had become a distinct person from the priest doctor. In response Mr. Steeler welcomed this opportunity to pay tribute to a country which had made such fundamental contributions to medicine. The toast of the guests was proposed by Mr. David N. Matthews, and Sir Ernest Gowers and Sir Cecil P. G. Wakeley spoke in response. At the close of the evening Mr. Steeler inaugurated the new president, Dr. J. N. Loring.

Society of Endocrinology.—The following officers have been elected: *chairman*, Dr. S. J. Folley, F.R.S.; *hon. secretaries*, Professor C. H. Gray and Professor N. F. MacLagan; *hon. treasurer*, Professor G. W. Harris, F.R.S.; *editor of Society's Proceedings*, Professor S. Zuckerman, F.R.S. *Ordinary members of committee*: Dr. T. Mann, F.R.S., Dr. C. J. O. R. Morris, Dr. I. W. Rowlands, and Dr. S. L. Simpson. Communications should be addressed to the hon. secretary, at the Department of Chemical Pathology, King's College Hospital, Denmark Hill, London, S.E.5.

Scientific Film Review.—This is a new quarterly review of scientific and medical films, prepared by the appraisal panels of the Scientific Film Association and published by the British Film Institute. The first issue published last month contains appraisals of 17 new films, two of which are medical. Specimen copies of the review can be obtained on application to the general secretary, Scientific Film Association, 164, Shaftesbury Avenue, London, W.C.2.

Toxicity of Industrial Solvents.—The Medical Research Council has published a revised edition of *Industrial Health Research Board Report No. 80*, "Toxicity of Industrial Organic Solvents." The revision has been carried out by Dr. Ethel Browning, who prepared the original report in 1937, under the general guidance of the Council's toxicology committee. The book will be invaluable to all industrial medical officers: it summarizes available information on the properties, use, and toxicity of 126 solvents in general use in industry. Each section of the book is completed by an extensive bibliography up to 1948, and there is a general index. (Pp. 411. Price 35s. net from H.M.S.O., York House, Kingsway, London, W.C.2.)

Examiners for F.F.A.R.C.S.—In our advertisement columns this week the Faculty of Anaesthetists of the Royal College of Surgeons invites applications for the appointment of examiner for the F.F.A.R.C.S. The subjects in which examiners are required are, for the primary examination, anatomy, physiology, pathology, and pharmacology, and, for the final examination, medicine, surgery, and anaesthetics.

Nepal has been admitted a Member State of the World Health Organization.

Léon Bernard Prize.—The Sixth World Health Assembly awarded the Léon Bernard Prize to Dr. Johannes Frandsen, director-general of the National Health Service of Denmark, on May 11. The prize is given for his outstanding achievement in the field of social medicine in his own country. Dr. Frandsen has directed the Danish Health Service since 1928.

Anglo-French Exchange Bursaries.—The following have been awarded bursaries for special studies in France, under the exchange scheme announced in the *Journal* on January 17 (p. 169): Mr. F. B. Cockett, senior lecturer in surgery, St. Thomas's Hospital; Dr. R. H. Gorrill, senior lecturer in bacteriology, St. Mary's Hospital Medical School; Dr. A. Macdonald, reader in bacteriology, Liverpool University; Mr. A. McPherson, 1953 Laming-Evans Research Fellow of the Royal College of Surgeons; Dr. J. W. F. Scrimgeour, senior obstetric registrar, Manchester; and Dr. E. C. Turton, tutor in electroencephalography, Bristol University.

Sir Daniel Davies has been created a Knight Commander of the Order of St. Sylvester by the Pope, for his services to the Roman Catholic Church. Particular mention is made of his services to Cardinal Griffin and to the Hospital of St. John and St. Elizabeth, St. John's Wood, London.

Surgeon Captain J. G. Holmes has been awarded the Gilbert Blane Medal by the Royal College of Surgeons of England for his work in the promotion of naval medical science and hygiene. The medal was founded in 1830 by Sir Gilbert Blane, F.R.S., who is best known for the sanitary reforms he introduced to prevent scurvy in the Navy.

Mr. David N. Matthews, vice-president of the British Association of Plastic Surgeons, is spending a week at Düsseldorf, lecturing and operating at the West German Plastic Centre. Dr. J. D. Ebsworth is accompanying him, to give the anaesthetics.

Dr. Bertram Mann, a consultant chest physician at Halifax, has been awarded a N.A.P.T. exchange scholarship to Canada. He will go there in September to study methods of tuberculosis control for three months.

Dr. J. R. Macintyre has been appointed a nominated member of the Executive Council of St. Helena.

COMING EVENTS

Bart's Coronation Ball.—The Coronation Ball of St. Bartholomew's Hospital is being held at the Royal Festival Hall on June 12 from 11 p.m. to 5 a.m. Tickets (£2 10s. double) are obtainable from the Ball Secretary, Abernethian Room, St. Bartholomew's Hospital, E.C.1.

United Hospitals Festival Choir.—A Coronation Concert is to be held on June 24 at the Royal Festival Hall at 7.45 p.m., when the Choir, accompanied by the London Symphony Orchestra, will give a performance of "The Messiah." Tickets (price 12s. 6d., 10s., 7s. 6d., 5s., and 3s. 6d.) are obtainable from the Royal Festival Hall Box Office.

Simpson Smith Lecture.—Sir Clement Price Thomas will deliver the Simpson Smith Lecture on June 11 at the Medical Society of London, 11, Chandos Street, Cavendish Square, London, W.1, at 4.30 p.m. His subject will be "Benign Tumours of the Lung."

St. Cyres Lecture, 1953, will be delivered by Professor J. McMichael in the Barnes Hall of the Royal Society of Medicine, 1, Wimpole Street, W.1, on June 12 at 5 p.m. His subject will be "Right Ventricular Failure."

National Association for Maternity and Child Welfare.—The annual conference will be held at St. Pancras Town Hall, Euston Road, London, N.W.1, from June 10 to 12. The theme will be "Education for Parenthood." The speakers will include Dr. Jean Mackintosh, Dr. John Burton, and Dr. Catherine Crane. Tickets (price £1 1s.) may be obtained from the secretary, N.A.M.C.W., Tavistock House North, London, W.C.1.

NEW ISSUES

British Journal of Preventive and Social Medicine.—The next issue (Vol. 7, No. 2) will be available in a week's time.

Journal of Clinical Pathology.—The next issue (Vol. 6, No. 2) will be available in a week's time.

These journals are issued quarterly. In each case the annual subscription is £2 2s., single copy 12s. 6d.

Abstracts of World Medicine.—The May issue (Vol. 13, No. 5), which is now available, contains abstracts of important papers on both medical and surgical subjects drawn from the medical literature of some 20 different countries and of all five continents. In addition to clinical medicine and surgery, the subjects covered include pathology, bacteriology, pharmacology, and chemotherapy, and there are also sections dealing with medical genetics, public health and industrial medicine, toxicology, anaesthetics, radiology, and the history of medicine.

Issued monthly; annual subscription £4 4s., single copy 8s. 6d.; a specimen will be sent free on request.

The above journals and *Abstracts of World Medicine* are obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Applications should be made first to the institution concerned.

Monday, May 25

EDINBURGH UNIVERSITY.—At University New Buildings, 5 p.m., Dr. Douglas Guthrie: Witchcraft and Witch-Doctors.
ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Dr. Irving S. Wright: Observations in Peripheral Vascular Disease.

Tuesday, May 26

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. D. I. Williams: Erythrodermia.
●INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Chelsea Hospital for Women, 4.30 p.m., Dr. A. H. Harkness: Non-specific Infections in Male and Female.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—3.45 p.m., Imperial Cancer Research Fund Lecture by Professor G. Hadfield: Hormones and Human Breast Cancer.
ROYAL EYE HOSPITAL.—5 p.m., Mr. T. M. Tyrrell: Traumatic Surgery of the Eye and Adnexa.
WRIGHT-FLEMING INSTITUTE OF MICROBIOLOGY, St. Mary's Hospital Medical School.—5 p.m., Almroth Wright Lecture by Professor C. L. Oakley: Site of Production of Antibodies.

Wednesday, May 27

EUGENICS SOCIETY.—At Royal Society, 5.30 p.m., Professor D. Baird and Miss E. M. Scott, M.A.: Intelligence and Childbearing.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Clefts, Vesicles, and Bullae.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Brigadier J. S. K. Boyd, F.R.S.: Phage Typing in Epidemiological Investigation.
ROYAL EYE HOSPITAL.—5.30 p.m., Mr. L. H. Savin: Ophthalmic Neurology.

Thursday, May 28

EDINBURGH UNIVERSITY.—At University New Buildings, 5 p.m., Dr. Douglas Guthrie: Ancient Drugs and Modern Remedies.
EPSOM AND SUTTON INTER-HOSPITAL PSYCHIATRIC ASSOCIATION.—At Belmont Hospital, Sutton, 8 p.m., Dr. A. S. Thorley and Dr. W. W. Kay: Prolonged Deep Coma; Dr. L. Minski: Legislation and the Aggressive Psychopath; Dr. C. C. Evans: Recent Advances in Electro-encephalography.
●HAMPSHIRE GENERAL HOSPITAL.—3 p.m., Dr. Una C. Ledingham: Common Mistakes in General Practice; 4.15 p.m., Mr. J. C. R. Hindenach: Pain in Shoulder and Arm.
INSTITUTE OF CHILD HEALTH.—5 p.m., Professor S. van Creveld (Amsterdam): Clinical Significance of New Clotting Factors.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. I. W. Whimster: Developmental Anomalies, Hyperplasias, and Tumours of Neuro-ectodermal Derivatives in the Skin.

NUFFIELD ORTHOPAEDIC CENTRE, Wingfield-Morris Orthopaedic Hospital.—8.30 p.m., Dr. A. X. Cavadias: The Vasculature of Bone and the Healing of Fractures: An Experimental Study.
●POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Professor R. V. Christie: Chronic Bronchitis and its Complications.
ROYAL EYE HOSPITAL.—5.30 p.m., Miss M. Savory: Ocular Tumours.
ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Professor Z. M. Bacq (Belgium): Chemical Protection against Ionizing Radiation; Therapy of Radiation Sickness.

Friday, May 29

INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. G. B. Dowling, Dr. P. D. Samman, and Dr. J. E. M. Wigley.
INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—3.30 p.m., discussion for general practitioners by Mr. W. S. McKenzie: Indications for Tonsillectomy.
LEEDS REGIONAL PSYCHIATRIC ASSOCIATION.—At Oulton Hall, near Wakefield, 3 p.m., Dr. J. Valentine: Plans for Mental Health in the Region.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Professor C. F. W. Illingworth: Bleeding Peptic Ulcer.
●POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. Patricia Benedict (Boston): Amenorrhoea, Types and Diagnosis.
ROYAL EYE HOSPITAL.—5.30 p.m., Professor C. A. Keel: Local Anaesthetics.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Obstetric and Gynaecological Conference on Puerperal Infection. Speakers, Dr. Melvin Ramsay and Professor Robert Cruickshank.

APPOINTMENTS

DAVIES, D. J., M.B.E., M.D., D.P.H., County Medical Officer of Health and School Medical Officer, Pembrokeshire.
FRANCIS SYDNEY GRAHAM MCKENZIE, M.B., Ch.B., Medical Superintendent, Royal Infirmary, Edinburgh.
FORSTER, ALBERT, M.B., B.S., D.P.H., Medical Officer of Health, Chester-le-Street Urban and Rural District Councils; Area Medical Officer, Durham County Council.
SOUTH-WESTERN REGIONAL HOSPITAL BOARD.—L. S. A. Boothroyd, M.B., B.S., F.R.C.S., Surgical Registrar, Taunton and Somerset Hospital; A. G. Moffoot, M.B., Ch.B., F.R.C.S., Surgical Registrar, Royal Cornwall Infirmary, Truro; R. R. Knowles, M.B., B.S., D.P.M. (Part I), Registrar in Psychiatry to South-western Region (Bristol Mental Hospitals); E. W. Hughes, M.D., M.R.C.P., Resident Physician, Trehid Chest Hospital, Camborne, Cornwall; J. M. Large, M.B., Ch.B., F.R.C.S.Ed., Senior Surgical Registrar to Thoracic Unit at Hawke Moor Chest Hospital, Bovey Tracey, Devon; L. S. A. Boothroyd, M.B., B.S., F.R.C.S., Senior Surgical Registrar, Exeter Clinical Area.
THOMAS, D. VERNON, B.Sc., M.B., B.Ch., D.A., Deputy Director of Anaesthesia, Strong Memorial Hospital, and Associate Professor of Anaesthesia, University of Rochester School of Medicine, Rochester, New York.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Crawford.—On May 9, 1953, at the Jessop Hospital for Women, Sheffield, to Dr. Barbara (formerly Moore), wife of Dr. Colin K. Crawford, a son.
Hotchkis.—On May 13, 1953, at Aberfeldy Cottage Hospital, Perthshire, to Jean, M.B., Ch.B. (formerly Smout), wife of Alistair Hotchkis, Balgowan, Pitlochry, Perthshire, a daughter.
Price.—On April 24, 1953, at The London Hospital, London, E., to Vina, wife of Dr. J. L. Price, a daughter—Susan Vina.
Stewart.—On May 11, 1953, at Beech Hill Nursing Home, Barnstaple, Devon, to Eunice, M.B.E., wife of P. B. Stewart, D.F.C., M.B., M.R.C.P., a son.

MARRIAGES

Moos—Jungalwalla.—On May 22, 1953, at Kensington, London, W., Jamshed Sorab Moos, M.D., M.R.C.P., to Perin Kaikobad Jungalwalla, M.B., B.S., D.T.M.&H.
Turner—Dence.—On May 9, 1953, at Tunbridge Wells, Kent, Winston M. L. Turner, M.D., M.R.C.P., to Helen M. Dence, M.R.C.S., L.R.C.P.

DEATHS

Cook.—On April 15, 1953, at Lyme Regis Hospital, Dorset, Philip Nield Cook, M.B., B.S.
Eadham.—On March 30, 1953, Joseph Eli Ellison Eadham, M.B., F.R.C.S.Ed., of Sleaford, Lincs.
Fell.—On April 19, 1953, at St. Mary's, Colchester, Essex, Alfred Nolan Fell, M.D., aged 75.
Hall.—On March 30, 1953, at 4, Shooters Hill Road, Blackheath, London, S.E., Sydney Octavius Hall, L.R.C.P.&S.Ed., L.R.F.P.S., Lieutenant-Colonel, R.A.M.C., retired.
Haslett.—On April 11, 1953, at Brookmeadow, Budleigh Salterton, Devon, Robert Woods Haslett, M.B., F.R.C.S.I.
Kent.—On March 30, 1953, at 3, Park Court, Barry, Glam, Percy Wheeler Kent, M.R.C.S., L.R.C.P., D.P.H.
Lee.—On March 29, 1953, John Robert Lee, O.B.E., M.D., F.R.C.S., of 39, Harley Street, London, W., late of Melbourne, Australia, aged 79.
Lund.—On March 24, 1953, at Cowper Cottage, Mundesley, Norfolk, Kenneth Fraser Lund, M.B., aged 82.
Massingham.—On March 31, 1953, at Lilac Cottage, Biddenden, Kent, Richard Massingham, M.R.C.S., L.R.C.P.
Metcalf.—On April 2, 1953, at Moor Lane, Sherburn-in-Elmet, Yorks, George Frederick Metcalf, L.M.S.S.A., aged 45.
Moorhead.—On March 21, 1953, at Truro, Cornwall, Robert Leishman Moorhead, M.B., C.M., of Birch Green, Haywards, Sussex.
Morris.—On April 17, 1953, Dennis Morris, M.R.C.S., L.R.C.P., of 671, Romford Road, London, E., and Bedford, aged 27.
Robinson.—On March 29, 1953, at Whitley Bay Rest Home, 4, Camp Terrace, North Shields, Amy Robinson, M.D., aged 73.
Simpson.—On February 18, 1953, in a nursing-home, Reading, Berks, Lilian Gertrude Simpson, L.R.C.P.&S.Ed., L.R.F.P.S.
Soden.—On March 31, 1953, at The Little House, Ditchling, Sussex, Wilfred Newell Soden, M.C., M.D.
Stocks.—On March 24, 1953, at Ash Lea, Silverdale, Carnforth, Lancs, William Percy Stocks, F.R.C.S., formerly of Withington, aged 89.
Tandy.—On March 24, 1953, at 128, Shorncliffe Road, Folkestone, Kent, Oswald Cornwallis Stratford Tandy, M.B., Ch.B., D.P.H., aged 67.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Swine Erysipelas in Man

Q.—Can swine erysipelas infect man? What treatment is advised?

A.—The human equivalent of swine erysipelas is fairly common in butchers and others who handle material from infected animals. It is known as "erysipeloid," the name given to it by Rosenbach, although it was described and named "erythema serpens" by Morrant Baker many years earlier. The lesion is almost invariably on a finger or the hand, and resembles streptococcal erysipelas only in the fact that the skin is raised, indurated, and reddened. The colour differs, that of erysipeloid being a darker bluish-red, and extension proceeds much more slowly. The affected skin has a smooth shiny surface, and, owing to its thickening, the edge of the lesion is raised above the level of the surrounding skin. It produces a burning sensation with pronounced itching. If untreated, the disease may extend considerably and persist for weeks. It is rarely serious, but a complicating endocarditis, as in the pig, has been recorded, and arthritis is also said to occur. Isolation of the causative organism is difficult unless tissue is excised for cultivation, but those familiar with the disease have no difficulty in diagnosing it on clinical grounds. *Erysipelothrix rhusiopathiae*, the causative organism, is highly sensitive to penicillin, the administration of which is curative.

When to Operate on Internal Haemorrhoids

Q.—What are the indications for operation in cases of internal haemorrhoids? A patient has had three injections and still bleeds from her piles. What is advised?

A.—In cases of internal haemorrhoids prolapse is the chief indication for operation; continued bleeding at stool, despite adequate injection treatment, will also necessitate operation.

Most patients who are troubled only by bleeding are relieved by submucous injections of 5% phenol in almond oil. If, however, at the initial examination there is tendency to prolapse (i.e., the rectal mucosa can be made to appear by either drawing the perianal skin outwards or getting the patient to strain down), relief is likely to be only temporary. In cases with prolapse the longitudinal muscle of the rectum is stretched, and the submucous fibrosis produced by injection cannot correct this, although it may relieve bleeding.

In the case in question it is important to be sure that the blood is coming from the haemorrhoids. Presumably a preliminary sigmoidoscopy was done. This should be a routine investigation in all such cases. If there is any doubt about the source of the bleeding sigmoidoscopy should be repeated, and, if necessary, followed by a barium enema examination. If there is no doubt about the diagnosis, then it may be that the injections have not been adequate. Apart from actual relief of symptoms, a satisfactory injection result is indicated by palpable induration at the site of injection, as well as difficulty both in inserting the needle into the submucous space and in injecting more phenol, when the patient is re-examined after a fortnight. In the absence of such findings further injection must be considered. In the textbooks it is frequently stated that 1 to 3 ml. should be injected above the site of each haemorrhoid; but in practice it is common for the expert proctologist to use as much as 10 ml. at a time at each site. Most authorities would agree, however, that it is unwise

to inject more than 20 ml. in all at any one session. If thorough injection fails, then operation may be necessary.

Oestrogens and Vasomotor Rhinitis

Q.—Are oestrogens effective in cases of vasomotor rhinitis? A patient whom I have been treating for menopausal symptoms with dienoestrol has been completely relieved of long-standing severe nasal congestion.

A.—I know of no evidence that oestrogens have proved effective in the treatment of vasomotor rhinitis. Indeed, one would suspect that, theoretically, they should exaggerate the condition. Like other steroid hormones, such as deoxycortone, they lead to retention of water and salt. This is especially noticeable in connexion with the "sexual skin" (of the vulva and perineum) of monkeys, which becomes markedly oedematous during the oestrus phase of the ovarian cycle. Oestrogens have been employed, and in some instances success has been claimed, in the treatment of atrophic rhinitis. Here it is argued that the nasal mucosa may be a female secondary sex organ—hence epistaxis as a sign of "vicarious menstruation"—and that the atrophic nasal mucosa may resemble the post-menopausal atrophic vaginal mucosa, which can be stimulated by oestrogens to show proliferative changes. Vasomotor rhinitis is often an allergic manifestation, and there is evidence that it responds to A.C.T.H. or cortisone therapy.

Food Value of Ice-cream

Q.—What is the composition and food value of the commoner forms of ice-cream sold in this country?

A.—Ice-cream considered as typical in the technical literature is said to contain 3.8 g. of protein, 12.6 g. of fat, and 19.6 g. of carbohydrate per 100 g. of the moist material, which adds up to a total of 207 calories. A typical commercial mix in the dry state could be made up with 40% of full cream dried milk, 45% of fat and sugar combined, 10% of soya flour, and 5% of various "food additives," such as glyceryl monostearate and the seaweed products agar and sodium alginate. The "food additives" are needed to make the ice-cream smooth and stable; by applying them skilfully it is possible to make a saleable product with a low percentage of fat, which is the most expensive constituent. Ice-cream made from dried milk and containing a good proportion of fat is certainly a highly nourishing form of food. Its use can be criticized only when its purchase uses up money which would otherwise be devoted to buying milk or other cheaper dairy products. In ice-cream of poor quality additional cereal products, such as wheat-flour and oat-flour, are sometimes included in place of the dried milk, which reduce the nutritive value of the product as a source of animal protein. Water ices, made of flavoured fruit juice, or artificial substitutes, have practically no nutritive value, but they are readily distinguishable from ice-cream. Some proprietary forms of ice-cream give a frothy fluid on melting, which suggests that the mixture is whipped up with air to give as much bulk as possible in the frozen state.

Aedes Albopictus and Yellow Fever

Q.—Is *Aedes albopictus* a potential vector of yellow fever? Has it been found naturally infected, or has it been only artificially infected under laboratory conditions?

A.—*Aedes albopictus* may be classed as a potential vector of yellow fever because, in addition to a number of other culicine mosquitoes, it has been proved to be capable of transmitting the virus by its bite. The evidence, however, is from laboratory experiments, not from the discovery of natural infections. In 1929, Dinger, Schüffner, Snijders, and Swellengrebel obtained *A. albopictus* from Java, and in their laboratory at Amsterdam were able to transmit yellow fever virus from monkey to monkey by the bite of this

mosquito.¹ More recently (in 1943) Schüffner² repeated the transmission and noticed that the virus became attenuated when passed by *A. albopictus*, so that mortality among the infected monkeys dropped from 100 to 20%.

Epidural Analgesia

Q.—What are the principal indications for sacral epidural analgesia?

A.—Sacral epidural injections of local analgesics are made for three main reasons. First, the procedure is carried out to produce analgesia for operations on the perineum or in the pelvis, although there is no reason why, if sufficient local analgesic is injected, the operation should not be anywhere in the body below the first cervical nerve root. Epidural analgesia is held to have advantages over spinal analgesia in that the risk of subarachnoid infection is eliminated, there is said to be less sympathetic paralysis and therefore circulatory upset, and there is a negligible incidence of neurological complications like headache. Apart from these considerations, the method can be considered similar in its effects and indications to that of spinal anaesthesia.

Secondly, the method is used, in the United States in particular, to provide analgesia during childbirth. The possibility of certain complications like extradural infection, broken needles, or inadvertent subarachnoid injection, and a very high forceps rate from the obstetrics point of view, as well as the need for sufficient personnel to supervise the administration, have together militated against its popularity in this country.

Thirdly, sacral epidural injection of certain long-acting analgesic solutions like "proctocaine" is used to abolish or diminish pain in pelvic carcinomatosis. A less common reason for doing this block is as an alternative to lumbar sympathetic block whether for diagnostic or therapeutic purposes.

Tuberculin Testing in the Presence of Active Disease

Q.—Are there any grounds for the belief that tuberculin testing may cause a severe exacerbation if active tuberculous disease is present? Should testing be avoided if there is strong suspicion of infection?

A.—There is no danger in any of the standard methods of tuberculin testing. The dose of tuberculin that is used in skin-testing is only a fraction of the amount that would be required to produce a general reaction. The usual procedure if there is a strong suspicion of infection is to test first with a Mantoux 1 tuberculin unit (1/10,000) and only to use stronger tests when this has proved negative.

Repellents for Wasps and Bees

Q.—Is there any effective wasp and bee repellent for use by persons hypersensitive to their stings?

A.—Many attempts have been made to discover repellents that would be effective against wasps and bees, but so far without success. Dimethyl phthalate, which has proved so successful against mosquitoes and other biting flies, is not effective as a bee repellent.

NOTES AND COMMENTS

Aspermia.—Mr. R. H. BOYD (London, W.C.1) writes: In "Any Questions?" (May 2, p. 1005) there is an able summary of the investigation and treatment of a case of azoospermia in answer to a question on aspermia, which is absence of semen and not absence of spermatozoa. This is a common mistake even among experts. Aspermia does occur, but is the finding in under 0.1% of males, whereas azoospermia is found in 7%. Aspermia

may be due to absence, or inflammatory obliteration, of the seminal vesicles; to retrograde ejaculation into the bladder; or the non-emission may be the result of sympathectomy for hypertension—potency not being affected; etc. In all probability, however, the question does really refer to azoospermia. Bayle is quoted as an opponent of testicular biopsy on account of blockage of the vasa efferentia by haemorrhage. In a large series of bilateral biopsies on cases of oligozoospermia there has not been one instance of this. And, indeed, biopsy is the most useful accepted method of investigation. It is not needed in cases of bilateral gonococcal epididymitis, where spermatogenesis can be safely assumed. In this group the success rate from epididymovasostomy is indeed high, approaching Bayle's 66%, but in no other cause group can these figures be reached. The operation is worth doing, but the patient must expect little more than a 10% or at most 20% chance of cure.

OUR EXPERT writes: As Mr. Boyd suggests, experts do indeed differ. I certainly would not agree to his definition of aspermia as the absence of semen. For this the term "seminal anorrhoea" or, more simply and better still, "failure of ejaculation" should be used. A distinction is sometimes, though I think not altogether necessarily, drawn between aspermia (implying the total absence of elements derived from the germinal epithelium) and azoospermia (meaning the absence of mature spermatozoa). I have no strong views on the danger of testicular biopsy, but merely quoted the point that Bayle raises. I agree that the likelihood of efferential blockage resulting must be small. I would further point out that Bayle's 66% success rate is in *surgically suitable cases only*, most of which—as Mr. Boyd says—have a gonococcal aetiology. In point of fact, suitability for surgery can be determined only at the time of operation.

Allergy to Condoms.—Mr. L. LANDAU (director, London Rubber Company, Ltd.) writes: I note with interest your answer to a question under the heading "Allergy to Condoms" ("Any Questions?" May 2, p. 1006). I have in the past investigated a considerable number of similar cases, and agree with you that in this particular case we are dealing with sensitivity to rubber. I am, however, of the opinion that this developed sensitivity is not due to any of the chemicals used but to the rubber itself. Chemicals used in the manufacture of rubber protectives—namely, vulcanizing agents, accelerators, antioxidants, stabilizers, and dusting powders—are quite harmless, and I have so far not seen a single case where a patch test carried out with any of these materials resulted in a positive reaction. Occasionally, however, minute traces of alkaline substances, potassium carbonate or triethanolamine, may be left in the rubber and result in irritation. These substances, however, produce an unmistakable soda dermatitis, an effect different from that described by your correspondent.

OUR EXPERT writes: Mr. Landau's experience is completely contrary to my own and, indeed, to all the recorded cases that I know of. The rubber dermatitis that occurred from contact with respirators during the recent war was almost, if not quite invariably, due to the chemical processing of the rubber rather than to the rubber itself. It was regularly remedied by an official arrangement of providing a different type of respirator in such cases. Quite recently a case where rubber sensitivity was due to benzothiazole has been recorded.¹ I think Mr. Landau will also find upon inquiry that dermatitis in rubber workers, as distinct from rubber users, is also due not to rubber but to chemicals used in processing.

FACTS AND FANCIES ABOUT CANCER OF THE LUNG*

BY

D. W. SMITHERS, M.D., F.R.C.P., D.M.R.

Director of the Radiotherapy Department, Royal Cancer Hospital; Radiotherapist, Brompton Hospital for Diseases of the Chest

The startling rise in the recorded death rate from cancer of the lung and the implication of one of our favourite indulgences as chief culprit have suddenly made this a matter of public interest, which is no doubt the reason why this topic was selected for me. It is perhaps as well to remind ourselves, however, that the rise in the recorded death rate which is causing so much public concern to-day was already well established before the first world war, though it was only after it was over that the dramatic increase occurred. Even if we go back to King and Newsholme in 1893, we see that they were then maintaining that the registered increase in cancer deaths was due to improved diagnosis and better death certification. Adler in 1912, in his famous monograph, attacked the current opinion that malignant neoplasm of the lung was rare and maintained that this was a common disease which a physician might meet "any day in his practice amongst the young as well as amongst the old."

Doctors in England and Wales by 1949 were writing "cancer of the lung" on death certificates 25 times more often than they had been doing in 1912. There is no doubt to-day that the lung is one of the commonest sites in the human body for primary as well as for secondary malignant disease. The work that has been done in recent years makes it clear that some real increase in lung cancer has occurred in many parts of the world. What is not at all clear at present is the extent of that increase.

Much of the recorded rise can be accounted for. The number of persons living in England and Wales has gone up by 7½ millions in the past 40 years, and the age distribution has so changed that 21 persons in every 100 alive to-day are over 55 years of age, while only 12 persons in every 100 were over 55 then. The number of doctors resident in this country has also increased in this period from 25,000 to 48,000, which is a change from about 1,400 persons per doctor to about 900. The recorded death rate from cancer as a whole has been increasing over the years, and although the lung has shown the most spectacular rise it has not been alone in this. Death rates from cancer of all sites taken together are steeply graded with increasing urbanization (Stocks, 1947), and they vary directly with the number of doctors per 100,000 people (Green, 1926). If you take the recorded

*A shortened version of a B.M.A. Lecture delivered in Manchester on November 14, 1952. Much of the first part dealing with incidence, predisposing factors, and post-mortem records has been omitted, as these aspects of the subject have since been dealt with far more comprehensively, if with some differences in emphasis, by Dr. Richard Doll in his Milroy Lectures, 1953, to be published shortly.

death rate from lung cancer per million persons living, by age and sex, and plot this on a logarithmic scale, you will see that the curve for each age group has almost the same overall slope, showing that the proportionate increase in death rates has been much the same at all ages (Stocks and MacKay, 1946). The rise has been recorded predominantly in men over 45 years of age, being most pronounced in those dying between the ages of 55 and 74, the age group which already had the largest death rate.

The sudden interest in this subject and the recent accumulation of many new facts has led to a fine display of fancy. The different fancies that people have about the same facts usually depend on their training and outlook. What the clinician so readily attributes to his diagnostic skill the research worker is apt to believe may well be due to the action of a specific carcinogen. Both need to take particular notice of the way their natural bias is apt to lead them and to remember their responsibility to an anxious and ill-informed public when they publish their views on serious problems of fatal disease.

Diagnosis

We are well aware that a revolutionary improvement has taken place in the diagnosis of lung cancer. It would be a most extraordinary thing if the rise in the recorded death rate which has accompanied this had no relation to it at all. The symptoms of bronchial carcinoma are common and non-specific. Doctors in practice inside and outside hospitals see large numbers of patients who complain of cough, many with dyspnoea, a number with haemoptysis, and not a few with pain in the chest. Many of these patients are past their first youth, but only a few have bronchial carcinomas.

In the same year that Röntgen discovered x rays, Killian used an instrument to remove a piece of bone from a bronchus, and in 1898 first wrote about his method of direct bronchoscopy. This was demonstrated in England in 1902. It was in 1917, when Chevalier Jackson first removed a tumour bronchoscopically, that the importance of this procedure as a means of diagnosis of bronchial neoplasms was recognized, but it was not until the 1930s that bronchoscopy became a common form of examination even in special chest hospitals. Bronchoscopies were performed at the Brompton Hospital in the 1920s by Sir James Dundas Grant, with the patient sitting in a special chair in the ear, nose, and throat room, but a search of the operating theatre records reveals only one bronchoscopy done there by the

surgeons between 1908 and 1925. In the next four years there were 29, and in 1930, 28; while the number to-day is over 800 per annum, or an average of nearly three in every full working day.

Improvement in the treatment of patients with chest infections has permitted more of them to recover from the pneumonia which may be associated with a bronchial carcinoma, and has also led to a change of thinking on the part of doctors who see patients with pneumonia who have failed to respond to treatment. The immense increase in diagnostic radiological examination of the chest has been another no less important factor in the diagnosis of bronchial tumours in the period since the 1914-18 war. The most rapid increase in registration of lung cancer deaths did not, in fact, occur until the modern facilities for diagnosis of this disease became generally available. Even to-day, however, the accuracy of the diagnosis of bronchial carcinoma in the country as a whole and the reliability of death certification from this cause must still be under grave suspicion.

In 3,280 cases of lung cancer registered from 46 centres in England and Wales during 1945 and 1946 (Stocks, 1950) only 11% had had post-mortem confirmation of the diagnosis and only 38% of the total had had any histological examination. The difficulties of diagnosis are considerable. Even with post-mortem examination mistakes can be made. We have found four cases in the past few years in which the post-mortem examination was in error, and three others in which the death certificates differed from the post-mortem findings.

In two of the first four cases, one was said to have had a primary carcinoma of the kidney and the other of the pancreas, both with widespread metastases. When we received these death certificates, in accordance with the usual practice of the joint consultation clinic for neoplastic disease of the Brompton Hospital and Royal Cancer Hospital, we sent a copy of our notes to the pathologists concerned to ask if there was any evidence that the primary might have been in a bronchus as suspected by us during life. In both these cases further examination of the slides induced the pathologist to change his diagnosis to primary bronchial carcinoma. In the second two cases a diagnosis of non-malignant disease of the bronchi was made; in one of these, further sections were cut at our request nearer to the bronchial wall and the presence of a carcinoma was confirmed; and in the other—a coroner's post-mortem examination following a street accident—the fact that the patient had a completely collapsed and contracted left upper lobe was not noticed by the pathologist and no piece was removed for examination from the tumour site (from which we had already obtained a positive section).

In the other three cases the diagnosis was made at post-mortem examination, but incorrect death certificates were signed beforehand by doctors who did not know the whole story, and these still remain as the official record at Somerset House. One was certified as dying of pulmonary tuberculosis, when, in fact, a carcinoma of the bronchus was present; another of carcinoma of the bronchus, although this diagnosis had been rejected during life and careful search at necropsy revealed only bronchiectasis in the lungs with no sign of recurrence of an old carcinoma of the rectum excised some years before; and the third of carcinoma of the bronchus, although multiple metastases from a primary carcinoma of the common bile duct was the diagnosis reached by the pathologist who performed the post-mortem examination.

An analysis of differences between the diagnoses made in hospital and those put on death certificates is interesting. Those patients who died in our hospitals naturally had death certificates in accordance with our diagnosis, and all those who died elsewhere had at one time or another had a letter giving our diagnosis sent to their doctors. In

respect of agreement between clinical diagnosis and death certification, therefore, ours is a specially selected group in which close agreement should be expected. A number of differences still occurred, however (Table I).

TABLE I.—Analysis of Differences between Diagnoses on 591 Death Certificates and Those Made at the Brompton Hospital and Royal Cancer Hospital Joint Consultation Clinic, 1944-50

1. Diagnosis of Bronchial Carcinoma Accepted at the Clinic			
	Death Certified for Some Non-malignant Disease	Death Certified for Some Other Malignant Disease	No. of Death Certificates Examined
(a) With histological confirmation	5	12*	330
(b) Without histological confirmation	5	7†	224
Total	10	19	554

2. Diagnosis of Bronchial Carcinoma Rejected at the Clinic, Death Certified as Bronchial Carcinoma

Reasons for Rejection			No. of Death Certificates Examined
Insufficient Evidence of Primary Site	Diagnosis of Tumour of Some Other Site Established	Diagnosis of Some Non-malignant Disease Accepted	
12	3‡	6	37

* Four were certified as dying with metastases from unknown primary site, 3 (all with recurrent laryngeal palsy) as dying from cancer of the larynx, 2 as mediastinal tumour, and one each as cancer of the liver, rectum, and pancreas.

† Four were certified as dying from mediastinal tumour, one as metastases from unknown primary site, and one each as larynx and bone primary tumours.

‡ One had a carcinoma of the breast and one a carcinoma of the bile duct, both with lung metastases, and the third a disseminated reticulum-cell sarcoma.

Prior to the 1914-18 war it was unusual for a diagnosis of bronchial carcinoma to be made before death. Nearly all the cases reported came from the post-mortem room records. Only 6 of Sehr's 178 cases collected in 1904 had been diagnosed correctly during life. Ferenczy and Matolcsy (1927) found only 2 out of 40 (5%) diagnosed during life from 1896 to 1900, 18 out of 80 (22.5%) from 1907 to 1916, and 44 out of 150 (29.3%) from 1917 to 1925. In 84 post-mortem examinations of patients with lung-cancer made in a large hospital with a thoracic unit, Willis (quoted by Kennaway and Kennaway, 1947) found that the diagnosis made before death had been wrong in 35, or 42%. In Denmark—where the post-mortem examination rate is higher than in most other countries—Clemmensen and Busk (1947) found that of 564 patients recorded as dying of lung cancer there had been a post-mortem examination in 47%, the clinical diagnosis of lung cancer before death in this group being regarded as certain in 37%, uncertain in 26%, unknown in 15%, and not given in 22%. Even in 1952 McConnell, Gordon, and Jones, collecting 100 patients with lung cancer for a study of their smoking habits, had to reject 24 of their original cases because of proved errors in diagnosis in 11 and suspected errors in 13.

At our joint consultation clinic we had 821 patients referred to us with a diagnosis of lung cancer from 1944 to 1950. All these patients had already been seen by specialists in thoracic disease and had undergone a thorough investigation—including x-ray examination in all cases, bronchoscopy in most, and thoracotomy in some—and yet we have so far rejected the diagnosis in no fewer than 95 (8.6%) of them, and will probably reject it in more as the result of the repeated review of the evidence on which each patient's diagnosis rests which we make in the light of what happens over the years. If the 112 patients with this diagnosis seen during the same period at the Royal Cancer Hospital but not at the joint clinic are added, the number in which the diagnosis has been rejected is raised to 115.

From the large pool of patients dying with symptoms common to many chronic lung and heart disorders, an increasing number are being labelled "lung cancer" on a decreasing post-mortem examination rate for the total, despite a rising post-mortem rate for those dying in many hospitals. There is a wide variation in the degree of uncertainty with which this diagnosis is made. Death from respiratory disorders is comparatively common, from lung cancer comparatively rare. Without taking any account of patients dying from cardiac disease with similar symptoms there would still have been little difficulty in losing our entire present lung cancer death rate in the general death rate from respiratory disease in the past if these cases were really there to lose (see Chart).

Treatment

Your view of the effect of treatment on patients with lung cancer depends (like most things in life) on the way you look at it. If you see over 13,000 deaths in 1951 on a steeply rising curve, and estimate that probably fewer than 250 pneumonectomies for lung cancer were performed in that year, that it is unlikely that more than 1,000 radical courses of x-ray treatment were given for this disease, and that the five year survival rate for the whole group is likely to be no more than a fraction of 1%, you may well feel hopeless about the situation. If you see an extremely difficult problem both in early diagnosis and in treatment in an often rapidly fatal disease which is at last being tackled with some success, you may take a more optimistic view. The fact is that at present we offer no effective treatment at all to most patients with lung cancer. Mackenzie (1939) estimated that 95% were not treated; and Tod (1949), ten years later, found that 87% of patients registered with lung cancer in Bradford were still receiving no treatment. In our special group of 818 patients with a diagnosis of lung cancer accepted who were sent to us for treatment in hospital from 1944 to 1950, we judged that we could do nothing helpful with surgery or radiotherapy for 24%, despite our anxiety to try at least to relieve symptoms whenever possible, and in only 28% was it possible for us to make an attempt at radical treatment by surgery or x rays.

It was, however, 20 years ago this April that Evarts Graham, starting to do a lobectomy on a 48-year-old doctor and finding no satisfactory interlobar fissure, boldly did the first successful pneumonectomy for bronchial carcinoma. This patient is, I believe, still working as an obstetrician in Pittsburg, and there are hundreds of patients who have followed this one. Nevertheless, it is still unfortunately most difficult to find out what surgery really has to offer, since the standard of recording the results of treatment in patients with cancer is so deplorably low. Despite the large numbers involved it is hard to find papers which provide information on the subsequent history of which groups of patients with bronchial carcinoma, which include all those seen at one hospital over a period of years, which say how these patients were selected, and which express the survival of those treated surgically in terms

of the group as a whole. I know of no such report in this country. There nearly always seems to be some important piece of information missing.

Ochsner, DeCamp, DeBailey, and Ray (1952) give a full account of 308 patients with lung cancer observed for more than five years after treatment. They do not say over what period these patients were seen, but we may presume that none were omitted. In this group 32% were resected and 6% lived five years (19% of those resected). No patient lived five years without resection. The percentage of patients who are suitable for resection when first seen varies greatly from hospital to hospital, according to the way the patients are selected. Whereas with Ochsner *et al.*, for instance, 35% were resected, at the Brompton Hospital in 1951 this was possible only in 18% of the total of 256 new patients with bronchial carcinoma seen in that year. The survival rates at five years for those resected vary around the 20% mark, but the rate in terms of all the new patients seen in hospitals is a great deal lower, and in

Crude annual death rates for cancer of respiratory system compared with similar rates for all other respiratory diseases (1921-49). (Taken from the Registrar-General's Statistical Reviews of England and Wales.) Since 1940, when multiple causes were certified, deaths have been assigned to the cause selected by the certifying doctor instead of by arbitrary rule.

terms of the recorded death rate for the whole country is still pathetically small.

Mass miniature radiography may bring a few more patients to hospitals in the early stage. Overholt (1950) has been enthusiastic about its possibilities, and has reported 145 patients in whom lung shadows were detected; of these, 51 were due to tumours, 35 of which were malignant. He believes that no more than 10% of patients with lung cancer are operable by the time symptoms appear, and that mass surveys may offer many the chance of operation in the silent phase and so set treatment ahead by months or years.

All patients with lesions discovered on survey and sent promptly for treatment have been resectable in his clinic, and 75% have shown no signs of lymphatic spread. It would be interesting to know how many pneumonectomies were performed for patients with asymptomatic non-malignant conditions and what happened to them afterwards. Overholt does say that of one group of 12 patients explored four were found not to have lung cancer. We have not been fortunate with our few cases found by surveys. Most have volunteered for examination because they were already worried about their chest, and the delay in reaching hospital for treatment when something abnormal was shown usually destroyed what value the examination might have had. Only 5 out of 27 sent as the result of surveys had been

symptom-free when x-rayed, and the average delay in receiving treatment after the radiograph had been taken was more than four months.

Radiotherapy is frequently said to have little effect on survival. That patients have survived for many years following radiotherapy for proved lung cancer is established; that this is a rare occurrence and that a few patients survive for these long periods untreated is also true. With many errors in diagnosis the claims of a few successes cannot be accepted without the most rigorous inquiry. From the point of view of survival following treatment most publications on the value of radiotherapy are therefore quite useless. When the few operable cases are taken away there is not much left for the radiotherapist to treat which presents him with even a reasonable chance of success. When we rightly doubt the diagnosis as soon as one of our patients lives for a year or more and reject all those which do not seem certain, no very impressive survival rate is to be expected. It is possible that pre-operative x-ray treatment (a trial of which I have advocated for some years, and which I have suggested might at least be given while the patient is on the waiting-list for a surgical bed) may have some value in increasing the resectability rate and reducing the risk of metastasis. We have treated too few this way to have learnt much, but the results in our small group are set out in Table II. An examination of the lungs in

TABLE II.—Patients with Bronchial Carcinoma Treated with Pre-operative Irradiation and Pneumectomy

Age	Sex	Radiotherapy: Date Treatment Finished and Dose Given	No. of Days Before Pneumectomy	Subsequent History	Length of Survival Since First Treatment
45	M	December, 1947. 5,800 r in 36 days	68	Alive and well September, 1952	4 years and 10 months
26*	F	March, 1949. 6,000 r in 44 days	112	Alive and well November, 1952	3 years and 8 months
33	M	November, 1949. 6,300 r in 41 days	72	Died May 16, 1950	6 months, died
59	M	March, 1950. 2,700 r in 19 days	8	Died October, 1950	7 months, died
52	M	March, 1950. 2,400 r in 26 days	22	Alive and well August, 1952	2 years and 5 months

* This patient had a positive section before treatment, but no residual tumour was found in the lung at operation.

these patients may also give us information, in time, about what might be expected from irradiation in the small favourable group at present treated surgically. Another possible extension of combined treatment is the implantation of radioactive gold grains at thoracotomy in patients found to have inoperable growths.

Survey of 933 Patients

Here is a brief account of what has happened to all the patients registered at the Royal Cancer Hospital from 1945 to 1950 who either came to hospital with a diagnosis of bronchial carcinoma or in whom such a diagnosis was later made. These patients have mostly been seen in the joint consultation clinic held with the Brompton Hospital (Brooks, Davidson, Price Thomas, Robson, and Smithers, 1951), and all those seen at this clinic from 1944 to 1950 are included. In this series there are 933 persons—521 with histological confirmation of the diagnosis accepted, 297 without histological confirmation but with the diagnosis accepted on clinical grounds subject to review, and 115 in whom the diagnosis has been rejected (in 11 despite positive pathological reports, Table III). There are therefore 818 patients with an accepted diagnosis of bronchial carcinoma. Only 35 of these were treated surgically, the low proportion (4%) being due to the fact that the main source of supply (726 patients) was through our reference clinic, which is for patients already judged unsuitable for surgery. Of these 35 surgical cases 10 were alive three years or more after treatment. A radical course of x-ray therapy was given to

TABLE III.—Eleven Patients with a Diagnosis of Bronchial Carcinoma Confirmed Histologically and then Rejected Clinically, 1944–50

Pathological Report Given On	Sex and Age	Pathological Reports	Reason for Rejecting Diagnosis
Piece obtained at bronchoscopy	M 38	Squamous-cell carcinoma	Living 8 years after radiotherapy. Section review doubtful
	M 54	Oat-cell carcinoma	Necropsy. Lung and brain abscesses only
	F 61	Undifferentiated carcinoma	Living 3½ years later with adenoma of bronchus
	F 58	Squamous-cell carcinoma	Operation revealed fibroma. First section found to have belonged to another patient
Piece removed with a drill	M 68	Oat-cell carcinoma	Living 4½ years after radiotherapy. Section review doubtful
Lymph node removed from neck	F 50	Squamous-cell carcinoma with pigment. Malignant melanoma. (Two pathologists)	Living 4½ years after radiotherapy to mediastinal mass; no further lymph node enlargement
Sputum	M 65	Squamous-cell carcinoma	Lived 3½ years after radiotherapy
	M 36	Oat-cell carcinoma	Necropsy. Hodgkin's disease
	M 36	Carcinoma cells	Living 4½ years after radiotherapy
	M 48	Oat-cell carcinoma	Living 2 years after small dose of x rays
	M 66	Clumps of carcinoma cells	Living 2½ years without treatment

192 patients, and 6 of these were alive three years or more after treatment (Table IV). The most interesting fact is perhaps the survival rate in the group where the diagnosis was rejected.

Really ill patients with bronchial carcinoma seldom benefit from radiotherapy—which may well add to their discomfort while prolonging their dying—but antibiotics may control infection and allow many more patients to be relieved of distressing symptoms by radiotherapy than was possible in the past. To my mind the relief of superior vena-caval obstruction or of haemoptysis and the appreciable lessening of cough, dyspnoea, or pain is well worth achieving. I hold the view that providing such relief is one of the most important functions of a doctor. Too many general practitioners, remembering the past, when irradiation sickness was a commonplace, local reactions were severe, and relief of symptoms was unusual and of short duration, seem to

TABLE IV.—Survival Times for 933 Patients Registered at the Royal Cancer Hospital in whom a Diagnosis of Cancer of the Lung was at One Time Made, 1944–50

821 Patients seen in the Joint Consultation Clinic with the Brompton Hospital, 1944–50, and 112 Patients seen at the Royal Cancer Hospital only, 1945–50.

Treatment	No. of Patients	Survived More Than			Remarks
		1 Year	2 Years	3 Years	
Surgical	35*	20	14	10	1 still living at 7 years. 1 still living at 6 years. 1 still living at 7 years
Radical x-ray therapy	192	66	17	6	
Palliative x-ray therapy	321	45	12	2	Mostly for the relief of one specific symptom only
Chemotherapy only	75	8	1	0	Some patients having x-ray treatment also had chemotherapy
Not treated	195	11	1	0	Mostly advanced cases with little prospect of symptomatic relief
Total	818	150	45	18	
Diagnosis rejected on review	115	50	28	24	One pneumonectomy, 3 lobectomies, 42 x-ray therapy, 3 chemotherapy, 66 not treated

* Five with pre-operative irradiation (two alive over three years); 12 with post-operative irradiation (all died under three years).

me to be far too ready to deny their less debilitated lung-cancer patients the benefits of the treatment which is available to them to-day. We have started an investigation in conjunction with the general practitioners who send patients to us, to try to assess how far the palliative treatment given has been worth while. We are anxious to know what quality of life these patients lead before death and how they die.

Surgery offers a real chance of cure to the fortunate few, but does not at present do more than begin to touch the fringe of the problem presented by the thousands of patients dying with lung cancer. Radiotherapy is shouldering the burden of treatment to an increasing degree, and is doing useful work in relieving suffering in a way which is not possible at present by any other means, and is still not sufficiently available to all who need it. Chemotherapy with the nitrogen mustards has so far, in my experience, added nothing to this group of patients to compensate for the general ill effects it has produced, let alone done anything to advance treatment.

Conclusions

The startling rise in the recorded death rate from lung cancer is in large part due to change in numbers and age of the population and to improved diagnosis. It is due in part to a real increase, but we are not yet in a position to say how great that real increase is.

The size and the difficulty of this problem are clear to us all. Although the five-year survival rate for the fortunate few who are operable when they first reach hospital has risen from nothing to between 20 and 30% in 20 years, and while much can be done with x-ray treatment to relieve suffering and sometimes prolong life for the less fortunate ones who are, nevertheless, still in fairly good general condition, there are still thousands of these patients each year for whom no real attempt at treatment is being made. Since we all have to die, since some 90,000 people are doing so each year with lung symptoms, and since this number is falling well, we should ask ourselves how far we are performing a useful service by helping to make a public issue of a comparatively small change within that group, which may be in large part due to our own method of recording. We should not be too readily swayed by those who demand that the public be told "the truth" while we are still attempting to sort the facts from the fancies for ourselves, especially since "the truth" when told may not appear to them in at all the same light as it does to us. Anthony Hope once wrote that "telling the truth to people who misunderstand you is generally promoting a falsehood."

The moment the word cancer is mentioned to the public (of which doctors are but a part) emotion is aroused and any calm objective view of the value of evidence presented becomes most difficult. It is important that the medical profession take note of this difficult problem of lung cancer and help to deal with it more efficiently, but it is also important that they do not make matters worse by merely joining in a cry and in-make the alarm. A sensible view of the relationship of smoking to this problem, for instance, should be and, after some wild comments in the lay and medical press, is now being presented to the general public; but no comparable effort seems to be going into an endeavour to persuade the authorities to cleanse the air of our industrial towns. As a profession which speaks so much and so rightly of the need to allay the cancer fear we should beware of putting extravagant accounts of rising cancer death rates and their causes before the public,

especially when neither the magnitude of the one nor the degree or responsibility of the other has yet been fully established.

I am greatly indebted to Sir Clement Price Thomas and Dr. Kenneth Robson, the other members of our joint consultation clinic at the Brompton Hospital and the Royal Cancer Hospital, for allowing me to use material collected from our records. Dr. J. R. Bignall, a research fellow jointly with the Institute of Diseases of the Chest and the Institute of Cancer Research, who is attached to our clinic, has kindly obtained much other information for me from the Brompton Hospital records; and Mr. P. M. Payne, the research fellow in medical statistics in the Radiotherapy Department of the Royal Cancer Hospital, helped me with the chart and tables. I am grateful to Miss J. Thompson and Miss M. Jeffries for the considerable amount of work which they did in the records department and library while we were preparing the original lecture of which this paper formed a part.

FACTORS IN THE MORTALITY OF CLOSED HEAD INJURIES

BY

WALPOLE LEWIN, M.S., F.R.C.S.

Assistant Neurological Surgeon, Radcliffe Infirmary, Oxford
(From the Accident Service, Radcliffe Infirmary, Oxford)

It has been estimated that in this country every year road accidents account for over 20,000 cases of head injury severe enough to require admission to hospital. Their number and mortality are matters of some concern. Mortality figures for non-missile head injuries vary widely, depending on the selection of cases and on the circumstances in which the particular series is compiled, but most clinics in this country and abroad quote rates of 12–20%, and emphasize that in 60–70% of the fatal cases death occurs within the first twenty-four hours. These early deaths are due frequently to the severity of the brain lesion, but there is a danger of assuming too readily that such is necessarily the case and of failing to recognize those complications for which treatment may be effective. Some early fatalities—and later ones too—are due to intracranial haematomas; and there are other cases in which extracranial factors such as chest complications are responsible.

The remarkable capacity of the brain to recover from or compensate for the effects of injury has also to be remembered. Thus, aphasia and hemiplegia are com-

monly seen in the early days after injury, but they do not frequently cause permanent disability. Patients with very severe lacerations of the brain may survive for days or weeks. Brain-stem lesions carry a high mortality, but even with them recovery is possible: in the present series one patient with clinical evidence of such a lesion remained unconscious for six months following injury, and thereafter made a steady recovery, so that ten months after the accident she was talking and was later able to return home and look after her family.

Such observations make it pertinent to inquire more closely into the immediate causes of death in these cases, even though in the last analysis the head injury may have been responsible, and to seek ways in which the mortality may be reduced. Broadly speaking, the factors responsible may be divided into four groups: (1) the effect of the injury on the brain itself; (2) intracranial complications, particularly haemorrhage, and to a less extent oedema and infection; (3) extracranial factors such as chest complications, fat embolism, and metabolic disorders; and (4) injuries elsewhere in the body and other incidents, as, for example, cardiovascular complications precipitated by the injury.

Many of these factors are interrelated, but in this paper attention is directed especially to three factors which previous experience had indicated were important in the mortality rate of head injuries and for which treatment may be effective—namely, intracranial haematoma, chest complications, and metabolic disorders.

Case Material

Between November, 1948, and February, 1952 (three and a quarter years), 1,000 patients were admitted to the accident service of the Radcliffe Infirmary, Oxford, with closed (non-missile) head injuries. As this hospital is the only one in Oxford to receive such cases and all accident cases are admitted to this service, the opportunity was taken to study an entirely unselected group of head injuries admitted direct from the scene of the accident. These numbered 821. The remaining 179 cases were transferred from other hospitals in the region for further treatment of a major head injury or a suspected complication.

Intracranial Haematoma

Although extradural, subdural, and intracerebral haematomas develop in no more than a small proportion of head injuries (6.2% in this series*), their recognition is important, for they are essentially acute operative problems and also carry a high mortality rate. A review a few years ago showed that when all cases, including those disclosed only at necropsy, are considered the average mortality from extradural haematoma was 50% and from acute subdural haematoma over 60% (Lewin, 1949).

The diagnostic problem was emphasized by James and Turner (1951), who found that in their district more patients died of untreated intracranial haematomas than were coming under their care. Recognition of them is not always easy, but, as a general guide in management, once the conscious level of a patient has begun to improve following the injury, then one should anticipate a steady recovery, even though this recovery may be arrested at any stage for hours, days, or weeks. Any deterioration in the patient's condition, whether it be in the level of his consciousness or in the development of fresh neurological signs, or both, should raise the question of an intracranial clot and lead to exploration if there is any doubt of the diagnosis. A full appre-

*62 patients with haematomas in the total series. Among the direct admissions there were 32, an incidence of 3.7%.

ciation of the patient's conscious level and neurological state at the outset of treatment is the foundation for further management.

In practice the indications for exploratory burr-holes are usually clear-cut, and this useful procedure need not be applied indiscriminately. Thus in this series 97 patients were explored; in 56 an intracranial clot was disclosed, and in 8 a subdural hygroma—a proportion of positive to negative exploration of 2:1. In a further 9 patients exploration disclosed raised intracranial pressure from the effects of cerebral contusion and oedema, and led to a decompression being performed. Within this same period there were four patients in whom a clot was disclosed at necropsy. These four patients remained in deep coma from the time of injury until death; in two there was a subdural haematoma with cerebral contusion, the patients dying one hour and three hours after injury; in one there was an extradural haematoma on the one side and a subdural haematoma on the other, with cerebral contusion and a fractured base, the patient dying six hours after injury; and in the fourth patient, who died 56 hours after injury with clinical evidence of a brain-stem lesion, there was, in addition to bruising of the pons and mid-brain, a frontal intracerebral clot. It is not the purpose here to discuss whether surgical treatment in these patients could have affected the issue, but to record that they had intracranial clots and to emphasize that it is in this group of patients who remain in coma from the outset that so many of the diagnostic difficulties lie.

Extradural Haematoma

In only half the cases of extradural haematoma is the march of events in any way classical and uncomplicated by other factors. In the others there is, in addition to the extradural clot, severe cerebral contusion or clots in other situations. These patients are usually unconscious from the outset, and this accounts for many of the diagnostic problems. Thus there were 29 patients with extradural clots in this series, of whom 23 recovered and 6 died—a mortality of 20%. Of these 29 cases 12 were complicated by other factors; 5 of these were fatal (one undiagnosed, see above), and at necropsy all showed severe cerebral contusion with a fractured base. These patients are very worrying and may tax all the resources of a neurosurgical unit. Thus three of the seven recovered patients in this group required

TABLE I.—Intracranial Haematoma in 1,000 Cases of Closed Head Injury (69 Haematomas in 62 Patients, of whom 43 Recovered and 19 Died. Gross Mortality, 30.6%)

Type	Single Haematoma		With Subdural		With Intracerebral		With Extradural		All Cases		
	R	D	R	D	R	D	R	D	R	D	Total
Extradural	21	2	2	3*	0	1	—	—	23	6	29
Acute subdural (<14 days after injury)	13	9†	—	—	0	1	2	3	15	13	28
Chronic subdural (>14 days after injury)	3	0	—	—	0	0	0	0	3	0	3
Intracerebral	4	3*	0	1	—	—	0	1	4	5	9

R = Recovered; D = Died.

* Includes 1 case disclosed at necropsy.

† Includes 2 cases disclosed at necropsy.

two or three operations before they finally improved. However, the remaining 17 cases of extradural haematoma were uncomplicated and only one was fatal: the patient stopped breathing as he came into the admission room, and did not recover, although the extradural clot was evacuated immediately under artificial respiration. It should be remarked that 10 of these 17 patients were operated on at a time when their pupils were equal and reacting. A dilated pupil in these circumstances is not so much a sign of extradural haematoma as an indication of impending death.

Delay in operating also results in an increase in the mortality: extradural haematoma is one of the few surgical emergencies in which success or failure is so dependent on the time factor. For example, if there has been a short

lucid interval of up to four hours, and then a rapid onset of coma with a dilated pupil, exploration should be made at once. The melancholy fact is that the patients in this group, untreated, are usually dead within six hours of the onset of coma and are probably beyond recovery for some time before this.

Another point concerns the nature of the exploration. It is not sufficiently realized that nearly one-third of these clots (in this series 31%) occur in sites other than temporal—frontal, parieto-occipital, or cerebellar—and the teaching that a temporal burr-hole is necessarily the correct exploratory site leads to these clots being missed. The site of scalp bruising and laceration, and the position of a fracture line, are reliable guides to the site of the haematoma, and burr-hole exploration should be made accordingly.

Thus, although there will always be an appreciable mortality in extradural haematoma for the reason that nearly half the cases are complicated by other brain lesions, with timely surgery the mortality from an uncomplicated extradural clot should be low.

Acute Subdural Haematoma

By contrast, acute subdural haematoma, by which is meant a haematoma coming to operation or necropsy within 14 days of injury and large enough to be causing cerebral compression, usually accompanies cerebral contusion and laceration, and is therefore associated with a correspondingly high mortality rate. Of 28 patients in this series with acute subdural haematoma, 15 recovered and 13 died—a mortality rate of 46%. Doubt has been expressed whether surgery has anything to offer during the first 24 hours after injury in these cases, in which deterioration in the patient's condition is so often due more to the cerebral lesion than to the pressure of the clot; but it is difficult to see how in some cases such a differentiation may be made clinically. It is safer to explore when there is evidence of compression and also of deterioration in the patient's condition. The mortality at this time is certainly high: of 12 patients operated on within the first 24 hours, three recovered and nine died. However, three patients did recover, and in retrospect this number might well have been increased by at least two if an early tracheotomy had been recommended in one patient and a further decompression performed in the other—points which illustrate the interdependence of the various factors present in the acute head injury.

Decompressive Operations.—Burr-hole drainage of the clot may be enough if the haematoma is fluid and is very large, but in our experience there have been several cases in which this proved inadequate and the underlying cerebral contusion and oedema has required a decompression. Thus in the 20 patients of this series with acute subdural haematoma in whom at operation no clot other than the subdural was found, a bony decompression was performed in 11, in addition to drainage of the surface haematoma. Six of the 11 patients so treated recovered, and it was estimated that in at least 8 of the 11 patients the underlying brain damage was as much a factor in their clinical picture as the surface clot. There are also some cases of cerebral contusion without gross haematoma in which the bruising and oedema lead to raised intracranial pressure and steady deterioration in the patient's condition. A timely decompression in these cases may prove helpful; of nine such patients in this series in whom a decompression was provided by a bone flap or a subtemporal craniectomy, five recovered.

The high mortality of this severely injured group of patients may have resulted in a too conservative swing in their management, and the fact that some of these patients may be saved by early surgery requires reconsideration.

Acute Traumatic Intracerebral Haematoma

Comparatively little attention has been given to the possibilities of surgery in this condition, but with the help of angiography in suspected cases in the future it should

be possible to diagnose these haematomas more often and to attempt treatment. Small intracortical clots and lacerations filled with clot are common enough, but these intracerebral clots are truly subcortical and usually measure 5 cm. or more in diameter. They may occur at all ages and in brains with apparently healthy vascular trees. There were nine such cases in this series. Decompression alone would seem inadequate for their treatment as judged by the fatal issue in the three patients in whom this was done; on the other hand, four of the five patients in whom the clot was evacuated through a cortical incision recovered.

Chest Complications

Intracranial haematomas are uncommon, but, unfortunately, chest complications are all too common, and almost the rule in any case of prolonged coma. They are undoubtedly the cause of many deaths after head injury, and this is not surprising when we remember the ways in which the chest may be involved soon after injury. Thus there may be an associated chest injury with haemothorax and pneumothorax. A serious head and chest injury is a very lethal combination; there were 15 such cases in this series, with six recoveries and nine deaths.

The second way, and by far the commonest, is by the inhalation of vomitus or of blood from a fractured base during the early hours after the injury, when the patient is still comatose. Such a calamity is promoted by the almost invariable rule of transporting these patients on their backs, and by nursing a comatose patient with his head elevated in order to lower his intracranial pressure. This it may do, but the small benefit derived is nothing compared with the fatal risks of such a position. Massive inhalation may result in pulmonary collapse and immediate death, but a treacherous condition may also arise in those patients who do not die immediately. The main air passages may have been cleared by suction or by coughing, but blood and vomitus remain in the small bronchioles. The resulting areas of peripheral pulmonary collapse and oedema leave the patient with a diminished pulmonary reserve, and then a further minor incident may be terminal.

A third complication is pulmonary fat embolism, seen usually in patients with multiple injuries and coming on some hours after the injury. There have been at least eight such cases in this series, and there were probably others which were not detected.

Fourthly, there is the hyperacute pulmonary oedema secondary to brain-stem compression, a condition well known to neurosurgeons and which has recently been produced experimentally by Cameron (1948). Its sudden onset, with the production of quantities of thin blood-stained fluid, may be as dramatic as is its relief if the intracranial pressure can be reduced as by evacuation of a clot.

The lungs, therefore, are particularly susceptible following head injury, and, in those patients who survive these early complications, secondary bronchopneumonia or even lung abscess may develop later, or may follow as a result of prolonged coma.

Effect on the Brain.—The effect of the head injury and the accompanying unconsciousness on the lungs is not, however, the only problem. Anoxia and chest infection have a profound adverse effect on the brain, perhaps especially after recent injury. The brain cannot tolerate even a few minutes' anoxia (Howkins *et al.*, 1946); yet this is a not infrequent risk following head injury, with the upper respiratory tract filled with secretions and the patient cyanosed and breathing rapidly and irregularly. Moreover, it has been recognized for a long time that infection elsewhere in the body adversely affects a neurological lesion: witness the loss of tone in a paraplegic patient who develops a urinary infection, or the access of neurological signs in the child with a cerebellar tumour who develops an incidental infection. In patients with head injuries the same obtains. Onset of chest infection halts recovery and may also result in a deterioration of the patient's mental condition.

Treatment of Chest Complications

To mitigate the effects of these chest complications the basic treatment for the unconscious patient in this series has been nursing, prophylactic penicillin, and oxygen. The first essential was to obtain an unobstructed airway 24 hours a day. The patients were nursed flat from the outset, lying on their side, and, if that was not completely satisfactory, in the semi-prone or "tongue" position. They were turned from side to side two-hourly. Suction was available at the bedside of all patients in coma so that the nurse could easily clear away secretions in the nose and mouth with a soft rubber catheter. Physiotherapy twice daily to favour full expansion of the lung bases was also given, and if there was difficulty in clearing the upper respiratory tract efficiently there was no hesitation in giving these patients the benefit of full postural drainage with the foot of the bed elevated for short periods. These methods were supplemented where necessary by the use of simple airways, and oxygen was given intermittently or, in the severest cases, continuously.

In these ways it was possible to prevent and treat many of these chest complications. Although it is difficult to present reliable figures, the use of antibiotics has undoubtedly helped to prevent and to lessen the effects of chest infection.

Tracheobronchial Toilet

In some cases in which the obstruction extended down into the trachea and bronchi it was not possible to clear them by the measures described above. In this event the anaesthetist has sucked out the main air passages either by a catheter passed down the trachea directly or through an endotracheal tube which was afterwards removed. These methods proved valuable in the early hours after the accident and were also successfully employed in eight patients at a later phase of their illness. In a further three patients, bronchoscopy was successful in relieving a lobar collapse.

Where it became necessary to intubate a deeply comatose patient soon after admission and the airway was found to be unsatisfactory without the endotracheal tube, it was sometimes left in for some hours. Endotracheal intubation in these circumstances is useful, but experience has shown that it is unwise to continue this method for many hours, particularly if it looks as if the patient may survive the immediate effects of the brain injury and is likely to remain in coma for some days. The tube becomes encrusted with secretions and is less effective; and frequent endotracheal intubation leads to oedema of the pharynx and larynx with ulceration, so that ultimately the respiratory embarrassment is aggravated rather than relieved.

Tracheotomy

It was in such circumstances that tracheotomy was first employed in March, 1949. In this series 13 tracheotomies were performed. In none have we regretted doing it, and in some we wished it had been done earlier. There have been no complications following this operation, even though many of them were performed when the patients were desperately ill. In some instances the operation took place in the patient's room so as to disturb him as little as possible. The figures in regard to ultimate recovery are not impressive, since this resulted in only 3 of the 13 patients; but this emphasizes that operation was considered only in the severest cases, and the benefit of special nursing which was available to all these patients rendered the number of cases in which the question of a tracheotomy arose relatively few. It is perhaps more important to observe that in all cases any chest infection present cleared up once the tracheotomy was performed, and the improvement in the patient's condition was usually immediately apparent; it became easy to clear the trachea adequately, there was no further trouble with the airway, and the patient could now be nursed with the head elevated if desired. It was striking to observe a bilateral bronchopneumonia resolving rapidly

after tracheotomy. Another feature noticed was the long survival of some patients with severe brain injuries who had a tracheotomy. Thus it was possible to nurse four patients in coma for periods of eight to twelve weeks and two others for periods of a year without chest complications.

To date, of 18 patients who have had tracheotomy performed, nine improved to such a degree that the tube could be removed; of these, four recovered satisfactorily and two are still improving. In patients from whom the tube was removed the stoma closed quickly without complications.

The experience of these first cases suggests that tracheotomy is a valuable adjunct in the treatment of selected cases, although one would deprecate its use save in the severest head injuries, for simpler measures and good nursing will usually suffice. An early tracheotomy should be seriously considered in patients who have survived the early hours but are likely to remain in coma for some days, and in whom respiratory incidents are beginning to appear. It is useless to wait until the patient is in *extremis* and has already suffered the effects of anoxia. Some of our early cases were operated on too late. Of the last four patients who underwent tracheotomy only one died, and necropsy of that patient showed a normal respiratory tract. Similar experiences of tracheotomy have been reported from America by Echols *et al.* (1950), who advise it in cases in which coma is likely to persist more than 24 hours, and in which other methods of maintaining an adequate airway are inefficient.

Results

Table II summarizes the chest complications present in this series. The total incidence was 6.7%, which includes every case at necropsy in which anything more than mild

TABLE II.—Chest Complications in 1,000 Cases of Closed Head Injury

Chest Complication	Recovered	Died		Total
		Main Cause of Death	Contributory	
Injury	6	4	5	15
Bronchopneumonia	10	5	11	26
Pulmonary collapse	4	3	5	12
Pulmonary oedema	1	—	4	5
Lung abscess	—	1	—	1
Fat embolism	2	1	5	8
Total	23	14	30	67

basal oedema was found. Thus 30 cases were listed as "contributory" in view of the necropsy findings, even though clinically there was no evidence that the lung changes played an important part in causing death. However, the fact that nearly half of all the fatal cases showed significant lung changes illustrates the importance of this extracranial factor.

Metabolic Disorders

It has been known for a long time that disturbances of fluid and electrolytic balance may arise in comatose patients, but their nature and the extent to which they are present in patients with head injuries who survive the early hours after injury have been little studied. The dangers of dehydration, whether from inability to administer fluids adequately to the unconscious patient, or as a result of over-zealous application of dehydration as a method of treatment in head injuries, have been recognized (Munro, 1938). Cumings (1942) reported some cases of uraemia following head injury; and earlier in this series (Higgins *et al.*, 1951) it was observed that some patients developed a striking disturbance of chloride balance characterized by retention of this ion in the blood without a corresponding excretion in the urine.

It was decided, therefore, to study biochemically a consecutive series of patients who after the first 24 hours following injury remained sufficiently unconscious to require tube feeding, and to follow their progress until recovery of

consciousness or death. It may be mentioned here that our general routine of treatment was to pass a small rubber oesophageal tube or polythene tube through the nose 12 to 24 hours after injury, and to administer fluids, three to four pints (4.7 to 2.3 litres) during the first day, and thereafter increasing the amount as required. All our patients were fed by mouth, and it was not found necessary to resort to intravenous drips for feeding purposes. The details of the treatment and the full biochemical findings are described elsewhere (Higgins *et al.*, in press).

Table III summarizes the results. The high incidence of transient disorders such as glycosuria and changes in the plasma proteins, which in general corrected themselves without specific treatment, were of interest, since they provided

Total	76

further evidence of the general systemic disturbance which may follow head injury, although they were of little importance therapeutically. On the other hand, the 21 major metabolic disorders which developed in 18 patients deserve further comment, for, from earlier experience with these disorders and with the results of similar disturbances in cases unassociated with head injury, it would appear that they are not usually correctable spontaneously and are associated with a high mortality. It is believed, therefore, that the successful therapeutic correction of these disorders in 12 of the 18 patients, with recovery of seven patients, played a part in lowering the overall mortality, although it will be appreciated how difficult it is in such a complex setting to ascribe recovery or death to any one single factor. Water deprivation was uncommon in this series owing to the policy of giving fluids early, and in those cases in which therapeutic dehydration was employed the effect of this treatment on the patient was carefully watched.

It is not proposed to discuss here the causes of these metabolic disorders. Some certainly follow coma from whatever cause, but clearly the possibility of a central factor in some cases of head injury has to be borne in mind. Further work requires to be done on these metabolic changes, but the evidence suggests that the patient's fluid and electrolytic requirements are important aspects of his treatment and that the time has come when their assessment, at least in severe head injuries, should be made in conjunction with our biochemical colleagues.

Multiple Injuries

In addition to his head injury a patient may sustain other injuries which may influence considerably not only the prognosis of the case but also its management. Thus among 821 direct admissions there were, excluding those patients with simple contusions and lacerations, 269 cases with injuries in addition to the head injury—an incidence of 32.7%. Of these 269 patients 27 died, and, as indicated in Table VI, it was concluded that in seven cases at least death was due mainly to these other injuries. In 107 patients there were two or more injuries in addition to the head injury. Table IV indicates the principal injuries sustained. Fractures of the face and limbs were the commonest injuries. It was clear that the ready availability of specialist services within the framework of an accident service for the many problems that arose in their management proved an important factor in the successful outcome of many cases.

TABLE IV.—Other Injuries Sustained by 269 Patients with Head Injuries (All Direct Admissions. Incidence 32.7%)

Injury	No. of Cases
Fractures	332
Face (malar only, 50; nasal bones only, 20; maxillae, 37)	107
Upper limb (clavicle, 40; shoulder, 14; humerus, 6; forearm and wrist, 35; hand, 13)	108
Lower limb (pelvis, 15; femur, 17; knee, 6; leg, 32; foot, 5)	75
Spine (body, 15; processes, 10)	25
Thorax (ribs only)	17
Chest (12 with rib fracture)	13
Abdomen	8
Spinal cord and peripheral nerves, without fracture	8
Eyes	7
Major facial lacerations and soft-tissue injuries	15
Total	383

One difficulty in the management of the unconscious patient who has multiple injuries is the recognition that other injuries are present, fractures of the spine and pelvis and injuries to the chest and abdomen being easily missed unless systematically looked for; another is to decide which injury should take precedence of treatment and to accept in some cases a compromise between what is ideal for the particular injury and what is practicable in the circumstances. One should not accept unnecessary delay in the treatment of other injuries merely on the grounds that the patient has had a head injury, for this may delay recovery from shock and increase the risks of infection; but it is also important, particularly in the early hours after injury, to avoid, if possible, procedures which may interfere with the essential management of the unconscious patient or mask the developing signs of an intracranial complication.

Results

Table V summarizes the results in this series. The overall mortality was 9%, weighted by the higher mortality of those selected cases transferred from other hospitals with severe head injuries and complications. Of the 821 patients admitted directly from the accident 62 died, a mortality of 7.5%.

TABLE V.—Mortality in 1,000 Consecutive Cases of Closed Head Injury

	Cases	Deaths	%
Direct admissions	821	62	7.5
Transferred cases	179	28	15.6

necropsy was performed in all but three cases. Although there were seven deaths due mainly to other injuries, two others from heart disease, and three in which the clinical and necropsy evidence left little doubt that intracranial haemorrhage from cerebrovascular disease had been precipitated by a trivial head injury, these have nevertheless been included in the total number of deaths, for a more complete account is then given of the many problems involved in accident work. Where there has been any doubt about the main cause of death the rule has been to ascribe it to the head injury. The three patients who died mainly from bronchopneumonia were all over 70 years of age. Of the 45 patients who died directly as a result of the head injury, five died within one hour of the accident.

Mortality of Head Injury.—To set alongside these figures one should mention those patients with minor head injuries who were treated in the casualty department and then sent home, and also those who died before reaching hospital. Within the period under review at least as many cases were treated in the casualty department for minor head injuries and sent home as were admitted. With the kind help of the local authorities it has also been found that during this same period 12 patients died of head injury on the roads before they reached hospital. One estimates, therefore, that the mortality of cases of head injury severe enough to be admitted to hospital was certainly well below 10%.

It may be encouraging to note that whereas the gross mortality of the first 500 cases in this series was 11.4%, in the last 500 cases it was 6.6%, and this lower figure has been maintained to date. The series would have to be extended much further, however, before one could conclude that this apparent improvement was due to anything other than extraneous circumstances.

Summary and Conclusions

Attention is drawn to the frequency and mortality of head injuries, and it is suggested that in addition to the immediate effects of the brain injury there are other factors, some of which are preventable or amenable to treatment, which play an important part in the mortality rate. The paper is based on 1,000 consecutive cases of head injury admitted to an accident service in the last three and a quarter years.

Intracranial haematoma developed in 3.7% of an unselected series. The need for urgency in the evacuation of extradural haematoma, and the incidence of these clots in sites other than temporal, are stressed. The value of decompression in some cases of acute subdural haematoma and in certain other cases, and the possibilities of surgery in acute intracerebral haematoma, are discussed.

Chest complications are common in head injuries and account for many deaths. Their causes and treatment are outlined. The use of tracheotomy in selected cases is described.

Evidence is presented to show that metabolic disorders may develop in these patients. It is suggested that their management, and attention to the patient's fluid and electrolytic requirements in the light of the biochemical findings, may help in lowering the mortality rate.

Injuries to other parts occur in over 30% of cases. Their frequency and variety illustrate the advantages of treating head injuries within the framework of an accident service.

The overall mortality of the 1,000 cases was 9%. Among the 821 unselected cases there were 62 deaths, a mortality of 7.5%.

It is concluded that there are several ways by which the mortality rate of head injuries may be reduced. Although further attention to intracranial complications is required, it is believed that as much benefit will be derived from the prevention and treatment of some of the extracranial factors.

It is a pleasure to thank Mr. J. C. Scott, Director of the Accident Service, for his help and encouragement in this work, and the staff for their ready co-operation at all times; Sisters B. Twining and B. Heaume and the nursing staff for their constant care and patience in nursing these patients whose injuries inevitably make such heavy demands on them; the staffs of the other departments in the hospital who have helped in the management of these patients, particularly the departments of dental surgery, plastic surgery, oto-rhino-laryngology, anaesthetics, and biochemistry; Dr. E. M. Buzzard and his registrars for their advice on the management of the chest complications; Dr. Dawn

Bosanquet and the staff of the department of pathology, who were responsible for the necropsy examinations; and Miss A. Edmonds for secretarial help with the analysis of these cases.

The problem of head injuries remained one of Sir Hugh Cairns's prime interests throughout his career. It was my privilege to have had the benefit of his advice and constant help throughout this study, and I wish to record my debt to him.

STREPTOMYCIN RESISTANCE IN PATIENTS WITH PULMONARY TUBERCULOSIS PREVIOUSLY TREATED WITH P.A.S. ALONE

BY

F. W. A. TURNBULL,* M.B., M.R.C.P.Ed.

A. T. WALLACE, M.D., D.P.H.

SHEILA STEWART,* B.Sc.

AND

J. W. CROFTON, M.D., F.R.C.P.

(From the Department of Tuberculosis and Diseases of the Respiratory System, University of Edinburgh)

In the treatment of pulmonary tuberculosis with streptomycin alone the emergence of strains of tubercle bacilli resistant to the drug is well known. That the same thing happens when isoniazid is used alone is now established (Medical Research Council, 1952a). But the possibility of resistant strains emerging when cases of pulmonary tuberculosis are treated with sodium or calcium para-aminosalicylate (P.A.S.) alone has received much less attention. This is perhaps partly because of the less rapid emergence of resistant organisms when an attempt is made to induce P.A.S. resistance *in vitro* (Steenken and Wolinsky, 1950) and partly because of the greater technical difficulty of the resistance tests. Nevertheless, the emergence of P.A.S.-resistant strains in a large proportion of treated cases has been reported in the literature. Some of these reports are summarized in Table I.

The results suggest that P.A.S.-resistant strains may emerge at a later period of treatment than is usual when streptomycin or isoniazid is used alone, but that, with prolonged treatment, they are isolated from a notable proportion of patients who remain sputum-positive. It is logical to imply that if these patients are later treated with streptomycin and P.A.S. in combination P.A.S. will no longer prevent the emergence of streptomycin-resistant tubercle bacilli. This probability has often been emphasized but is still ignored by many clinicians, partly perhaps because no direct evidence has, so far as we know, been provided. In addition it has been suggested that resistance to P.A.S. is transient and, by impli-

cation, not of importance to later combined treatment (Tempel *et al.*, 1951). It is the purpose of this paper to provide evidence that P.A.S.-resistant organisms may be isolated from a high proportion of patients treated with the drug alone and whose sputum remains positive, that the resistant organisms may persist in the sputum for many months after treatment has ceased, and that streptomycin-resistant organisms may emerge rapidly if such cases are later treated with both streptomycin and P.A.S.

Material and Methods

The first group consists of nine patients with pulmonary tuberculosis who were treated with streptomycin, 1 g. daily, and P.A.S., 20 g. daily, for at least three months. (In one the daily dose of P.A.S. had to be reduced to 15 g. daily for five days a week at the end of two months, but her organisms were already streptomycin-resistant.) All had elsewhere had treatment with P.A.S. alone for periods varying from 6 weeks to 16 months, the exact daily dosage being in most cases unknown. The interval between the end of the course of P.A.S. alone and the beginning of the course of streptomycin and P.A.S. in combination varied from a few days to 39 months. Estimations of the drug sensitivity of the tubercle bacilli isolated from these patients, and the results of serial cultures and sensitivity tests while under treatment with streptomycin and P.A.S., were compared with similar results from a second group of five patients who began streptomycin and P.A.S. in the same doses about the same time, but who had not previously received P.A.S. alone. All the patients were initially included in the current chemotherapeutic trials organized by the Medical Research Council (1953).

Cultures of the sputum were obtained on Löwenstein-Jensen medium before the beginning of the course of streptomycin and P.A.S. in combination. Further cultures were made at least at monthly intervals for six months. Streptomycin- and P.A.S.-sensitivity tests were carried out in liquid medium according to accepted techniques (Medical

Research Council, 1948, 1950). Tubercle bacilli were regarded as drug-resistant if they were inhibited only by at least eight times the concentration which prevented growth of the sensitive control organism H37Rv; that is to say, if their "resistance ratio" was eight or above.

Comparability of the Two Groups.—The patients in the two groups were investigated with respect to factors in the pre-treatment state known to affect the emergence of resistant organisms. For this purpose we recorded the pre-treatment temperature and the extent of cavitation and confluence of shadows in the radiograph. The radiographic assessments were made by an independent panel unaware of the group to which the patient belonged, and the films were placed in previously defined categories. The results are recorded in Table II. It will be seen that the groups are roughly comparable, though in the first group gross cavitation was commoner.

Results (see Table III)

P.A.S. Resistance

It will be seen that in eight out of the nine patients who had previously been treated with P.A.S. alone tubercle bacilli isolated before beginning the combined streptomycin-P.A.S. course were P.A.S.-resistant, the resistance ratio varying from 16 to greater than 256 in different cases. In some cases there was a further substantial rise in the resistance ratio while on combined treatment. In the one patient, Case 9, whose bacilli were P.A.S.-sensitive before treatment, no P.A.S.-resistant organisms were subsequently isolated.

In three out of five of the patients who had not received previous P.A.S., bacilli isolated before the start of combined treatment were P.A.S.-sensitive. In the other two cases, for technical reasons, no pre-treatment culture was available for testing, but subsequent cultures were P.A.S.-sensitive. In none of these patients were P.A.S.-resistant bacilli isolated up to the end of the six months' observation period, though in three the sputum became negative.

It is clear, therefore, that P.A.S.-resistant tubercle bacilli emerged in a high proportion of those patients who had been treated with P.A.S. alone, and that the organisms might remain resistant for up to three years and more after stopping the drug.

Streptomycin Resistance

In 13 out of the 14 patients the tubercle bacilli were streptomycin-sensitive before the start of the combined course; in the thirteenth case (No. 10) the pre-treatment culture was contaminated but the bacilli were shown to be sensitive a month later.

Of those who had received previous P.A.S. alone, the one patient (Case 9) whose organisms were P.A.S.-sensitive before starting combined streptomycin and P.A.S. continued to excrete bacilli sensitive to both drugs up to the last available test, six months after starting the combined treatment. In all the eight other patients streptomycin-resistant organisms were isolated, in the first six cases within three months of starting treatment. In Case 7 the resistance ratio was 4, the upper limit of normal, after two and three months' treatment; at four months a culture slightly but definitely resistant (resistance ratio 8) was obtained for the first time, the ratio reaching 32 a few days later. In the remaining patient (Case 8) a resistance ratio of 4 was found at three months, the culture was contaminated at four months, and the first definitely resistant strain was isolated at five months. This last patient was the only one of the group whose bacilli attained only a low degree of streptomycin-resistance (resistance ratio 8); in the other seven the organisms became moderately or highly resistant.

Of the five patients who had not had previous P.A.S. alone, the sputum became negative in three (Cases 10, 12, and 14). In each case the last positive culture, on the 90th, 44th, and 31st days of treatment, remained streptomycin-sensitive throughout the six months' observation. In only one patient (Case 11) were slightly resistant organisms, with a resistance ratio of 8, isolated after five months' treatment.

 ‡ Two days after first resistant culture.

Streptomycin-resistant tubercle bacilli, therefore, emerged in all of eight patients who had been previously treated with P.A.S. alone and whose organisms were P.A.S.-resistant before starting combined treatment with streptomycin and P.A.S. Of the six patients whose organisms were P.A.S.-sensitive before starting combined treatment, including one who had had previous P.A.S. alone, bacilli slightly resistant to streptomycin were isolated from only one, although in three the sputum became negative during the period of observation.

Discussion

The control group of patients who had not previously received P.A.S. alone was, of course, small. It was made smaller in the later stages of the investigation by a number of patients becoming sputum-negative. But a good deal of information is elsewhere available about the proportion of cases from which streptomycin-resistant organisms are likely to be isolated if streptomycin and P.A.S. are given in the same doses as in our patients. In the earlier Medical Research Council series the proportion did not exceed 10% (Medical Research Council, 1952b). In our group treated with previous P.A.S. alone the organisms were P.A.S.-resistant before combined treatment in eight out of nine, and in all of these streptomycin-resistant bacilli were isolated when they were later treated with streptomycin and P.A.S. in combination.

The implications of these findings are obvious. P.A.S., like streptomycin and isoniazid, should never be given alone to tuberculous patients. There is evidence that the use of streptomycin prevents or diminishes the emergence of P.A.S.-resistant organisms, just as P.A.S. prevents or diminishes the emergence of streptomycin-resistant organisms (Medical Research Council, 1950; Veterans Administration, 1951). If a patient is known to have had a long course, perhaps more than a month, of P.A.S. alone, it should be assumed, until the results of sensitivity tests become available, that his bacilli are P.A.S.-resistant. If chemotherapy is necessary he should be treated with streptomycin and isoniazid in combination. Finally, it is clear that tests for P.A.S. sensitivity are as important to the patient as those for sensitivity to streptomycin or isoniazid.

Summary

Tubercle bacilli from eight out of nine patients who had previously received sodium *para*-aminosalicylate (P.A.S.) alone for pulmonary tuberculosis were found to be resistant to the drug. The original course of treat-

ment lasted from 6 weeks to 16 months in different cases and the interval between the finish of the course and the resistance tests varied from a few days to 39 months.

When treated with daily streptomycin and P.A.S., streptomycin-resistant tubercle bacilli emerged in all the eight patients whose bacilli were P.A.S.-resistant before the start of the combined treatment. The streptomycin-resistant bacilli were obtained in six out of the eight cases within three months on combined treatment, in the seventh after four months, and in the eighth after five months.

By contrast a slightly streptomycin-resistant organism was isolated, after five months' treatment, from only one out of six similar cases whose organisms were P.A.S.-sensitive at the start of the combined course. Five of the cases had had no previous treatment with P.A.S. alone.

It is concluded that P.A.S.-resistant tubercle bacilli are likely to emerge if patients with pulmonary tuberculosis are treated with P.A.S. alone; that the resistant organisms may persist for long periods; and that, if the patients are later treated with P.A.S. and streptomycin, P.A.S. will then no longer prevent or diminish the emergence of streptomycin-resistant bacilli.

This work was generously supported by the Royal Victoria Hospital Tuberculosis Trust. We should also like to thank Drs. N. W. Horne, I. W. B. Grant, and J. D. Ross for allowing us to investigate their patients, for making the radiographic assessments, and for their keen interest in the work. Unstinting help was received in this and other investigations from the registrars, house-physicians, nursing staff, and laboratory technicians of the Edinburgh Royal Victoria and associated group of hospitals.

TREATMENT OF PRIMARY PULMONARY TUBERCULOSIS WITH P.A.S.*

BY

R. McLAREN TODD, M.D., M.R.C.P., D.C.H.

Senior Lecturer in Child Health, University of Liverpool;
 Consultant Paediatrician, Alder Hey Children's Hospital,
 Liverpool, 12

Lehmann (1946) was the first to use *para*-aminosalicylic acid (P.A.S.) in the treatment of patients suffering from tuberculosis, and during the succeeding six years many workers have employed this drug in a variety of tuberculous conditions. P.A.S., combined with streptomycin, has been used successfully in miliary tuberculosis and tuberculous meningitis, conditions which result from dissemination of tubercle bacilli from a primary tuberculous complex, but as yet there have been few reports of the treatment of primary tuberculosis with P.A.S. Scarzella (1949) used it in eight children suffering from primary tuberculosis. Debré *et al.* (1950) treated two children aged 14 months and 11½ years, Lesné *et al.* (1951) 28 children aged 2 to 6 years, and Haggmüller (1951) 72 children aged 2 to 15 years. These workers claimed that P.A.S. seemed to be of value when judged by the return of temperature and sedimentation rate to normal, by gain in weight, and by improvement in the radiological appearances. It is, however, the experience of workers in this field that when children suffering from primary tuberculosis are removed from contact with adults who have open pulmonary tuberculosis and are given adequate rest and a suitable diet, progress is usually satisfactory. The assertion that P.A.S. is of value in primary tuberculosis may be justifiably questioned because in none of the above-mentioned papers was a control group of children of the same age and with identical hospital care studied.

The present investigation was planned to assess more critically the value of P.A.S. in primary tuberculosis. The children were seen during 1951 in Liverpool, where the mortality rate for tuberculosis is higher than the average for England and Wales, and the incidence of primary tuberculosis provides a large enough number of cases to be studied in one centre.

Plan of Investigation

Most of the children were admitted to Alder Hey Children's Hospital, Liverpool, where they were at rest in bed for a period of three months and received a diet adequate in protein, calories, and vitamins. On admission the following investigations were undertaken: tuberculin test, gastric lavage, full blood count, sedimentation rate, x-ray film of the chest, lumbar puncture, and weight. Subsequently the white-cell count and sedimentation rate were evaluated every two weeks, and lumbar puncture was performed at fortnightly intervals during the first six weeks and monthly thereafter. X-ray films of the chest were taken every month, and the children were weighed at weekly intervals.

Sixty-nine patients were studied, and for the purpose of this investigation they were divided into four age groups (see Table I). Alternate patients (trial group) in each age

*A paper read in the Section of Child Health at the Joint Annual Meeting of the British Medical Association and Irish Medical Association, Dublin, 1952.

assessment was made on the time of appearance of erythema nodosum, phlyctenular conjunctivitis, and Mantoux conversion, and by a detailed investigation of the contact history.

Assessment of Progress

The progress of these cases cannot be estimated by any one test, and in this investigation six criteria were used—namely, clinical impression (based on appetite, vitality, temperature, pulse rate), serial blood counts, serial sedimentation rates, weight gain, serial chest x-ray films, and incidence of complications.

The clinical impression was that progress was equally satisfactory in both trial and control groups. In the majority of patients the temperature was normal throughout or it returned to normal within two weeks of admission. Appetite was good in most patients, and persistent tachycardia was not recorded.

White-cell counts and sedimentation rates were estimated on admission and at fortnightly intervals thereafter. The

*The preparation of P.A.S. used throughout this investigation was "paramisan sodium," kindly supplied by Herts Pharmaceuticals Ltd. It was given in the following mixture:

P.A.S. 1 g.
 Liquid extract of liquorice or syrup of
 orange 5 minims (0.3 ml.)
 Water ad 1 dr. (3.5 ml.)

general trend in all cases was towards normal figures, and, although there was a wide degree of scatter, no significant difference was found in the control and trial groups. The children were weighed on admission and at weekly intervals, and the percentage weight gain above the admission weight in each of the four age divisions was compared in the control and trial groups. No significant difference was shown. The x-ray appearances in the trial and control groups were compared one, two, three, and six months after admission to hospital (see Chart). Decrease in the

3 to 6 years	1 patient: collapse of R.M.L. 1 patient: ascitic tuberculous peritonitis at 3 months 1 patient: PAS sensitivity—rash, oedema	1 patient: miliary spread at 1 month
7 to 15 years	1 patient: collapse R.M.L. 1 patient: occasional vomiting with PAS	

x-ray shadow is indicated by plus 1, 2, or 3 (plus 3 indicates complete radiological resolution); when the shadow remained unchanged it is recorded as 0, and the extent of increase in size of the shadow is indicated by minus one, two, or three. There appeared to be no difference in radiological progress of trial and control cases using this method of assessment.

Table IV shows the complications encountered. These were of three main types: (1) complications of the tuberculous process, both local in the lung and generalized; (2) those resulting from P.A.S.; and (3) those, such as gastroenteritis, due to hospital cross-infection.

Local lung complications were more common in the trial group. Spread of the disease to the meninges occurred in

two children in the control group, and in spite of treatment with streptomycin and P.A.S. they died. One patient in the control group who developed miliary tuberculosis responded satisfactorily to these drugs. Renal tuberculosis and ascitic tuberculous peritonitis developed in two patients who had received P.A.S. for three months, and both subsequently recovered when streptomycin was given. One child in the trial group developed a generalized scarlatiniform rash and oedema of face, hands, and legs, but these toxic manifestations quickly subsided when P.A.S. was discontinued. In almost all patients the drug was well tolerated, and in only two patients were nausea and vomiting troublesome.

Discussion

There is general agreement with Wallgren (1945) that the mortality rate from tuberculosis is higher in infants and young children. In his series the mortality rate was 35.9% in the age group 0 to 1 year, 15.6% in the group 1 to 3 years, 4.4% in children from 3 to 7 years, and 0.8% in those aged 7 to 16 years.

Furthermore, the serious complications such as tuberculous meningitis usually arise within three months of the development of the primary complex. It is therefore not surprising that the two patients in the present investigation who died from tuberculous meningitis were under 3 years of age. In the children under the age of 3 years there was no obvious difference in the course of the disease in the trial and control groups when judged by clinical response, white-cell count, sedimentation rate, weight gain, and serial chest x-ray films. The serious complications, however, did arise in the control group, but even in the trial group one child developed renal tuberculosis and one developed tuberculous peritonitis.

Debré (1951) considers that, because primary tuberculosis in children under 2 years of age is likely to be severe, since early detection of general dissemination is difficult, and because tuberculous meningitis has a bad prognosis, streptomycin and P.A.S. should be given to all patients with primary tuberculosis in this age group. There is no doubt that as a general principle young children with primary tuberculosis should be under strict observation, and that early detection of complications may be possible by regular examination of the optic fundi for choroidal tubercles, routine lumbar punctures at intervals of not more than two weeks, and frequent x-ray films of the chest. Streptomycin may then be reserved for the treatment of these complications. A further controlled investigation is being carried out at the present time to assess the value of P.A.S. combined with streptomycin in children under the age of 3 years, but the number of cases so far treated is too few to assess the value of combined therapy.

The dosage of P.A.S. used in this investigation (0.5 g. per lb. (1.1 g. per kg.) per day) is higher than that given by Debré *et al.* (1950), Haggemüller (1951), and Lesné *et al.* (1951); their patients received approximately 0.3 g. per lb. (0.66 g. per kg.) per day, and it may be thought that the dosage used in the present cases was excessive, but the intention was to maintain a minimum blood level of about 8 mg. of P.A.S. per 100 ml. Lehmann (1946) recommended a level of up to 7 mg. per 100 ml., and Dempsey and Logg (1947) suggested 10 mg. per 100 ml. Blood P.A.S. levels were estimated in all our cases half an hour and two hours after the ingestion of the drug, and wide variations were found in the same patient on different occasions, but the average blood level at half an hour was 12.5 mg. per 100 ml. and at two hours (immediately before the next dose of P.A.S. was given) 7.5 mg. per 100 ml. Almost all the 35 patients tolerated this dosage, and in only one child did a generalized rash and oedema arise.

Electrocardiograms were taken on a number of patients, but no evidence of potassium deficiency (Cayley, 1950) was found. No other toxic manifestation such as bone-marrow depression, hypothermia, liver damage, or renal damage were observed in this series.

Summary and Conclusions

Sixty-nine children with primary tuberculosis were studied in Liverpool during 1951. Of these, 35 were given P.A.S. for a period of three months, and 34 were given the same general treatment but without P.A.S. When judged by clinical progress, white-cell count, sedimentation rate, weight gain, and serial chest x-ray films, there seemed to be no benefit from P.A.S. therapy. The severe complications occurred in children under the age of 4 years who did not receive P.A.S. Treatment with streptomycin and P.A.S. of young children with primary tuberculosis is discussed.

P.A.S. seems to be most useful in acute exudative tuberculosis (Marsh, 1952), and its value is limited in fibrous and caseous disease. In primary tuberculosis the most striking pathological feature is caseation in the regional lymphatic glands, and the primary focus in the lung is often small. It is therefore not surprising that P.A.S. has not caused a dramatic improvement in patients with primary tuberculosis.

I am grateful to the paediatricians, tuberculosis officers, and chest physicians of the Liverpool area for their help and co-operation in this investigation.

INCIDENCE OF BLACK TONGUE IN ANTIBIOTIC TREATMENT

BY

W. TOMASZEWSKI, M.D., Ph.D.

(From the Department of Therapeutics, University of Edinburgh, and the Clinical Laboratory, Royal Infirmary, Edinburgh)

Black tongue (brown tongue, glossophytia, melanglossia, nigrities linguae) has been described by many authors, but its aetiology is so far unknown. It is usually associated with hypertrophy of the filiform papillae. In cases of extreme hypertrophy there is an accumulation of matted hair-like processes on the surface of the tongue, and the condition is known as black hairy tongue. Heavy smoking, dyspepsia, irradiation, various inflammatory lesions, washing the mouth with hydrogen peroxide, boric acid, silver nitrate, or chromic acid, and the use of certain tooth pastes have been rightly or wrongly blamed for the production of black tongue.

With the introduction of antibiotics into therapeutics black tongue is seen much more often, and is now regarded as one of the side-effects of antibiotic treatment. It was first reported in connexion with treatment with penicillin lozenges (Bedford, 1946; Ellinger and Shattock, 1946b; Ackers, 1947; Cross, 1949; Wolfson, 1949), but it has also been reported after parenteral penicillin therapy (Lahiri, 1947). It was soon noticed that systemic treatment with other antibiotics—for example, aureomycin and chloramphenicol—also pro-

duced this syndrome (Harris, 1950; Phillips, 1950; Wilheims, 1950; Tomaszewski, 1951a, 1951b).

In this paper an account is given of clinical observations and direct microscopical examination of the tongue scrapings in cases of black tongue associated with antibiotic therapy and in cases of idiopathic black tongue. Very few histological examinations of this condition have so far been reported (Heidingsfeld, 1910; Swinburne, 1939). An attempt was made to ascertain whether there was a common bacterial or fungal factor in these two types of the condition which might be of aetiological significance. The use of antibiotics in the treatment of a few cases of idiopathic black tongue is also described.

Material and Method

Investigations were made in various wards of the Royal Infirmary, Edinburgh, in cases of idiopathic black tongue; patients treated systemically with aureomycin, chloramphenicol, and penicillin; and in healthy volunteers who sucked penicillin, aureomycin, chloramphenicol, and streptomycin lozenges. Scrapings of the surface of the tongue from as far back as possible were taken with a sterile slide, and the material was pressed with another slide in order to obtain an even film. The scrapings were made at intervals of one to three days before, during, and after treatment. The films were examined unstained and after staining with Gram. For the unstained films phase-contrast microscopy was found to be particularly useful.

Black Tongue Occurring During Systemic Treatment with Chloramphenicol, Aureomycin, and Penicillin

In all, 21 cases of black tongue produced by oral administration of chloramphenicol and aureomycin in capsule form were examined. They comprised about 10% of a group of patients treated with these antibiotics. The incidence of black tongue was approximately the same with either treatment. Two cases appearing after the intramuscular administration of penicillin were also studied. The results of the investigations are given in Table I.

TABLE I.—Microscopical Examination of Black Tongue which Developed in 23 Patients Receiving Systemic Treatment with Antibiotics

Antibiotic	No. of Cases	Days of Treatment Before Discoloration	Onset of Discoloration		Blotchy Cells	Leucocytes
			Absence of Bacterial Flora	Presence of Fungi		
Aureomycin	9	5–21 (8)	4	6	5	1
Chloramphenicol	12	5–14 (7)	6	7	6	2
Penicillin	2	14–18 (16)	—	1	1	1

Figures in parentheses = average.

In most patients no subjective symptoms accompanied the discoloration, which was often first noticed by the doctor. Some patients, however, complained of a feeling of some foreign body or a tickling sensation on the tongue. The discoloration usually appeared after a few days' treatment (average about one week). In one-third of the cases the change in colour was associated with some degree of hypertrophy of the papillae, but in the remainder the papillae were normal or atrophied. In a few cases the number of leucocytes in the scrapings increased. Staining with Gram revealed a few peculiarly marked epithelial cells, the so-called "blotchy" cells, in about half of the cases.

These antibiotics exerted a pronounced influence on the bacterial flora of the tongue. In about 40% of cases bacteria were absent when the discoloration appeared. In the others the bacteria were greatly decreased in number and changed in character; but the development of the discoloration was not associated with the presence of any particular type of bacterial flora. Fungi were present in about 60% when the discoloration first appeared, and were invariably monilia.

different types of renal tumour has been roughly 13:3:1, and is similar to that reported by Dick and Flint (1951) and Riches, Griffiths, and Thackray (1951).

Whereas tumours of the renal parenchyma and renal pelvis usually occur in adults, renal embryomas usually occur in children. There have been no exceptions to this general rule in our series; the ages of patients with parenchymal tumours ranged from 35 to 77 years, those with pelvic tumours from 47 to 72 years, and those with embryomas from 2 to 7 years.

All three types of renal tumour are usually unilateral, but three adult patients (6%) in our series had bilateral parenchymal tumours: one of these, however, had multiple metastases, and the tumour in the contralateral kidney was therefore not necessarily a second primary.

Clinical Features

Pain, palpable loin swelling, and haematuria are said to be the cardinal clinical features, but it is recognized that one or more of these symptoms and signs may be absent even when a tumour is large. On occasion it is a distal metastasis which first draws attention to the disease (Creedy, 1935).

Pain.—Three of the 38 patients with carcinoma of the renal parenchyma were admitted in a comatose condition and no reliable history could be obtained. In the remaining 35 pain occurred sooner or later in 24 and was the first and most prominent symptom in 11. Pain also occurred in 3 of the 10 patients with tumours of the renal pelvis, but was absent in all three children with renal embryomas. The 24 patients with carcinoma of the renal parenchyma who complained of pain included 16 with severe intermittent aching in the affected loin, five with severe intermittent pain in one or other upper abdominal quadrant, one with typical renal colic associated with the passage of clots of blood, one with painful clot retention of urine, and one with pain in the neck and shoulder due to extensive metastases in the cervical vertebrae and cervical lymph nodes. Twelve of the 16 patients with loin pain and three of the five with abdominal pain were found to have extensive tumours infiltrating the vertebral or paravertebral tissues: of the remaining six patients, three were found to have hydronephrosis and three had considerable haemorrhage into apparently circumscribed tumours. The three patients with painful tumours of the renal pelvis all had squamous carcinomas; two had marked hydronephrosis due to obstruction of the pelvi-ureteral junction by tumour, and one had extensive local infiltration of the growth.

Palpable Loin Swelling.—A palpable loin swelling was noted in 23 of the 38 patients with carcinoma of the renal parenchyma, 2 of the 10 patients with tumours of the renal pelvis, and in all three children with renal embryomas. All the palpable tumours exceeded 3 in. (7.5 cm.) in diameter, and, as might be expected, those tumours which were situated at the lower pole of the right kidney were felt more often than those which were situated at any other site. A renal tumour which is less than 3 in. (7.5 cm.) in diameter does not materially increase the dimensions of a kidney unless it grows outwards from one or other pole, and is not likely to be palpable unless it develops in a lower pole.

Haematuria.—Sixteen of the 38 patients with carcinoma of the renal parenchyma complained of one or more attacks of haematuria, and 7 of the 16 had haematuria as a primary symptom. In 12 of these 16 patients the tumours were found to have grown into the pelvis of the kidney, but in the other four the tumours were well circumscribed and had spread the calices apart without invading them. Congestion of the radicles of the renal veins may possibly account for the haematuria of these latter patients. Excluding the three patients who were admitted in coma and from whom no history was obtainable, 19 of 35 patients with carcinoma of the renal parenchyma denied any history of haematuria. Yet 15 of them had large necrotic growths wholly or partly

replacing the kidney and involving the pelvis, and only four had well-circumscribed tumours nowhere invading the pelvis. Nine of the 10 patients with tumours of the renal pelvis had haematuria; indeed, intermittent painless haematuria was the sole complaint in eight. The single instance of a tumour of the renal pelvis occurring without haematuria was found in a patient who had a carcinoma which had invaded the peritoneum and spleen and other adjacent structures. Painless haematuria was the first symptom in one of the children with a renal embryoma, but a very large tumour was found in the right flank a few weeks later. The other two children had no haematuria at any stage of their illness.

Weakness.—Weakness, or a feeling of tiredness, was a frequent and often dominant symptom in patients with carcinoma of the renal parenchyma; in fact, 14 of 35 patients made specific mention of it, and in nine it was the first indication of disease. Where weakness accompanies a renal parenchymal cancer it generally has a sinister significance: 7 of the 14 patients who complained of this symptom died within six months, four others died within eighteen months, and only three survived more than two years from the onset of the first symptoms of disease. Weakness was not a symptom in any of the 10 patients with carcinoma of the renal pelvis or in the three children with renal embryomas. The weakness did not seem to bear any relation to the degree of anaemia, and several patients who complained of weakness were found to have normal haemoglobin values. Loss of weight, however, often seemed to be associated with the weakness, and a notable preponderance of pulmonary and pleural metastases was found at necropsy in these particular cases.

Fever.—Temperatures ranging from 99 to 100° F. (37.2 to 37.8° C.) occurred in 21 of the 38 patients with carcinoma of the renal parenchyma, in 3 of the 10 patients with tumours of the renal pelvis, and in two of the three children with renal embryomas. When fever occurs in patients with carcinoma of the renal parenchyma it may be due to extensive necrosis in the primary tumour and may be relieved by nephrectomy. This was the case in three of our patients. In general, however, pyrexia is an indication of a poor prognosis (Griffiths and Thackray, 1949), and is often associated with the presence of extensive pulmonary metastases. The fever that was present in three of our patients with tumours of the renal pelvis was due in one case to a closed pyonephrosis on the same side as the tumour, in another to obstruction of the opposite kidney by tumour spread in continuity, and in a third to extensive lymph-node and osseous metastases as well as bilateral pleural effusions.

Varicocele.—Varicocele was noted in 3 of the 21 men with carcinoma of the renal parenchyma and was an early manifestation of disease; two patients had large tumours of the left kidney with extensive perineal infiltration and nodules of growth along the renal pedicle and inferior vena cava; the third patient had a large tumour of the lower pole of the right kidney with infiltration of the peritoneum and other neighbouring structures.

Investigations

Urinalysis

Twenty-five patients with carcinoma of the renal parenchyma and seven with tumours of the renal pelvis had their urine examined by microscopy and bacterial culture. The urine of 21 of the 25 contained some pus cells and red blood cells; 12 had moderate or marked pyuria, but in only three was the urine infected. The urine of the other four was reported to show no red corpuscles or pus cells, yet all four had large tumours and two had gross haematuria; it is likely that repeated examinations of the urine would have shown some abnormality in these particular cases.

The urine of seven patients with tumours of the renal pelvis was reported to contain scanty or numerous pus cells,

and in all but one there was an excess of red blood cells; in five of these the urine was sterile on culture and in two it was infected.

Urinalysis was omitted in the three children with renal embryomas.

Radiology

Plain radiographs of the urinary tract were available for study in 23 of the 38 patients with carcinoma of the renal parenchyma and showed enlargement of a renal shadow in 11 and calcification in one.

Intravenous pyelography was performed on 20 of these 23 patients and the pyelograms suggested the correct diagnosis in 18 but gave no clue to the diagnosis in two. The main abnormalities seen on intravenous pyelography were defective filling of part or disappearance of the whole of a calix in six cases, defective filling or disappearance of the renal pelvis in nine, distortion of calices in four, dilatation of the renal pelvis in two, displacement of the kidney in five, and displacement of the ureter in two. Absence of excretory activity, shown by intravenous urography, is generally interpreted as an indication of a poor prognosis (Wade, 1933; Griffiths and Thackray, 1949). Five of our patients showed no excretion from the affected kidneys, and were found at operation or necropsy to have either infiltration of the renal pedicle by tumour or practically complete replacement of the kidney by tumour tissue. A normal excretion pyelogram, however, does not necessarily mean that a tumour is small or the prognosis good, and 5 of the 11 patients with normal excretion pyelograms were found at operation to have inoperable tumours widely infiltrating the surrounding tissues.

Retrograde pyelograms were made on nine patients with carcinoma of the renal parenchyma, and the films suggested the correct diagnosis in all nine. They showed abnormalities similar to those seen in the intravenous pyelograms, but the clearer pictures obtained by the retrograde technique proved more valuable for diagnosis.

Plain radiographs of the urinary tract of all 10 patients with tumours of the renal pelvis showed no abnormality of the renal shadows. Intravenous pyelography was performed on nine of these patients, and the films suggested the correct diagnosis in five, but gave no clue to the diagnosis in four. Absence of excretory activity occurred in two affected kidneys, and was found to be due in one case to a pyonephrosis with a large papilliferous carcinoma of the pelvis and in another to a transitional-cell carcinoma lining the whole of the pelvis and everywhere infiltrating the kidney parenchyma.

The main abnormalities seen in the intravenous pyelograms of the patients with tumours of the renal pelvis were dilatation of the pelvis or of a calix in five instances, defective filling of the pelvis in three, and defective filling of a calix in two.

Retrograde pyelography carried out in two patients with tumours of the renal pelvis showed a distinct filling defect of the pelvis together with a moderate hydronephrosis in both cases. In a third patient it was impossible to pass a ureteric catheter beyond the pelvi-ureteric junction because it was blocked by an extensive squamous-celled cancer.

X-ray films of the spine, pelvis, and long bones for bony metastases may be misleading. Out of 26 patients submitted eventually to post-mortem examination, nine with tumours of the renal parenchyma and one with a tumour of the renal pelvis were all proved at necropsy to have extensive metastatic deposits in bones which, x-rayed within a month or so of death, had showed no bony abnormality.

Anaemia

Nineteen of the 38 patients with carcinoma of the renal parenchyma had moderate or severe anaemia, while, in contrast, at least 8 of the 10 patients with tumours of the renal pelvis had normal haemoglobin values. The cause of the anaemia is obscure and cannot be related either to the degree of haematuria or to the site and extent of metastases. It is

possible that unknown products of tumour necrosis are capable of suppressing blood formation, and it may be significant that seven of nine severely anaemic patients also had fever.

Treatment

The treatment of choice for renal tumours is nephrectomy, or nephro-ureterectomy in the case of renal pelvic tumours. Extensive local infiltration may prevent operative removal, but distal dissemination is not necessarily a contraindication to surgical excision of the primary growth; a solitary metastasis of a renal parenchymal tumour may be reasonably excised, and on occasion it is justifiable to carry out a palliative excision of a necrotic or bleeding primary tumour.

In our series nephrectomy or nephro-ureterectomy was carried out in 17 of the 38 patients with carcinoma of the renal parenchyma, 8 of the 10 patients with tumours of the renal pelvis, and the three children with renal embryomas.

Twenty patients with carcinoma of the renal parenchyma were considered to be inoperable; two being moribund on admission, four having extensively infiltrating and excessively vascular tumours, and 14 having multiple metastases in the lungs, skeleton, brain, or skin. A single patient refused surgical treatment.

Two cases of carcinoma of the renal pelvis were considered to be inoperable, one having extensive local infiltration and another extensive spinal and general metastases.

In all, 55% of our patients with renal tumours were treated by nephrectomy or nephro-ureterectomy and 43% were inoperable; this operability rate is lower than that reported by Riches, Griffiths, and Thackray (1951), perhaps because our series includes all hospital cases, medical and surgical.

Post-operative irradiation was given to seven patients with carcinoma of the renal parenchyma, to one with a renal pelvic tumour, and to the three children with embryomas. Two patients with inoperable tumours of the renal parenchyma were treated by deep x-ray therapy alone.

Results

The overall picture of the end-results of our series of patients with tumours of the kidney must be regarded as unfavourable, for 39 (76%) of the 51 patients were dead within an arbitrary period of four years from the time they were first seen. This sad state of affairs, however, is not really a true reflection on the treatment, since 23 (43%) of the patients proved to be inoperable.

Of the 38 patients with carcinoma of the renal parenchyma, 27 died of their disease at times varying from three weeks to eight years from the time they were first seen at hospital. One who was inoperable lived for just over four years after exploration; one other died six months after nephrectomy from causes unassociated with the kidney lesion and at necropsy there was no evidence of tumour; four others died shortly after operation; and five still survive—one at eight years, one at two years, two at two and a half years, and one at one year after nephrectomy.

Of the 10 patients with carcinoma of the renal pelvis, two were inoperable and were dead within four months of their admission to hospital, four died of their disease within two years of their nephrectomy, one survived eight years to die of natural causes, and three still survive at two, three, and three years after nephrectomy.

The three children with renal embryomas died of their disease three, five, and eighteen months after nephrectomy.

Comment

It is unfortunately true that renal tumours, like other deep-seated growths, remain for long inconspicuous. This means that the chances of successful treatment are often correspondingly poor, a fact borne out by the high proportion of inoperable cases in our series of patients and the indifferent end-results of treatment.

The symptoms of pain and haematuria usually cause a patient to seek medical advice, but there can be no guaran-

tee that the disease is still curable even when hospital attendance quickly follows the onset of symptoms.

Loin pain may sometimes be due to the associated hydro-nephrosis, but is often caused by extensive local infiltration of the paravertebral and vertebral tissues, which is synonymous with inoperability.

The presence or absence of haematuria has, in our experience, proved to be of little value in deducing either the size or the pathological picture of renal parenchymal tumours, but it is rare for a tumour of the renal pelvis to occur without bleeding.

The close relation between the cells of all three types of renal tumours and the blood vessels of their stroma increases the risk of distal dissemination. Occult metastases (Shackman and Harrison, 1948) may already be present at the time of operation, and there is a considerable risk of vascular dissemination as the result of handling the tumour at operation unless early ligation of the renal pedicle is practised. This is best achieved through an abdominal or thoraco-abdominal incision.

The prognosis in any individual patient depends not only on the histological grading of the primary tumour but also on the presence or absence of metastases. The former may be accurately assessed by the microscopist (Riches, Griffiths, and Thackray, 1951), but the latter is often proved only by time. Subsequent appearance of metastases after nephrectomy represents the progress of previously present but "hidden" tumour deposits.

All the surgeon can do is to extirpate, where possible, the primary tumour and the associated lymph nodes, and on occasion an apparently isolated distal metastasis. The radiotherapist may have something more to offer, but our experience in this direction, admittedly limited, has not been particularly encouraging.

The Association of Children's Officers has prepared a memorandum, *Cruelty to Children*, in response to a request made by the Joint Committee of the B.M.A. and the Magistrates' Association. The memorandum sets forth the views of children's officers on the secondary effects of cruelty to children, its definition, types, causes, and incidence. Remedies for neglect and physical violence are not difficult to apply, but prevention of mental cruelty is a much wider problem, says the memorandum, and one on which a lead can be given only by the medical profession, for there is as yet little public awareness of emotional suffering. The legal remedies are outlined and the importance of stable family life as a factor in reducing cruelty is stressed. The economic aspect of prevention is also considered. It may cost up to £5 a week to maintain a child in a children's home, over £6 in an approved school, and as much as £8 in a residential nursery. Children should not be removed from home simply for failure to attend school; it is less expensive to send the school attendance officer to fetch them every day. They should not be removed simply because the home is dirty; it is less expensive to put in a family service unit. Neither should they be removed simply because the house is overcrowded or insanitary or because there is no house; it is less expensive to provide a house. Children should not be removed from their mother simply because she is widowed, unmarried, or deserted, and so has to go out to work; it is less expensive to pay an adequate National Assistance allowance to keep her at home with them. The memorandum is obtainable from the association at Bradninch Hall, Castle Street, Exeter, price 4d.

PEPTIC ULCER IN WOMEN

BY

D. H. CLARK, Ch.M., F.R.C.S.Ed.

Surgical Registrar, Western Infirmary, Glasgow

Many writers have claimed that the symptoms of peptic ulcer—and presumably its activity—are influenced by menstruation and by pregnancy. Thus Taussig (1908), Sutherland (1910), and Szenés (1924) have suggested that menstruation causes an exaggeration of the symptoms of ulcer, while Mussey (1927), Crohn (1927), Hurst and Stewart (1929), and many others have claimed that pregnancy commonly has a beneficial effect. There is some evidence also to suggest that the symptoms of ulcer may be influenced adversely by the onset of the menopause. The investigation reported below was designed to test the validity of these observations.

The evidence here presented was obtained by interviewing 400 women in whom peptic ulcer had been demonstrated either by radiology or at operation. The ulcer was duodenal in 330 cases, gastric in 70. The patients' ages ranged from 21 to 74 years. In most cases the symptoms were of more than five years' duration.

Method of Interview

In a disease which remits and relapses with such facility the manner of eliciting and correlating the evidence is obviously of importance. During the interviews every effort was made to eliminate the element of suggestion. Much of the information was volunteered; much was obtained by questioning, as indirect as possible; some had to be obtained by direct questioning. All of these women had already been interviewed at least once previously, and the standard case record of the peptic ulcer clinic had been completed, so that information was already available on such relevant points as year of birth, age of onset of symptoms, and age at which complications occurred. At interview for the present investigation these points were confirmed. Thereafter inquiry was made into the gynaecological and obstetric history—for example, age at menarche, age at which pregnancies occurred, age at menopause, etc. Finally the effect of those events on the ulcer history was correlated.

Often the patient volunteered some information. If not, the standard questions were asked, "Have you noticed any relationship between your ulcer and menstrual period/pregnancy/menopause? Was your ulcer made better or worse, or did it remain the same? Apart from paraphrasing these questions according to the patient's understanding of them, no further attempt was made to elaborate a correlation. According to the patient's answer, "better," "worse," or "no change noted," the results were assessed. If a relationship had been noticed inquiry was made into the time relationship and the quality and quantity of the worsening or improvement.

Menstruation

Of the 400 patients, 291 had had ulcer symptoms before the menopause. In this group 81 (28%) claimed to have noted some relationship between menstruation and the occurrence of ulcer symptoms. In all these cases the symptoms were worse for a few days or a week before the onset of menstruation. In eight the ill-effect persisted during the menstrual period. In none had the symptoms been noted to increase in the post-menstrual phase.

In interpreting these findings it must be remembered that the symptoms of quite unrelated diseases may be aggravated in the pre-menstrual phase—the result, perhaps, of psychic influences or of the general malaise which many women experience at that time. In those patients who had noted pre-menstrual increase of symptoms there was no evidence

to indicate whether the exacerbation was due to such causes or to factors directly related to the menstrual cycle, or even to the use of aspirin and similar analgesics. On the whole, however, it may be concluded from the present series that the effect of menstruation on ulcer symptoms is inconsiderable.

Pregnancy

In assessing the effect of this state on the symptoms of peptic ulcer it must be remembered that normal pregnancy in healthy women is commonly associated with symptoms not unlike those of peptic ulcer.

Nausea, vomiting, and heartburn are said to occur during the first few months of pregnancy in almost 40% of cases. Usually they disappear about the end of the third month, but they may persist until term. Occasionally more severe dyspepsia occurs, and its resemblance to ulcer is heightened by the relief afforded by antacids. Rarely, hyperemesis gravidarum may lead to confusion.

In attempting to decide whether such symptoms were attributable to the ulcer, attention was paid to their severity and to the patient's own view regarding their origin. With their previous experience of peptic ulcer, most of the patients with heartburn, nausea, and vomiting during the early months attributed the symptoms to pregnancy and regarded the ulcer as "cured." In cases with more severe pain, relieved by alkalis, the patients were unable to distinguish it from the previous ulcer dyspepsia.

Of the total of 400 women 118 had been pregnant (see Table). The total number of pregnancies was 344. Of these, 313 had occurred subsequent to the onset of the peptic ulcer. On the criteria laid down above, it is believed that

Effect of Pregnancy

Total no. of women	400
Women with pregnancies	118
Total no. of pregnancies	344
No. of pregnancies after onset of ulcer symptoms	313
Free from ulcer symptoms	140 (44.8%)
Improved	136 (43.4%)
Not improved	37 (11.8%)

pregnancy was associated with a remission of the ulcer symptoms in 276 cases (88.2%). More than half of these patients claimed to have been completely symptom-free during the whole pregnancy; the remainder had minor symptoms which they regarded as unconnected with ulcer. In the remaining 37 pregnancies (11.8%) symptoms persisted which were indistinguishable from those of ulcer. In some of these the symptoms were much worse than previously, and 14 of the patients were admitted to hospital for treatment of the indigestion. At least four of these were found to have albuminuria, and it is possible that the exacerbation was not entirely due to renewed activity of the ulcer. In no case did a complication of ulcer (haemorrhage or perforation) occur during pregnancy.

Thus it would appear that in almost 90% of ulcer patients symptoms are in abeyance during pregnancy. In some of the cases the ulcer had been inactive immediately before the conception, and in them the remission persisted. In others the symptoms cleared up dramatically at an early stage of the pregnancy. In still others they improved gradually or the pregnancy became obscured by minor symptoms attributed to the pregnancy itself. Several patients averred that their successive pregnancies had been their only euphoric respites and that they had enjoyed the pregnant state for the well-being it afforded.

The benefit derived from pregnancy is generally short-lived, as Fig. 1 shows. By the end of the third month after parturition symptoms had recurred in almost half the cases, and by the end of the sixth month in three-quarters. At the end of two years almost every patient had suffered a recurrence.

Menopause

The distribution curve of the ages of the 400 patients at the onset of ulcer symptoms is shown in Fig. 2. In Fig. 3 it is compared with a similar curve for male patients, based

upon figures derived from 1,393 cases from the peptic ulcer clinic. It will be seen that, while in both sexes there is a steep rise of incidence between the ages of 15 and 24 years, thereafter there is a difference, in that in females there is a deficit during the age period 25–40 years, followed by a

FIG. 1.—Recurrence of ulcer symptoms after parturition.

FIG. 2.—Age at onset of symptoms of peptic ulcer in 400 women.

FIG. 3.—Age at onset of symptoms of peptic ulcer in males (1,393) and females (400).

secondary rise of incidence between 40 and 50. These features suggest a possible relation to the child-bearing period and the menopause.

In order to explore this possibility the time relationship between the onset of ulcer and the menopause has been noted in 204 of the women. In Fig. 4 these cases have been plotted in five-year groups according to whether the ulcer began to produce symptoms before or after, or about the time, of the menopause. Those cases in which ulcer symptoms developed in the five-year period which includes the year of the menopause and the two years before and after it are recorded at M. Others are included in the appropriate earlier or later five-year groups. It will be seen that there is a striking peak of incidence at or about the menopause.

The remaining 196 women have not yet attained the menopause. In order to produce a composite curve, comparable with Fig. 2, relating all 400 cases to the menopause, the onset of ulcer symptoms in this remaining group has

FIG. 4.—Relation of age at onset of symptoms to date of menopause in 204 women who have reached or passed the menopause.

FIG. 5.—Relation of age at onset of symptoms to actual or expected date of menopause.

been related to the expected age for that event. On the information available for the 204 cases the age of menopause varied between 37 and 56 years, with over 90% between 40 and 50 years; the average was 45 years, and this figure was treated as the expected age of menopause in the remaining 196 cases.

Working on this basis, Fig. 5 shows the time relation of the onset of ulcer symptoms to the actual or expected age of menopause in the whole series of 400 cases. It will be seen that it again emphasizes the two peaks of incidence in women, the former occurring in later adolescence and early adult life, the latter at about the time of the menopause.

FIG. 6.—Duodenal ulcer (330). Relation of age at onset of symptoms to actual or expected date of menopause.

FIG. 7.—Gastric ulcer (70). Relation of age at onset of symptoms to actual or expected date of menopause.

FIG. 8.—Relation of date of complications (haemorrhage or perforation) to actual or expected date of menopause (haemorrhage 95, perforation 33).

In this series of 400 there were 330 patients with duodenal ulcer and 70 with gastric ulcer. In Figs. 6 and 7 the two types have been treated separately in the manner described above for the series as a whole. It will be seen that the menopausal rise of incidence is not confined to one type, though, perhaps owing to paucity of numbers, the peak is less evident in the case of gastric ulcer.

In those women who had had ulcer symptoms before reaching the menopause inquiry was made concerning the progress of the symptoms at that time. There were 92 in this group and 41 (45%) of them either volunteered or agreed on indirect questioning that their symptoms had worsened at or about that time. This trend was confirmed by the fact that a large number of them were then constrained to attend hospital for the first time on account of ulcer symptoms.

The incidence of complications of ulcer gives added evidence of the harmful effect of the menopause on the activity of the lesion. Among the total series of 400 patients there was a history of 128 complications (95 haemorrhages and 33 perforations). Fig. 8 shows the time of occurrence of those complications in relation to the expected or actual time of the menopause. It will be seen that again there is a striking correlation, the number of complications occurring in the five-year period centred on the year of menopause being more than double that of any earlier or later period. Study of individual case records seems to give emphasis to the correlation, for several patients had more than one complication within a short time of the menopause, while one had two haematemeses and two perforations within the actual five-year period.

Discussion

Since peptic ulcer is prone to spontaneous remissions, great caution is necessary in attributing variations in symptoms to external events. However, the regularity with which remission of symptoms occurs in pregnancy and the frequency with which ulcers start, flare up, or undergo complications at or about the time of the menopause give us justification for concluding that those two states do influence the activity of the ulcer.

The manner in which they do so is uncertain, but two lines of speculation suggest themselves. (1) The effect of psychological disturbances on gastric function has been known for a long time, and has been demonstrated convincingly in recent years by many workers, notably Mittelman and Wolff (1942) and Wolf and Wolff (1943). It may well be that the remission of ulcer symptoms in pregnancy is related to the general feeling of well-being, success, and fulfilment characteristic of that state, while the mental stresses, irritability, and emotional imbalance of the menopause may account for the renewed ulcer activity at that time. (2) The mechanism may possibly be a hormonal one. It is well established that pregnancy is a period of increased hormonal activity with a marked increase in the gonadotrophic, luteal, and oestrogenic hormones, while the menopause is associated with a diminution in the sex hormones, and particularly the oestrogens.

Recent reviews of the literature by Sandweiss *et al.* (1939), Bralow *et al.* (1948), and Sandweiss (1951) make it clear that despite much research there is no clear proof of a relationship between the sex hormones and peptic ulcer. Certainly the use of these hormones in the treatment of ulcer has been disappointing, though it should be observed that they are present in pregnancy in much larger amount than can be given therapeutically.

Summary

The natural history of peptic ulcer in 400 women has been investigated with reference to menstruation, pregnancy, and the menopause.

Menstruation has an inconsiderable effect on ulcer symptoms.

Relief of symptoms occurred in nearly 90% of pregnancies. In most of them the remission occurred early

in pregnancy and persisted until term. Those patients who gained no relief had a higher proportion of abnormalities such as albuminuria and hyperemesis.

After parturition, recurrence of ulcer symptoms was common, especially during the first six months.

An unduly large proportion of ulcers start, flare up, or undergo complications at or about the time of the menopause.

I am indebted to Professor C. F. W. Illingworth for his help and criticism in the preparation of this paper; and to Miss S. Murray, of the peptic ulcer clinic, for secretarial help in arranging the interviews.

A CASE OF GRANULOMA INGUINALE IN SCOTLAND: RESPONSE TO AUREOMYCIN

BY

A. GIRDWOOD FERGUSON, M.D., F.R.F.P.S.

AND

G. B. S. ROBERTS, M.B., Ch.B., B.Sc.

(From the Department of Dermatology, Stobhill Hospital, and the Department of Pathology of the University and Western Infirmary, Glasgow)

Granuloma inguinale, first described by McLeod (1882) and later by Conyers and Daniels (1896), is often thought of as a tropical disease, but it has been found in almost every country and climatic zone. Donovan's non motile encapsulated coccobacillus, long regarded as the probable causal agent, has been confirmed in this role by inoculation experiments in negro volunteers (Greenblatt *et al.*, 1939; Dienst *et al.*, 1947). Anderson (1943) described a method of cultivating the organism in the yolk sac of developing chick embryos; Dunham and Rake (1948) and Dienst (1948) reported successful culture in an artificial medium consisting mainly of yolk obtained from both fertile and infertile eggs. A positive skin reaction in human cases of the disease has been demonstrated by Kornblith (1944), with triturated infected material as antigen, and by Dienst *et al.* (1947), with a yolk sac culture of Donovan's organisms.

Although similar to the response evoked by the Leishman-Donovan body and by *Histoplasma capsulatum* (Hutchinson, 1952), the lesion in granuloma inguinale differs from these by the presence among its predominating plasma-cell and endothelial-cell masses of small polymorphonuclear micro-abscesses described by Allen (1948). Pund and Greenblatt (1937) showed that the organism has a characteristic morphological appearance in the tissues of the host, and the demonstration of these bodies is a further point in the differentiation of these lesions from leishmaniasis and histoplasmosis. An even closer similarity is seen to the lesions of rhinoscler-

oma, in which the main difference is the greater abundance and size of monocytic cells containing the causal organism.

The exact mode of transmission of the infecting agent remains unsettled. Males appear to be comparatively seldom affected; and the almost constant freedom from infection of the coital partners of manifest cases renders a venereal origin extremely improbable. Transmission of infection by an insect vector (*Phthirus pubis*) has been suggested by Butts and Olansky (1946).

Before modern antibiotics became available the treatment of choice was antimony, in the form of tartar emetic and later as stibophen. Greenblatt *et al.* (1947), however, found that antimony preparations were proportionately less effective as the disease became more chronic. From 1947 to 1950 the efficiency of streptomycin, chloramphenicol, and aureomycin in combating even the most recalcitrant cases has been amply demonstrated.

We are prompted to record the following case of granuloma inguinale, recently encountered in Glasgow, because it shows classical clinical and pathological features; because of its rapid response to oral aureomycin therapy despite manifest chronicity; and because of obscurity as regards the source of infection. Furthermore, a search of the literature failed to reveal any previous record of a case in which infection was apparently contracted in the United Kingdom.

Case Report

An unmarried woman aged 29 noticed a small warty growth at the anal orifice about five years ago. The lesion, although remaining localized to the perianal region, increased in size and finally ulcerated. At this stage (September, 1947) she was referred to a Glasgow hospital, where a biopsy from the affected part showed the features of a chronic non-specific plasma-cell granuloma. The Wassermann reaction was negative and the clinical diagnosis then made was that of non-venereal warts. X-ray therapy was administered (total: 1,500 r in daily doses of 300 r at 85 kV). There was some transient improvement after treatment, and in October, 1947, applications of carbon dioxide "snow" reduced the lesion to a small pea-sized warty growth.

FIG. 1.—The lesion before treatment, showing the extensive ulceration encircling the vagina and extending along the groin.

affected area was often macerated and foul-smelling, and the patient again sought advice from her practitioner. In consultation, one of us (A. G. F.) made a provisional diagnosis of granuloma inguinale and arranged her admission to Stobhill Hospital on September 11, 1951, for further investigation and treatment. She denied sexual intercourse and stated that she had

never been out of Scotland. There was no history of local injury or of pre-existing disease of the skin at or near the area involved.

Examination revealed a raised and sharply demarcated vegetative plaque with central linear ulceration. This lesion extensively involved the perineal cleft, vulva, and groins, the skin of the left groin being most severely affected.

The lesion was in general moist and foul-smelling (Fig. 1); the inguinal lymph nodes were not enlarged and there was no evidence of sinus formation. The Wassermann and Frei tests were negative.

Bacteriology.—Tissue smears made from the under surface of material excised for histological examination showed large mononuclear cells containing intracellular organisms which were Gram-negative but stained with Wright's stain, when they appeared as cocco-bacilli with clear unstained capsules. These organisms presented the morphological appearances of Donovan bodies (Fig. 2). An attempt was made to culture the Donovan bodies on egg yolk, using the method of Anderson (1943). Although various antibiotics were mixed with the tissue suspension, in all instances the eggs became heavily infected with pyogenic organisms and the embryos died.

Histology.—The lesion was a raised papillomatous granuloma covered by a very hypertrophic epithelium. No ulceration was noted in the material submitted, but in the upper and mid-corium there was granulation tissue of a rather open texture through which were scattered inflammatory cells, chiefly plasma cells, polymorphs, and mast cells. Small polymorphonuclear abscesses were seen between the dermal papillae. In the deeper portions of the lesion the fibrous tissue was very dense, and in its meshes there were large collections of plasma cells.

Examination of the superficial portion of the lesion revealed a number of large macrophages which contained intracytoplasmic cysts. These cysts in turn contained small round bodies which often appeared to be arranged at the periphery (Fig. 3) but could sometimes be seen throughout the cyst. The appearance of these cells corresponded with that of the "pathognomonic cells" of granuloma inguinale described by Pund and Greenblatt (1937). The bodies seen in these intracytoplasmic cysts stained with haematoxylin but were Gram-negative. They did not stain satisfactorily by the Romanowsky methods (Leishman, Giemsa, Dominici). Both the Donovan bodies and the wall of the cyst stained positively with the periodic-acid Schiff technique. In view of the statement by Pund and

FIG. 2.—Smear from the lesion, showing Donovan bodies in a large mononuclear cell. (Leishman's stain. $\times 2,000$.)

FIG. 3.—Donovan bodies are seen lying in an intracytoplasmic cyst in the mononuclear cell in the centre of the field. (Haematoxylin and eosin. $\times 1,000$. Paraffin section.)

Greenblatt (1938) that the Donovan bodies have an affinity for silver, various silver-staining techniques were tried, but all gave negative results, which may have been due to the material being fixed in formol corrosive fluid, which has a generally deleterious effect on this form of staining.

Treatment.—When investigations had been completed aureomycin therapy, 2 g. daily in divided dosage by mouth,

FIG. 4.—The lesion after treatment with aureomycin. The ulcerated area has been completely healed by a smooth epithelium.

the proliferative and ulcerative lesion was replaced by soft and pliable scarring. Aureomycin and dibixin were discontinued on November 13 (the total dosage of aureomycin being 80 g.). Improvement has since been maintained and healing was complete (Fig. 4). Examination on June 11, 1952, revealed no evidence of recurrence.

Discussion

Although granuloma inguinale is most common in tropical and subtropical areas, sporadic cases are occasionally seen in temperate climates. Our patient, who had never been abroad, developed her disease in Scotland; we have been unable to trace any record of a previous example, but it is possible that cases occur which are either unrecognized or not reported, particularly in seaport towns.

The question of a source of infection is one of considerable interest. Despite a wealth of available material in the New World and the Tropics, opinions remain divided about the venereal origin of this disease. The comparatively low infection rate among males and the apparent resistance to contagion of coital partners are points of importance as regards a possible non-venereal aetiology. In our case there was an emphatic denial of exposure to venereal infection, and there is nothing in the history to suggest that this statement should not be accepted. There is therefore no clear indication of the method of transmission of the causal organism. The possibility of an indirect mode of infection—for example, by pubic lice—cannot, however, be entirely discarded, and in this connexion the observations of Butts and Olansky may well be important.

Since the advent of the antibiotic series of drugs it has become evident that antimonial preparations, ineffective in chronic and long-standing cases of granuloma inguinale, are outmoded. Penicillin has been found by Chen *et al.* (1951) to produce a potent bacteriostasis in the laboratory, but has proved disappointing *in vivo*. Streptomycin, terramycin, chloramphenicol, and aureomycin have all proved useful in actual practice, the dosage varying according to the duration of infection and the chronicity of the disease. Important

observations regarding the potency of aureomycin are to be found in the work of Wright *et al.* (1948), Hill *et al.* (1949), and Wammock *et al.* (1950). Further, Greenblatt *et al.* (1950) reported good results using aureomycin by mouth in a series of 46 patients, five of whom had not responded to streptomycin. The average total dosage was 20–30 g. over a period of ten to fifteen days, and only two relapses were observed. The smallest total dose was 10 g. and the largest 70 g. In this latter instance the patient's lesions were extremely chronic and had been streptomycin-resistant. In general it appeared that extensive or slowly responsive cases required from 40 g. to 70 g. of the medication in order to effect a complete cure. Our case was given a total of 80 g. in view of the long duration and extensive nature of the disease process. Up to the time of writing there has been no evidence of recrudescence.

The infecting agent persists for a long time in tissue. Here the material removed in 1951 showed "pathognomonic" cells containing numerous Donovan bodies which had remained unaltered in spite of x-ray and other local therapy. Nevertheless, it would appear easier to confirm the diagnosis by the examination of smear preparations than by histological examination of the material removed. The diagnosis was readily apparent in 1951 on the examination of smears, in which the organisms have a very characteristic appearance, but the bodies were found only in sections after prolonged search. Furthermore, the presence of the infecting organism in tissue was not appreciated in 1947, although the chronic granulomatous nature of the lesion was then fully apparent and the question of a specific causal agent was raised.

The lesions in our case showed well-marked pseudo-epitheliomatous hyperplasia, a feature which has been stressed by Philpotts (1947). This, together with widespread plasma-cell infiltration in the corium, should always suggest a search for "pathognomonic" cells and organisms in suspected examples of the disease.

Summary

A case of granuloma inguinale of the chronic ulcero-vegetative type is described.

The patient contracted the disease in Scotland, and this would appear to be the first recorded example of such an occurrence in Great Britain.

A venereal origin of the disease could not be established.

Despite the chronicity of the condition a complete cure was achieved by means of a total dose of 80 g. of aureomycin over a period of five weeks.

Our thanks are due to Mr. P. S. Waldie, Department of Medical Photography, Stobhill Hospital, for the clinical photographs.

PYRIMETHAMINE IN TREATMENT OF VIVAX MALARIA

PRELIMINARY REPORT

BY

JASWANT SINGH, M.B., Ch.B., D.P.H., D.T.M.&H.

A. P. RAY, M.B., B.S.

P. C. BASU, M.B.

AND

B. G. MISRA, L.M.F., L.T.M.

(From the Malaria Institute of India, Delhi)

Pyrimethamine ("daraprim"), a 2:4-diaminopyrimidine compound, has been shown to be highly effective against blood-induced infection of *Plasmodium gallinaceum* and *P. berghei* (Falco *et al.*, 1951). Jaswant Singh, Misra, *et al.* (1951) recently observed that the drug is four times as active as proguanil against *P. knowlesi* in rhesus monkeys, and that it has causal prophylactic action against *P. gallinaceum* in fowls (Jaswant Singh, Basu, and Ray, 1952). Jaswant Singh, Krishnaswamy, *et al.* (1952) have also reported that *P. berghei* in albino mice showed phenomenal sensitiveness to pyrimethamine.

In *P. falciparum* and *P. malariae* infections, McGregor and Smith (1952) have demonstrated that the compound has powerful action on dividing schizonts, but less so against trophozoites. But so far, to our knowledge, very little has appeared in the literature on the effect of the drug against *P. vivax* infections.

Present Investigation

The present report records findings on the effects of this compound on the clinical symptoms and also on the parasites in the first 30 cases of vivax malaria attending hospitals in Delhi State. Seventeen patients gave a previous history of malaria during the past year or so, and in these the spleen was palpable in five cases. On the first examination of blood smears, besides other forms, gametocytes were detected in 11 cases. In 13 other cases there was no previous history of malaria, the spleen was not palpable, and gametocytes were detectable in 9.

Pyrimethamine was administered orally, and each patient received a single dose of 25 mg. (2½ tablets, each containing 10 mg.) of the base. The results are tabulated. The overall

Clearance of Clinical Symptoms, Asexual Parasites, and Gametocytes in Hours

Clearance of	In Hours						Total Cases
	24	48	72	96	120	144	
Clinical symptoms:							
Group I	9	3	5	—	—	—	17*
Group II	5	2	6	—	—	—	13
Total	14	5	11	—	—	—	30
Asexual parasites:							
Group I	6	8	3	—	—	—	17
Group II	5	5	2	1	—	—	13
Total	11	13	5	1	—	—	30
Gametocytes:							
Group I	1	1	4	5	2	1	14
Group II	—	—	3	2	1	3	9
Total	1	1	7	7	3	4	23

Group I = with previous history of malaria.
Group II = No history of previous attacks.
* Five out of 17 cases had enlarged spleen.

picture appears to be that 46.6% (14 out of 30) of the patients became afebrile within 24 hours, 63.3% within 48 hours, and 100% within 72 hours. In 36.6% of the cases clearance of asexual parasites was attained within 24 hours, in 80% within 48 hours, and in 96.6% within 72 hours.

Out of 14 patients who became afebrile within 24 hours, 9 (64.3%) were from Group I—that is, they had had previous attacks of malaria during the course of a year or so—as compared with 35.7% in Group II, without any previous history. Further, it was observed that 6 out of 13 cases (46.1%) in Group II had the second paroxysms 48 hours after the treatment, as against 5 out of 17 (29.4%) in Group I.

The rate of asexual parasite clearance within 24 hours was 54.5% (6 out of 11) in Group I, and 45.5% (5 out of 11) in Group II. Moreover, parasite clearance in all cases in Group I occurred within 72 hours, against 96 hours in Group II.

Thus it would seem that clearance of symptoms and asexual parasites was more rapid in those who had a previous history of malaria than in those who had not. McGregor and Smith (1952) observed that in *P. falciparum* and *P. malariae* malaria the drug acts "just as swiftly in non-immunes as in subjects who possess considerable immunity." But in view of the present observations we are unable to lend support to this view so far as vivax malaria in India is concerned. Therefore the question of repeating the dose may have to be considered, particularly in cases without any previous history of malaria.

The action of pyrimethamine on gametocytes was found to be much slower, and in only 39.1% of the cases did the gametocytes disappear within 72 hours; in 4 out of 23 cases (17.3%) they persisted for 120 hours or more.

The redeeming feature of pyrimethamine seems to be its remarkable effectiveness against *P. vivax* in so small a dose (25 mg.). It would appear that the drug has a future, and further work is indicated.

In view of the high degree of cross-resistance between proguanil and pyrimethamine, recently demonstrated in simian malaria by Jaswant Singh, Ray, *et al.* (1952), one must withhold final judgment until reports on large-scale and continued observations are available, particularly from areas where some strains of plasmodia have been reported to be refractory to proguanil (Field and Edeson, 1949; Gilroy, 1950, personal communication; Chaudhuri, 1951; Wilson *et al.*, 1952).

We wish to thank Brigadier J. S. K. Boyd, of the Wellcome Laboratories, London, for his valuable suggestions from time to time since the beginning of the series of investigations with pyrimethamine, and also for the supply of the drug whenever required.

A new edition of the *Alphabetical and Local List of Old Students* has just been issued from St. Thomas's Hospital Medical School. The list, which is revised to March 30, 1953, and supersedes the 1948 issue, gives brief details of nearly 3,000 alumni of the Medical School. It may be obtained from the Beadle of the Medical School, Albert Embankment, London, S.E.1, price 5s. 3d., including postage.

GOITRE AND HYPOTHYROIDISM DEVELOPING DURING TREATMENT WITH P.A.S.

BY

H. T. DAVIES, M.B., B.S.

House-Physician, St. Bartholomew's Hospital, London

AND

H.-J. B. GALBRAITH, M.D., M.R.C.P.

Medical Registrar, St. Bartholomew's Hospital, London

Since the introduction of *p*-aminosalicylic acid (P.A.S.) for the treatment of tuberculosis by Lehmann in 1946, many thousands of patients must have received large doses of this drug for long periods. It is only during the past year or two that a few reports have appeared on the development of goitre and hypothyroidism in patients being treated with P.A.S. In these reports, as in the case here described, the circumstances are most suggestive that P.A.S. has a goitrogenic action in some individuals.

Case Report

A male medical student aged 28, with no personal or family history of thyroid disease, was admitted for treatment of pulmonary tuberculosis. On February 21, 1952, intramuscular streptomycin, 1 g. every three days, and P.A.S. (as the sodium salt), 10 g. daily, were started; later the dosage of P.A.S. was increased to 12 g. The patient's progress was satisfactory until, on July 29, after 56 g. of streptomycin and 1,600 g. of P.A.S. had been given, a symptomless diffuse non-tender goitre was noticed. Recently the patient had felt some impairment of appetite and possibly an increased susceptibility to cold; his upper face appeared puffy, but there was otherwise no clinical evidence of hypothyroidism. The serum cholesterol was 220 mg. per 100 ml.

On August 6 the basal metabolic rate was -10%, and on August 19 the streptomycin and P.A.S. were replaced by isoniazid. At this time the basal metabolic rate was -21% and the serum cholesterol 268 mg. per 100 ml. Radio-iodine studies seven days after discontinuation of the drugs suggested excessive thyroid activity with, however, no corresponding increase in the rate of organic binding of the iodine. This pattern is compatible with the incomplete removal of a thiouracil-like block of thyroid activity. Radiographs showed no recent increase in size of the heart. The electrocardiogram was normal.

Four weeks after discontinuation of streptomycin and P.A.S. the appetite and facies had returned to normal, the goitre was only just palpable, and the basal metabolic rate had risen gradually to -1%, although the serum cholesterol had fallen to only 245 mg. per 100 ml. Four months later the thyroid was still just palpable, the basal metabolic rate was +5%, and the serum cholesterol was 215 mg. per 100 ml.

Discussion

The development of myxoedema during P.A.S. therapy was first described by Clausen and Kjerulf-Jensen in 1951. Three patients developed hypothyroidism and goitre after taking 610 g., 1,780 g., and 2,500 g. of P.A.S. respectively in the usual dosage. The endocrine state and the gland size in the usual dosage. The endocrine state and the gland size in the usual dosage. The endocrine state and the gland size in the usual dosage.

Bergqvist and de Maré (1952) reported two cases of hypothyroidism with goitre and two cases of goitre without objec-

tive evidence of hypothyroidism in patients treated with simultaneous thiosemicarbazone and P.A.S. Streptomycin had been given to three of the patients for part of the time, but it would seem difficult to incriminate this drug. One patient died of myxoedema and cerebral oedema; at necropsy the thyroid showed a glandular hyperplasia identical with that seen after the administration of thiouracil. In two other cases the authors thought the thyroid condition improved when the thiosemicarbazone was stopped, the administration of P.A.S. continuing; while in the fourth the goitre had disappeared five months after simultaneous withdrawal of P.A.S. and thiosemicarbazone. These authors suggested that the thiosemicarbazone and P.A.S. may have a synergistic action or that the thiosemicarbazone may act by retarding the renal excretion of P.A.S. A further case of goitre following treatment with P.A.S. and thiosemicarbazone has been described by Librach (1952). Bergqvist and de Maré also quote a personal communication from Stavanow, who has seen "a few cases of goitre and one case of mild hypothyroidism following P.A.S. medication."

In animal experiments, principally on rats, Kjerulf-Jensen and Wolffbrandt (1951) showed that P.A.S. and its degradation product in the body, meta-aminophenol, produce a thyroid hyperplasia qualitatively comparable with, but quantitatively much less than, that induced by thiouracil. This hyperplasia can be prevented by the simultaneous administration of thyroid extract.

Hanngren (1952), in a preliminary communication on radio-iodine studies of three patients before and during P.A.S. therapy, showed that P.A.S. inhibited the uptake of iodine by the thyroid.

Astwood and his colleagues (1945) found that many aminophenol compounds, including 4-aminobenzoic acid, had a goitrogenic effect. It is not surprising, therefore, that P.A.S. (4-amino-2-hydroxybenzoic acid) has been shown to have a similar action.

Summary and Conclusions

A case in which goitre and mild hypothyroidism occurred during treatment with P.A.S. and streptomycin is described; the thyroid condition returned to normal within four weeks of discontinuing treatment.

The literature, in which at least 10 similar cases are mentioned, is reviewed.

It would seem that P.A.S. has a definite although feeble antithyroid action similar to that of the thiouracil drugs, and in a small proportion of patients receiving such treatment goitre and, possibly, hypothyroidism may develop without the dosage being excessive or the duration of treatment very prolonged. Fortunately, the process appears to be reversible if the situation is realized, and the administration of P.A.S. stopped, before the myxoedema is severe.

Our thanks are due to Dr. A. W. Spence and Dr. F. H. Young for permission to publish this case and to Professor J. Rotblat for the radio-iodine studies.

The Annual Federal Conference of the Flying Doctor Service of Australia was opened in Sydney by Sir John Northcott, Governor of New South Wales, on April 20. During 1952 aircraft maintained at nine stations in the Australian outback made nearly 1,000 flights, covering just over 253,000 miles.

Medical Memorandum

Polyarteritis Nodosa Presenting as Acute Diabetes Mellitus

In view of the manner in which the following case presented, it is felt that it may be of value as yet another form in which polyarteritis nodosa may be encountered.

CASE REPORT

The patient, a South Indian pipe-fitter aged 30, was admitted to hospital on December 17, 1951, having had fever and headache for three days. Three months previously he had been an in-patient for a disease that resembled enteric fever, and his serum at that time gave a Widal reaction of 1 in 250 to *Bact. typhosum* H. He had a continuous high temperature for 20 days, but with relative bradycardia and a palpable spleen. He was discharged after five weeks. The only medicine received was aspirin in small amounts.

On examination his temperature was 102° F. (38.9° C.), pulse 110, respirations 28; no physical signs were found. Total white cells were 10,000 (74% polymorphs, 16% lymphocytes, 8% monocytes, 1% eosinophils, 1% basophils). No malaria parasites were seen. The Widal reaction was negative. His temperature fell to normal at the end of 72 hours, and he was symptomless; he had been given aspirin, 5 gr. (0.32 g.) thrice daily, and Dover's powder, 15 gr. (1 g.) at night, for three days.

Early on the sixth morning he complained of severe pain in the left abdomen, lateral to the umbilicus; there was deep tenderness in this area and the abdomen was soft. He was given $\frac{1}{4}$ gr. (16 mg.) of morphine and 2 ml. of nikethamide intramuscularly. Later in the morning the tip of the spleen could be felt for the first time. At 3 p.m. he had a "fit," observed by the nurse, which consisted of twitching of the face, both eyes, hands, and legs. After this he was very quiet for 10 minutes, but then became noisy and started throwing himself about the bed for 30 minutes; this was followed by a similar fit to the first. When seen by the doctor the patient was in coma, but the corneal reflex was present; there were no localizing signs, but both pupils were widely dilated. No reflex changes were found, but there were gentle squirming movements of both arms. His blood pressure was 120/80.

A catheter specimen of urine showed a heavy cloud of albumin, sugar +, and acetone +. Many pus cells, a few red blood cells, and granular casts were present in the deposit. The blood sugar was 265 mg. per 100 ml. Cerebrospinal fluid examination showed a yellowish fluid, under normal pressure; proteins 0.04 g.%; no globulin; chlorides 656 mg. per 100 ml.; a few red blood cells; and 9 lymphocytes per c.mm. The flow increased on jugular pressure.

The following measures were taken on the assumption that this was a diabetic coma: normal saline intravenously, gastric lavage with normal sodium bicarbonate solution, 50 units of insulin subcutaneously, and 2 gr. (0.13 g.) of phenobarbitone sodium intramuscularly.

He showed great restlessness, but this was controlled by 4 ml. of paraldehyde intramuscularly and 1/100 gr. of hyoscine. The blood sugar on the following morning (seventh day) was 50 mg. per 100 ml., and shortly after he vomited dark-brown material suggesting altered blood. He was still in coma. His blood pressure was 130/90. Urine was collected from an indwelling catheter, and penicillin, 1,000,000 units four-hourly, was ordered. Urine output was only fair after substitution of 5% glucose in half normal saline; the acidosis was controlled with small amounts of insulin, the carbon-dioxide-combining power rising from 29 to 60 vols.% over the next 48 hours, sugar and acetone disappearing from

the urine. In addition the patient was given 8 g. of potassium chloride as a rectal drip of 2% potassium chloride over the next 24 hours. The chest remained free of adventitious sounds, though the temperature rose to 100° F. (37.8° C.).

On the ninth day the blood pressure rose to 170/115, with a pulse of 116. Intravenous therapy was stopped and 2,000 ml. of 5% glucose in normal saline was given per rectum. There was no relief from the deep coma; the urine continued to show albumin +, W.B.C. ++, R.B.C. +, but no casts, and it was acid. Ophthalmoscopic examination revealed early papilloedema but no disease of vessels and no exudates or haemorrhage. Plasma cholesterol was 70 mg. per 100 ml., and the Widal reaction was again negative. On this day it was noted that arterial pulsation in both femoral arteries ceased just below the groins and there were bilateral colour changes in the legs below the knees. The temperature of both limbs was reduced.

On the tenth day the blood pressure rose to 200/120 and the condition of both legs was the same. There was no change in his general condition; he continued to secrete urine on a total rectal intake of 1,400 ml. He died quietly on the fifteenth day. The temperature rose terminally to 102° F. (38.9° C.).

Post-mortem Examination.—An emaciated male with bilateral dry gangrene of legs below the knees. The following points were of interest: (1) 2 oz. (28 ml.) of straw-coloured fluid in the pericardium; a small discoloured area in the posterior myocardium of the left ventricle suggesting a healed infarction. (2) Pleura and lungs appeared normal. (3) Liver showed an area of yellowish discoloration in the left lobe. (4) Greater omentum showed a small area of greenish discoloration in its free edge. (5) Pancreas apparently normal. (6) Spleen showed a massive infarct. (7) Both kidneys showed massive infarcts progressed to necrosis. Adrenals apparently normal. (8) The brain showed no evidence of meningitis, abscess, haemorrhage, thrombosis, or emboli. The pituitary fossa and pituitary gland were apparently normal.

Histological examination showed an acute arteritis in both the larger and the smaller vessels, well seen in the femoral arteries and the arteries of the spleen, liver, brain, and kidney. There was a panarteritis with degenerative changes in the intima and media of both arterioles and larger vessels, with considerable perivascular inflammatory cell reaction and penetration of all layers. In the afferent arterioles of the kidney, fibrinoid degeneration was seen with arteriolo-necrosis. The aneurysmal formation in the larger vessels was of interest in that it is seldom seen in the modern form of polyarteritis (Robb-Smith, 1952, personal communication).

COMMENT

In this case the only known possible antigens were the *Bact. typhosum* and aspirin, but the former rests only on the evidence of a positive Widal reaction, which may have been an anamnestic reaction in the absence of positive blood, stool, or urine cultures.

During the patient's last illness the diagnosis of polyarteritis nodosa was not considered until the appearance of bilateral arterial block in the legs. Then in retrospect the onset of acute abdominal pain followed by convulsions and cerebral vascular accident suggested the diagnosis. The absence of an eosinophilia was not thought to be of significance.

It is believed that the acute diabetes was due to an associated acute haemorrhagic pancreatitis.

My thanks are due to Dr. A. H. T. Robb-Smith, of Oxford, for kindly giving his opinion on the sections, to Dr. W. B. Roantree, late Chief Medical Officer, Kolar Gold Field, and to Messrs. John Taylor and Sons (India), Ltd., for permission to publish this case.

GEOFFREY FRENCH, M.D.,
Senior Assistant Medical Officer, Kolar Gold Field.

Reviews

NEW TEXTBOOK OF MEDICINE

Medicine. Vols. I and II. Edited by Hugh G. Garland, T.D., M.D., F.R.C.P., and William Phillips, M.D., F.R.C.P. (Pp. 2,146; 167 pages of art. plates, 7 in colour. £6.) London: Macmillan and Co. 1953.

The publication of a new textbook of medicine in two volumes and costing £6 would in any event be a major happening in British medicine. In the present instance it is even more exciting because Garland and Phillips have made the experiment of writing a textbook which attempts to describe and integrate the whole work of the physician. The dilemma of modern medicine is the increasing accumulation of knowledge and the great variety of approaches to the patient. Recent authors and editors have met this dilemma in different ways. The Edinburgh school, under the leadership of Professor Davidson, produced a short textbook last year by means of being exclusive and by omitting much that many of us would feel properly belongs to internal medicine. Harrison and his colleagues in America produced an extremely large book, of which perhaps a half consisted in morbid physiology or phenomenology—to my mind a somewhat unfortunate legacy of Mackenzie and Lewis to the modern generation of medical students—while the other half consisted in a rather short clinical account of disease which did not interdigitate exactly with the physiological section. Price in this country, and Cecil and Loeb in America, have adhered to the type of textbook in which organic disease, as met in the consulting-room and clinic, is treated in a relatively encyclopaedic fashion, so that their books can be used as working manuals. Although this type of book is in the direct line of descent from Osler, the philosophy of medicine and many of its social and psychological aspects are deliberately eschewed.

Garland and Phillips have tried to be inclusive and to produce a whole out of the ordered grouping of the units, like Smuts in his philosophy of holism. The unique quality of their book is shown by the fact that of the forty-two contributors there are only about eleven whom I should feel justified, or shall I say invulnerable, in picking as examiners in medicine in the final examination. A large part of the first volume is devoted to subjects which have hitherto been confined to semi-philosophical treatises, such as Clark-Kennedy's *Medicine* or Halliday's *Psychosocial Medicine*, or else to special monographs as, for example, aviation medicine and industrial medicine. To the general physician this unconventional first volume is intensely interesting, and I know colleagues who are reading steadily through it, evening after evening, with manifest delight.

The more conventional remainder of the book probably contains as much as any ordinary person needs to know about internal medicine. There is, perhaps, less detailed information about organic disease than in Price or Cecil, and rarities such as gynaeomastias and the Klinefelter syndrome are not indexed. Some common things are also omitted, such as the importance of chronic bronchitis in the aetiology and prognosis of pneumonia at the present time. It is, of course, always possible for the specialist to time. It is, of course, always possible for the specialist to look through a book and find minor faults. It is not true, as here stated, that subacute combined degeneration is confined to pernicious anaemia and total gastric resection; it is found occasionally, though rarely, in association with macrocytic anaemia of steatorrhoea and intestinal stenosis. It is also not true that in subacute combined degeneration liver is effective only by the parenteral route, as a reading of the paper published by Suzman in 1931 will show. It would be easier to understand the mechanism of pernicious anaemia if liver or liver extracts by mouth, usually of course in high dosage, had not been shown to be effective in subacute combined degeneration.

It is not always easy to find the name of the writer of the section one is reading, and I must confess that I hanker

after a few references or footnotes. It would be a useful luxury if the complete index could be inserted at the end of the first volume as well as the second. The Achilles' heel of any large textbook of medicine nowadays is treatment, for the larger the book the slower the interval between the writing of the article and publication. Neither terramycin nor iso-nicotinic acid hydrazide is indexed, nor is there mention of aplastic anaemia after chloramphenicol. The tempo of the writing is irregular, and it is something of a shock to turn from the leisurely story of little John and his fantasies of aggression, so happily illustrating the Freudian dialectic, to the austerity of the passage on cystic disease of the lungs. Indeed, the reader must constantly remind himself that Garland and Phillips, like the Walrus in *Alice in Wonderland*, are deliberately talking of cabbages and kings.

As I have said, this is an experiment and an exciting one. Time will show how successful it is, but all teachers of medicine will thank Garland and Phillips and their team for having made the experiment and having put such an immense amount of labour into it. In spite of multiple authorship, the general framework is closely knit and the clinical articles read smoothly. There are many reproductions of radiographs, and most of them are excellent. The book is beautifully produced, and is in every way a credit to British medicine.

L. J. WITTS.

OBSTETRICS IN GENERAL PRACTICE

A Guide to Obstetrics in General Practice. By Professor William C. W. Nixon, M.D., F.R.C.S., F.R.C.O.G., and Eric B. Hickson, M.R.C.S., L.R.C.P., D.Obst.R.C.O.G. (Pp. 301. £1 10s.) London: Staples Press. 1953.

With the rapidly changing face of obstetrics in general, and of the scope and nature of domiciliary midwifery in particular, the information and instruction offered to the general-practitioner obstetrician by the standard undergraduate textbooks is not always appropriate to his needs. This contention is implied, if not stated, by Professor Nixon and Dr. Hickson. But in setting out to remedy this deficiency perhaps their most difficult task was to decide on the subjects for inclusion and for emphasis. It is characteristic of the care and trouble they have taken with this book that in making this decision they did not rely merely on their own wide experience, one in consulting and hospital practice, and one in general practice, although this must have served as a very reliable guide. They also paid attention to every obstetrical problem which appeared in the "Any Questions?" column of this *Journal* during five years, and they analysed the reasons for midwives' calls to doctors in one county during two years.

With this basis the authors have given us a book of reasonable size and price, which deals essentially with day-to-day practical issues. Thus, they dismiss the cause of toxæmia of pregnancy as unknown, and the valuable space saved by avoiding a discussion on theories is devoted to a detailed account of the diet suitable for this or for some other complication of child-bearing. Again, they omit the technical minutiae of operations such as internal version or bringing down a leg in favour of detailed advice on matters such as low-forceps delivery, analgesia and anaesthesia, and post-partum haemorrhage. They pay proper attention to such subjects as the management of those common upsets and symptoms of pregnancy which are labelled "minor" only by those who have never experienced them: the preparation and education of the expectant mother and father; the matters requiring the attention of the attendant during normal labour; the management of the healthy and sick newly born child; breast-feeding and its problems; and indeed many of those aspects of midwifery which in the past have been neglected by the doctor and left rather to the midwife.

What are the doctor's responsibilities by way of certificates and notifications in relation to childbirth? What

advice is to be given to a woman wanting to adopt a baby, or to have one adopted? All manner of practical issues such as these are raised and answered in a simple authoritative way—one in which the idealistic and academic outlook of the head of a teaching unit, accustomed to working under the best hospital conditions, is tempered by that of a general practitioner, who knows only too well the limitations as well as advantages imposed by attending a woman in her own home. The two authors have also not hesitated to obtain help from other authorities, one of these being Dr. H. Waller, who discusses breast-feeding. They and their associates deserve commendation for their common sense and courage in deliberately omitting so much of the academic and specialist aspects of obstetrics in the interests of producing a book which should prove a real help to those who undertake, or propose to undertake, midwifery as part of their general practice.

T. N. A. JEFFCOATE.

CLINICAL MISTAKES

Klinische Fehldiagnosen. By Professor M. Bürger. (Pp. 480; 209 figures. M.58.50.) Stuttgart: Georg Thieme. 1953.

Mistakes in diagnosis have come to all of us, and we are only too happy to forget them. To gather them together and to build from them the brilliant account which this volume presents was an inspiration of genius. The author first considers what we ought to aim at in diagnosis, pointing out that at the present day such terms as debility, dropsy, jaundice are altogether inadequate, and that we should never be satisfied until we have placed our finger upon the essential abnormality of structure or function which underlies the illness or disability of which the patient complains. He points out what a snare laboratory tests and x rays may prove to be by revealing abnormalities which are irrelevant to the real diagnosis, and pleads for the incalculable value of the eye and hand of experience.

But the greater part of the book is devoted to clear and accurate descriptions, well illustrated, of cases in every field of medicine and surgery where errors in diagnosis have occurred. Each case is carefully analysed to see how a mistake might have been avoided and how it actually arose. At every turn one feels the vast experience and clear insight which lie behind it all. Both in conception and in execution the book is unique. It is well worthy of translation. To anyone engaged in the practice and still more in the teaching of medicine or surgery it will be an inspiration.

HENRY SOUTTAR.

AUSTRALIA AT WAR

Clinical Problems of War: Australia in the War of 1939-1945. Volume I. By Allan S. Walker, M.D., Ch.M., F.R.A.C.P. (Pp. 726; illustrated. £1 15s.) London: Angus and Robertson (48, Bloomsbury Street, W.C.1), on behalf of the Australian War Memorial.

This is a very long book. It is both comprehensive and selective. On the one hand it deals with the whole of war medicine and surgery, with tropical diseases, systemic affections, nutritional problems, psychiatry, wound treatment in general and the surgery of the regions and the specialties, and with the special aspects of medicine and surgery in captivity. On the other hand it is concerned only with the experiences of the medical services of the Australian Forces; it discusses their methods and their results and it quotes their writings. Though some of the chapters, such as those on chemotherapy and traumatic shock, take a broader view, it is more concerned with detail than with a general survey. It reports the war much as a pathologist might report on a malignant tumour from the examination of a biopsy specimen from a part of it, describing the appearances seen under the oil immersion. As a whole it is tough reading, but in detail it provides a valuable record that will be of great assistance to future historians.

H. PAYLING WRIGHT.

In some aspects the views expressed are at variance with those of others who went through the same campaigns. It would be interesting to know whether the recommendation that compound fractures should be plated under penicillin cover is supported by a review of the after-history of cases so treated.

The most valuable thing about this book to the general reader is that it gives a picture of war medicine and surgery under conditions of real war, where the medical officers are doing all that is possible under impossible conditions, when transport fails, supplies are unobtainable, and the assaults of the enemy and the forces of Nature forbid any but makeshift methods. In the Western Campaigns such conditions were found only for a short time in 1941. After the battle of Alem Halfa in August, 1942, the medical services could leave the possibility of serious interference with their plans by the enemy out of the question. The Australian Forces in New Guinea and the Pacific faced conditions that can be inferred from their writings and the results, and realized even more clearly from the excellent illustrations which form such a striking feature of this book.

HENEAGE OGILVIE.

BLOOD COAGULATION

Human Blood Coagulation and its Disorders. By Rosemary Biggs, B.Sc.(Lond.), Ph.D.(Toronto), M.D.(Lond.), and R. G. Macfarlane, M.A.(Oxon.), M.D.(Lond.). (Pp. 406; 57 figures. £1 12s. 6d.) Oxford: Blackwell Scientific Publications. 1953.

In recent years studies on blood coagulation have assumed such complexities that many workers in this field find it difficult to keep abreast of current progress. This is the book for which many have been waiting. Drs. Biggs and Macfarlane consider the factors known to take part in the mechanism of clotting and point out where nomenclatures overlap and where experimental observations may be related to one another. Each chapter is summarized to facilitate rapid reference.

Of the book's twenty chapters the first seven are on coagulation factors, thrombin, fibrinogen, prothrombin, thromboplastin, factors V and VII, and the natural inhibitors of clotting. There are also chapters on clot retraction, fibrinolysis, anticoagulants, and the basic pathological coagulation phenomena met with in disorders of the clotting mechanism. Part II covers abnormalities observed clinically in patients. The authors discuss fibrinogen deficiency, haemophilia, thrombocytopenia, hypoprothrombinaemia, and anticoagulants, together with laboratory methods for the investigation of such conditions. Finally, they consider haemostasis and the significance to the body of coagulation. Technical methods of many tests frequently used in the study of these problems are set out in appendices.

This should prove a most useful book to anyone concerned either clinically or experimentally with blood coagulation. Its lucidity of style makes it suitable for recommendation to undergraduate students anxious to learn more than is usually found in textbooks, while for post-graduates and physiologists it should help to clarify many complex theories. Its general format, with copious sub-headings, makes it easy for reference on specific points. The line diagrams are clear and self-explanatory, the index is good, and the printing and general production are satisfactory. It is inexpensively priced at 32s. 6d., an important feature in specialized publications of this kind.

The authors have produced a readable and understandable book on a difficult subject. They have brought together many controversial studies and, as far as possible, produced an intelligible general picture of present knowledge. The width of their view is indicated by the 900 references to original papers quoted in the text. This is undoubtedly the most important book on blood coagulation to have appeared in Britain for many years.

HOMAGE TO LIND

In 1753, with George II on the throne and only six years after the defeat of Prince Charles Edward Stuart at Culloden, James Lind published the first edition of his *Treatise on Scurvy*. He was a medical graduate of Edinburgh University who had followed his profession as a ship surgeon in the Navy. In those days the perils of the sea were reinforced by the frequent appearance of scurvy, which afflicted most crews that had been afloat for more than a few weeks. Thus in a voyage spent harassing the Spaniards in the South Seas Lord George Anson had recently buried about three sailors out of every four in his squadron as victims of the disease. These losses were incurred even though the protective action of fresh foods, and particularly fruits, was widely, if only vaguely, realized. Lind's contribution to the eradication of the disease can therefore hardly be classed as an original discovery. But he performed an immense service for humanity by correlating the experience of previous authorities, by distinguishing between truth and error, and by finally putting his theories to experimental tests. In H.M.S. *Salisbury*, a 50-gun fourth-rater, he dosed six pairs of scorbutic seamen with the supposed remedies then in favour, which included cider, elixir vitriol, vinegar, sea water, oranges and lemons, and an electuary made with garlic, mustard seeds, and other ingredients. Both the seamen given the oranges and lemons improved rapidly, and one was completely healed after receiving the fruit for only six days. Among the rest of the seamen, those given the cider, which unfortunately had gone sour, finished the fortnight of the trial in a better condition than any of the others.

Some forty years later, and two years after Lind's death, the force of his treatise impelled its way through the slowly moving machinery of the eighteenth century Admiralty, and provision was made for an allowance of lemon juice for every seaman. Except for the unfortunate substitution of the inactive lime juice for lemon juice half a century later the practical problem of preventing scurvy was solved. Dr. C. P.

¹ Published by the Edinburgh University Press, price 45s.
² Preliminary Report of the Vitamin C Subcommittee of the Accessory Food Factors Committee of the Medical Research Council, *Lancet*, 1948, 1, 853. See also leading article in *British Medical Journal*, 1948, 2, 828.

Stewart and Dr. A. P. Meiklejohn, therefore, are to be congratulated for their happy idea of organizing a symposium of the Nutrition Society to mark the bicentenary of the appearance of the *Treatise*, and to blend a historical appreciation of Lind's work with modern developments on vitamin C. A fortnight ago they drew together at the University of Edinburgh a distinguished international gathering, which included most of the best-known authorities on the subject.* A series of interesting papers ranged from the early investigation of scurvy and of the antiscorbutic vitamin, by Dame Harriette Chick, to the role of chromosomes in the synthesis of ascorbic acid in plants and animals, by Drs. Mapson and Isherwood. Members of the conference were received at the Royal College of Physicians of Edinburgh, of which Lind was once a member, by its President, Dr. W. A. Alexander. Sir Sheldon Dudley, who was awarded the honorary degree of doctor of laws of Edinburgh University by Sir Edward Appleton, F.R.S., gave the Lind Oration on May 22, and the proceedings also included a formal lecture on "The Impact of Vitamin Research on the Practice of Medicine" by Dr. Sydenstricker. The celebrations concluded with a light-hearted dinner composed mainly of rich sources of vitamin C, including scurvy grass as a garnish, adrenal capsules dressed with paprika, and parsley as a savoury.

To coincide with the conference Drs. Stewart and Douglas Guthrie have produced a new edition of Lind's *Treatise*.¹ This has been reinforced by notes on modern developments, for which the editors have enlisted the help of various authorities. The book makes fascinating reading, and few will disagree with the editors when they say that Lind's writing is surprisingly modern both in style and in outlook. "In order to make way for the restoration of solid learning" he found it necessary to "expunge all terms as were contrived to give an air of wisdom to the imperfections of knowledge." In spite of our ability to prevent scurvy, moreover, some of the problems which faced Lind are still awaiting solution. He considered that the predisposing cause of scurvy was constant exposure to damp air and that diet was only the secondary cause. Thus, in his experience, sailors would contract scurvy at sea within a few weeks, even when they were given much the same diet as would keep them in health for months on land. He observed that scurvy was most apt to afflict those

*Vice-Admiral Sir Sheldon Francis Dudley, F.R.S., and Surgeon Rear-Admiral J. Hamilton represented the Royal Navy. Sir Edward Mellanby, F.R.S., Dame Harriette Chick, Professor H. A. Krebs, F.R.S., Professor R. C. Garry, and Drs. L. J. Harris, L. W. Mapson, and F. A. Isherwood were other British representatives. America was represented by Drs. C. G. King, V. P. Sydenstricker, J. H. Crandon, R. M. Kark, and W. J. Darby, France by Drs. H. Gounelle and H. Tenlon, Belgium by Professor E. J. Bigwood, and Holland by Dr. M. van Eekelen.

who were indolent or melancholy by nature. Alcoholic spirits, but not wines or beer, tended to precipitate scurvy. Fever made the sailor prone to scurvy, and scurvy in turn increased liability to fevers. Two hundred years ago, therefore, Lind recognized the conception of "secondary" or "conditioned" dietary deficiencies which is still a fertile field for modern research. It would have caused him no surprise if he could have known that the conscientious objectors at Sheffield who volunteered to subsist on a diet deficient in vitamin C developed only slight signs of scurvy after four to six months.² They spent their nights in dry beds, not in wet hammocks. He would have been intrigued by American work which suggests that good temper depends on a high concentration of ascorbic acid in the blood. The failure of Dr. Kark to influence the ascorbic acid metabolism of his soldiers by exhausting marches through the snow, or by an overnight flight between regions of extreme heat and extreme cold, would have come as a challenge to his powers of observation and experiment. When we remember also his other treatises, which did much to abolish typhus from the Navy and to improve its general hygiene, we may well regard him as the true founder of the Royal Naval Medical Service. We may also rejoice with Sir Sheldon Dudley that the Lind tradition is still alive to-day.

PENICILLIN IN TISSUE FLUIDS

It has often been claimed, and is widely believed, that a large dose of aqueous penicillin exerts a much more prolonged effect than the rate of its elimination from the blood would suggest. The high concentration initially attained is said to facilitate diffusion from the blood into foci of infection where the penicillin remains and continues to act long after the blood has been cleared of it. That this is true of certain types of lesion there can be no doubt: it was first proved by Florey, Turton, and Duthie¹ in a study of the penicillin content of exudates in wounds in a more or less chronically septic condition. After an intramuscular dose of 100,000 units penicillin was always present in the exudate after eight hours, often after twelve, and sometimes for even longer. Ungar² reported similar findings in abscesses experimentally induced in rabbits by the intramuscular injection of turpentine. Weinstein, Daikos, and Perrin³ planted fibrin clots subcutaneously in rabbits, and, by removing them at intervals after an injection of penicillin, digesting them, and assaying their drug content, showed that it persisted much longer in them than in the blood.

The more cautious have questioned the applicability of these findings to other kinds of lesion. That they apply to a focus into which exudation is proceeding and in which the exudate accumulates is evident from the findings of Florey and his colleagues. What has not been proved is that they are true of an area of acute inflammation without tissue breakdown, fully and indeed excessively supplied with blood, and with adequate lymph drainage. This describes the earlier stages of many infections of various tissues for which penicillin is used, and it is important to know how long the drug may be expected to remain effective in such an area after a known dose. This question has been re-examined by Eagle and his co-workers,⁴ to whom we owe much of our more exact knowledge of the mechanism of penicillin action. They injected a measured large inoculum of haemolytic streptococci intramuscularly in one hind leg of mice and followed this two hours later with a single dose of sodium penicillin, varying from 0.05 mg. to 50 mg./kg., into the other leg. Groups of mice were killed at intervals of one and a half to fifteen hours, the infected muscle being removed, emulsified in a Waring blender, and cultivated quantitatively. It was thus possible to plot curves showing the progressive destruction of the streptococci while the drug was acting and their subsequent growth when its effect was lost. Regardless of the size of the dose, the initial killing proceeded at the same rate. That there is no advantage in high concentrations of penicillin *per se* has been shown before by Eagle⁵ himself and by others. At the end of the period for which a given dose is known (from the authors' previous studies) to provide a blood concentration effective against streptococci, the rate of killing almost immediately fell off, and was succeeded by slow multiplication within three hours. Even the two largest doses, equivalent to 1 and 4 million units in a man, had ceased to kill after six hours, and rapid multiplication followed them after six and nine hours respectively.

These findings need to be interpreted with the reservation that penicillin is eliminated more rapidly by the mouse than the human kidney, but the fact remains that the effect of large doses was not much more prolonged than that of small ones after the point at which the blood concentration fell below the critical level. These experiments seem to afford inescapable proof that in normal tissues, or

⁶ *Proc. Soc. exp. Biol. (N.Y.)*, 1948, 89, 297.

tissue in the earliest stages of inflammation, the supposed persistence on which the policy of large infrequent doses of aqueous penicillin depends is a myth.

A method previously used by Ercoli and his colleagues⁶ provides another approach to the problem. These workers gave the drug first and an inoculum of bacteria at intervals after it, and claimed to have shown that protection is still afforded after penicillin has ceased to be detectable in the blood. As Eagle and his colleagues point out, Ercoli used procaine penicillin in oil, which continues to be absorbed in slowly diminishing amounts for a long period, and may thus affect a highly sensitive organism for some time after it has ceased to be assayable. In their own experiments, in which a large dose of aqueous penicillin was followed at intervals by inoculation with pneumococci or streptococci in mice or streptococci (group B) in rabbits, there was a high mortality even in animals inoculated about one hour *before* the blood penicillin had fallen below the effective level. There is only one further reservation to be made before translating such findings to the clinical field: they evidently apply only to the non-immune animal, and few patients are as susceptible to their infections as mice are to highly virulent pneumococci and streptococci. When the body itself can also put up some resistance, bacterial recovery from a dose of penicillin may perhaps be slower. Similar studies need therefore to be made in animals partly protected by antibodies, and this interesting and almost entirely unexplored field Eagle and his colleagues are now investigating. Unless these further studies reveal an entirely different picture, the appropriate conclusion seems to be that, in certain forms of infection at least, "depot" preparations of penicillin, giving a moderately high blood concentration for many hours, are theoretically preferable to infrequent doses of aqueous solutions, however large.

MEDICAL AUXILIARIES

The decision of the Minister of Health in March this year not to implement the recommendation of the Cope Committee came as a great disappointment to those who wish to see the position of medical auxiliaries firmly established within the medical firmament. In 1933 the Representative Body of the B.M.A. approved the establishment of a national register, and in 1936 the Board of Registration of Medical Auxiliaries was incorporated. The Board is a voluntary organization. With the advent of the

National Health Service the question of a statutory register took on a new and more urgent look. In 1949 what has come to be known as the Cope Committee was set up by the Government. The work was done by eight committees dealing with eight different auxiliary services. The report of the Cope Committee was published in 1951,¹ and two years of rumour about the fate of its recommendations were brought to a head by Mr. Macleod's announcement in the House of Commons on March 19 of this year. It was a long time to wait for such a meagre conclusion.

Mr. Macleod gave as his reason for inaction his belief that "there was insufficient agreement on fundamental matters to proceed with statutory registration on the lines proposed by the Cope Committees."² There were, it is true, three minority reports to the Cope Committee Report, in which representatives of the almoners, the occupational therapists, the speech therapists, and the physiotherapists dissociated themselves from certain conclusions of the Report. Among such a wide range of medical auxiliary activity such disagreement was bound to arise. Some objection was raised, for example, to the term "medical auxiliary": could this be applied equally to almoner and laboratory technician? Surely all these valuable workers help in the work of medicine even though not medical men and women themselves. And what more convenient word than auxiliary could be found to express this? And there have been disputes about who should be included among the physiotherapists. Objection was also raised to the predominance of the medical profession on the council recommended in the Cope Report to administer a system of statutory registration of medical auxiliaries in the National Health Service. But the report showed that a majority in every committee was in favour of a statutory register and the setting up of a central council to keep it. Every medical man on every committee supported this recommendation, and to ignore this weight of opinion, as Mr. Macleod seems to have done, is, to say the least, unfortunate.

What the public needs first and foremost—and the medical profession—is a guarantee that medical auxiliaries are adequately trained in their work. Any system which allows half-trained persons to treat patients cannot possibly be countenanced by doctors whose ultimate responsibility for the care of patients it is, by the medical auxiliaries themselves, or by the public. Public and profession alike must be able to identify properly trained medical auxiliaries by reference to a statutory register, admission to which

¹ *British Medical Journal*, 1951, 1, 869 and 877.

² *Ibid.*, 1953, 1, 736.

must offer safeguards parallel to those for admission to the medical, dental, and nursing registers. Statutory registration confers not only safeguards but also status on those registered. As Lewis and Maude have shown, there is a growing clamour for professional status among persons following a wide variety of vocations. This is a movement which must command sympathy in the established professions. Yet it is not just arrogance in the medical profession that claims that medical auxiliaries should come under the wing of the doctor. In the medical profession itself there is concern at increasing specializing among doctors, and at the apparent consequent weakening of the influence of the general consultant and the general practitioner. There is a very great danger in the attempts to foster independence of medical auxiliaries from the medical profession—in fostering further specialization outside the control of the doctor, on whom ultimate responsibility for the patient must ultimately lie. Such a trend is not in the interests of the public, nor, indeed, in the interests of that indispensable and growing band of workers known as medical auxiliaries. It is, for example, the close voluntary association with doctors that has been largely responsible for the fine work done by the chiropodists, especially in the evolution of their excellent course of training. As more and more skills develop, and as the division of labour grows ever more refined in the field of health, the more necessary it becomes to co-ordinate all this work under medical guidance. We can only hope that the Minister of Health will look into this matter once more, and, too, that we shall not see in the regulations he may issue on the work of medical auxiliaries anything that may undermine the steady uphill efforts of those who have had this matter at heart during the past twenty years.

PREVENTIVE WORK IN HOSPITALS

Preventive medicine as a hospital function was one of the main themes of the eighth International Hospital Congress held last week in London. The promotion of health and protection against particular diseases—the most important aspects of preventive medicine—depend only slightly on hospitals, though they must be based in part on knowledge established by hospital research workers. Thus, as Dr. Godber told the Congress, the organization of the British National Health Service does not place the hospital in the forefront of the national programme of preventive medicine; the hospitals' part in preventive work is a supporting one, but the sup-

port should be active and neither grudging nor condescending.

Some recent circulars from the Ministry of Health about the control of infection in hospitals are a reminder of certain special problems in preventive medicine. For, despite the decline of the ordinary infectious diseases, hospitals carry their own serious environmental hazards of infection among patients and staff, and constant vigilance is necessary. Overcrowding of in-patient departments, and more noticeably of out-patient departments, is not so rare as might be hoped, and it constitutes what ought to be an avoidable danger to the health of patients and staff. Nor is the food served to in-patients always of a sort apt to stimulate a sense of well-being. But plenty of fresh air, sunlight, and appetizing food ought to be prominent among the hospital's preventive-medicine work. Hospitals should set a good example in such matters and also in the effective immunization of staff against such diseases as smallpox and diphtheria—and, we may now hope, tuberculosis. While it may not be in the forefront of the national programme of preventive medicine, the hospital service is the most conspicuous part of the Health Service; any failing on its part to secure health promotion and specific protection against particular diseases for hospital patients and staff sets a bad example which may have widespread repercussions.

Early recognition and prompt treatment of disease, important features of preventive medicine, are fully within the province of hospitals in partnership with general practitioners. Unfortunately, long waits for out-patient consultation and for admission are still too common. Great expansion of general hospital in-patient accommodation in the near future is unlikely; indeed it is doubtful whether many more general hospital beds are required throughout the country as a whole. But many hospitals lack adequate facilities for consultative out-patient work and for pathological and x-ray investigation of both in-patients and out-patients. Despite the great expansion of specialist medical staff since July, 1948, more consultants are required if, soon after request by a general practitioner, all patients are to be seen by an appropriate consultant able to give adequate time personally for examination, diagnosis, prognosis, treatment, and follow-up. Hurried work is often poor work, and the evil of excessive litigation against hospital staff may indirectly bring benefit if it impels consultants to demand reasonable time to deal carefully with each patient.

The early recognition of disease is seriously impeded in most hospitals by inadequate consulta-

tive out-patient accommodation. Here two pertinent sentences may be quoted from the interesting paper given by Professor Vines at the Congress:

"As an immediate step a programme might be devised to raise the importance of the polyclinic services to a level more comparable with the service accorded to in-patients, and some principle might be accepted to the effect that all general hospitals of 100 beds or more should offer out-patient services varying in scope from a full range of specialisms at the largest hospitals to a minimum of general medicine and general surgery at the smallest. The aim of the service would be directed to keep the patients out of the hospital beds as far as possible, in contact with their home life and even with their normal occupations."

A programme such as that would be very much cheaper to carry out than would a large expansion of in-patient accommodation. Unfortunately there is risk now that recognition of the just claims of mental-health and mental-deficiency hospitals for a fair share of capital and running-cost expenditure, entailing greatly increased in-patient accommodation, will push the necessary expansion of general hospital out-patient accommodation into the background again.

A further aspect of preventive work is limiting the patient's disability and rehabilitating him. Here it may be doubted whether the lessons about hospital rehabilitation learnt in the last great war are being remembered. In particular, the question arises whether there is a reasonable future for physicians in charge of the physical medicine services in hospital groups. It will be most unfortunate if hospitals, preoccupied by discussions about preventive medicine as a hospital function, and misled by certain exaggerated and false claims that they are the centre of all health services, should fail in one of their own preventive functions—helping the patient to attain the highest possible degree of recovery. There is still a tendency to regard hospital rehabilitation as something confined to the orthopaedic department, and to forget that a physician skilled in physical medicine, acting in consultation with the other clinical consultants, is an essential member of the medical team in a hospital group. A director of physical medicine can deal with a population of a quarter of a million or more; he can save much expenditure on physiotherapists by eliminating unnecessary physical-medicine treatment; and he is the doctor most likely to maintain liaison with the other rehabilitation services outside the hospital service: it therefore appears shortsighted policy to allow so slow an increase in the number of physicians in charge of physical-medicine services, and such meagre development of rehabilitation departments, as we have seen since July, 1948.

ALCOHOL AND BARBITURATES

Alcohol and barbiturates are among the drugs most often taken in Britain and the U.S.A. It is somewhat remarkable therefore that so little is known about the effects of taking them in combination. When two drugs are administered together they may help or oppose one another. The first type of effect is called synergism, the latter antagonism. If the combined effect is no greater than the sum of the effects of each drug separately, their actions are said to be additive; if it is greater, they are said to potentiate one another. These phenomena and methods for their investigation are well explained by Gaddum.¹ Unfortunately, bacteriologists appear to use the term synergism where pharmacologists would speak of potentiation.²

It is hardly surprising that alcohol and the barbiturates are synergistic, since each separately may, in appropriate doses, cause excitement from loss of cortical control, sleep, anaesthesia, or death from paralysis of the respiratory centre. Observations on animals, however, suggest that these drugs are not only synergistic but actually potentiate each another.³ Thus alcohol potentiated the effect of sodium pentobarbitone after injection into rabbits,⁴ and barbiturates injected into mice potentiated the effect of inhaled alcohol.⁵

In these observations statistical methods were used to overcome variations in susceptibility between different animals. It is far more difficult to assess the significance of the few recorded observations on the combined effect of alcohol and the barbiturates in man. Great natural variations in susceptibility to both drugs occur. A subject used to taking alcohol is unlikely to die until the blood alcohol is in the region of 0.4 to 0.5%, a level equivalent to the consumption of a full bottle of whisky.

The mean fatal dose of phenobarbitone is probably about 5 g. (75 gr.), and in general the fatal dose of a barbiturate is about fifteen times the usual hypnotic dose. Yet death has resulted from as little as 2.0 g. (30 gr.) of quinalbarbitone ("seconal") and it is impossible to foretell how any given individual will react.⁶ Jetter and McLean⁷ have reported three cases in which patients who had taken barbiturates died shortly afterwards—an unusual event with long-acting barbiturates—and who were found to have blood alcohol levels insufficiently high in themselves to endanger life. Fisher and his colleagues,⁸ studying patients who had died after taking barbiturates as well as alcohol, found blood concentrations of barbiturates not usually associated with a fatal outcome. Thus one case with a blood alcohol of 0.17% (equivalent to about 9 oz. (250 ml.) of whisky)

had a barbiturate blood level of only 0.6 mg. per 100 ml., a level which may result from as little as 0.6 g. (9 gr.) of quinalbarbitone ("seconal"). The balance of evidence suggests that in man synergism at least, if not potentiation, may occur between alcohol and the barbiturates. It is possible that the taking of alcohol increases the rate of absorption of a barbiturate from the alimentary canal as well as enhancing its effect on the central nervous system.

But all this should be seen in its proper perspective. Vast quantities of strong spirits are consumed every year in most parts of the world and have been for centuries. In Britain about 10% of all prescriptions on form E.C.10 are for barbiturates,⁹ and in the U.S.A. it is estimated that in 1948 300 tons were administered—equivalent to nearly 5,000 million doses of 1 gr. (65 mg.). Fatalities arising from a combination of alcohol and a barbiturate must be very rare in relation to the population at risk, although it is possible that those who take the edge off life with alcohol do not require another drug to assist them and vice versa. It is highly unlikely that a person receiving the usual sedative dose of phenobarbitone will endanger his life by taking his usual evening cocktails. But if a patient is given heavy doses of a barbiturate, as is common in the treatment of psychiatric conditions, it would appear wise to advise him to be very sparing in his consumption of alcohol.

Much more important—and there is almost no reliable information on it—is the problem of the combined effect of small quantities of alcohol and low doses of barbiturates on the capacity to drive a motor vehicle safely. There is ample evidence that small quantities of alcohol impair driving efficiency—as little as 3–4 oz. (85–114 ml.) of spirit in the road tests described by Bjerver and Goldberg.¹⁰ Goldberg¹¹ states that barbiturates "have a deteriorating effect on driving." It is to be expected, although not yet proved, that a few drinks soon after an ordinary pharmacopoeial dose of a barbiturate would make dangerous a person in charge of a vehicle. The prescriber would be well advised to warn a patient of this possibility, since it is an offence to be in charge of a vehicle while under the influence of any drug to such an extent as to be incapable of having proper control. Indeed, the risks of combining alcohol and a barbiturate lie here rather than in the possibility of death arising from gross overdosage of the two substances.

PEPTIC ULCER IN WOMEN

Fifty years ago Borri¹ suggested that there might be some connexion between peptic ulcer and the sex hormones: he had noted the common occurrence of peptic ulcer at, or shortly after, the menopause. Children rarely suffer from peptic ulcer, and the incidence in boys and girls is the same until puberty.² Thereafter peptic ulcer and its complications are commoner in men than women—in the ratio of five males to one female.

Szenes³ in 1924 was impressed by the beneficial effect that pregnancy had on peptic ulcer, and Mr. D. H. Clark in a paper in our columns this week confirms this

observation: he finds that in almost 90% of his female patients the symptoms of a peptic ulcer are in abeyance during pregnancy. Various suggestions have been made to account for this finding, and attempts made to relate it to many isolated observations. The gastric secretion response to histamine or alcohol is lowered in pregnancy.⁴ Ahlmark⁵ in Stockholm found the blood histaminase to be increased one hundred times at the end of the first month of pregnancy, a finding which is as yet unexplained.

Over thirty years ago Kosaka and Lim⁶ extracted a hormone, which they called enterogastrone, from the intestinal mucosa; this inhibited both the secretory and motor activity of the stomach. A similar substance derived from urine was named urogastrone. Sandweiss⁷ and his colleagues found that the urine of pregnant women contained a substance which had a protective and curative effect on experimental Mann-Williamson ulcers in the dog. In small doses it did not inhibit gastric secretion or motility. Sandweiss found this anti-ulcer substance, which he named "anthelone," to a lesser extent also in male urine, but extracts of urine from patients with active ulcers were less effective. It is possible that these three factors are the same, or different components of the same extract. How they act on ulcers is still unknown. They have been used with varying results in patients, but as yet are not sufficiently purified or concentrated for more general clinical trials.

Clark records two peaks of incidence of peptic ulcer in women, one early in adult life and the other at the menopause. In his patients complications were particularly common at the menopause. In general, perforation of a peptic ulcer occurs much more commonly in men than in women—DeBakey,⁸ for instance, in a large series found over 90% to have occurred in men—but the mortality rate from haemorrhage and the liability of peptic ulcers to recur is approximately the same in both sexes. It may be, as Clark suggests, that the mechanism of ulcer activity at the menopause is hormonal. Nearly every endocrine gland has at some time or other been brought into the picture, but the consensus of present-day opinion is that no single hormone or combination of hormones is of therapeutic value in peptic ulcers. The one exception to this may be sex hormones, which might be tried as part of the treatment of peptic ulcer in women during the menopause. Much research is concerned with answering the question, Why do patients get peptic ulcers? It might be profitable to put the question another way—why do people not get peptic ulcers?—and examine more closely the mechanisms of protection against the formation of peptic ulcers.

SWIMMING-POOL TUBERCULOSIS

Swimming-pools, with some justification, have been blamed for the spread of a variety of cutaneous infections, such as warts, molluscum contagiosum, and epidermophytosis. They would seem likely to help the transference of infection by such organisms as thrive or even survive in a watery medium, and the public health problems they raise are of interest and importance. Measures such as chlorination are normally adopted to counter these hazards, though the protective measures themselves are not always harmless to the skin. Knowledge gained from research into contamination and infection from confined swimming-pools can to some extent be applied to countering river pollution and contamination. And the increasing use of chemicals in industry and the home will create plenty of new problems, such as that occasioned by the considerable discharge of modern detergents into our waterways.

In 1951, at the International Congress of Clinical Pathology, Herlitz, Linell, and Norden reported an epidemic of skin lesions caused by a special type of acid-fast bacillus in 80 patients attending swimming-pools at Örebro, Sweden. The rough walls of the bath caused abrasions of the skin, and the epidemic ceased when the walls were smoothed. A mycobacterium, possibly related to *Mycobacterium marinum*, was recovered from lesions and from the pool and was described. There were resemblances bacteriologically to the tubercle bacillus, and histologically there was a tuberculoid structure in the lesions. Hellerström raised the question whether the organisms might be tubercle bacilli modified by chlorination of the water or other factors. He reported, first in 1939¹ and more recently at the International Congress of Dermatology in London, a series of patients showing lesions resembling lupus vulgaris following abrasion of the skin in swimming-pools. Further cases of a similar nature have been reported in the U.S.A.² and in Scandinavia.³ The abrasion fails to heal and in a few weeks presents a reddened, papular, inflammatory, and sometimes ulcerated appearance. As healing proceeds, apple-jelly nodules are manifest which resemble lupus vulgaris histologically. In a case reported by Brück⁴ the tubercle bacillus was cultured, and it infected guinea-pigs. A swimming-pool attendant was found in one instance to have open pulmonary tuberculosis.

Invasion of the skin by the tubercle bacillus from without commonly produces either a tuberculous chancre, if the patient has not previously been infected, or warty or necrogenic tuberculosis otherwise. But on occasion we see in farmers, butchers, and others a tuberculous lesion of the skin resembling pyoderma which may or may not ulcerate; it gives rise to a multitude of rather glassy, apple-jelly nodules in the course of slow resolution. Hellerström's patients would appear to show this type of lesion, though it is of interest that many had previously had a negative tuberculin test, which became positive after the swimming-pool lesions developed. It is also of interest that adenitis was in most patients negligible. The problem is clearly of importance, for

¹ *Acta derm. Venereol. (Stockh.)*, 1939, 20, 276.

² *J. Amer. med. Ass.*, 1953, 151, 724.

³ Hellerström, S., *Acta derm. Venereol. (Stockh.)*, 1952, 32, 449.

⁴ *Ibid.*, 1952, 32, 443.

tuberculous infection from rivers and swimming-pools may not always be cutaneous; indeed, there are reports of pulmonary infection from such sources. Probably chlorination as normally practised is not an adequate safeguard.

CORONATION HONOURS

The Coronation Honours were announced on Monday of this week. As the *Journal* went to press early because of the Coronation, the full list of honours bestowed on members of the medical profession cannot be published until next week.

The conferment of knighthoods on Professor David Campbell, President of the General Medical Council, and on Dr. F. M. R. Walshe, President of the Royal Society of Medicine, is a fitting recognition of their services to Medicine. Professor Campbell, a graduate of Glasgow University, has since 1930 been Regius Professor of Materia Medica and Therapeutics at Aberdeen, and since 1949 President of the G.M.C. Dr. Walshe is one of that distinguished group of neurologists who have upheld the tradition of the National Hospital for Nervous Diseases, Queen Square, and his contributions to neurology have earned him election to the Fellowship of the Royal Society. His writings have not been confined within the limits of his specialty, and in his essays on the wider aspects of medicine he has blended a scholarly and philosophical approach with a wit that has sharply punctuated a literary style of supreme excellence. The K.B.E. has been bestowed on Acting Air Marshal J. M. Kilpatrick, a graduate of Belfast University who occupies the highly responsible post of Director-General of the Medical Services of the R.A.F. Lieutenant-General Sir Bennett Hance, formerly Director-General of the I.M.S. and now Medical Adviser and President of the Medical Board, Commonwealth Relations Office, has been elevated to the K.C.M.G. The Hon. Mr. Nicholas Attygalle, F.R.C.S., President of the Senate, Ceylon, has been made a knight bachelor in recognition of his services to medicine, and the K.B.E. has been bestowed on Mr. F. G. Bell, F.R.C.S., formerly Professor of Surgery at Otago University. Dr. George Macdonald, Professor of Tropical Hygiene and Director of the Ross Institute at the London School of Hygiene and Tropical Medicine, has been awarded the C.M.G., as has Mr. P. S. Foster, F.R.C.S., of Christchurch, New Zealand.

Among those awarded the C.B.E. are Dr. W. G. Barnard, Professor of Pathology, London University; Dr. G. Brown, honorary consulting anaesthetist to the Adelaide Hospital; Dr. T. M. Davies, Deputy Director-General of Medical Services, Ministry of Pensions; Dr. A. D. Marston, senior honorary anaesthetist, Guy's Hospital; Dr. A. A. Miles, Director of the Lister Institute; Dr. G. I. Strachan, Professor of Obstetrics and Gynaecology, Welsh National School of Medicine; and Dr. R. R. Trail, Medical Director of Papworth and Enham-Alamein Village Settlements.

The medical profession will also wish to congratulate Miss Enid Russell-Smith, Under-Secretary of the Ministry of Health, who is made Dame Commander of the Order of the British Empire.

fatal disease. Other people die in old age with a number of pathological conditions present that have originated mainly from the process of ageing, as, for example, arteriosclerosis or myocardial degeneration. If among these senile conditions there is one that has mainly contributed towards causing the death to occur when it did, this condition should be given preference upon the death certificate, with old age or senility (these terms are synonymous) either unmentioned or shown entirely as a contributory condition. The third and last group of elderly people are those fortunate few who die without any particular disease or degenerative condition playing a recognizably major part, and in such cases it is reasonable and correct to certify that death was due only to old age. If the deceased was 70 years or more such a certificate will be accepted without question; but if death occurred at a younger age a medical inquiry will be sent to ascertain whether or not some other more definite condition was also present, and, if so, the death will be assigned to this other condition.

Next Refresher Course Article.—"Intermittent Claudication," by Mr. J. B. Kinmonth.

Nova et Vetera

SIR HANS SLOANE AND THE BRITISH MUSEUM

By a happy accident the Coronation of her Majesty Queen Elizabeth II coincides almost exactly with the bicentenary of one of our greatest national institutions. The British Museum—a term which very appropriately includes not only the vast collection at Bloomsbury but the no less important natural history collection at South Kensington—was founded by Act of Parliament passed on June 7, 1753. It was the direct result of the design of that great physician, Sir Hans Sloane, who died a few months earlier aged 93. With certain reasonable provisos, he left his immense collections to the nation, desiring that they should be used for public enjoyment and instruction and kept together "to the manifestation of the glory of God, the confutation of atheism and its consequences, the use and improvement of physic, and other arts and sciences, and the benefit of mankind." Parliament wisely and happily decided on June 7 of that year to combine with it two other considerable collections then available into one great national institution. This was the beginning of the British Museum. Of these collections, that of Sloane was by far the largest and most diverse. This fact and the action of the trustees named in his will, who brought the matter to the attention of Parliament, make Sloane the real founder of our national museum. Its two branches are rightly controlled by the same standing committee, thus emphasizing that any separation between the humanities and those other arts that we are accustomed to call the "sciences" is but accidental, artificial, and temporary, and that in many regions they do in fact overlap each other. This is wholly in accord with the feelings and outlook of the founder. The actual physical separation of the two types of objects was not effected for another century. It was in 1856 that the greatest of British comparative anatomists, Richard Owen (1804-92), was called as first director from the Hunterian Museum of the Royal College of Surgeons to South Kensington. It may well be that there is, for all institutions, an optimum size beyond which growth is harmful rather than helpful. Nevertheless the separation of the "sciences" from the "arts" is a misfortune which Sloane himself foresaw and one which the present cordial relations of the two great branches of our national museum are now doing much to remedy.

Study in France

Hans Sloane was born at Killyleagh, County Down, Ireland, in 1660. The name Hans—a shortened form of Johannes or John—implies no German relationship but was

a recognized Scottish-Irish form used at that time. He came of a fairly well-to-do family and seems never to have been in want. He had a sickly youth and never enjoyed perfect health, though this did not prevent him from reaching extreme old age. At 19 he came to study in London, and there he made friends of the illustrious naturalist, John Ray (1627-1705), and the "father of chemistry," Robert Boyle (1627-91). Both of these distinguished men influenced him deeply. After four years he left for further study in France, where he attended medical, botanical, chemical, and anatomical lectures in Paris and Montpellier and took his degree at the obscure and now extinct university of Orange in Provence. He returned to London in 1684 and called on that distinguished physician Thomas Sydenham (1624-89) with a letter from Boyle commending him as skilled in scholarship, botany, and anatomy. Sydenham read the letter, looked at the young man, and said: "That is all mighty fine, but it won't do—Anatomy, Botany—Nonsense! Sir, I know an old woman in Covent Garden who understands botany better, and as for anatomy, my butcher can dissect a joint full as well; no, young man, all this is Stuff: you must go to the bedside, it is there alone that you can learn disease."

Nevertheless the two became fast friends, both professionally and personally. Sloane went to the bedside and became, beyond doubt, one of the most effective practitioners of his day, for, despite the unscientific state of medicine, he was a very careful observer and had just that calm and cautious yet optimistic temperament that inspires hope and confidence in the patient. He disliked complex prescriptions, preferred to try one remedy at a time, and was deeply aware of the influence of the mind on disease. Under all circumstances and in any age he would have been a first-class physician.

It is not necessary here to recount Sloane's life, which has just been admirably told in an attractive little book by G. R. de Beer, the Director of the British Museum (Natural History). In 1687 Sloane sailed for the West Indies in the suite of the Duke of Albemarle, Governor of Jamaica. He spent some sixteen months in that island, and his report on its natural history is a classic. He returned to practice in London, occupying his spare time in accumulating, arranging, and cataloguing his collections. In 1695 he married and settled at 3, Bloomsbury Place, where he practised for many years. In 1712 he became physician to Queen Anne and in 1706 Physician-General to the Army. In 1716 he was made a baronet, being the first medical man to receive that title. In 1719 he became President of the Royal College of Physicians, and in 1727, on the death of Newton, he succeeded him as President of the Royal Society. Among his medical activities is his physiciancy of Christ's Hospital for thirty-six years, his assistance to Captain Coram (1668-1751) in instituting the Foundling Hospital in 1739, and his attempt to establish a free dispensary. He practised till he was 82, when he retired to Chelsea. He died there eleven years later and was buried there.

Varied Collections

The number and variety of the collections that Sloane accumulated are truly astonishing. There were about 50,000 printed books that formed the basis of the British Museum Library, about 3,800 volumes of manuscripts, about 32,000 medals and coins, 334 volumes of dried plants which formed the basis of the British Museum Herbarium, 12,500 other specimens of plants, 5,500 insects, 1,900 quadrupeds, 1,500 fishes, 1,200 birds, and thousands of other specimens under other headings, including anatomical preparations. Some idea of the variety of the collection can be gathered from a special issue of the *British Museum Quarterly* that has just appeared as a special bicentenary number. In its articles by keepers of various departments, under the general charge of the Director and Principal Librarian, Sir Thomas Kendrick, K.C.B., details may be learned of the nature of the treasures in their keeping. It is noteworthy that in the great Sloane collection of manuscripts a very high pro-

portion are medical. Among them is a volume containing William Harvey's lecture notes of 1616. In this issue of the *Quarterly* the passage containing the first public statement of Harvey's discovery of the circulation is reproduced in facsimile. Another famous but more beautiful medical manuscript is Roger of Parma's treatise on surgery written and exquisitely illustrated in France in the thirteenth century.

We cannot end without an anecdote of Sloane which is perhaps not known to all our readers. In 1740 the composer Handel was taking tea with Sloane, who showed him his library. Handel placed his buttered muffin on the volume in his hand. The outraged silence of Sir Hans did not appal him with a sense of guilt. "To be sure," Handel admitted, "it was a careless trick, but it did no monstrous mischief; yet it put the poor old bookworm terribly out of sorts. I offered my apologies but the old miser would not have done with it. If it had been a biscuit, it would not have mattered." And Handel went on to suggest that Sloane's displeasure was due to his parsimoniousness. "But Sloane's displeasure was due to his parsimoniousness. 'Ach, mein Gott, muffin and butter. And I said to myself, 'Ach, mein Gott, that is the rub! It is the butter'—which indeed it was, but not for the reason which Handel alleged. In those days butter was not rationed—except in libraries."

INTERNATIONAL HOSPITAL CONGRESS PREVENTION: A MAJOR HOSPITAL FUNCTION

The eighth International Hospital Congress was held at Church House, Westminster, from May 25 to 30. It was attended by more than 500 participants from 35 different countries. The Chairman of the Congress was Dr. René Sand, Emeritus Professor of Social Medicine, University of Brussels, and President of the International Hospital Federation. The central theme of the Congress was "Preventive Medicine as a Major Function of the Hospital," and after two plenary sessions on Whit-Monday the Congress broke up into sectional groups and study and research committees, which reported to plenary sessions on the closing day.

The Congress was opened by the Minister of Health, Mr. IAIN MACLEOD, who declared that a new breeze was blowing down the rather dusty corridors of their long debates on health. He had been particularly impressed by the desire in many quarters to get away from what was called the tyranny of the hospital bed. It would be a proud boast when a Minister of Health could say that he no longer needed 10,000 hospital beds because the demand for them was not there. It might be that this was a long way off in the future, yet the conquest of so many infectious diseases and the massive fall in the incidence of tuberculosis gave ground for hope.

If the task of prevention was formidable, Mr. Macleod continued, powerful allies could be enlisted in its pursuit—the achievements of doctors and scientists, the great advances in chemistry, better food and housing, the growing consciousness of the importance of public and private hygiene, as well as new standards of hospital architecture and administration. It had been said that hospitals were once only isolation. It had been said that hospitals were hostels, the ante-room to the morgue; at best they were prisons, and at worst prisons. All that had gone and progress was still continuing. The link between welfare services and the hospital was becoming stronger.

Importance of Polyclinic Services

The first contribution in the general discussion was by Professor H. W. C. VINES, of Charing Cross Hospital Medical School, who restated the argument which he had put forward at the recent conference of hospital administrators at Hastings (*British Medical Journal*, May 16, p. 1104). The real future of the hospital service might well

come to lie, not in the wards, but in the polyclinics. As an immediate step a programme might be devised to raise the importance of the polyclinic services to a level more comparable with the services afforded to in-patients. All general hospitals of 100 beds or more should offer out-patient services, varying in scope from a full range of specialisms at the largest hospitals to a minimum of general medicine and surgery at the smallest. The clinics should have direct linkage with the ancillary services of radio-diagnosis and pathology, and the provision of treatment rooms and recovery rooms should in particular be ample.

Professor C. A. ROMANZI, of the Medical School, University of Genoa, whose paper was read in his absence, declared that the difficult task of creating a harmonious system of medico-social assistance should be entrusted not to an administrator or to a hospital physician, but to a new type of person remaining to be created, one who would not treat patients but act as their guardian, and one who understood how a hospital could give its best service to society.

The debate was continued by Dr. EDWIN L. CROSBY, president of the American Hospital Association, who said that the close integration of the hospital in-patient department with its out-patient department and with the home was fundamental if the most economic and efficient care of all patients—particularly the elderly—was to be achieved. It was here, said Dr. Crosby, that the closest co-operation between the health department and the hospital was to be seen. As the patient left the hospital and was discharged from its area of responsibility, he was followed by the health department to see that the results attained were not lost and that the individual resumed his full responsibilities as a citizen.

Dr. Crosby added that in the United States and Canada, working in close co-operation with hospital trustees and administrators, physicians had established certain standards of hospital care, and as a result the Commission on Accreditation of Hospitals (of which the speaker was director) could place its stamp of approval on a hospital and indicate to the community that it was a safe place to enter for treatment and care. The actual licensing of hospitals remained the responsibility of the Government and was largely delegated to health departments.

"Rehabilitative Medicine"

Professor G. PORTMANN, dean of the Faculty of Medicine at Bordeaux, gave some examples of the function of the hospital in what he called "rehabilitative medicine"—that is, returning the patient to normal life in society, better able to resist the recurrence of his illness or the contraction of a new disease. One example concerned deaf patients. At the Hôpital St. André in Bordeaux there had been set up a university laboratory for the study of deafness. It had been provided with the most up-to-date equipment, and it was now possible to examine the hearing of a child under the age of 3. Psychogalvanic tests were employed to detect the existence of the smallest remnant of the auditory function, all the more accurately in that they were carried out without the patient's knowledge, and therefore not disturbed by psychological factors. This remnant of the auditory function having been assessed, electrical rehabilitation was undertaken, followed by the wearing of a hearing-aid which enabled the child to go to an ordinary school, to talk, and to develop its intelligence. In this way large numbers of children, some from homes for the backward, others from homes for the deaf and dumb, had been restored to normal activity.

Sir ALLEN DALEY, former chief medical officer of the L.C.C., said that it was always being urged that people ought to come under treatment earlier. Public health could do something to bring this about by health education, but elsewhere the initiative must lie with the individual. One of the ways in which the hospital and also the family practitioner could help the public health department was by giving more information about the illnesses which afflicted

the population, so that the department could better ascertain what preventive services should be installed. The liaison between public health people and clinicians might be still closer.

Dr. ROBERT BUECKI, of Detroit, found himself differing at one point from Professor Vines's contentions. Professor Vines had suggested that the hospital bed unit should be separated from the diagnostic, or preventive medicine, or positive health unit. That, however, would be a mistake. From the standpoint of efficient use of their facilities and equipment hospitals could not afford such duplication.

An account of the rehabilitation and follow-up services available in Great Britain was given to one of the sections by Dr. J. A. SCOTT, medical officer of health of the L.C.C. He began with the work of almoners, nearly 1,000 of whom were employed in nearly 500 hospitals, and he went on to survey the rehabilitation centres in this country, in particular Roffey Park (industrial fatigue, depression, and anxiety states), the Farnham Park Recuperative Centre (surgical, traumatic, orthopaedic, and medical), and Stoke Mandeville Ministry of Pensions unit (spastic and paraplegic cases). There were nearly 5,000 convalescent homes as part of the national hospital service in England and Wales, and 52,000 persons had convalescent treatment in 1951. What the hospitals started the Ministry of Labour did much to complete, and Dr. Scott described the disabled persons register, the industrial rehabilitation units, and the Remploy factories. The register, now in its eighth year, contained the names of nearly 900,000 persons, of whom 40% came into the surgical group and 38% into the medical. He concluded with a reference to the various voluntary bodies which supplemented hospital treatment.

District Units

Dr. K. J. MANN, the director-general of the Hadassah Medical Organization at Jerusalem, spoke of the need for small units to meet effectively the day-to-day demands. His own organization (which also maintained Israel's own medical school in partnership with the Hebrew University) had opened five district medical stations in the area served by the University Hospital in Jerusalem. These outposts, staffed by public health nurses and general practitioners, were taking medical care into the homes of patients, tackling after-care problems, giving instruction in twentieth-century hygiene to members of ancient communities, and dealing with everyday ailments on the spot, thereby saving specialized hospital and clinic staff.

A warning about the cost of what he called "closed care"—that is, in-patient provision, as opposed to "open care" in the form of out-patient departments or the service of private or public doctors—came from Sweden. Dr. O. JOHANSSON, superintendent of the Karolinska Sjukhuset at Stockholm, said that the average running expenses for each hospital bed in Sweden reached a figure of at least £3 a day. Public opinion tended more and more to declare that the limit of taxation had been reached, and people were not willing to accept heavier burdens to pay for medical attendance. If the building of new hospitals were avoided large amounts would be saved, and he thought this could be done if closed and open care were better co-ordinated. Hospital beds should be used for the care of acute cases only. Preventive care and treatment during convalescence should be carried out in out-patient departments, which should be used for longer periods, up to 12 hours a day, and the laboratories perhaps up to 24 hours. Why not shift-work in these departments as well as in the wards?

After plenary sessions the Congress broke up into sectional groups and study and research committees, where less formal discussions were held on hospital planning, construction, equipment, and maintenance, medical and nursing care, and social and welfare services. The members of the Congress paid a comprehensive series of visits to hospitals and other centres of interest, and one of their social arrangements was a reception in the Great Hall of B.M.A. House.

Patient Care

At its closing plenary sessions the Congress received reports from its committees. One committee, with Dr. T. ROWLAND HILL (who was appointed B.M.A. representative at the Congress) as its chairman, reported on the care of the acute case. It pointed out that in Great Britain, with medical service free, patients did tend to seek doctors' help early, but there was need for the education of the public in the recognition of early signs and symptoms. But even early consultation was not enough. The family doctor must have adequate facilities to help him.

So far as the out-patient department was concerned, again to quote British experience, the "open" department had virtually disappeared, and had been replaced by an appointments system. The old system, however inconvenient, had its points, for the department was then like a great health centre where the patient could call when he had a sudden feeling that he should seek medical aid. The present form of consultative appointments, under which patients must be referred by their family doctor, had the disadvantage that the family doctor and the consultant met only on rare occasions.

Another committee, under the chairmanship of Sir GEORGE HENDERSON, Secretary, Department of Health for Scotland, reported its conclusions on various matters of hospital administration. One of the most pressing problems, Sir George Henderson declared, was how to give hospital care to everyone who needed it, without overloading the hospitals unduly. This became more difficult as the responsibility was transferred to public authorities or to prepaid insurance schemes, and in almost every country it was aggravated by the plain fact that the span of life was increasing. In Great Britain the immediate question resolved itself into reducing waiting lists. There was much evidence of support for some kind of home-care service—a projection of the hospital service designed to supplement, and partly to replace, orthodox hospital care. Where there was opposition to the home-care organization it came mainly from the doctors themselves. Professor E. M. BLUESTONE, of Montefiore Hospital, New York, had outlined a programme of home care which was inaugurated in New York in 1947. As originally conceived, it was for indigent patients only, but it was now proposed to extend it to patients who could afford a reasonable doctor's fee. A system of home medical care which had been organized in Cincinnati had also been described to the committee. This provided many varieties of hospital service at the patients' own homes at the lowest possible cost, but the position of the family doctor was not made specially clear.

Health centres, unfortunately, said Sir George Henderson, had not so far attracted very much attention, but it might be found that the health centre could take a load off the hospital by enabling family doctors to work far more than at present without turning themselves into hospital assistants.

Social and Welfare Services

A sectional group, of which Professor J. M. MACKINTOSH was chairman, concerned itself with the social and welfare services centring around a hospital. Professor E. M. BLUESTONE, of New York, acting as rapporteur, said that the section felt that the emotional effects of prolonged illness, with special reference to age and to the family, should be given most careful consideration in organizing medical care, inasmuch as social and psychological factors in disease were often of as much consequence as physical factors. The Congress was recommended by this group to adopt the social concept of rehabilitation in preference to the medical concept of cure; the former was felt to be more continuous, complete, and comprehensive.

Another recommendation was that the distribution of medical care among the available practitioners of medicine should be reconsidered with a view to including more health examinations, for which purpose more physicians should be trained. The Congress and its affiliated agencies were

also asked to consider the fee-for-service method of providing medical care. It was felt that some form of voluntary or compulsory health insurance would meet the situation.

Another group, under the chairmanship of Professor G. SOLLAZZO, of Italy, brought forward certain conclusions on preventive medicine in hospitals. An opinion voiced by this group, though not unanimous, was that there should be B.C.G. vaccination of all newborn infants in hospital; also that the chests of all patients passing through the out-patient department and of all in-patients should be radiographed in order to detect tuberculosis. In another report on nursing care, brought forward by Miss M. J. MARRIOT, matron of Middlesex Hospital, it was urged that the nurses' curriculum should take more note of the social aspects of disease.

Other groups reported on hospital planning, construction, and equipment, and administration, organization, and finance.

PHYSICAL TREATMENT OF RHEUMATIC DISEASES AT BRITISH SPAS

The British Spas Federation Medical Committee—of which Lord Horder is chairman and Dr. G. D. Kersley secretary—has been investigating the value of hydrotherapy and physical treatment in certain types of rheumatic diseases, the results obtained at a number of spas being pooled. We have received the following brief summary of the statistical data analysed by Dr. E. Lewis-Fanning, statistician to Cardiff University.

At the suggestion, and under the direction, of the Medical Committee of the British Spas Federation, an investigation of the effect of physical treatment, including hydrotherapy, on rheumatic cases at a number of centres has been carried out.

It was realized from the start that a completely controlled therapeutic trial was not possible, as it was impossible to rule out psychological influences. Such factors must, however, play their part in the effect of therapy, and every effort has been made to give genuine clinical assessments. Only typical cases of rheumatoid arthritis, osteoarthritis, and fibrositis were investigated, and no parenteral therapy was used during the period of observation. Cases were assessed before treatment, directly after treatment—that is, in 3 to 6 weeks—and again three months later.

128 cases of rheumatoid arthritis, 227 of osteoarthritis, and 112 of fibrositis were followed up in this way, and the results statistically analysed by Dr. E. Lewis-Fanning, of Cardiff University. Degree of pain on movement or at rest, swelling, tenderness, and range of movement were numerically recorded, together with age and sex, on a special proforma drawn up for the purpose. No points of especial interest were forthcoming from analysis of age and sex group, but the general effect of treatment, both immediate and after three months, is of importance, and accords well with clinical impressions.

In the rheumatoid arthritis group, of 128 patients approximately half appeared to derive significant immediate benefit, and a slightly larger number were definitely improved on and a three-months review. This applied both to a more "active" and to a more "quiescent" subgroup. In the former, 68% showed decrease in tenderness and 54% of swelling of the worst-affected joint, but only 36% had reduction of pain at rest. One patient only appeared to be worse.

In the group of 227 osteoarthritis, approximately two-thirds stated that they had less pain, and half had increase in range of movement. After three months the result was slightly less good, with only 62% stating that they had less pain than before treatment.

In the group of 112 patients with "fibrositis," again two-thirds claimed improvement, and the result of assessment three months later showed neither increase nor decrease in this benefit figure.

Correspondence

Habitual Abortion

SIR,—In their paper "Progesterone Implantations in Habitual Abortion" (*Journal*, May 16, p. 1073) Dr. G. I. M. Swyer and Miss Doreen Daley criticize quite fairly some findings of mine on the spontaneous cure rate of abortion sequences—I notice they still cling to the stupid term "habitual abortion"—but then unkindly add: "The results we obtained . . . suggest either that the population we were sampling was not comparable with those which provided the basis for the Malpas and Eastman calculations or that those calculations were themselves fallacious. We incline towards the latter possibility."

As your annotator points out in the same issue (p. 1095), these figures of mine were never claimed as an absolute yardstick against which to measure the results of empiricism; their one object was to establish that there is a high spontaneous cure rate for recurrent abortion and that this spontaneous cure rate varies according to which of several reasonable assumptions is made, all such assumptions being necessarily nothing more than intelligent guesses. My guess seemed to fit the population I knew, but MacGregor and Stewart, in a subsequent paper,¹ saw fit to modify, and I think improve, the original calculations. Whatever assumption is made, the spontaneous cure rate remains quite high.

In a later paper, "The Categories of Abortion Sequences,"² I pointed out that cases of recurrent abortion can be divided into two groups, one group that in which a cause can be discerned and in which the prognosis depends on the nature of the cause, the other that in which no cause can be discerned and in which the prognosis is uniformly good. This conclusion takes the problem out of the field of statistics, as indeed it should be.

Recurrent abortion will never be comprehended until we have a better understanding of the conditions of early foetal growth. My present feeling is that the problem of early spontaneous abortion is tied up with the interrelationship between conceptus volume and the mechanism for nervous inhibition of the uterus in pregnancy.

To end on a more general note, a quotation from *Walden* seems apposite: "If we knew all the laws of Nature, we should need only one fact, or the description of one actual phenomenon, to infer all the particular results at that point. Now we know only a few laws, and our result is vitiated, not, of course, by any confusion or irregularity in Nature, but by our ignorance of essential elements in the calculation." This last phrase of Thoreau lightens the dilemma.—I am, etc.,

PERCY MALPAS.

Liverpool.

- ² *Ibid.*, 1942, 49, 12.

SIR,—I have read with great interest the paper by Dr. G. I. M. Swyer and Miss Doreen Daley (*Journal*, May 16, p. 1073) and your annotation (p. 1095) on this subject. I should like to correct the impression that my colleagues and I, having claimed good results from treatment of cases with a history of habitual abortion with progesterone implants in the pregnancy under consideration, were "challenged to treat alternate cases with implants of an inert compound," and that for reasons not specified in your annotation we declined the challenge.

In the papers quoted^{1,2} the nearest we got to claiming good results from this treatment was the comment of our expert statistical colleague Dr. Richard Doll, expressed as follows: "Provided the 'normal' incidence of spontaneous abortion is of the order of 10% and the incidence of abortion due to recurrent factors is not much less than 0.1% it is reasonable to conclude that the present figures indicate an effect of treatment." It was we ourselves who suggested that this effect might be psychotherapeutic. Com-

menting on Bevis's studies¹ we pointed out that serious consideration should be given to the possibility that a considerable proportion of the patients "who had experienced more than three early abortions had done so for psychological reasons and that any procedure which is likely to gain their confidence may well prove successful." In this connexion I note that "extensive preliminary investigations," including "five or more consecutive pregnanediol assays," were performed on a number of the cases in the series reported by Swyer and Daley. May not these investigations have had a powerful psychotherapeutic effect? Finally, it was we who issued the challenge to treat alternate cases with implants of an inert compound, for in our second paper we said: "There is of course an obvious way of settling the question whether a progesterone implant is endocrinologically or merely psychologically therapeutic—namely, to treat alternate cases with implants of progesterone and an inert compound such as cholesterol."

In your annotation you say: "For reasons given" (in a subsequent letter to which you give a reference,² though you do not disclose the reasons) "the challenge was declined" (by us). The reasons are that I did not, as you, Sir, I gather do not at present time, feel convinced that the contention had been proved that progesterone implants were without effect in the treatment of habitual abortion (be this effect "endocrinotherapeutic" or psychotherapeutic). I expressed my attitude in a further letter³ as follows: "If my wife had had three miscarriages and was pregnant I should most certainly ask one of my colleagues to give her a progesterone implant. How could I, therefore, implant an inert substance in similar circumstances into any patient entrusted to my care?"—I am, etc.,

London, W.1.

Post-partum Haemorrhage

SIR,—I also would like to endorse the importance of the paper by Drs. J. D. Martin and J. G. Dumoulin on the subject of the use of intravenous ergot (*Journal*, March 21, p. 643), as does Mr. Keith Vartan (*Journal*, May 16, p. 1108), but from a different point of view.

From the sphere of a general practitioner in a country district, I can foresee this method earning unjustified condemnation because of the high incidence of manual removal of the placenta, to which the paper and Vartan's letter both refer. May I therefore emphasize, as forcibly as I can, a point of technique which is of paramount importance if this method is used, and which I have not seen emphasized before? My own preference is to give the ergot as soon as the contraction which enables the head to be crowned has subsided, or, in the case of a forceps delivery, as soon as the head has been eased out. The vitally important step comes next. Knowing that a long and powerful contraction will arrive in a matter of 30 to 40 seconds, the need to deliver the shoulders and the rest of the baby with all reasonable speed has gone. This feeling of urgency is almost an instinct in the older midwives, and is surprisingly difficult to resist. It is this which must be changed. The shoulders can be delivered slowly and gently, as they need only to be guided and controlled. Once the thorax is born, the abdomen, thighs, and extremities should be deliberately delayed instead of allowing them to arrive at the normal speed. It is this which is so surprisingly difficult to do and even more difficult to teach midwives to do, so deeply ingrained is the feeling that delivery should be completed "before the pain goes." If one follows this seemingly minor change of technique, it will usually be found that as soon as the cord is clamped, tied and cut, and the baby out of the way, the placenta is resting in the upper vagina with a firmly contracted uterus above. Completion of the third stage is over in two minutes.

To digress from the bare bones of tables and statistics, I would add that most of my midwifery is in cottages and houses in a rural district. I expect to be able to deal with some of the complications of labour—and am equipped to do so—which involve anaesthesia and a forceps delivery. My anaesthetic of choice is still chloroform, and the adoption of this intravenous ergot technique has robbed these manipulations of the fear of a post-partum haemorrhage which always lurked in the background previously. Indeed, on one occasion, when chloroform was given for me by a consultant anaesthetist instead of by my partner, intravenous ergot was the only thing which saved a devastating bleeding from an almost atonic uterus. Over a period of three years I have used this method when the need or opportunity arose, and in some sixty cases retention of the placenta has not occurred, and it goes without saying that the small loss of blood has been striking.

As I said, I am writing from the point of view of the general-practitioner obstetrician to endorse the great value of the intravenous ergot technique and to emphasize the importance of this detail of its performance which I think is the keystone of the whole thing. It may save the method from hasty and unfair condemnation in that very sphere of midwifery where it is of the greatest value—the cottage in the country.—I am, etc.,

Ilminster.

HUGH CARTWRIGHT.

Transverse Arrest of Head

SIR,—I have read with great interest the correspondence which has appeared since the publication of Mr. Bryan Williams's excellent article on "Transverse Arrest of Head and the Occipito-posterior Position" (*Journal* April 18, p. 865). It speaks highly for present-day obstetrics that Mr. Williams's advocacy of Kielland's forceps has not provoked a repetition of the unjustified criticisms made by Continental writers following the publication of Kielland's original article in 1916.¹ At that time a few, but very vocal, obstetricians condemned the instrument even though some had never used it.

I note that the old controversy of whether Kielland's forceps should be used only by obstetricians still persists, but I am surprised that Dr. C. Rutherford Morison (*Journal*, May 16, p. 1107) considers the "wandering method" to be a new one. Not only did Kielland refer to this in his original paper but many writers have done so during the last 37 years.²⁻⁴—I am, etc.,

St. Asaph.

Proctalgia Fugax

SIR,—The article by Mr. M. R. Ewing on proctalgia fugax (*Journal*, May 16, p. 1083) raises many interesting questions, and prompts me to describe a condition which, though dissimilar, presents sufficient points of resemblance to proctalgia fugax to make one wonder whether the two conditions may not have a common origin.

The condition, which recurs at intervals of four to six months, consists essentially in a dream of which the main content is a sense of forcible compression in the region of the waist, causing intense anxiety, inability to take a breath, and fear of asphyxiation. Sometimes this sensation is accompanied by an objective dream content, such as that one's waist is being compressed by the hands of another person, by a rope, a metal band, or other apparatus, and that one is endeavouring vainly to escape. At other times there is no objective content, the sole matter of the dream being the sense of compression. At the height of the dream, when the sensation becomes unbearable, and reminiscent of the "being held very tightly by the rectum and unable to escape" of Mr. Ewing's patient, waking occurs.

The first feeling on waking is one of terror. This, however, is rapidly replaced by relief on discovering that the incident was, after all, merely a dream. The dream, which began in childhood, has persisted well into middle age, and has become somewhat more frequent of late years. I have been unable to associate it with food, fatigue, temperature, mental anxiety, ill-health, or any other predisposing cause.

The points of resemblance between proctalgia fugax and the condition which I have described but cannot name are as follows: (1) occurrence of an acute distressing spasmodic condition in an apparently healthy person; (2) absence of recognizable physical cause; (3) nocturnal incidence, usually in the small hours; (4) "aura," in some cases a feeling of malaise, in mine a frightening dream; (5) a sensation of violent gripping, in one case in the rectum, in the other round the middle of the trunk; (6) rapid disappearance of the symptom without after-effects.

I believe the cause of both these conditions to be psychological, probably an unresolved anxiety state. I should be greatly interested to learn the views and experience of others, and especially to know whether the condition I describe is as relatively common in women as proctalgia fugax would appear to be in men.—I am, etc.,

London, N.W.11.

SYLVIA G. CHAPMAN.

SIR,—I enjoyed Mr. M. R. Ewing's survey (*Journal*, May 16, p. 1083) of this distressing complaint. When it was discussed at the Gastro-Enterological Club in 1948, Ryle raised objection to the name as being a Greek-Latin hybrid, but clearly the term has come to stay. At this time I remarked that, as Mr. Ewing suspects, the disease is not rare. As a leading symptom it seldom appears, and, in fact, over a five-year period I was consulted primarily for this pain eight times only. Six of the patients were doctors. During the next five years at the end of the history-taking I asked every patient, no matter what disease, whether he or she had ever suffered from rectal pain. Sixty-six replied in the affirmative, and analysis of their discomfort made it clear that they were suffering from proctalgia fugax. It is the transient nature of the pain and the long intervals of freedom which induce forgetfulness or lack of sufficient anxiety to drive the victim to the doctor.

Of the different methods of treatment, Ryle was convinced that sustained deep pressure on the perineum was the most effective. Many others, notably W. E. Tanner, declared that distension of the rectum by enema of water or even air would abolish this unbearable pain. Mr. Ewing is impressed by the rapid response to the taking of food. If this is, in fact, effective it will certainly be welcomed by "proctalgics" as a substitute for their previous therapeutic gymnastics. It is in relation to aetiology that this point is of especial interest. Mr. Ewing assumes that initiation of the gastro-colic reflex inhibits painful muscle spasm, and implies, I think, that it is colonic or rectal spasm he has in mind. I wonder if this is so? I agree that amyl nitrite is useless. May it not be that the pain is due to segmental cramp of a section of the levator ani? When I described the pain in the *Lancet* (1928, 2, 1263) I described the finding in one case of simultaneous contraction of the iliac colon and rectum, but I am sure that this finding is quite exceptional. In fact it has not since been confirmed by nine doctor patients who at my request have repeatedly explored their rectums in attacks. In two of them no abnormality was found. In seven a tense tender band was palpable through the rectal wall on one or other side, never anteriorly, and always at the full length of the examining finger.—I am, etc.,

London, W.1.

Liver Injury by Antibiotics

SIR,—We did of course read with great interest the annotation (*Journal*, April 4, p. 777) concerning liver injury due to antibiotics.

We would, however, like to point out that certain statements made therein are subject to misinterpretation by the casual reader. In particular, the toxic effects of

aureomycin administered to humans, which were demonstrated by Lepper and his associates,¹ have not been demonstrated to our knowledge for terramycin. While it is true that Lepper and his group did show that large doses of terramycin intravenously in mice were capable of producing liver damage, clinical studies have not demonstrated such toxicity.—I am, etc.,

New York.

Litigation Against Doctors

SIR,—The council of this association, representing the staffs of the regional hospitals in England and Wales, wishes to register its grave concern about the increase of litigation involving members of the medical staffs of hospitals. It has been stated that the number of successful cases, in which an action for negligence against a medical officer is proved, has not increased. This is beside the point. The increase in claims against members of the profession, whether successful or not, whether justifiable or not, is not in doubt. It is certain that such claims and actions hinder the proper function of hospitals. They disturb the confidence of the hospital medical staff, particularly junior staff, in undertaking the responsibility of casualty and anaesthetic work, and lead to extravagant and frequently unnecessary precautionary investigations and to estrangement between hospital authorities and the medical staff.

It has been stated that a new definition of "negligence" as it affects a medical practitioner is called for. It is perhaps too much to ask for a complete restoration of confidence between doctor and patient against a background of an all-providing State and the infinite possibility of free litigation. The litigious or aggrieved patient is, however, still fortunately in the extreme minority. An effort wherever possible should therefore be made to point out to a public which may be satisfied though apathetic that increase in claims or actions against the profession is bound, for reasons already detailed, to react unfavourably upon the particular patient by increasing the cost of the service and disturbing that mutual harmony and confidence without which the best work is impossible.—I am, etc.,

London, W.C.2.

Succinylmonocholine

SIR,—Lehmann and Silk report (*Journal*, April 4, p. 767) that succinylmonocholine acts in the rabbit as a muscle-relaxant drug of lower potency and longer duration than suxamethonium (succinylcholine). They also find it is destroyed by cholinesterases. Whittaker and Wijesundera¹ had previously identified succinylmonocholine as a product of the enzymatic hydrolysis of succinylcholine *in vitro*. These findings raise two questions of importance to anaesthetists. To what extent could succinylmonocholine itself be used as a muscle-relaxant of longer duration than succinylcholine? To what extent may the production of succinylmonocholine in the body, after administration of succinylcholine, account for the occasional prolonged reactions to the latter drug? Our findings in the mouse and cat may help to answer these questions. We used the chlorides of both compounds, and results are given in terms of active cation.

The intravenous dose of succinylmonocholine required to paralyse 50% of mice running on a rotating drum was 1.8 mg. per kg. (30 mice). The corresponding figure for succinylcholine was 0.11 mg. per kg. Succinylmonocholine has been administered intravenously to eight cats under chloralose anaesthesia. The dose of succinylmonocholine required to abolish response from the tibialis muscle stimulated through its motor nerve was about 1.7 mg. per kg. The corresponding dose of succinylcholine was 0.04 mg. per kg. The ratio of activity of succinylmonocholine to succinylcholine, of about 1 to 40, is the same as that reported by Fraser² for the cat's gastrocnemius. After administration of succinylmonocholine the muscular contraction was briefly enhanced before the onset of paralysis. Succinylmonocholine

caused considerably longer paralysis in the cat than did an equivalent dose of succinylcholine. As might be expected, succinylmonocholine was prolonged and potentiated by neostigmine.

As with high doses of succinylcholine (Somers⁴), succinylmonocholine had a marked pressor effect in the cat at doses of 7 and more mg. per kg. For example, to a cat maintained by artificial ventilation, successive doses of 17, 34, and 68 mg. succinylmonocholine per kg. were given at intervals of 1½-2 hours. After 34 mg. succinylmonocholine the blood pressure rose from 120-230 mm. Hg and returned to its previous level within 2½ minutes. The dose of 68 mg. per kg. was fatal. The rise in blood pressure caused by succinylmonocholine was abolished by hexamethonium and is therefore "nicotinic" in type. In some cats there was also a transitory fall in blood pressure after succinylmonocholine which was abolished by atropine. The pressor effect of succinylmonocholine would be an objection to the use of the drug in man, if it occurs at doses close to the fully effective dose. Since the rate of destruction of succinylmonocholine by plasma cholinesterase is lower than that of succinylcholine, and since in man an effective dose of succinylmonocholine would no doubt be higher than that of succinylcholine, there would seem to be a greater danger of prolonged reactions to succinylmonocholine. If succinylmonocholine were to be widely used, a preparation of plasma cholinesterase should presumably be available as an antidote. The danger of prolonged reaction might, however, be somewhat offset by the fact that cell cholinesterase slowly destroys succinylmonocholine.

With regard to the second question, succinylmonocholine is so much less potent than succinylcholine in animals that we might expect that the amounts of succinylmonocholine produced in man by the enzymatic breakdown of single doses of succinylcholine would be insufficient to exert any appreciable blocking action on the neuromuscular junction. An exception might occur, however, where very large doses of succinylcholine are administered by intravenous drip. For example, Bourne, Collier, and Somers⁵ report delayed recovery in a patient who received a total of 2.3 g. of succinylcholine during three hours. The gradual return of strength seen in this patient would be in keeping with the continued presence of a just effective quantity of a longer-acting relaxant such as succinylmonocholine.

Our thanks are due to Miss M. P. Hatton for technical assistance, and to Mr. E. Eastwood for preparation of succinylmonocholine.—We are, etc.,

Dangers in the Use of Thorotrast

SIR,—A case showing chronic changes in the central nervous system following "thorotrast" ventriculography shown at the Royal Society of Medicine by Dr. Robert Hughes, of Liverpool, and the basis of an article by him,¹ prompts me to report a similar case.

The patient had thorotrast introduced into the ventricles in 1941 for an unexplained hemiplegia which probably, in the light of future evidence, was of vascular origin. Four years later, in 1945, he began to lose control of his micturition. In 1947 he noticed loss of control of his bowel function and is now completely incontinent of both urine and faeces. On examination, he had a low cauda equina lesion and had slight sensory loss over the first and second sacral roots. He had completely lost his sexual function. The anal canal was patulous, and at least three fingers could be inserted into the anus without discomfort. X-ray examination of the lower spine showed that the thorotrast was collected at the base of the theca and surrounding the roots. X-ray of the skull showed that thorotrast was still present in the ventricular system.

The patient refused to come in for lumbar puncture, so we were unable to investigate him further, but x rays of the spleen and liver showed thorotrast in these organs. It would appear, as in Dr. Hughes' case, that most of the original thorotrast is still within the patient. The cauda equina lesion must be caused by either arachnoiditis due to chemical irritation; continuing radioactivity of the material, which was shown to be present in Dr. Hughes' case and our own; or even the possible development of a tumour in the region of the cauda equina, malignant disease having been found to result from thorotrast introduced into the system.

This case is recorded to emphasize the importance of realizing the dangers associated with the use of thorotrast, which is still used too freely as an opaque medium, and also the delay in the development of symptoms. Several years often elapse before the patient complains of any symptoms. At a later date it is wellnigh impossible to remove this substance from the theca, as it becomes intimately bound to the spinal roots and no treatment alleviates the serious cauda equina lesions.—I am, etc.,

Bristol, 8.

Reaction to Blood Transfusion

SIR,—There is nothing that offers a better opportunity for legal action than a transfusion reaction. The public not unnaturally thinks that every mishap is due to some carelessness in grouping or cross-matching. It is, however, not aware that a dangerous or fatal reaction can occur in the absence of any such error, and it is to afford evidence in support of some unfortunate pathologist who gets caught out in this way (as I myself was) that I consider that the following case should be given as much publicity as possible.

A woman aged 52 was admitted for operative treatment of a hernia. Her haemoglobin was 67%. Complete blood count showed mild secondary anaemia, but was otherwise not illuminating. Blood group A, Rh positive. It was thought advisable to give her a pint of blood pre-operatively. Rh-positive blood was cross-matched for her. After about 5 ml. of this had been transfused, she developed all the signs of a complete incompatibility with violent pain in the back, extreme pallor, and collapse with almost imperceptible pulse. The transfusion was instantly stopped and cross-matching was quickly repeated with entirely negative results. A fresh specimen of blood was grouped with exactly the same result as before, and a cross match of the fresh serum with the original pint of blood also showed no incompatibility.

The patient fortunately survived, contrary to all expectation, and the operation was carried out successfully without transfusion. Probably on account of the very small amount of blood transfused there was no haematuria. A fresh specimen of blood was sent, together with the peccant bottle of blood, to Dr. Platt at the North London Blood Transfusion Centre, who verified our grouping and stated that no abnormal agglutinins or other reasons for incompatibility were found.

It is therefore suggested that the incompatibility was not a cellular one but was due to plasma. As against this, it is surely unusual for a plasma incompatibility to show itself in this way with pain in the kidney region. It more commonly seems to take the form of rigors occurring after rather more than 5 ml. of blood has been given, or possibly even the next day.

She was never very well afterwards, a fact that she did not hesitate to attribute to the transfusion, but the real reason (as also that of her anaemia) became apparent about a year later when she was admitted moribund with an inoperable carcinoma of the stomach and secondary deposits in the liver from which she died.

In 30 years of transfusing blood I have only once seen such a catastrophe happen before, and that was with blood on which no cross match had been carried out. But in those days only the most enlightened persons thought this necessary. I hope the record of this case may be of service to anyone who encounters a similar disaster.—I am, etc.,

London, W.1.

J. W. SHACKLE.

Half-way Houses for the Elderly

SIR,—Because it has been difficult to place certain elderly sick people into the categories of regional board (hospital) or local authority (hostel) responsibility there has arisen the idea that there must be a category of people who fall between these two groups. It is stated that some people need more care than they can receive in local authority accommodation, and do not need sufficient care to warrant their admission to hospital. King Edward's Fund for London and the National Corporation for the Care of Old People have provided accommodation in large houses in the London area which are variously designated as half-way houses or rest homes. These homes provide accommoda-

tion for 20 to 40 patients, and, I am informed, have been established for experimental purposes. No doubt the appropriate bodies will issue one of their most valuable statements when they have had time to assess the value of this type of accommodation, but I believe we should consider now what function this type of accommodation does fulfil and whether it is really necessary.

I believe that all patients can be grouped into those falling within the categories of sick or well, and, while it is said that the elderly readily move from sickness to health and back again, this does not invalidate the ability to place them in the group most suitable for their needs. If a patient can dress himself, wash himself, and feed himself, although he may need some assistance, and provided that he is neither mentally deranged nor incontinent, he should be regarded as the responsibility of the local authority. All other patients should fall within the responsibility of the regional board. The patients who are well one day and ill the next should be placed under regional board responsibility if their illness lasts for a few days continuously. The regional board would therefore be responsible for all types of sickness in the elderly, ranging from those who need the most expert medical and nursing care to those who need simple nursing care, and finally to those who are "frail ambulant." These needs can best be supplied by a geriatric unit, and in many parts of the country this type of service has been provided.

The various homes established by voluntary bodies and known as half-way homes, etc., do fulfil a most useful function, but, as I believe, a function not originally intended, and certainly do not treat the type of patient who is popularly supposed to need "half-way" care. One doctor working in one of these homes considers that convalescence is half way between health and sickness, and his home is used entirely as a convalescent home for the elderly people following acute illness. Other homes cater for the less seriously ill, and I believe others provide accommodation for healthy people which should be provided by the local authority.

One would suggest that a grave difficulty in the service for sick elderly patients is the absence of facilities for convalescence. Such accommodation is extremely desirable and would, if provided in conjunction with a geriatric unit of a hospital, enable many patients to leave hospital earlier and than they do, would reduce thereby the waiting-list, and would provide accommodation at less cost than a hospital bed. Would it not be possible for the regional boards and the local authorities to agree on a suitable method of financial support for this type of establishment?—I am, etc.,

J. M. GREENWOOD.

Manchester.

Gold Therapy in Rheumatoid Arthritis

SIR,—I have read carefully the paper by Drs. R. A. Peebles Brown and J. P. Currie (*Journal*, April 25, p. 916) on observations on gold therapy in rheumatoid arthritis. Being responsible for the introduction of gold salts in the treatment of rheumatoid arthritis, and being quoted in this article, I wish to present the following remarks.

It is highly desirable to check the treatment of rheumatoid arthritis against the response of control cases. But the value even of such experiments is practically annihilated by the fact that it is impossible to collect a sufficient number of cases which are strictly similar as regards duration, gravity, and anatomical changes, and which can be kept over a sufficient length of time in identical conditions of observation. The paper of Drs. Peebles Brown and J. P. Currie is based on a single course of gold salts and placebo injections given during a few weeks and on the assessment of the patients after 13 months. It overlooks entirely several important factors which we indicated more than 15 years ago and which are now generally accepted. No judgment can be passed on the value of chrysotherapy in rheumatoid arthritis after a single course of injections, since almost half of the patients show the first definite signs of improvement only after the second course or even later; even in cases which have been improved during the first course of gold salts, if a second course is not given after a period of six to eight weeks, there occurs almost certainly a relapse within the following months.

In choosing an interval of 13 months for the assessment of their cases—that is, 8-10 months after the end of the treatment—they have availed themselves of the most unfortunate time, since they estimate the condition of their patients at the very moment of the relapse. It is hard to believe that the authors are unaware of the usual and irregular course of rheumatoid arthritis. But the

most powerful argument against any investigation based on short-term experiment on such a chronic disease as rheumatoid arthritis is that no therapeutic results can be assessed except after several years of clinical observation, certainly not less than five years.

As gold salts are still used in rheumatology after 24 years and in spite of the introduction of cortisone and A.C.T.H., there seems to be some clinical evidence to the medical profession at large of their therapeutic value. Why are gold salts the only antirheumatic drugs which have resisted the test of time after 20 years? And are the clinical results not the best evidence from which to evaluate the therapeutic value of our treatments? Gold salts are certainly not a panacea and should be associated with all the recognized forms of treatments of rheumatoid arthritis, but they would not remain in use if they did nothing more than saline injections.—I am, etc.,

J. FORESTIER.

Aix-les-Bains.

Carcinoma of the Breast

SIR,—I have read with much interest and pleasure the erudite article in the Refresher Course series by Mr. Hedley Atkins on carcinoma of the breast (*Journal*, May 16, p. 1099). Under the heading of diagnosis he very rightly emphasizes the difficulty of saying with certainty what a lump is until it has been removed and carefully examined; and that all single lumps in the breast should be removed, with the possible exception of fluctuant lumps all the physical signs of which disappear after aspiration.

Years ago I was taught that pain was a favourable sign suggesting "chronic mastitis" and that carcinoma was a painless lump. I used also to teach this, but have long given up doing so after seeing many cases of carcinoma of the breast in which pain was coming in sharp sudden stabs. Corry recently wrote an article¹ emphasizing this point and giving records of his cases over many years. I have at present under my care two ladies, one of whom was first made aware of anything wrong by being awakened at 3 a.m. by a severe pain in the breast which persisted for some hours. It was a typical carcinoma. The second had initially a persistent pain going on for some days. She had a Stage I carcinoma. The presence or absence of pain in the breast should not influence one in following Mr. Atkins's advice about removing all single lumps in the breast.

Another point in diagnosis is the dimple in the breast with, or without, a lump. I have another lady under my care at present who noticed a dimple in her right breast as long ago as two years; she watched it gradually get deeper and was not at all disturbed, because an article in a popular magazine made no mention of dimples, but only referred to the importance of showing all lumps to the doctor. She was only able to feel a lump for the first time six weeks ago. She has a deep carcinoma with involvement of axillary nodes.—I am, etc.,

Smoking and Cancer of the Lung

SIR,—Mr. J. A. Heady and Mr. R. G. Barley (*Journal*, May 16, p. 1105) have attempted to put the data of Dr. Richard Doll and Professor A. Bradford Hill (*Journal*, December 13, 1952, p. 1271) into a suitable form for showing to the man in the street the difference in his chances of dying from cancer of the lung if he smokes a given number of cigarettes per day. To this end the authors take 1,000 young men aged 25 and calculate the numbers who would survive to ages 55, 65, and 75 under the alternative assumptions that they do not smoke, that they smoke 15-25 cigarettes per day, or that they smoke 25-50 cigarettes per day. I have examined this problem, using a slightly different approach, but one that I feel would give the ordinary layman a more precise answer to the blunt question: "What happens if I smoke x cigarettes per day?"

If a group of men aged 25 are considered and the average time that they live from then on is found, this average is designated

the expectation of life of a man aged 25. To work out this average a simple method is to take, say, 1,000 men aged 25 and using the appropriate death rates find the number who would be alive at ages 26, 27, 28, and so on. It is then a fairly straightforward matter to transfer this series of numbers into an average length of life. Owing to the form in which the smoking data are available the exact numbers surviving to each individual age cannot be obtained. Instead a number of pivotal values are obtained and a graphical graduation employed to get the intermediate values. To obtain the values for ages over 75, for which there are insufficient data, the following artifice is adopted. On a large sheet of graph paper the numbers surviving for ages 25-75 are plotted for each of the three groups of smokers. On the same sheet the appropriate figures from the 1942-4 male life table compiled by the Government Actuary's Department for the whole of life are superimposed. It is then assumed that the three curves under consideration would have the same form above the age of 75 as that of the life table curve and a suitable extrapolation is made by eye. In passing it should be noted that quite wide differences in the forms of the three curves for these advanced ages did not materially affect the final figures.

The results found by the methods described are given in the table, which relates to greater London.

Expectation of Life of a Man aged 25

Non-smoker	45.9 years
Smoking 15-25 cigarettes per day	44.9 years
Smoking 25-50 cigarettes per day	44.2 years

Whilst these results cannot be regarded as exact, they show that a man aged 25 suffers a reduction of about 2.2% in his expectation of life if he is a moderate smoker and about 3.7% if he is a heavy smoker. The question as to whether this is regarded as being an appreciable reduction or not must be left to the individual to answer for himself.—I am, etc.,

P. G. MOORE.

London, W.C.1.

Controlled Hypotension in Neurosurgery

SIR,—I have read with interest the paper on controlled hypotension in neurosurgery with hexamethonium and procaine amide by Dr. David Aserman (*Journal*, May 2, p. 961). I feel, however, that it is unwise to inject a dose of 100 mg. of hexamethonium when the patient is placed in a 30 degrees anti-Trendelenburg tilt, as a sudden cardiac arrest can and has occurred in the young and robust who happen to be sensitive to this drug. I am in agreement with a large initial dose of the hypotensive agent, but would rather give it when the patient is flat. After due time has elapsed to assess its effect the patient can then be postured to the degree required for the optimum blood-pressure level. If the blood-pressure fall is inadequate, or the pulse rate increases by more than 10 beats per minute, procaine amide can be employed.

Dr. Aserman makes the important statement that the blood flow through the brain is less than is indicated by the brachial blood pressure, and if cerebral anoxia is to be avoided it should be realized that for every 15 in. (37.5 cm.) that the head is raised above heart level there may be a drop of some 30 mm. Hg. Dr. Aserman states that in general surgery under hypotension reactionary haemorrhage has been one of the most frequent complications, but this has not been my experience. Furthermore, he suggests doses of thiopentone up to 1 g., but I feel the total dose of this drug can with profit be kept down to 0.5 g. even in the robust, although in this type of patient an initial dose of procaine amide in the region of 1 g. may be necessary, together with the infiltration of the area to be incised with an analgesic without adrenaline. The development of an attack of asthma he mentions in a man 70 years old adequately anaesthetized and under such vagolytic drugs as gallamine triethiodide, pethidine, and hexamethonium is difficult to accept. One is tempted to blame some degree of mechanical obstruction associated with the endotracheal tube for the trouble.

The problems of cerebral anoxia and "retractor anaemia" discussed are interesting and it may well be that these dangers will be mitigated in the future by the use of the new phenothiazine derivative R.P.4560 ("largactil") at present under clinical trial. This drug appears to have a wide

spectrum of activity, for in addition to being analgesic, anti-histaminic, vagolytic, and adrenolytic, it lowers body temperature and metabolism. Oxygen consumption is thereby reduced and the resistance of tissues to anoxia is increased. Indeed the future use of hypothermia and artificial hibernation in surgery and anaesthesia would appear to be assured.—I am, etc.,

Hull.

W. N. ROLLASON.

The Premenstrual Syndrome

SIR,—Over the last decades it has become abundantly clear that the adrenal cortex exhibits a cyclical activity in the female, that it produces both male and female sex hormones, that it responds to gonadotrophin, that the ovaries probably respond to A.C.T.H., and that progesterone has a cortical hormone-like action. In short the interrelations of the ovary and the adrenal are so close that the steroid metabolism of the mature female moves as one biochemical unit. Under these circumstances the fact that you were able to publish three articles on the premenstrual syndrome without so much as mentioning the adrenal gland must be taken as an illustration of a general reluctance to look further than the ovary when dealing with disturbances of the menstrual cycle.

I have elsewhere¹ pointed out the many difficulties and inconsistencies inherent in any attempt to explain the premenstrual syndrome on a purely ovarian basis, and Drs. Raymond Greene and Katharina Dalton (*Journal*, May 9, p. 1007) seem to be well aware of the many snags to their hypothesis. The idea of a disturbed ratio between mineralocorticoids and oestrogens on the one hand and glucocorticoids and progesterone on the other goes considerably further in explaining the totality of the syndrome. At the same time, it is probably wrong to attribute to direct endocrine action all the complaints met with in the premenstrual phase. Many of these depend on an uncovering of basic physical and psychological defects. This seems especially true of premenstrual manifestations of allergy, which are almost certainly due to the withdrawal of steroid protection from hypersensitive shock organs and not to a pathogenic effect of hormones upon normal organs, as Greene and Dalton suggest.

Whilst thus disagreeing with their pathogenic concepts I congratulate your authors on having accurately described the clinical manifestations of a very important disorder. I also fully agree that progesterone treatment will relieve most cases. I have even found it effective in a very obdurate case of premenstrual ulceration of mouth and vulva. In view of the intricate interrelations of the steroid hormones, however, no pathogenic conclusions can be drawn from the pharmacological action of progesterone.—I am, etc.,

Glasgow.

Sliding Hernias Through the Oesophageal Hiatus

SIR,—Dr. G. Rios-Solans (*Journal*, May 9, p. 1029) expresses surprise about the comparative discrepancies between necropsy and x-ray findings in cases of hiatus hernias. He contrasts his own findings of 26% of such hernias with x-ray findings of only 11%.

It is by no means easy to demonstrate a hiatus hernia radiologically unless the patient is tilted into the Trendelenburg position and screened prior to the taking of the films. I have found repeatedly that it is only possible to demonstrate a hernia if the patient is slightly turned into either a left anterior oblique or left posterior oblique position. Radiologists frequently desist from carrying out this examination in the elderly because they do not like to submit the patient to the additional discomfort of such positioning. If, however, the examination is carried out in the manner indicated, I have found a hiatus hernia rate of 20-25% in all patients submitted to barium meal examination who are over the age of 60.—I am, etc.,

London, W.1.

J. RABINOWITCH.

Obituary

WILLIAM FORBES, M.B., F.R.C.P.Ed.

We record with regret the sudden death on May 17 of Dr. William Forbes, senior lecturer in pathology in the University of Edinburgh. He was 38 years of age.

Born at Edinburgh on September 4, 1914, William Forbes attended George Heriot's School, of which his father, Mr. William Forbes, had been physics master, and became *proxime accessit* to the head of the school and the first winner of the nature science medal in 1932. He then began his university career, taking a combined course in medicine and science at Edinburgh. After distinguishing himself as an undergraduate, and gaining many prizes and the medal and first place in pathology, he graduated M.B., Ch.B. in 1938. A year devoted to the intensive study of pathology followed, and he obtained the B.Sc., with first-class honours in pathology, in July, 1939. After holding a hospital clinical appointment, he passed the M.R.C.P.Ed. examination in 1941. About that time he joined the staff of the pathology department in the university and at the Royal Infirmary, and did strenuous work in both during the period of the last war. Forbes was very anxious to go on active service with the Forces, but, partly from health reasons and mainly because the Central Medical War Committee considered he should be reserved for his civilian duties, he loyally carried on in the university and in the hospital service. His hospital work included duties not only at the Royal Infirmary but at many other hospitals, including the municipal hospitals and the Emergency Medical Service hospitals around Edinburgh. The heavy strain of that period told on a frame already not too robust, and left effects from which it is doubtful if he ever really recovered. In appreciation of his good work Forbes was elected F.R.C.P.Ed. in 1945.

When Dr. William Blackwood went to the National Hospital in Queen Square, London, in 1947, Forbes succeeded him in the University of Edinburgh as senior lecturer in neuropathology—he had been a lecturer himself since 1944—and a year later he became honorary consultant in his subject to the South-eastern Region of Scotland. The laboratory, formerly financed and managed by a laboratory committee of the Scottish mental hospitals, now became involved in a much wider field than that of the mental hospitals and dealt with material not only from within but from sources outside the region. It became necessary to second assistants from the main department of pathology to cope with the volume and variety of work, which continued to increase. The department of neurological surgery, under Professor Norman Dott, utilized the resources of the neuropathological laboratory, and joint weekly conferences were held. Teachers had also to be provided for the increasing number of postgraduate courses. All of these activities absorbed Forbes's energies, leaving him with little time for any sustained research. In addition, his health was never good, and despite six months' leave in 1948 he was still obliged to take things quietly for several months after that.

Forbes had shown promise of good work during his honours course in pathology, gaining the Gunning Victoria Jubilee Fund Prize in Pathology in 1940 for original work on histamine in relation to eosinophils. He later published several papers on pathological sub-

jects and was intending to proceed with work on the grading of gliomata, cerebral oedema, and cerebral anoxia, but the constant pressure of routine examinations and of teaching precluded him from finding time for all he would have liked to do. This preyed upon his sensitive mind and greatly worried him, making further inroads on his physical reserve.

Greatly interested in classical music, Forbes had a fine collection of records, which he gladly lent to those who appreciated them. During the war he gave "concerts" of his records on Sunday evenings to members of the University Naval Division, to their delight and profit. He also had a wide knowledge of English literature and could be a most entertaining conversationalist. It is a tragedy that one so full of energy and promise should have fallen by the way so early. Deep sympathy is extended to his widow.—A. M. D.

ALEXANDER MILES, M.D., LL.D., F.R.C.S.Ed.

R. E. A. has sent us the following appreciation of the late Mr. Alexander Miles, whose obituary notice was printed in the *Journal* of April 25 (p. 942): As women students in the "dark ages," we were allotted to the wards in the Edinburgh Royal Infirmary of the junior surgical and junior medical lecturers. Those of us who had Mr. Miles as chief can never be sufficiently grateful for the care and interest he took in teaching us. One aspect of his character stands out clearly in my memory. At the end of the session Mr. Miles reviewed the work done in wards 5 and 6, in which several cases of sepsis had developed. He went over all the possible causes, and finished by saying, "But I have to admit that at the same time some of my outside cases have also gone wrong, and I fear I must own to being the culprit." This shows the character of Mr. Miles, who could admit before a class of the despised women medicals that he had made a mistake. I doubt if many other teachers at that time would have done so.

Squadron-Leader A. T. MITCHELL died on April 18 at the early age of 26. After an outstanding career at school and university, Andrew Tannock Mitchell, who was born on September 12, 1926, graduated M.B., Ch.B. from the University of Glasgow in 1949. He then became house-surgeon to Mr. Arthur Jacobs at the Glasgow Royal Infirmary and later was house-surgeon at Greenock Royal Infirmary. On entry into the Royal Air Force for National Service he was accepted for surgical duties, attaining the rank of squadron-leader. He did his work conscientiously and well, treating all his patients with equal care and courtesy. He was a delightful person, honest and true. Strength of mind and doggedness of purpose were covered by a quiet and unassuming manner. His character was put to the test little over a year ago, when the first signs of a fatal disease appeared. When this was confirmed soon afterwards he did not give way to self-pity. Instead he faced the future with a courage which won everyone's admiration. He kept his illness secret from all he could, continuing on full duty till near the end. His death, therefore, came as a shock to many people. During his illness he was sustained by his fiancée, a friend from childhood days, and after their marriage in August last year he was ideally happy. Her professional skill and loving care also lightened the last few weeks, when he was unable to get up. To his wife, his parents, and his brother will go out the sympathy of numerous friends in whose hearts the memory of "Mitch" will long remain.—J. N. M.

The death of Dr. J. E. G. THOMSON at Montrose on April 29 has removed one who, before his retirement in 1947, was an outstanding general practitioner. James Ettershank Gordon Thomson graduated M.B., Ch.B. from the University of Aberdeen in 1907, before he was 21 years

of age, and then went straight to Arbroath, which was to be the scene of his life's work. He was called up as a member of the Territorial Army on the outbreak of war in 1914 and saw service in France and Gallipoli, and was awarded a well-earned Military Cross in 1918. Of a shy and retiring disposition he was beloved by his patients, to whom he gave unstinting service. His clinical acumen was exceptional, and he was a capable surgeon in the days when general practitioners in Arbroath performed appendicectomies, among other operations. A member of the British Medical Association for many years, Dr. Thomson was president of the Dundee Branch in 1928-9. He is survived by a widow and a daughter, to whom we extend our sincere sympathy.—J. W.

Dr. JAMES CHALMERS, who died in hospital at Stoke-on-Trent on April 29 at the age of 65, was in general practice at Alton, Staffordshire, for some seventeen years before he retired to live at Oakamoor, North Staffordshire, in 1951. James Chalmers was born at Aberchirder, Banffshire, on August 22, 1887, and was educated at the University of Aberdeen, where he graduated M.B., Ch.B. in 1912. After graduation he held a resident appointment at Aberdeen City Hospital, and in 1913 he took the D.P.H. On the outbreak of war in 1914 Dr. Chalmers entered the R.A.M.C. and served throughout in Egypt, where he was D.A.D.M.S. at the general headquarters of the Egyptian Expeditionary Force, with the rank of major. For his services he was mentioned in dispatches. After the war he returned to Scotland, and then in 1924 he obtained a senior resident appointment at the City Hospital, Birmingham. In the following year he entered general practice at Tamworth, where he also acted as medical officer of health to the urban and rural district councils. He was joint honorary secretary of the Nuneaton and Tamworth Division of the B.M.A. in 1927-8, and honorary secretary from 1928 to 1931. After moving to Alton in 1933 he continued in general practice there until he retired two years ago. Dr. Chalmers's chief interest was in the practice of medicine, and he kept up his reading of British and American medical literature until almost the end of his life. To an ever-increasing number of patients he endeared himself by his unvarying kindness and his care and attention to their welfare. He was devoted to salmon fishing, and he would have liked to know that his ashes would be buried in a churchyard overlooking his beloved Deveron, in his native Scotland. He is survived by his widow.—J. M. K.

We record with regret the death of Dr. E. A. S. SHAW at his home in London on May 2 at the age of 76. Evan Alan Sivell Shaw was born at Callao, Peru, on September 13, 1876, and was educated at Bonn and Brussels. He received his medical training at Glasgow, Edinburgh, and at the Rotunda Hospital, Dublin, and took the Scottish triple qualification in 1910. After taking a post as a ship surgeon in 1910-11, he settled in general practice in London, working in the Kensington, Bayswater, and Notting Hill districts for 40 years. During the first world war he served abroad as a captain in the R.A.M.C. For 20 years he was deputy medical officer at Wormwood Scrubs Prison. Dr. Shaw will be very much missed in the district in which he practised. The welfare of his patients was his life's work, and although broken-hearted by the death of his wife two years ago he hid his sorrow and continued to administer help and comfort wherever needed. He was rewarded by the affection and gratitude of his patients. Mrs. Shaw also was greatly loved in the district, for she never heard of any sick persons who were alone without visiting them and offering her help. In an area of London where many people live alone in lodgings her kindness was especially appreciated.

Dr. WINEFREDE M. GIBSON writes: I read with regret the obituary notice of the late Professor WARFIELD LONGCOPE in the *Journal* of May 16 (p. 1113). The postgraduates who visited Johns Hopkins Hospital while Professor Longcope was physician-in-chief will remember him with affection.

Both he and Mrs. Longcope gave friendly hospitality to them, and I shall always remember being present, one Christmas Day, at their Christmas dinner, and being welcomed as one of the family. Since 1938 they never missed sending a greeting at Christmastide; it is no wonder, indeed, that he was greatly loved by his students and his friends.

The death of Dr. ALFRED NOLAN FELL was recorded in the *Journal* of May 23 (p. 1169). We are indebted to "J. H." for the following further appreciation. As a fellow-student at Edinburgh University of the late Dr. A. N. Fell, I also would like to pay tribute to his memory and to his prowess at Rugby football. The University fifteen of his day had a great reputation in Scotland, and a following in keeping with that reputation. Fell was the fastest three-quarter of his time; to see him gain possession of the ball and then streak for the line was an experience never to be forgotten. Scotland these days is in the Rugby doldrums and could well do with another Fell. One of his last public appearances was at a jubilee reunion last June of some of the survivors of his year (1902) at Edinburgh. He was in the chair on that occasion, and his speech proposing the toast of Alma Mater will linger long in the memory of those who were present. He, like the rest of his year who were present at that reunion, was very happy in the knowledge that he had completed fifty years in the practice of his profession, and that he had been able to return to his Alma Mater to acknowledge his indebtedness to her. He was the kindly family doctor at his very best, and so his patients and friends will miss him very much indeed. But they will have very happy memories of him.

Universities and Colleges

UNIVERSITY OF OXFORD

Professor H. R. Dean, Professor of Pathology in the University of Cambridge and Master of Trinity Hall, Cambridge, has been elected to an Honorary Fellowship of New College, Oxford.

In Congregation on April 30 the following medical degrees were conferred:

D.M.—J. V. Garrett, J. M. Jefferson.
B.M.—W. H. Allchin.

In Congregation on May 5 the appointment by the Board of the Faculty of Medicine of Dr. J. E. French as University Demonstrator in Pathology from October 1, 1953, to September 30, 1958, was approved.

UNIVERSITY OF CAMBRIDGE

Professor J. D. Boyd has been appointed a member of the Board of Research Studies, to serve until December 31, 1955, in place of Mr. C. L. G. Pratt, resigned.

The following medical degrees were conferred in Congregation on April 25:

M.CHIR.—P. G. Somerville.
M.B., B.CHIR.—E. T. Stacey.

In Congregation on May 9 the following degrees were conferred:

M.A.—B. W. Davy, M.D., D.P.H.
M.D.—G. Osborne (by proxy), J. W. B. Forshaw, P. B. Kunkler.

M.CHIR.—J. P. Stephens.

UNIVERSITY OF WALES

In Congregation on February 13 the following medical degrees were conferred:

M.B., B.Ch.—H. L. S. Davies, Barbara M. Evans, W. Harrop-Griffiths, G. Harry, Margaret Land, E. B. Phillips, M. S. I. Wilkinson.

The following candidates at the Welsh National School of Medicine have satisfied the examiners at the examination indicated:

DIPLOMA IN PUBLIC HEALTH.—G. M. Davies, E. H. B. Hopkins, Sadie M. James, P. K. Murphy.

UNIVERSITY OF BIRMINGHAM

Professor T. McKeown has been appointed representative of the University at the International Congress of Genetics to be held at Bellagio, Italy, in August; Professor E. Brodie Hughes,

Professor J. M. Smellie, and Emeritus Professor W. H. Wynn, in addition to the Dean of the Faculty of Medicine, have been appointed representatives on the Standing Joint Committee of the University, the United Birmingham Hospitals, and the Regional Hospital Board; Dr. E. Bulmer has been nominated for re-appointment and Professor Smellie for appointment as representatives on the Board of Governors of the Teaching Hospital; and Professor C. F. V. Smout has been reappointed representative on the Regional Hospital Board.

Dr. J. H. Cort has been appointed Lecturer in Physiology and Dr. Constance A. C. Ross a Research Fellow in the Departments of Paediatrics and Child Health and of Pharmacology, from January 19, 1953.

Dr. A. B. L. Beznak has resigned his post as Lecturer in Physiology in the University, as from April 30, 1953, on appointment to the Chair of Physiology in the University of Ottawa, and Dr. Robert Morrison his post of University Clinical Lecturer in Radiology on appointment as Senior Scientific Officer at the Radiotherapeutic Research Unit at Hammersmith Hospital.

The title of honorary part-time Lecturer in Medicine has been conferred on Dr. O. L. Wade, Senior Registrar in the Medical Professorial Unit, United Birmingham Hospitals, during the tenure of his present appointment. The title of University Research Fellow has been conferred on the following for the duration of their present appointments: in the Department of Experimental Pathology, Dr. H. Bickel, Dr. J. D. Blainey, Dr. J. P. Bull, and Dr. D. S. Rowe; in the Department of Physiology, Dr. I. D. Singh.

Dr. Mario Manzotti has been appointed temporary Assistant Lecturer in the Department of Physiology.

Sir Harold Himsworth, Secretary of the Medical Research Council, will distribute the prizes and give an address to students at the opening of the 1953-4 session on October 5. He will also open the new block for clinical teaching and research, which is now nearing completion.

The title of University Research Fellow has been conferred on Dr. J. S. Howell, a cancer research worker (corrected announcement).

UNIVERSITY OF LEEDS

The following appointments are announced: Mr. Herbert Agar, Clinical Lecturer in Obstetrics and Gynaecology, as Honorary Demonstrator in Anatomy; Dr. F. G. W. Marson, as Lecturer in the Department of Medicine; and Dr. R. L. Langley, as Honorary Lecturer in the Department of Paediatrics and Child Health.

Dr. C. K. Anderson has been appointed Research Fellow in Genito-urinary Pathology for one year in the first instance, from November 1, 1953, and renewable annually thereafter, and Dr. P. G. Keates Research Fellow in Radiodiagnosis for one year, from October 1, 1953.

UNIVERSITY OF SHEFFIELD

The following appointments are announced: T. Hanley, M.D., M.R.C.P., Full-time Lecturer in Medicine; D. S. Munro, M.B., M.R.C.P., Full-time Lecturer in Therapeutics; A. Young, F.R.C.S., F.R.C.S.Ed., Part-time Clinical Teacher in Diseases of the Ear, Nose, and Throat; A. H. Cameron, M.B., B.S., Lecturer in Pathology.

Dr. J. E. Mitchell has resigned from the appointment of Demonstrator in Anatomy on returning to clinical work.

Dr. P. G. Walker has been appointed honorary part-time Lecturer in Biochemistry.

Dr. Lorna H. Drought has resigned her appointment as assistant medical officer to the Student Health Service.

QUEEN'S UNIVERSITY, BELFAST

The following medical degrees were conferred on December 19, 1952:

M.D.—*D. T. Gilchrist, *D. A. R. Orr, *I. D. Thompson, J. F. Breach, D. T. Glass, F. D. Honneyman, S. H. S. Love, E. A. Murphy, W. A. Norris, G. U. Thomas, Irene M. Thompson. M.B., B.Ch., B.A.O.—D. J. Acheson, Barbara D. Allen, G. A. Balmer, Ann T. Bowden, G. W. Donaldson, T. N. Elmwood, A. Gaston, Mary S. Gilbody, K. I. McD. Heath, Sheila H. Hoey, A. K. Irvine, R. H. Johnson, J. Kelly, G. W. C. McCartney, J. D. McDowell, A. C. M. L. Miller, H. R. St. L. Ormonde, G. B. Purce, Ellen D. Shilliday, A. B. Siewers, F. A. Thompson.

*With commendation.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

At a meeting of the Faculty held on April 13, with the President, Dr. Andrew Allison, in the chair, the following candidates were admitted Fellows of Faculty: *Qua Physician*. E. B. Hendry, S. J. Irani, J. H. R. Ramsay, C. Ratnavel, R. S. Walker. *Qua Surgeon*, M. I. Anwar.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending May 16 (No. 19) and corresponding week 1952.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1953					1952

STILLBIRTHS ..	205	25	17			199	26	28		

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenza pneumonia.

‡ Includes puerperal pyrexia.

Vital Statistics

Infectious Diseases

Only small fluctuations occurred in the trend of infectious diseases in England and Wales during the week ending May 16. The largest were an increase of 225 in the number of notifications of measles, from 9,809 to 10,034, and decreases of 149 for whooping-cough, from 3,461 to 3,312, and 101 for scarlet fever, from 1,387 to 1,286.

The largest rises in the incidence of measles were 113 in Lincolnshire, from 218 to 331; 72 in Lancashire, from 1,417 to 1,489; 72 in Cornwall, from 215 to 287; and 59 in Sussex, from 354 to 413. The largest falls were 74 in Staffordshire, from 364 to 290; 59 in Nottinghamshire, from 177 to 118; 55 in Warwickshire, from 308 to 253; and 58 in Essex, from 348 to 290. Only small variations were reported in the local trends of scarlet fever. The largest fluctuations in the returns of whooping-cough were falls of 149 in Lancashire, from 531 to 382; and 40 in Warwickshire, from 221 to 181; the largest rise was 50 in Surrey, from 96 to 146. 17 cases of diphtheria were notified, being 5 fewer than in the preceding week. The chief features of the returns of diphtheria were a rise of from 2 to 5 in Warwickshire and a fall from 6 to 1 in Staffordshire.

36 cases of acute poliomyelitis were notified during the week, 3 fewer for paralytic and 1 more for non-paralytic cases than in the preceding week. The largest returns were London, 6 (Lewisham 2, Woolwich 2), Kent 6, Berkshire 4 (Bradfield R.D. 2).

The notifications of dysentery numbered 736 and were 7 more than in the preceding week. The largest centres of infection were London 119 (Kensington 35, Islington 18, Chelsea 11, Greenwich 11, Westminster 11, Wandsworth 10), Middlesex 108 (Edmonton 35, Enfield 19, Tottenham M.B. 14, Southgate M.B. 10), Lancashire 100 (Liverpool C.B. 30, Stretford M.B. 21, Manchester C.B. 15), Norfolk 74 (Great Yarmouth C.B. 66), Durham 56 (Stanley U.D. 48), Essex 34 (Walthamstow U.D. 10), Yorkshire West Riding 28 (Leeds C.B. 11), Leicestershire 28 (Leicester C.B. 28), Warwickshire 28 (Birmingham C.B. 26), and Bedfordshire 26 (Bedford M.B. 15).

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1944-52 are shown thus -----, the figures for 1953 thus ————. Except for the curves showing notifications in 1953, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Industrial Accidents and Diseases

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in April was 106, compared with 122 (revised figure) in the previous month and 127 (revised figure) in April, 1952. The number of cases of industrial disease reported was 45, including lead poisoning 10, anthrax 4, epitheliomatous ulceration 15, and chrome ulceration 16. There were no deaths.—*Ministry of Labour Gazette*, May, 1953.

Week Ending May 23

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,306, whooping-cough 3,103, diphtheria 19, measles 10,277, acute poliomyelitis 29, dysentery 754, paratyphoid fever 4, and typhoid fever 3.

Sixty-two mass radiography units are now operating in England and Wales. This was stated by Miss P. Hornsby-Smith, speaking at a Mass Radiography Campaign meeting in Orpington on April 27. Miss Hornsby-Smith appealed to the individual to co-operate with the State by making full use of the units when they came to his area.

Medical News

The Practitioner.—Various medical journals in their various ways have celebrated the Coronation, one austere with verse. Among them the *Practitioner* comes out with flying colours and a most attractive cover. Its main piece is an assembly of photographs of British medical institutions and houses of consultants and general practitioners (inside and outside), and health centres, and in particular of the early homes of some famous general practitioners. The pictures alone make the special number a good buy. A foreword by the Minister of Health on general practice hits three nails firmly on the head: "The status of the general practitioner," he writes, "depends essentially upon three things: the trust of his patients, the respect of his colleagues, and the means to do his job adequately." An editorial comment in the opening pages strikes a timely note: "The *Practitioner* has never been merely a journal of general practice; that is taking the narrow specialist view which is doing so much harm in medicine to-day. It is a journal for practitioners of medicine—whether general practitioners or consultants—and if it is to subserve this function it must not only be able to present the advances in medicine which it is the duty of consultants to propagate for the benefit of general practitioners, it must also present the consultants with the accumulated wisdom of the general practitioners of the country." This is a sound recipe for the repast our contemporary is putting before its readers each month.

each month.

Westminster Hospital Medical School Dinner.—The Old Students' dinner was held at Grosvenor House on May 29. The occasion was marked by the farewell of Dr. I. W. Magill, founder of the school of anaesthesia at the Hospital and chairman of the dinner, who retires this year from the staff. When the Loyal Toast and the toast to the Hospital and Medical School had been drunk, Mr. H. E. Harding, the Dean, proposed "The Guests," whom he referred to as "friends of Westminster Hospital and School: people who have given rather than taken." They included Sir Robert Young, "the doyen of practising physicians," the Lords Wigram, Addison, and Kershaw, members of the Board of Governors, and the directors-general of the three armed Services. In his reply Sir Robert Young referred to some of the differences between medicine now and when he began: there were then no x rays, clinical laboratories were only just being set up, and diagnosis depended solely on history-taking and the evidence of the five senses. "Although," as he epitomized the change, "the science of medicine has advanced greatly, I am not quite sure that the art of medicine has advanced with equal steps." Dr. R. Machray proposed the health of the chairman, Dr. Magill. He reminded his audience how Dr. Magill had been the first member of the staff to devote himself entirely to the practice of anaesthesia. To no one man, he said, perhaps

he looked forward to further discoveries from the department of anaesthesia at the Westminster.

W.H.O. Budget for 1954.—The Sixth World Health Assembly's committee on programme and budget has recommended that the W.H.O. budget of \$8½m. for the financial year 1954 should be spent as follows: nearly \$4½m. on advisory services, \$1½m. on technical services, \$1m. each on regional offices and administrative services, and the remainder (less than \$½m.) on organizational meetings, expert committees, and conferences. In the words of the retiring Director-General, Dr. Brock Chisholm: "What W.H.O. is now spending on international action for the protection of the health of the men, women, and children of the world is no more than the amount many a large city spends on its own municipal sanitary arrangements. Indeed the budgets of the Organization have been and are ridiculously small, when viewed against the background of the tremendous health needs of a world in which two-thirds of the population is still deprived of the benefits of modern scientific and medical knowledge."

Award of Albert Medal.—The gold Albert Medal of the Royal Society of Arts for 1953 has been awarded, with the warm approval of the Duke of Edinburgh, President of the Society, to Dr. E. D. Adrian, O.M., P.R.S., Master of Trinity College, Cambridge, for his outstanding contributions to neurophysiology. The Albert Medal, which is the highest award in the gift of the Society, was instituted in 1864 to commemorate the Presidency of the Prince Consort from 1843 to 1861. It is awarded annually for "distinguished merit in promoting Arts, Manufactures, and Commerce."

The Annual Conference of Prison Medical Officers was held at the Home Office on May 22, the chair being taken by Dr. H. K. Snell, Director of Medical Services, Prison Commission. At the morning session Dr. N. J. deV. Mather, consultant psychiatrist at Crumpsall Hospital, Manchester, addressed the conference on "Schizophrenia in Relation to Criminal Behaviour." The afternoon was devoted to the subject of the management of the homosexual in prisons and Borstal Institutions, papers being read by Dr. W. J. Gray and Dr. D. A. Ogden. The papers were followed by a discussion.

Tavistock Clinic.—The Tavistock Clinic, London, has issued a prospectus of the training courses available there during the year 1953-4. These include courses on child psychiatry and psychotherapy, clinical psychology, the Rorschach method of personality assessment, and psychogenic speech disorders. There are also two courses for general practitioners, on "Psychology in General Practice" and "Speech Disorders in General Practice." The number of vacancies for these courses is very limited. Applications for the prospectus should be made to the Training Secretary, The Tavistock Clinic, 2, Beaumont Street, London, W.1.

China.—The Government of the Republic of China has notified the Director-General of the World Health Organiza-

Medical Members of the Everest Expedition

Dr. M. Ward.

Dr. L. G. C. Pugh.

Mr. R. C. Evans.

tion that it will again participate in the organization's work. China withdrew from W.H.O. in 1950.

Bart's Journal Coronation Number is being sent to all Bart's men, whether regular subscribers or not. Any who do not receive a copy should write for one to the Editor, St. Bartholomew's Hospital Journal, St. Bartholomew's Hospital, London, E.C.1.

COMING EVENTS

Surrey Coronation Ball.—The Coronation Dinner and Ball of the Surrey Branch of the British Medical Association will be held at Selsdon Park Hotel, Sanderstead, on June 25 at 7.30 p.m. Tickets (price 2 guineas) may be obtained from Dr. L. A. Gibbons, Fulham House, Waterlow Road, Reigate, or from Dr. J. W. Starkey, 9, Lovelace Road, Surbiton.

Society for Endocrinology.—A lecture on "The Prostatic Glands as Targets for Steroids" will be given by Dr. Charles Huggins, of the Ben May Laboratory for Cancer Research, University of Chicago, at the Royal Society of Medicine, Wimpole Street, W.1, on June 23 at 5.30 p.m. The chair will be taken by Dr. J. F. Folley, D.Sc., F.R.S. Admission free without ticket.

A Refresher Course on the Anterior Pituitary Hormones will be held at the Hôpital Laennec, Paris, from June 23 to 27. Apart from lectures by Professor H. M. Evans, director of the Institute of Experimental Medicine at Berkeley, California, there will be clinical and therapeutic papers. Registrations should be sent as soon as possible, accompanied by the fee of 5,000 francs, to Centre d'Etudes et de Recherches Endocrinologiques, 37 rue Spontini, Paris.

British Association of Sport and Medicine.—A meeting will be held in the Westminster Hospital Medical School on June 24 at 5 p.m., when Sir Adolphe Abrahams and Dr. A. McEldowney will open a discussion on "The Doping of Athletes."

British Association of Urological Surgeons.—The annual meeting of the British Association of Urological Surgeons will be held in Leeds from June 25 to 27. The meeting will include operating sessions, clinical demonstrations, and the reading of papers. There will also be a discussion on urinary tuberculosis opened by Mr. J. Cosbie Ross. Members are asked to make their own hotel reservations, and those requiring further information should communicate with the hon. secretary, 45, Lincoln's Inn Fields, London, W.C.2.

NEW ISSUES

Abstracts of World Medicine.—The June issue (Vol. 13, No. 6), which is now available, contains abstracts of important papers on both medical and surgical subjects drawn from the medical literature of some 20 different countries and of all five continents. In addition to clinical medicine and surgery, the subjects covered include pathology, bacteriology, pharmacology, and chemotherapy, and there are also sections dealing with public health and industrial medicine, forensic medicine, anaesthetics, radiology, and the history of medicine.

Issued monthly; annual subscription £4 4s., single copy 8s. 6d.; a specimen will be sent free on request.

SOCIETIES AND LECTURES

Monday, June 8

EDINBURGH UNIVERSITY.—At University New Buildings, 5 p.m., Dr. Douglas Guthrie: Early Days of Medical Education in Scotland.
MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.—7.30 p.m., E. Gurney-Clark (Columbia University, New York): Natural History of Acquired Syphilis and its Relationship to Preventive Medicine.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. A. L. Cochrane: Medical Field Work.
ROYAL EYE HOSPITAL.—5 p.m., Mr. R. A. Burn: Blood Diseases and their Ocular Complications.

Tuesday, June 9

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Professor C. A. Keele: Hyperidrosis.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Moynihan Lecture by Dr. H. L. Jaffe (New York): Giant Cell Tumour (Osteoclastoma) of Bone: Its Pathological Definition and the Inherent Clinical Implications.
ROYAL EYE HOSPITAL.—5 p.m., Mr. T. M. Tyrrell: Corneal Grafting and Indications.
WRIGHT-FLEMING INSTITUTE OF MICROBIOLOGY, St. Mary's Hospital Medical School.—5 p.m., Almon Wright Lecture by Professor J. R. Squire: Hypersensitivity and Disease.

Wednesday, June 10

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Mycology—Pathogenesis of Tinea Capitis.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. R. E. O. Williams: Control of Air-borne Infection.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor Milroy Paul: Surgery of the Congenital Anomalies of the Midline Ventral Abdominal Wall.
ROYAL EYE HOSPITAL.—5.30 p.m., Mr. L. H. Savin: Ophthalmic Neurology.

Thursday, June 11

EDINBURGH UNIVERSITY.—At University New Buildings, 5 p.m., Dr. Douglas Guthrie: Evolution of Sick Nursing.
HAMPSTEAD GENERAL HOSPITAL.—3 p.m., Mr. A. Emyln Williams: Common Diseases of the Anus and Rectum; 4.15 p.m., Dr. E. W. Hart: Minor Ailments in Childhood.
HONYMAN GILLESPIE LECTURE.—At University New Buildings, Edinburgh, 5 p.m., Dr. J. A. Tulloch: The Prognosis after Myocardial Infarction.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Mycology—Superficial Fungus Infections of the Skin.
NUFFIELD ORTHOPAEDIC CENTRE, Wingfield-Morris Orthopaedic Hospital.—8.30 p.m., Dr. H. L. Jaffe: Solitary Fibro-osseous Lesions of Bone and their Relation to Fibrous Dysplasia.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. B. Ackner: Depression.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Bradshaw Lecture by Sir James Paterson Ross: Unsolved Problems in the Surgery of the Sympathetic Nervous System.
ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Professor D. Campbell: Function of the General Medical Council and its Influence on Medical Education and Ethics.
ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. A. S. Paterson: Postgraduate demonstration in neurology.
WEST LONDON HOSPITAL MEDICAL SCHOOL.—At Medical Society of London, 4.30 p.m., Alex Simpson Smith Memorial Lecture by Sir Clement Price Thomas: Benign Tumours of the Lung.

Friday, June 12

INSTITUTE OF CARDIOLOGY.—At Royal Society of Medicine, 5 p.m., St. Cyres Lecture by Professor J. McMichael: Right Ventricular Failure.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. F. R. Bettley.
LEEDS UNIVERSITY.—At Littlewood Hall, Instructional Block, General Infirmary, Leeds, 8.15 p.m., Professor Sydney Sunderland (Melbourne): Applied Anatomy of Peripheral Nerve Trunks.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. C. L. Cope: Adrenal Cortical Function.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Obstetric and Gynaecological Conference. Mr. Aleck Bourne: Delay in Labour.

Saturday, June 13

ASSOCIATION OF CLINICAL BIOCHEMISTS: SOUTHERN ENGLAND AND SOUTH WALES REGION.—At Courtauld Institute of Biochemistry, regional meeting. 1.30 p.m., demonstrations; 2.30 p.m., papers.

APPOINTMENTS

NORTH-EAST METROPOLITAN REGIONAL BOARD.—The following consultant appointments are announced: J. Suchet, M.R.C.S., L.R.C.P., Hospital, Bow, and Poplar Hospital; A. Giordani, M.R.C.S., L.R.C.P., D.M.R.D., Part-time Radiologist, Harold Wood and Goodmayes Hospitals; R. H. V. Hafner, F.R.C.S., Part-time Orthopaedic Surgeon, Mildmay Mission and Queen Elizabeth Hospital for Children; Mrs. Helen Gillespie, M.R.C.S., L.R.C.P., Part-time Psychiatrist, West Essex Child Guidance Clinic, Walthamstow; S. F. Hans, M.D., F.R.C.S., M.R.C.O.G., Part-time Obstetrician and Gynaecologist, Hertford Group of Hospitals; S. D. Perchard, M.D., M.R.C.O.G., Part-time Obstetrician and Gynaecologist, Mile End Hospital; Lord Amulree, M.D., F.R.C.P., Part-time Geriatrician, St. Matthew's Hospital; N. E. France, M.B., B.Ch., Full-time Pathologist, Queen Elizabeth Hospital for Children; Ivy M. Tuck, M.B., B.S., Full-time Pathologist, St. Margaret's Hospital, Epping.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Herst.—On May 8, 1953, at Guy's Hospital, London, S.E., to Pamela, M.B. (formerly Green), wife of Edward R. Herst, M.B., a son—law Malcolm.
MacAuliffe.—On May 16, 1953, to Judy (formerly Baldry), wife of Dr. Richard MacAuliffe, of Saltburn, Yorks, a daughter.
McCoy.—On April 28, 1953, at the University College Hospital, London, W.C., to Dr. and Mrs. James McCoy, 14, Great Russell Street, a daughter—Katherine Mary.
Miller.—On May 22, 1953, at St. Mary's Hospital, Harborough, Magna, near Rugby, Warwickshire, to "Prue," wife of Dr. Peter Miller, a sister for Anne and Susan—Jean Rosemary.
Nathanson.—On May 17, 1953, to Margaret (formerly Milman), wife of Dr. N. E. Nathanson, a daughter.
Reid.—On May 21, 1953, at 2, The Mount, Pontefract, Yorks, to Nicky, wife of James A. Reid, F.R.C.S., twins—a son and a daughter.
Whittaker.—On May 8, 1953, at the European Hospital, Kitale, Kenya, to Beth (formerly Morgan), wife of Dr. Leslie R. Whittaker, a son—Clive Leslie.

DEATHS

Boyd.—On May 8, 1953, at Birchington, Kent, John Errol Moritz Boyd, M.C., M.R.C.S., L.R.C.P., Colonel, R.A.M.C., retired.
Carling.—On May 2, 1953, Albert Carling, M.B., B.Ch., formerly of Bristol, aged 88.
Chalmers.—On April 29, 1953, in hospital, James Chalmers, M.B., Ch.B., D.P.H., of Woodbank, Oakmoor, Staffs.
Fenn.—On April 26, 1953, Arthur James Fenn, M.R.C.S., L.R.C.P., of 199, Southampton Way, London, S.E., aged 69.
Fernando.—On May 2, 1953, in London, Charles Walter Solomon Fernando, M.R.C.S., L.R.C.P., D.M.R.E., of Horton Place, Colombo, Ceylon.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Prognosis after Accidental Haemorrhage

Q.—Please can you give the prognosis for future pregnancies after a stillbirth due to accidental haemorrhage?

A.—The future outlook in such a case depends very much on whether the accidental antepartum haemorrhage was associated with toxæmia of pregnancy, chronic hypertension, or chronic nephritis. It depends on whether the woman still has evidence of hypertension or impairment of renal function; and her age and parity may also have a bearing.

Unless there is any special predisposing factor present, the risk should be assessed against the fact that the overall incidence of this complication is less than 1% of all deliveries, and this figure includes the less severe cases in which the foetus often survives.

Hormones and Peptic Ulcer

Q.—What part do hormones play in the aetiology and treatment of peptic ulcer?

A.—There are, unfortunately, more theoretical than practical considerations in our present knowledge of the relation of hormones to the aetiology and treatment of peptic ulcer. Hypersecretion is a common finding in duodenal ulcer, and it is at least conceivable that interference with normal hormonal control of secretion might play a part. It is possible that the gastric phase of secretion due to the production of gastrin by the pyloric mucosa could be prolonged if a normal inhibiting mechanism failed. There is some evidence that inhibition is caused when the acid in the stomach reaches a certain concentration. Again, the small intestine hormone enterogastrone normally reduces gastric secretion, and if its production was inhibited hypersecretion could result.

There appears to be some relation with the adrenal glands, for increased gastric secretion is also produced by A.C.T.H. or cortisone, and experience has shown that patients suffering from gastric or duodenal ulcer tend to relapse and may bleed or perforate under treatment with these substances. There is, however, no evidence that adrenal cortical hyperactivity in the absence of steroid therapy plays a part in duodenal ulcer, although it is suspected that it might explain the exacerbation of ulcer symptoms which may follow acute emotional disturbances. It is also likely that sex hormones may play a role in the determination of peptic ulcer. 80% of ulcers occur in men and there would appear to be substantial sex protection in the female, a protection which is most marked during the reproductive years of life. Before puberty the incidence of ulcer is small, but the sex incidence is equal. After the puberty the frequency of ulcer rises in both sexes, but the increase is far greater in men. There is a sudden increase in frequency of peptic ulcer in women at and after the menopause, and in the later decades of life the frequency of ulcer approximates in the two sexes. Peptic ulcer appears to be particularly inactive during pregnancy and acute perforation is then excessively rare. Peptic ulcer in women is discussed in an article at p. 1254 and an annotation at p. 1270.

Unfortunately experience with oestrogens, progesterone, gonadotrophins, and testosterone has not demonstrated any significant effect on gastric secretion or beneficial results

on the healing of ulcer. The possibility of an anti-ulcer hormone promoting healing of the ulcer crater apart from any effect on gastric acidity has been postulated to explain the prolonged absence of ulceration which may occur after the administration of enterogastrone in dogs subjected to the Mann-Williamson operation (a method of diverting duodenal juice away from the pyloric region, by transplanting the duodenum into the ileum and anastomosing the cut end of jejunum to the pylorus). Sandweiss and his fellow workers have claimed that the urine of pregnant and non-pregnant women contains a substance capable of facilitating the healing of Mann-Williamson ulcers in dogs without affecting gastric acidity, and that this protective factor is not present in the urine of ulcer patients. It is conceivable that the isolation of such a factor, if it really exists, or the chemical identification of urogastrone excreted in the urine and derived from enterogastrone, would offer hope of a hormonal cure of duodenal ulcer.

In the vast medical literature on peptic ulcer all the endocrine glands have been implicated, but there is no real evidence of the part they play.

Holiday T.A.B.

Q.—For which Western European countries is T.A.B. inoculation a wise precaution before a holiday? How long before the holiday should inoculation be performed, and what dosage is advised for adults and children? How long will immunity last, and are booster doses recommended for subsequent years?

A.—Enteric fever (typhoid and paratyphoid) is still an endemic infection of some prevalence in France, Spain, and Italy. In Germany after the war there were numerous large epidemics which have probably left their mark in an increased incidence of enteric carriers. Infection is less common in the Low Countries and relatively rare in Scandinavia.

T.A.B. inoculation should preferably be completed a few weeks before going on holiday, as it sometimes causes systemic as well as local reactions. The effects of such reactions can be minimized by having the injection in the late afternoon or evening, and by taking an antipyretic tablet before going early to bed. The dosage depends on the type of vaccine used: for alcoholized vaccines the dose is 0.25 ml. and 0.5 ml. for adults (0.2 and 0.4 for females), half the adult dose for children aged 5 to 14, and one-fifth to one-third of the dose for younger children. Babies under 1 year do not need to be immunized. With phenolized or heat-killed vaccines the dose is roughly double that for the alcoholized vaccine. The two injections are best given at an interval of seven to fourteen days, and a considerable degree of protection is believed to last for one to two years. A booster dose should be given after that time if the individual is going back to a country where the infection is still prevalent and the water supplies are suspect.

It must, however, be emphasized that infection may occur in spite of active immunization with any type of vaccine, and every precaution should be taken to avoid unnecessary risks with food and drink, particularly in country districts or small towns where piped water supplies are not available. Fortunately, chloramphenicol has a specific curative effect on enteric fever, and anyone holidaying abroad who develops a suspicious illness should consult a doctor, who will presumably prescribe chloramphenicol if he is at all worried about the possibility of enteric infection.

Foetal Asphyxiation by the Cord

Q.—Can an infant in utero be asphyxiated by its own cord?

A.—Anomalies of the umbilical cord can certainly cause asphyxia and death of the foetus in utero, and this can occur at any stage of pregnancy or labour. Knots which

tighten, loops which form around the foetus, and even torsion of the cord, sometimes cause foetal death and abortion as early as the 12th week. Usually, however, such arrangements of the cord remain loose enough to avoid interference with the circulation in the umbilical vessels until labour is in progress. Then, with the descent of the foetus, the knot or loop tightens sufficiently to cause asphyxia. Looping of the cord around the foetal neck can sometimes be suspected or diagnosed as a cause of asphyxia during labour—one test being to study the behaviour of the foetal heart when the head is deliberately pushed down towards the pelvis.

Nevertheless, the cord is very often looped once or twice round the foetal neck without any harm resulting. It remains loose until the foetal head is actually delivered. Moreover, "cord round the neck" is such an easy explanation to offer for the death of the foetus that it becomes suspect as a cover for bad obstetrics. This diagnosis is undoubtedly made more often than is justified, and it is therefore often viewed with suspicion. Despite this, there can be no doubt that tightening of a loop of cord round the foetal neck or trunk, or tightening of a true knot, is a definite although rare cause of foetal asphyxia.

Coital Posture and Obesity

Q.—What coital position is best for a man with a small penis who is married to an obese wife? At present they are having difficulty in the act.

A.—Variation in the size of the male phallus, and obesity in one or other partner, are common, and yet it is surprisingly rare for such mechanical factors to prevent coitus, even though they make it less satisfactory. The case in question should be reviewed to make sure that the blame for failure in coitus is not being wrongly placed, and that other causes such as male impotence or vaginismus are not present. If the trouble proves to be entirely mechanical then an intelligent couple might be expected to find the most satisfactory posture by experiment, and in this they could be helped by some book such as Van de Velde's *Ideal Marriage* (Wm. Heinemann Medical Books), which devotes a whole chapter to coital postures. The position which might prove most satisfactory is the one in which the wife lies on her back and extends her trunk either by placing a firm pillow under the lumbar spine or by allowing her legs to hang downwards over the edge of a couch, as in Walcher's position, which was formerly used in obstetric practice.

Recurrent Gall-stones

Q.—What is the likelihood of stones recurring in the common bile duct after cholecystectomy or choledochotomy? Is there any satisfactory way of preventing recurrence?

A.—Most of the so-called "recurrent stones" have been overlooked at the original operation, and the incidence of recurrence therefore bears an inverse relationship to the diligence with which the original operation has been carried out. Even with routine exploration of the common bile and hepatic ducts it is possible for stones to be missed, for they may easily slip far up into the latter, or a small stone can be missed at the lower end of the common duct as a result of a bougie or forceps being passed beside it. For this reason many authorities on biliary surgery have advocated cholangiography on the operation table, but this is not a method which is likely to be of any practical value outside a large surgical centre.

Truly recurrent stones are more likely to occur in the presence of residual infection, or because a fragment of stone has been left behind. A piece of suture material in the duct may act as a nidus for further stone formation, as also may a small stump of cystic duct. Poor drainage through the sphincter of Oddi may occur as a result of narrowing at the lower end of the common duct, and dilata-

tion with bougies may be advisable at the primary operation in these circumstances. A measure which has not attained wide popularity is the practice of side-to-side choledochoduodenostomy to assist drainage. This alternative channel may certainly allow an overlooked stone to be passed subsequent to operation, but many regard the possible regurgitation of duodenal contents as a real objection to the procedure.

To summarize, therefore, most recurrent stones have been previously overlooked, and even with the most careful surgery this may still occur, although the likelihood is then very largely ruled out. Mere scrutiny of the ducts and external palpation are often a very unsatisfactory method of exploration.

Compensation and Industrial Pulmonary Disease

Q.—What industrial pulmonary diseases are eligible for compensation?

A.—The important industrial lung diseases for which benefit is paid under the National Insurance (Industrial Injuries) Act, 1946, are pneumoconiosis and byssinosis. Where the pneumoconiosis is accompanied by respiratory tuberculosis, the effects of the tuberculosis are treated as the effects of the pneumoconiosis. Pneumoconiosis is defined in the Act as meaning "fibrosis of the lungs due to silica dust, asbestos dust, or other dust, and includes the condition of the lungs known as dust reticulation." Claimants for benefit must have worked in specified occupations and processes after July 5, 1948. These occupations and processes cover practically all processes where there is a risk, and they are listed in Ministry of National Insurance Leaflet N.I.3, obtainable at any local office of the Ministry of National Insurance. Claimants who have worked in these occupations, but not since July 5, 1948, may be able to claim compensation under the Workmen's Compensation Acts. Byssinosis is not included in the above definition, as it is not a fibrosis of the lung. Claimants to benefit for byssinosis must have been employed "in any occupation in any room where any process up to and including the carding process is performed in factories in which the spinning or manipulation of raw or waste cotton is carried on" for at least 20 years.

Beryllium poisoning, with its pulmonary manifestations, is prescribed disease No. 36. In the same way, pulmonary tuberculosis is an industrial disease (disease No. 38) when contracted by those whose insurable employment involves close and frequent contact with some source of tuberculous infection in certain occupations. These occupations are, shortly, those involving the treatment or nursing of cases of tuberculosis, attendance as a health visitor or home help, or research or laboratory work connected with tuberculosis.

Correction.—William Harvey was physician to Charles I, not Charles II as stated in the *Journal* of May 30, p. 1208, and he was not President of the Royal College of Physicians: though offered the honour, he declined it.

PARENTERAL HEXAMETHONIUM IN HYPERTENSION

BY

BRENDA MORRISON, M.D.

(From the Department of Medicine, Postgraduate Medical School of London, and Hammersmith Hospital)

Hexamethonium has now been used for over three years in the treatment of hypertension, and Table I summarizes briefly the results reported in 15 groups of patients, using hexamethonium (C6), pentamethonium (C5), and/or M & B 1863 (a homologue of hexamethonium); most investigators have used the oral route, entirely or for the major part of treatment, and

incomplete realization of the value in treatment of this postural fall, one author even referring to it as an undesirable side-effect. The time which has elapsed since the last dose of hexamethonium was administered must also be of some importance when assessing the effect on the blood pressure, yet in many cases no reference to this time interval was made. It seems likely that variations

TABLE I.—Summary of Results of Treatment of 15 Groups of Hypertensive Patients with Hexamethonium and Allied Drugs.

there is much difference of opinion concerning the benefit obtained. Only Smirk and Alstad (1951) have reported the treatment of a large number of patients for many months by subcutaneous injection, and they have no doubt that adequate control of the blood pressure can be maintained, with relief of symptoms. The present paper presents a study of a rather different group of patients treated by subcutaneous injection.

It was felt that if the value of a new remedy is in doubt, and especially when dealing with a complex condition like hypertension, the most decisive indications of its effects would be seen in severe or even hopeless cases. For this reason, and also because the treatment was felt to be too rigorous to warrant its employment in milder cases, the patients in this series were selected from the more limited numbers affected by complicated-essential, malignant, and renal hypertension.

Although it was made clear in the earliest reports on the action of the drug that there is a notable accentuation of the fall of blood pressure in the upright posture, some authors have not stated in which position their pressure readings were obtained, and there seems to have been

in route of administration and recording of data might account for much of the divergence of opinion among different authors.

Conclusions reached in a study of the effects of hexamethonium bromide on normal individuals (Morrison and Paton, 1953) have been helpful in interpretation of the results reported here, and especially in the approach to the problem of tolerance to the drug.

Case Material

Of the 39 patients studied, 17 were men and 22 were women, and their ages ranged from 22 to 64 years. The patients were classified in the following manner:

Group A. Essential Hypertension Without Complications.—All this group were considered unsuitable for treatment.

Group B. Essential Hypertension complicated by (1) headaches of typical hypertensive character; (2) clinical, radiological, or electrocardiographic evidence of left ventricular enlargement; (3) central nervous system episodes, including giddy attacks, black-outs, encephalopathy, or minor cerebral vascular accidents. All group B cases were regarded as requiring treatment unless they were too old.

A man aged 30 (group F) had already suffered from encephalopathy and a thrombosis of the central artery of the retina, and had very severe headaches. He was one of the first patients to be treated, and received the drug only by mouth for a few weeks. The blood pressure was resistant and he required 3 g. daily to produce a moderate fall. After some trouble with constipation produced by the drug, he collapsed in the lavatory with hypo-

tension and coma. He remained unconscious for some days after the blood pressure had risen, and was left with evidence of permanent cerebral damage, particularly dysarthria.

This case drew attention to the hazards of oral therapy, and all patients have since been treated by subcutaneous injection.

In the remaining three patients subsequent experience indicated that they were really unsuitable for this form of treatment, and it was accordingly discontinued.

A man aged 61, an arteriosclerotic, was unable to co-operate; hypertension was not very severe. Treatment was persisted in for only two to three weeks.

A woman aged 57 had chronic renal hypertension, but was very labile and not progressive. She was rather unintelligent and lived too far from the hospital for adequate supervision.

A woman aged 63 had chronic nephritis with severe headaches. She had periods of mental confusion, which made her unable to co-operate in treatment outside hospital.

Patients Giving up Treatment (6)

In two of these the side-effects were very severe (excessive faintness and weakness with marked constipation, visual upset, and difficulty in micturition), and both felt worse on treatment. (One also had Sturge-Weber syndrome with epilepsy and very severe headaches, which did not improve when his blood pressure was lowered.)

Two further patients had well-marked cardiac enlargement and signs of congestive failure before treatment; they improved considerably, but gave up treatment against advice after two months. They returned with severe heart failure after three months and six weeks, and restarted treatment. They both responded again, one very remarkably (see below).

The remaining two patients who gave up were young subjects with little disability, and, having obtained symptomatic relief, decided that they did not wish to continue injections.

Patients Continuing Regular Treatment

Of these 24 patients 18 are leading active and practically normal lives, doing a full day's work and able to undertake such activities as gardening and dancing. The other six are much improved, but are still restricted in their activities. Three of these are cases of malignant hypertension, the first one having a severe degree of cardiac damage which necessitates a very quiet life, the second having a good deal of faintness and weakness but able to do some work and steadily improving, and the third being still in the initial stages of treatment, but able to get about normally. Two have other disabilities (chronic bronchitis and emphysema and aortic thrombosis causing claudication), and it is these disabilities rather than the hypertension which restrict their activity. The sixth is a 59-year-old woman who has not felt well enough to resume work in a laundry.

Details of Results

Blood Pressure

In a previous investigation of the effects of hexamethonium on normal subjects a very wide variation in sensitivity was demonstrated (Morrison and Paton, 1953). These hypertensive patients showed a similar wide scatter, but, judged on percentage fall of blood pressure, they seem to be somewhat more sensitive to an initial dose than normal individuals. The general course of the blood-pressure response (Fig. 1) was the same as in the normal individuals, with the same correspondence between the falls in the standing, sitting, and recumbent postures; the degree of postural accentuation, however, showed a considerable variation.
